The aim of one study was to describe the prevalence, trends and associated factors of dietary supplements and anabolic-androgenic steroids (AAS) use among Finnish adolescents. The sample comprised 30 511 adolescents aged 12-18 years, of which 22 519 (74 %) answered a questionnaire. It was also studied associations between 14 socioeconomic, health and health behavioural variables and dietary supplements and AAS use by logistic regression. The proportion of respondents using dietary supplements was 45 percent during the past year and it increased linearly by age. Vitamins (37 %) and herbal products (13 %) were the most common dietary supplements. In 1991, 9 percent of the boys aged 16-18 years reported protein use, while the frequency in 2005 was 17 percent which was a significant increase. Anabolic steroid use was uncommon; only 53 boys (0.5 %) and 20 girls (0.2 %) reported AAS use. The strongest factors associated with dietary supplements use in multivariate model were physical exercise outside sports clubs (odds 1.9), and in sports clubs (odds ratio 1.7). Recurrent drunkenness (odds ratio 5.8) and peer drug use in boys (odds ratio 2.1) were the risk factors for AAS use, whereas physical exercise outside sports clubs (odds ratio 0.3) was a protecting factor. Although the overall use of dietary supplements remained at the same level during the study period, there was a slight trend towards increasing use of vitamin and protein supplements. Dietary supplements use is associated with frequent sports participation and poorer than average health, while AAS use is associated with health-compromising behaviours [09314].

Germany

Little is known about the prevalence and motives of supplement use among elite young athletes who compete on national and international levels. Therefore, the current survey was performed to assess information regarding the past and present use of dietary supplements among 164 elite young athletes (17 ± 3 years of age). A 5-page questionnaire was designed to assess their past and present (last 4 weeks) use of vitamins, minerals, carbohydrate, protein, and fat supplements; sport drinks; and other ergogenic aids. Furthermore, information about motives, sources of advice, supplement sources, and supplement contamination was assessed. Eighty percent of all athletes reported using at least 1
supplement, and the prevalence of use was significantly higher in older athletes. Among supplement users, minerals, vitamins, sport drinks, energy drinks, and carbohydrates were most frequently consumed. Only a minority of the athletes declared that they used protein/amino acids, creatine, or other ergogenic aids. Major motives for supplement use were health related, whereas performance enhancement and recommendations by others were less frequently reported. Supplements were mainly obtained from parents or by athletes themselves and were mostly purchased in pharmacies, supermarkets, and health-food stores. Among all athletes, only 36 percent were aware of the problem of supplement contamination. The survey shows that supplement use is common and widespread among German elite young athletes. This stands in strong contrast to recommendations by leading sport organizations against supplement use by underage athletes [09316].

Spain

One article describes a study that evaluated the adequacy of 2 different menu settings in a group of elite adolescent Spanish soccer players. Five-day food intake was assessed on 2 occasions, while athletes were consuming a flexible "buffet-style" diet (B; n=33) and a fixed "menu-style" diet (M; n=29). For all principal meals of the day food weighing was performed, and snacks were recorded by self-report. M provided significantly higher total energy and carbohydrate intakes than B. Breakfast and snacks both provided more energy in M. Calories obtained from fat were excessive in both settings. Calcium and vitamin D were below recommendations in B but not in M. Fiber, magnesium, folate, vitamin A, and vitamin E intake fell below recommended values in both settings. M provided significantly greater quantities of magnesium and vitamins D and E. Both feeding options were far from optimal in satisfying current scientifically based recommendations for active adolescents [07234].

The abuse of all types of substance to improve sport performance and physical fitness has spread to regularly gym users. The aim of one study was to evaluate the intake of nutritional and dietary supplements in a group of 415 individuals (260 males and 155 females) from 4 gyms in Seville (Spain). The users completed a previously designed questionnaire whose content validity had been tested in a pilot study. Out of the total sample, 56 percent had consumed a supplement at some time. Among these, the objective was improvement of physical appearance in 57 percent, health care in 17 percent, and sports performance enhancement in 13 percent. The profile of the supplement consumer is a young man who has performed activities in gyms for some time, goes to the gym for several hours a week and is on some type of diet. The percentage of nutritional supplement users (56 %) is within values reported in other studies. The five supplements most frequently consumed by these individuals were (in decreasing order): proteins (28 %), L-carnitine (19 %), sport drinks (18 %), creatine (17 %) and vitamin complex (17 %) [09317].

Greece

The aim of one study was to monitor the nutritional status of 9 Greek national top-level swimmers during a competitive season of eight months. The swimmers were assessed through recording of food and supplement intake, blood sampling, and anthropometry at four landmarks: in the beginning of the season (baseline), after completing a phase of intensive and voluminous training (at 10 weeks), at a minor taper (19 weeks), and during the major taper (32 weeks). Energy and macronutrient intake did not change significantly over time, and only a few significant changes were found in micronutrient intakes. Low carbohydrate and high fat intakes (e.g. 36 and 42 % of total energy, respectively, in males), inadequate intake of some micronutrients, and improper use of supplements indicated suboptimal dietary habits. Blood hemoglobin fluctuated significantly during the season. No significant changes in parameters indicative of the iron stores (transferrin saturation and ferritin) were found,
although iron intake increased by supplementation with the onset of training. Serum markers of training stress were not significantly altered. In conclusion, Greek top-level swimmers should be guided toward a balanced diet and a rational use of supplements. Monitoring of dietary intakes during a competitive season is highly recommended [07233].

Italy

The aims of one study were to collect data on consumption of different food supplements in a sample of the adult Italian population and to characterize users by demographic, physical and health-related characteristics, lifestyle and behaviour. The study was conducted in 2008 in ten towns of Italy (two towns from each of the five macro-areas: Northwest, Northeast, Centre, South and Islands). Adults (n=10 000) aged ≥18 years were randomly selected and asked to fill in a self-administered questionnaire regarding their use of food supplements and the above variables. The effect of these variables on food supplement use was evaluated by univariate and multivariate logistic regression. Of the 1723 individuals who returned the questionnaire, 49 % were users of food supplements. A large proportion (54 %) of users used more than one category of food supplement: vitamin and/or mineral supplements were the most used (61 %), followed by supplements with botanicals and botanical extracts (28 %). The results obtained by logistic regression showed that gender, town size, education level, sports practice, regular use of wholemeal cereal-based foods and presence of a low stress level were determinants for the use of food supplements in the examined population. However, these determinants were not shared by all categories of supplements. The results of this preliminary study highlight that associations between demographic, dietary and lifestyle factors and use of different categories of food supplements differ according to products, and cannot be accounted for simply by dichotomizing individuals as users or non-users [12367].

Slovenia

Little is known about the prevalence of nutritional supplement use in European adolescents. We conducted the present study to analyse the prevalence of nutritional supplement use and factors associated with this use among Slovenian adolescents. The nutritional supplementation practices of 818 adolescents were studied using an anonymous questionnaire. Information was sought on the type of supplements used, frequency of use and sources of information. Some 19 percent of all the schoolchildren from twenty primary schools and twelve secondary schools reported using at least one nutritional supplement and the prevalence of use was significantly higher in adolescents who were members of sports clubs. Multivitamins were the most common nutritional supplement. Older adolescents were significantly more likely to be supplementing with iron, protein and minerals. Less than 16 percent of supplement users in the study sought information from health-care professionals. Nearly 62 percent obtained information from parents and coaches, and many adolescents appear to decide on nutritional supplementation themselves, without advice. Older adolescents were significantly more likely to combine supplements than younger adolescents. It was concluded that one-fifth of Slovenian adolescents use nutritional supplements. There are clear differences in supplement use between younger (age 12 years) and older (age 17 years) adolescents. Multiple use of supplements, coupled with self-managed supplementation in older adolescents, is concerning. Hence, there is an urgent need to provide accurate information regarding nutritional supplements, which will help adolescents, their parents and coaches to make informed choices about their use [12368].

Poland
The purpose of one study was to determine the prevalence of the use of dietary supplements among the young people exercising in fitness rooms in Kraków and environs. In the study, 81 percent of the population used some form of dietary supplement; nutritional supplements were used by 21 percent of women and 60 percent of men, and were used most frequently by young people 21-25 years of age. The most popular supplements were creatine (20 %) and HMB (beta-hydroxy-beta-methylbutyrate) (19 %). Only 14 percent of the respondents asked for the opinion of qualified personnel, such as doctors, pharmacists or dieticians.

Singapore

Nutritional supplements used by athletes can be classified as sports food, dietary supplements and ergogenic aids. The aim of one study was to examine the use of such supplements among university athletes in Singapore. Eighty-two athletes from 16 sport disciplines completed a questionnaire which sought information on demographical parameters, type of supplements, frequency of use, motivations, knowledge, expenditure and side effects. The prevalence of supplement use was 77 percent and 20 different products were used. Each individual consumed a mean and standard deviation of 3.2 ± 1.7 products over a 12-month period. The mean number of products consumed daily was 2.1 ± 1.2. Popular products included sports drinks, vitamin C, multivitamins and traditional/herbal preparations such as essence of chicken, bird’s nest and ginseng. Before using a product, 66 percent sought information, usually from the media, the Internet, coaches and fellow athletes. However, many did not know where to obtain reliable information and 86 percent were also unaware that supplementation can have adverse effects. Although there is a high prevalence of supplement use in the study population, many do not have accurate information about these products. Hence, there is an urgent need to provide athletes with education and access to scientific and unbiased information.

Canada

Dietary supplementation is a common practice in athletes with a desire to enhance performance, training, exercise recovery, and health. Supplementation habits of elite athletes in western Canada have been documented, but research is lacking on supplement use by athletes across Canada. The purpose of this descriptive study was to evaluate the dietary supplementation practices and perspectives of high-performance Canadian athletes affiliated with each of the country’s eight Canadian Sport Centres. Dietitians administered a validated survey to 440 athletes (63 % women, 37 % men; age 20 ± 5 years) representing 34 sports who predominantly trained ≥16 hr/week, most competing in “power” based sports. Within the previous 6 months, 87 percent declared having taken ≥3 dietary supplements, with sports drinks, multivitamin and mineral preparations, carbohydrate sports bars, protein powder, and meal-replacement products the most prevalent supplements reported. Primary sources of information on supplementation, supplementation justification, and preferred means of supplementation education were identified. Fifty-nine percent reported awareness of current World Anti-Doping Agency legislation, and 83 percent subjectively believed they were in compliance with such anti-doping regulations. It was concluded that supplementation rates are not declining in Canada, current advisors on supplementation for this athletic population are not credible, and sports medicine physicians and dietitians need to consider proactive strategies to improve their influence on supplementation practices in these elite athletes.

It is well documented that athletes report greater dietary supplement (DS) usage than nonathletes; however, limited data exist for Canadian athletes, especially relative to competitive performance levels. One descriptive and analytical, cross-sectional research
investigated DS practices and opinions, preferred means for DS education, and antidoping opinions among elite Canadian athletes competing at various performance levels. Subjects completed a validated questionnaire by recall. Combined, 582 high-performance athletes (314 M, 268 F) between the ages of 11 and 42 years and representing 27 sports activities participated. Respondents were categorized into five competitive performance levels: provincial (68), national (101), North America (61), international or professional (89), and varsity (263). Overall, most (88 %) reported taking one or more DS during the previous 6 months (mean 3 ± 2 DS per user). From a total of 1555 DS declared, sport drinks (22 %), sport bars (14 %), multivitamins and minerals (14 %), protein supplements (9 %), and vitamin C (6 %) were most frequently reported. Athletes at the highest performance level were significantly more likely to use protein supplements, to be advised by strength trainers regarding DS usage, to have a higher self-rating of their diet, to prefer individual interviews for DS educational purposes, to perceive greater awareness of antidoping legislation, and train more h/week. Furthermore, differences were observed for the types of DS reported and justifications for use. This dataset, the first of its kind in Canada, was generated with a validated and reliable questionnaire and has the potential to be extended nationally and internationally to provide greater insight into the patterns and opinions of elite athletes regarding supplementation and antidoping [06247].

To learn more about the prevalence of dietary supplement and medication use by Canadian athletes in the Olympic Games in Atlanta 1996 and Sydney 2000 data were collected from personal interviews with Canadian athletes who participated at the 1996 Atlanta and 2000 Sydney Olympic Games. The athletes were interviewed by Canadian physicians regarding the use of vitamins, minerals, nutritional supplements, and prescribed and over-the-counter medications. Of the 271 Canadian athletes who participated at the Atlanta Olympics, 257 athletes were interviewed; at the Sydney Olympics, 300 of 304 Canadian athletes were interviewed to get a quantitative and qualitative description of the use of dietary supplements by Canadian athletes at the Atlanta and Sydney Olympics. At the Atlanta Games, 69 percent of the athletes used some form of dietary supplements, whereas 74 percent of the athletes used dietary supplements at the Sydney Games. Vitamins were taken by 59 percent of men and 66 percent of women in Atlanta, and 65 percent of men and 58 percent women in Sydney. Mineral supplements were used by 16 percent of men and 45 percent of women in Atlanta, and 30 percent of men and 21 percent of women in Sydney. Nutritional supplements were used by 35 percent of men and 43 percent of women in Atlanta, and 43 percent of men and 51 percent of women in Sydney. The most popular vitamins were multivitamins in both Olympics. The most popular mineral supplements were iron supplements. The most commonly used nutritional supplement in Atlanta was creatine (14 %), but amino acids (15 %) were the most commonly used nutritional supplement in Sydney. In Atlanta, 61 percent of the athletes were using some form of medication, 54 percent of the athletes were using medications in Sydney. Nonsteroidal antiinflammatory drugs (NSAIDS) were the most commonly used medications at both Olympic Games. Among all sports, the highest prevalence of vitamin use occurred in boxing (91 %) in Atlanta and swimming (76 %) in Sydney. Rowers (56 %) and cyclists (73 %) demonstrated the highest use of mineral supplements. Nutritional supplement use occurred most often in swimming (56 %) and cycling (100 %). The use of NSAIDs was highest in softball (60 %) in Atlanta and gymnastics (100 %) in Sydney. The review demonstrates that dietary supplement use was common among Canadian athletes at both the Atlanta and Sydney Olympic Games. There was a slight increase in total dietary supplement use at the Sydney Games. Widespread use of supplements, combined with an absence of evidence of their efficacy and a concern for the possibility of “inadvertent” doping, underscore the need for appropriately focused educational initiatives in this area [06248].

Use of supplements administered by a doctor to the Canadian Olympic athletes was
measured by a questionnaire. The percentage of current users was 69 percent in the Atlanta Games and 74 percent in the Sydney Games. Use of supplements was also measured by a self-administered questionnaire distributed to the World Master Athletes in Germany. A total of 69 percent of the men used nutritional supplements. The use of supplements in the general US population of men was lower, around 47 percent in the National Health and Nutrition Examination Survey. This survey suggests that subjects reporting strenuous physical activity are more likely to be supplement consumers. The high use of supplements in professional athletes is not surprising, especially because they are recommended in order to reduce physical exercise-induced oxidative stress and tissue damage. Growing evidence indicates that reactive oxygen species are responsible for exercise-induced protein oxidation and contribute to muscle fatigue. In addition, high-level physical activity may lead to suppression of the immune system, which could be compensated for by supplementation with dietary micronutrients [07230].

To determine the nutritional intake of Canadian high-performance athletes a prospective survey study of 324 high-performance athletes (114 males and 201 females) from 8 Canadian sport centers participated in the study. Subjects prospectively completed a 3-day dietary records, reporting all food, fluid, and supplement consumption. Average daily energy intake was $2533 \pm 843$ Kcal/day with males consuming significantly more calories than females ($2918 \pm 927$ and $2304 \pm 713$ Kcal/day, respectively). Both genders consumed below recommended levels. Carbohydrate, protein, and fat accounted for 53, 19, and 28 percent of daily calorie intake, respectively. Average daily carbohydrate and protein intake was $5.1 \pm 1.8$ and $1.8 \pm 0.6$ g/kg body weight, respectively. Protein intake, but not carbohydrate intake, met recommendations. Supplementation significantly increased athletes' energy, total carbohydrate, protein, and fat intake. Of 17 micronutrients assessed, intake ranged between 120 and 366 percent of recommended daily intake with food alone and between 134 to 680 percent of recommended daily intake with supplements. It was concluded that Canadian high-performance athletes do not consume adequate energy or carbohydrates. However, their intake of micronutrients exceed current recommended daily intakes, even when supplements are not considered, indicating that athletes make high-quality food choices [09315].

**USA**

*College athletes*

The objective of one study was to assess dietary intakes and eating habits of female college athletes and compared them with the minimum sports nutrition standards. Data were obtained from 52 female college athletes from a National Collegiate Athletic Association (NCAA) Division I university between 2009 and 2010. Participants completed anthropometric measurements and dietary assessment using a 3-day food record, a 24-hour recall, and a nutrition questionnaire. Statistics indicated the energy and carbohydrate intakes were below the minimum recommended amount, with only 9 percent of the participants meeting their energy needs. Seventy-five percent of the participants failed to consume the minimum amount of carbohydrates that is required to support training. The majority of the participants reported no regular breakfast, 36 percent consumed <5 meals/day, and only 16 percent monitored their hydration status. Effective nutrition interventions are needed to improve dietary intakes and eating habits of female college athletes [13579].

While the use of performance enhancing substances by professional, collegiate, and Olympic athletes is well described, the rate of use in the general population is not well studied. It was explored the use of energy drinks, dietary supplements, and prescription medications for the enhancement of athletic performance among college students using an ongoing survey.
system. It was conducted a multi-round online questionnaire collecting data from self-identified students at two-year colleges, four-year colleges, online courses, or technical schools at least part-time during the specified sampling period. The sample is obtained through the use of a survey panel company in which respondents voluntarily register. Survey data were collected from December, 2010 through August, 2011. Subjects who reported participating in athletics were asked if they used any of the following substances to enhance athletic performance (1) energy drinks (2) dietary supplements (3) prescription medications within the last year. Data were analyzed from October, 2011 through January, 2012. There were 462 college students who responded to the survey reporting they participate in sports at various levels. Of these, 397 (86 %) responded that within the last year they used energy drinks, dietary supplements, or prescription medications to enhance athletic performance. Energy drinks had the highest prevalence (80 %), followed by dietary supplements (64 %) and prescription medications (53 %). Use was most prevalent amongst intercollegiate athletes (89 %) followed by club (89 %) and intermural (82 %) participants. The vast majority of survey respondents reported using energy drinks, dietary supplements, and prescription medications within the last year for athletic performance enhancement [13580].

**Supplement inquiries**

To characterize the types of drug and dietary supplement inquiries submitted to the National Center for Drug Free Sport through the Resource Exchange Center athletes and athletic personnel associated with the National Collegiate Athletic Association (NCAA) it was classification he drugs and dietary supplement of inquiries. Inquiries for prescription medications for albuterol inhalers, methylphenidate, amphetamines, and prednisone were the most common using a drug lookup function. The most common inquiries for over-the-counter medications included pseudoephedrine, loratadine, cetirizine, and caffeine. Among dietary supplements, inquiries for amino acids/metabolites, vitamins and minerals, and herbal products occurred most frequently. One dietary supplement, N.O.-Xplode (Bio-Engineered Supplements and Nutrition, Inc.), accounted for the majority of individual dietary supplement inquiries. Banned substances accounted for 30 percent of all inquiries submitted to the REC and 18 percent of medications searched in a drug lookup database. Almost 25,000 inquiries were submitted to the REC. Pharmacists can use this information to advise, counsel, and refer NCAA athletes regarding the use of banned and permitted substances. Education programs regarding stimulants, dietary supplements, and the risk of using substances such as animal byproducts are needed, and pharmacists can participate in these programs [13581].

**US position statement**

To help athletic trainers promote a “food-first” philosophy to support health and performance, understand federal and sport governing body rules and regulations regarding dietary supplements and banned substances, and become familiar with reliable resources for evaluating the safety, purity, and efficacy of dietary supplements a position statement was made. The dietary supplement industry is poorly regulated and takes in billions of dollars per year. Uneducated athletes need to gain a better understanding of the safety, eligibility, and efficacy concerns associated with choosing to take dietary supplements. The athletic trainer is a valuable athletic team member who can help in the educational process. In many cases, athletic trainers are asked to help evaluate the legality, safety, and efficacy of dietary supplements. Proper nutrition and changes in the athlete's habitual diet should be considered first when improved performance is the goal. Athletes need to understand the level of regulation (or lack thereof) governing the dietary supplement industry at the international, federal, state, and individual sport-participation levels. Athletes should not assume a product is safe simply because it is marketed over the counter. All products athletes are considering using should be evaluated for purity (i.e. truth in labeling), safety, and efficacy [13582].
US children

Dietary supplements may improve sport performance in adults. However, this has not been established in children. The aim of this study was to assess self-reported or parental-reported dietary supplement use to enhance sports performance among the child subset of the National Health Interview Survey (NHIS) dataset and determine national population estimates for that use. NHIS 2007 Child Alternative Medicine files containing records for children aged 18 years were used. Typical demographic variables were utilized as well as parental presence; parental education level; use of any herb, vitamin, and/or mineral use for sports performance by children; and age. Most (95%) who reported using supplements used multivitamin and/or mineral combinations followed by fish oil/omega-3 s, creatine, and fiber. Males were more likely users (OR = 2.1) and whites reported greater usage. Mean user age was 11. Most were US born and reported living with both parents. Parents and children report child use of a wide variety of herbal and vitamin/mineral supplements to improve sports performance. Usage could be predicted by age, gender, and level of education but less likely by parent-based demographics [12369].

Saudi Arabia

The objective of one study was to understand the usage patterns of dietary supplements among professional athletes in Saudi Arabia. The survey consisted of sixteen questions divided into four categories: use of supplements, reason for consumption of supplements, personal beliefs about supplements, and behavior. The questionnaires were given to the three teams residing in Riyadh: Al Hilal, Al Nasr, and Al-Shabab. Out of the 105 athletes surveyed, we found that only 98 are currently taking dietary supplements and the mean age was 26. The survey results showed a high percentage of athletes (93%; n=98) using different dietary supplements throughout the season, 44 percent (n=43) reported using supplements for performance, and 33 percent (n=32) believed in health benefits as a reason for using dietary supplements. The results showed that a total of 87 (89%), 81 (83%), and 51 (52%) athletes are consuming sports drinks, vitamin C, and multivitamins, respectively. Meanwhile, those supplements ranking among the least used included omega 6 (19%), creatine (16%), and Ginkgo biloba (10%). A majority of athletes indicated that their use of supplements was for the purpose of improving their health and performance [13583].

Oman

Adequate dietary intake is crucial for optimum training and performance of athletes. There is almost no available information related to dietary practices among Omani athletes, especially during the competition. One study aimed to assess the nutritional practices (nutritional knowledge, eating habits and daily nutrients intake) among Omani male handball athletes in Muscat city, Oman. It was a cross sectional study including 35 male handball athletes involved in serious training for no less than three years. Data collection was done through personal interviews using a study questionnaire which enlisted questions relating to socio-demographic information, anthropometric measurements and nutritional practices. All the study participants declared no intake of anabolic steroids. The mean age of the study participants was 27 ± 3 years. Their anthropometric assessment revealed that their mean height was 166 ± 12 cm, mean weight was 75 ± 10 kg, and body mass index was 27 ± 3. Nutritional knowledge analysis revealed that 80 percent had no nutritional supervision by a nutritionist/dietitian. Their knowledge of nutritional requirements was only 23 percent correct for total energy intake, 63 percent for protein intake, 46 percent for carbohydrate intake, 11 percent for fat intake and 83 percent for water intake. Eating habits indicated that 55 percent had <3 meals/day, 51 percent had lunch as the principal meal, 51 percent always added extra salt to their food, 28 percent took protein supplements on a daily basis, and 51% used pre-competition glycogen load diet. However, none consumed vitamins or mineral
supplements. The mean daily caloric intake was 3674 ± 265 kcal/day, which was roughly comprised of 596 ± 66 g carbohydrates, 147 ± 28 g of protein and 78 ± 20 g of total fat.

**Judo**

One research investigated the use of dietary supplement patterns and doping awareness among high-ranked Judoists from two countries. Korean (70 males and 31 females) and Japanese (37 males and 34 females) national Judo team members were divided into two groups (high and low competitive performance levels) according to their international and national rankings. Fifty-nine percent of Korean and 61 percent of Japanese Judoists consumed dietary supplements. Eighty-eight percent of high and 51% of low competitive performance level Korean Judoists consumed dietary supplements. Sixty-eight percent of high and 57 percent of low competitive performance level Japanese Judoists consumed dietary supplements. Oriental supplements (34 %), vitamins (23 %), and protein powder (12 %) were most commonly consumed dietary supplements in Korean Judoists. Otherwise, vitamins (45 %), protein powder (33 %), and minerals (15 %) were most commonly consumed dietary supplements in Japanese Judoists. Thirty-eight percent of Judoists from both countries had not received any proper education about anti-doping and 44 percent of Judoists from both countries had not received about knowledge of anti-doping legislation. There was a significant difference in education about anti-doping between high and low competitive performance levels of Korean Judoists. Korean Judoists received significantly less anti-doping education than Japanese Judoists. The findings showed Judoists' use of dietary supplement from both countries was increased followed by experiencing anti-doping education.

**Sailing**

Olympic sailing classes were first used in sailing (also known as yachting) during the 1896 Olympic Summer Games. Since then, 46 different classes have been used. As of this writing, 8 Olympic classes are currently used. Apart from tactical and strategic factors, performance
in Olympic sailing relates directly to the sailors’ ability to overcome the external forces imposed on the boat. Although dietary supplements (DSs) in sports are considered a natural need resulting from athletes’ increased physical demands, and although they are often consumed by athletes, data on DS usage in Olympic sailing are scarce. The aim of one study was to study the use of and attitudes towards DSs and doping problems in high-level competitive sailing. The sample consisted of 44 high-level sailing athletes (5 of whom were female; total mean age 24 years) and 34 coaches (1 of whom was female; total mean age 37). An extensive, self-administered questionnaire of substance use was used, and the subjects were asked about sociodemographic data, sport-related factors, DS-related factors (i.e., usage of and knowledge about DSs, sources of information), and doping-related factors. DS usage is relatively high. More than 77 percent of athletes consume DSs, and 38 percent do so on a regular basis (daily). The athletes place a high degree of trust in their coaches and/or physicians regarding DSs and doping. The most important reason for not consuming DSs is the opinion that DSs are useless and a lack of knowledge about DSs. The likelihood of doping is low, and one-third of the subjects believe that doping occurs in sailing (no significant differences between athletes and coaches). The logistic regression found crew number (i.e., single vs. double crew) to be the single significant predictor of DS usage, with a higher probability of DS consumption among single crews. It was concluded that because of the high consumption of DSs future investigations should focus on real nutritional needs in sailing sport. Also, since athletes reported that their coaches are the primary source of information about nutrition and DSs, further studies are necessary to determine the knowledge about nutrition, DSs and doping problems among athletes and their support teams (i.e. coaches, physicians, and strength and conditioning specialists) [12371].

Football

Physical training and competition in football markedly increase the need for macro- and micronutrient intake. This requirement can generally be met by dietary management without the need for dietary supplements. In fact, the efficacy of most supplements available on the market is unproven. In addition, players must be cautious of inadequate product labelling and supplement impurities that may cause a positive drug test. Nonetheless, a number of dietary supplements may beneficially affect football performance. A high endurance capacity is a prerequisite for optimal match performance, particularly if extra time is played. In this context, the potential of low-dose caffeine ingestion (2-5 mg/kg body mass) to enhance endurance performance is well established. However, in the case of football, care must be taken not to overdose because visual information processing might be impaired. Scoring and preventing goals as a rule requires production of high power output. Dietary creatine supplementation (loading dose: 10-20 g/day, 4-5 days; maintenance dose: 2-5 g/day) has been found to increase muscle power output, especially during intermittent sprint exercises. Furthermore, creatine intake can augment muscle adaptations to resistance training. Team success and performance also depend on player availability, and thus injury prevention and health maintenance. Glucosamine or chondroitin may be useful in the treatment of joint pain and osteoarthritis, but there is no evidence to support the view that the administration of these supplements will be preventative. Ephedra-containing weight-loss cocktails should certainly be avoided due to reported adverse health effects and positive doping outcomes. Finally, the efficacy of antioxidant or vitamin C intake in excess of the normal recommended dietary dose is equivocal. Responses to dietary supplements can vary substantially between individuals, and therefore the ingestion of any supplement must be assessed in training before being used in competition. It is recommended that dietary supplements are only used based on the advice of a qualified sports nutrition professional [06251].

There are surveys of the use of drugs in adolescents in school and college sport teams, but few data are available on professional players, mostly because access to large numbers of
elite athletes is restricted, and because elite athletes are generally reluctant to discuss their habits. One study conducted on English professional soccer players reported data on supplement and vitamin use in a selected sample of subjects, and another study reported information on permitted drug usage in Olympic athletes, not involving soccer. A cohort of 1041 professional soccer players from the two Italian major leagues was now assembled during the season 2003-4; 743 of the 785 (95 %) subjects available on the day of the interview answered an epidemiological questionnaire, which included questions on the type and frequency of use of several permitted drugs. The main aim of this study was to collect information about the health status of the soccer players; therefore the questionnaire did not ask about players' own use of drugs or about recreational drugs. In addition, a brief questionnaire was filled in by the team doctors, to gather details on the therapeutic schemes used for traumas and for other common pathologies, as well as the type and dosage of vitamins and supplements usually prescribed to the players. Information on recommended vaccinations and on general preventive activity performed by the doctor on the team was also collected. Of the 18 team doctors from the A league, 12 answered the questionnaire, and 17 of 18 doctors from the B league answered the questionnaire. Ninety-three percent of players reported having used oral anti-inflammatory products in the previous year, and most of them were current users (86 %). Thirty-six percent of the players, mostly current users, reported the use of analgesics. Eighty-three percent of the players reported current use of supplements, and 28 percent reported using vitamins. Some aspects of players' use of permitted drugs merit further comment. From the team doctors' questionnaires, it seems that the use of supplements and vitamins should be less than that reported by the players. This suggests that team doctors are not always consulted by players about their use of supplements and vitamins, and perhaps about the use of other drugs. This is of particular concern because creatine is often included among the supplements, and could consequently be used in excessively high and potentially dangerous doses. Another reason for concern is the reported possibility that supplements may be contaminated with banned substances; therefore unregulated use may create health concerns. It was concluded that the regular use of several permitted drugs is very high among professional soccer players. The description of players' behaviour is the first step towards regular monitoring of the players' need for, and use of, vitamins, supplements and other permitted drugs [07230].

**Track and field**

Many athletes use dietary supplements as part of their regular training or competition routine, including about 85 percent of elite track and field athletes. Supplements commonly used include vitamins, minerals, protein, creatine, and various "ergogenic" compounds. These supplements are often used without a full understanding or evaluation of the potential benefits and risks associated with their use, and without consultation with a sports nutrition professional. A few supplements may be helpful to athletes in specific circumstances, especially where food intake or food choice is restricted. Vitamin and mineral supplements should be used only when a food-based solution is not available. Sports drinks, energy bars, and protein-carbohydrate shakes may all be useful and convenient at specific times. There are well-documented roles for creatine, caffeine, and alkalinizing agents in enhancing performance in high-intensity exercise, although much of the evidence does not relate to specific athletic events. There are potential costs associated with all dietary supplements, including the risk of a positive doping result as a consequence of the presence of prohibited substances that are not declared on the label [07231].

**Rowing**
The aim of one study was to compare the effectiveness of different nutritional recovery strategies between weigh-in and racing on 2000-m rowing ergometer performance among oarsmen undertaking short-term weight loss before competition. Competitive rowers (n=12) completed four ergometer trials, each separated by 48 h. No weight restrictions were imposed for the first trial (TR1). Thereafter, athletes were required to reduce their body mass by 5.2 percent in the 24 h before trial 2 (TR2), again reaching this body mass before the final two trials (TR3 and TR4). Athletes were provided with one of three nutritional recovery strategies in the 2 h between weigh-in and racing in a counterbalanced fashion according to a Latin square design: fluid (2.8 kJ/kg, 0.0 g/kg carbohydrate, 0.6 mg/kg sodium, 28.5 mL/kg fluid; FLU), carbohydrate/sodium (45.3 kJ/kg, 2.2 g/kg carbohydrate, 32.9 mg/kg sodium, 7.2 mL/kg fluid; CHO), and a combination of water and carbohydrate/sodium (44.8 kJ/kg, 2.3 g/kg carbohydrate, 33 mg/kg sodium, 28.5 mL/kg fluid; COM). Performance was slower for CHO compared with both COM and FLU. However, FLU was not significantly slower than COM. The present investigation has shown that although carbohydrate and sodium intake may be important in the recovery period between weigh-in and 2000-m rowing ergometer performance, fluid intake has a greater influence on performance among lightweight male rowers who undertake short-term weight loss to achieve specified body-mass limits [07232].

**Males and females**

One study was designed to determine if differences exist between male and female collegiate athletes' supplement use and behaviors to modify body appearance. Collegiate athletes who participated in this study were 241 females and 210 males, aged 17 to 28 years. Participants completed a questionnaire about the average number of times each week they performed specific supplementing, exercise, or dietary behaviors. The authors found differences associated with gender for 9 of the 18 behaviors. Specifically, 2 of these 9 behaviors were dietary, 1 was supplementary, 3 were physique concerns, and 3 involved personal motivation for weightlifting. It was concluded that male athletes reported a higher drive for size, speed, and power, whereas female athletes were more concerned with body fat, more likely to restrict caloric intake, and more prone to consume weight loss supplements. No differences were found by gender regarding supplement use to increase body size [09319].

**Use of nutritional supplements among master athletes**

It was assessed the use of nutritional supplements among master athletes focusing on their source of information and source of supply of nutritional supplements. 1560 standardized, anonymous questionnaires were distributed among participants of the World Masters Athletics Championships Indoors 2004. These questions were related to biometric parameters, social indicators, training parameters, illicit drugs, and nutritional supplements. Chi2-tests were computed to reveal meaningful associations between basic information (age, gender, family status, children, education, country of origin, disciplines, training years, smoking, and the use of alcohol, illicit drugs, and doping) and the intake of nutritional supplements. Descriptive information on the history of their use of nutritional supplements was also provided. Sixty-one percent of all participants reported the actual use of nutritional supplements. It was found no significant differences between nutritional supplement users and non-users with regard to basic information. The substances predominantly used were vitamins (35 %) and minerals (30 %). In contrast to elite athletes who use nutritional supplements to increase their athletic performance, master athletes use these substances predominantly for health reasons and, thus, have a closer contact to the health care system. Physicians are their preferred source of information about nutritional supplements. More than half of the interviewed athletes obtain their nutritional supplements from pharmacies or
physicians. The results of this study indicate that nutritional supplement users in master athletics show no specific user profile. Since it is not rare for nutritional supplements to contain trace contaminations of anabolic androgenic steroids or pro-hormones, physicians should also inform master competitive athletes of the dangers of testing positive for doping substances due to their intake of nutritional supplements and advise them accordingly [06246].

Use of dietary supplements among adolescents

USA
The purpose of one study was to investigate the prevalence of dietary supplement use among adolescent athletes. The project was also directed at identifying the sources these student-athletes used for acquiring information about dietary supplements. One hundred thirty nine high school athletes (99 males; 34 females; mean age 16 years) volunteered to participate in this study. A 16-question anonymous survey instrument examined use of dietary supplements, reasons for use, type of sport participation, and sources of information regarding dietary supplements. Of the participants in this study, 22 percent (n=31) reported currently taking dietary supplements. There was no relationship found between dietary supplement use and age. There were a significantly higher number of males reporting current dietary supplement use. Of those who reported to be currently taking dietary supplements, sports performance (n=25) was the most reported reason for use. There were no significant differences found in reported dietary supplement use between any of the sports. Of the participants, 38 percent (n=53) listed their coach as their best source of information on dietary supplements. The results of this study offer the current literature some additional insight into trends in supplement use among high school student athletes. Practical implications suggest that it may be necessary to ensure coaches have sufficient knowledge about dietary supplements so that adolescent athletes are receiving accurate information [06249].

The role of the school nurse

An alarming trend in the United States is the use of performance-enhancing supplements by children and adolescents. These widely available over-the-counter products, often marketed as natural substances, are not regulated by the Food and Drug Administration and are thus widely available. High school and even middle school students are using these supplements because they are misled into thinking that supplements will enhance their athletic skills resulting in an improvement in their performance. Yet, the safety and long-term effects of these supplements have not been established in reputable or prevalent studies. School nurses have a unique opportunity and even an ethical responsibility to help in efforts to address this growing trend. Specific roles for the school nurse include serving as a student advocate for the health and safety of children and adolescents; identifying at-risk students; forming partnerships with teachers, parents, students, coaches, athletic trainers, and local health care providers; evaluating and refining health-oriented curricula; collecting and disseminating new knowledge; and staying abreast of new findings [06250].

Recovery after sports

To reduce the magnitude of fatigue and to accelerate the time to fully recover after completion, several recovery strategies are now used in professional soccer teams. During congested fixture schedules, recovery strategies are highly required to alleviate post-match fatigue, and then to regain performance faster and reduce the risk of injury. Fatigue following competition is multifactorial and mainly related to dehydration, glycogen depletion, muscle
damage and mental fatigue. Recovery strategies should consequently be targeted against the major causes of fatigue. Strategies reviewed of one article were nutritional intake, cold water immersion, sleeping, active recovery, stretching, compression garments, massage and electrical stimulation. Some strategies such as hydration, diet and sleep are effective in their ability to counteract the fatigue mechanisms. Providing milk drinks to players at the end of competition and a meal containing high-glycaemic index carbohydrate and protein within the hour following the match are effective in replenishing substrate stores and optimizing muscle-damage repair. Sleep is an essential part of recovery management. Sleep disturbance after a match is common and can negatively impact on the recovery process. Cold water immersion is effective during acute periods of match congestion in order to regain performance levels faster and repress the acute inflammatory process. Scientific evidence for other strategies reviewed in their ability to accelerate the return to the initial level of performance is still lacking. These include active recovery, stretching, compression garments, massage and electrical stimulation. While this does not mean that these strategies do not aid the recovery process, the protocols implemented up until now do not significantly accelerate the return to initial levels of performance in comparison with a control condition. In conclusion, scientific evidence to support the use of strategies commonly used during recovery is lacking. Additional research is required in this area in order to help practitioners establish an efficient recovery protocol immediately after matchplay, but also for the following days. Future studies could focus on the chronic effects of recovery strategies, on combinations of recovery protocols and on the effects of recovery strategies inducing an anti-inflammatory or a pro-inflammatory response [13586].

Individualized nutrition as doping

Food has societal, economic, medical and ethical implications, being fundamental for life. It plays an important role also in sports medicine, since a healthy diet is an important part of an athlete's training. Nutrigenomics and nutriproteomics are emerging as a result of a convergence of nutritional, genomics and proteomics knowledge strands in the postgenomics era. These fields of inquiry present an opportunity for the design of customized diets potentially able to counterbalance the extant obesity epidemic and remedy metabolic diseases, among others. They are noteworthy for sport medicine as well since they could provide athletes with crucial information for personalized training and nutrition, in order to achieve the best results possible and express one's own potential. But they could also be used as a form of personalized doping, thus constituting an advancement of "classical nutrition-based doping" (i.e. the use of nutraceuticals, stimulants and supplements). However, nutrigenomics (or nutriproteomics)-based nutritional doping is different from the first-generation doping because it is specifically tailored to the genomics and proteomics makeup of the athlete, although their effectiveness remain to be discerned in future systematic studies. Against this scientific background, ethical issues of nutrigenomics and nutriproteomics are discussed in the present paper with emphasis on the current limitations and the dizzying potentials of the omics data-intensive research for science and society. Additionally, I discuss the need to communicate uncertainty as a fundamental construct and intrinsic part of postgenomics personalized medicine, not to forget the gaps regarding the lack of adequate governance, and issues over providing a proper nutritional education to athletes as onus of the international sports organizations. "Let food be your medicine, and medicine be your food" Hippocrates [13587].

Side effects

Cholestatic jaundice
A 50-year-old Hispanic male presented to the hospital with a 1-week history of significant painless jaundice; total bilirubin on admission was 29.4 mg/dL. He reported use of both herbal (creatine and whey protein) and designer (Incredible Bulk and Spartan 45) supplements concurrently for approximately 2 months. Upon admission, all supplements were discontinued and multiple laboratory and diagnostic tests were ordered. On day 6 of his hospital admission, a liver biopsy was performed, the results of which indicated drug-induced hepatic toxicity. On day 9 he was discharged with prescriptions for ursodeoxycholic acid and hydroxyzine. Three months post hospital discharge, the patient continued to be supplement-free and bilirubin had decreased substantially. Anabolic-androgenic steroids are capable of causing hepatotoxicity, and multiple cases reported in the literature support this. A case report described hepatotoxicity secondary to both creatine and whey protein consumption, and several reports have described liver damage secondary to designer supplement use. This is the first case to describe hepatotoxicity as a result of combination herbal and designer supplement use. The Roussel Uclaf Causality Assessment Method score for drug-induced hepatotoxicity indicated a highly probable correlation between the use of combination supplements and cholestatic jaundice [13588].

Contaminated supplements

Based upon recent sales numbers, nutritional supplements play a key role in the lifestyle of a substantial proportion of the population. As well as products such as vitamins or minerals, several precursors of anabolic steroids are marketed as nutritional supplements. Another group of commercially available supplements are products for weight loss based upon herbal formulations originating from Ephedra species. Apart from supplements indicating the presence of these active compounds, numerous non-hormonal nutritional supplements were found that were contaminated with non-labelled anabolic steroids. Stimulating agents other than naturally occurring analogues of ephedrine were detected. A major group using dietary supplements are sportsmen, ranging from amateur level to elite athletes. Besides the possible health risks associated with the use of dietary supplements, athletes should take care not to violate the rules of the World Anti-Doping Agency because athletes remain responsible for substances detected in their biofluids, irrespective of their origin. Several analytical methods have been developed to determine the presence of doping agents as contaminants. One review attempted to address the issues concerning the use of nutritional supplements and the detection of doping agents as contaminants in dietary supplements [06243].

One of the key factors that elite athletes need to consider in negotiating the complex world of supplements and sports foods is whether the consumption of these products could lead to an inadvertent case of doping. Following the wave of nandrolone findings in the late 90s, several studies have sought to explore the extent of contamination. In 2000-2001, the International Olympic Committee (IOC) funded an extensive research project using the then IOC-accredited laboratory in Cologne to analyse independently 634 non-hormonal nutrition supplements purchased across 13 countries. This pivotal research confirmed the contamination issue, with 15 percent (94 products) being found to contain undeclared steroids banned by the World Anti-Doping Agency. Altogether, 289 samples (21 % positives) were from companies that were known to sell steroids/prohormones but, perhaps more worrying, 345 samples (10 % positives) came from companies that did not sell steroids/prohormones. In 2007, HFL Sport Science (a WADA-experienced laboratory, part of the Quotient Biosciences group) in the UK analysed 58 supplements purchased through standard retail outlets in the USA. They found that 25 percent were contaminated with
prohibited steroids and 11 percent were contaminated with prohibited stimulants. In 2008, HFL Sport Science followed this up with the analysis of 152 products purchased from standard retail outlets in the UK and found that over 10 percent were contaminated with steroids and/or stimulants. The amounts of steroids detected have been extremely variable, even within a single batch, but have generally been extremely small. However, very low levels of contamination (measured in parts per billion) can cause positive drug tests in an elite athlete at a level much lower than acceptable impurity levels (typically around 0.01 %) in good manufacturing practice regulations. It is important to note that, although this minimal amount of contamination could produce dire consequences for an athlete competing under the WADA code, in most cases, this amount is unlikely to cause detrimental health problems for the general consumer. There are daily food product withdrawals and recalls because of mislabelling and undeclared allergens. This, together with concerns about impurities and contamination from medicine residues, insects and small pieces of metal and plastic, shows that inadvertent contamination is not just a problem for sports nutrition products. The inadequate regulation of dietary supplements means there is no way for consumers to know what many supplements actually contain or how pure the product and its ingredients are. Manufacturers with good-quality controls and banned substance testing are better able to control the risk. The inception of the WADA code and the implications of strict liability means that an athlete is held responsible for whatever is in their body irrespective of how it got there. Therefore, athletes who compete under the WADA code should be extremely cautious about using supplements and always work with a qualified professional on risk minimisation of supplement use [09308].

Practitioners who work with elite athletes know that the pressure and considerable rewards involved with success provide a high level of motivation to look for any safe and legal strategy that might enhance performance, even by small margins. Dietary supplements operate in this space, whether they promise a large performance boost or just create the fear that an athlete cannot afford to miss out on what everyone else is using. It is often tempting to overlook the lack of evidence to support the claims made about a supplement on the basis that the stakes are higher for elite athletes; therefore the cost:benefit ratio favours experimentation in the absence of clear proof. Over the past decade, however, we have become aware that the cost of getting it wrong has also escalated for elite athletes. A new hazard related to supplement use has emerged: inadvertent ingestion of substances that are banned under the antidoping codes in place in elite sport, but present in supplement products. In some cases, the level of the presence, or contamination, of banned substances in supplements presents a health hazard for all consumers. In some cases, the concentration may be too small to achieve any health or performance effect but large enough to record an infringement for athletes who submit to doping tests. Newspapers, the internet and Courts of Arbitration in Sport now bear stories of dedicated athletes whose careers have been or are being jeopardized because of the ingestion of a banned substance via a dietary supplement [11425].

The increasing availability and use of sports supplements is of concern as highlighted by a number of studies reporting endocrine disruptor contamination in such products. The health food supplement market, including sport supplements, is growing across the Developed World. Therefore, the need to ensure the quality and safety of sport supplements for the consumer is essential. The development and validation of two reporter gene assays coupled with solid phase sample preparation enabling the detection of estrogenic and androgenic constituents in sport supplements is reported. Both assays were shown to be of high sensitivity with the estrogen and androgen reporter gene assays having an EC50 of 0.01 ng/mL and 0.16 ng/mL respectively. The developed assays were applied in a survey of 63 sport supplements samples obtained across the Island of Ireland with an additional seven reference samples previously investigated using LC-MS/MS. Androgen and estrogen bio-
activity was found in 71% of the investigated samples. Bio-activity profiling was further broken down into agonists, partial agonists and antagonists. Supplements (n=13) with the strongest estrogenic bio-activity were chosen for further investigation. LC-MS/MS analysis of these samples determined the presence of phytoestrogens in seven of them. Supplements (n=38) with androgen bio-activity were also selected for further investigation. Androgen agonist bio-activity was detected in 12 supplements, antagonistic bio-activity was detected in 16 and partial antagonistic bio-activity was detected in 10. A further group of supplements (n=7) did not present androgenic bio-activity when tested alone but enhanced the androgenic agonist bio-activity of dihydrotestosterone when combined. The developed assays offer advantages in detection of known, unknown and low-level mixtures of endocrine disruptors over existing analytical screening techniques. For the detection and identification of constituent hormonally active compounds the combination of biological and physio-chemical techniques is optimal [11371].

Since 1999 several groups have analyzed nutritional supplements with mass spectrometric methods (GC/MS, LC/MS/MS) for contaminations and adulterations with doping substances. These investigations showed that nutritional supplements contained prohibited stimulants as ephedrines, caffeine, methylenedioxy-metamphetamie and sibutramine, which were not declared on the labels. An international study performed in 2001 and 2002 on 634 nutritional supplements that were purchased in 13 different countries showed that about 15 percent of the nonhormonal nutritional supplements were contaminated with anabolic-androgenic steroids (mainly prohormones). Since 2002, also products intentionally faked with high amounts of "classic" anabolic steroids such as metandienone, stanozolol, boldenone, dehydrochloromethyl-testosterone, oxandrolone etc have been detected on the nutritional supplement market. These anabolic steroids were not declared on the labels either. The sources of these anabolic steroids are probably Chinese pharmaceutical companies, which sell bulk material of anabolic steroids. In 2005 vitamin C, multivitamin and magnesium tablets were confiscated, which contained cross-contaminations of stanozolol and metandienone. Since 2002 new "designer" steroids such as prostanozol, methasterone, androstatrienedione etc have been offered on the nutritional supplement market. In the near future also cross-contaminations with these steroids are expected. Recently a nutritional supplement for weight loss was found to contain the beta2-agonist clenbuterol. The application of such nutritional supplements is connected with a high risk of inadvertent doping cases and a health risk [08382].

The potential for contaminated dietary supplements to result in a failed doping test remains a concern for athletes, trainers, and sporting authorities despite improvements to regulatory guidelines. Previous surveys of readily available supplements confirm that many are contaminated with steroids and stimulants prohibited for use in elite sport. Suggested responses to this issue include the complete avoidance of all supplements. Many athletes, however, use nutritional supplements to achieve effective training and also to ensure that daily nutritional requirements are met (e.g. recommended levels of vitamins and minerals). This ensures that the use of supplements is and will remain the norm for a range of sports. As a result, an alternative approach of rigorous testing of materials destined for use by elite athletes has been introduced in several countries. While the testing of final product for banned substances may help mitigate the problem, it will not help to remove the underlying issue of contamination. In one article it was described an alternative approach that uses appropriate quality assurance procedures backed up by testing to remove sources of contamination. The decrease in the incidence of contamination amongst supplement companies adopting such a system is explained, and contrasted with the relatively high incidences of contamination found in products that are not part of a quality system. These findings are of key importance to both supplement manufacturers and those involved in advising athletes about supplement use [10310].
A simple and effective analytical method for the determination of anabolic steroids and related compounds in nutritional supplements was reported. Target compounds are extracted with ethyl acetate, crude extract is purified using dispersive solid-phase extraction (SPE) with primary secondary amine as sorbent, and finally they are identified and quantified as underivatized compounds using two-dimensional gas chromatography with time-of-flight mass spectrometric detection (GCxGC-TOF MS). This method was validated for 25 steroids in two types of commercially available solid nutritional supplements: protein concentrate and creatine monohydrate. Repeatability expressed as the relative standard deviation of analyte concentration ranged from 4.1 to 20.5%. Recoveries between 70 and 123 percent were obtained for the target compounds except for oxymetholone in protein concentrate where the recovery was low as a result of strong interactions with primary secondary amine. Excellent linearity was obtained for six-point calibration with regression coefficients of 0.997-1.000 for all compounds. The limits of quantification ranged from 0.007 to 0.114 mg/kg. For a monitoring programme of 48 samples of nutritional supplements, three were positive. Nandrolone, testosterone, dehydroepiandrosterone (DHEA), 5alpha-androstan-3,17-dione, 19-norandrostendione and progesterone were found in positive samples at concentrations between 0.022 and 0.398 mg/kg.

In the 1990s the IOC issued a public warning when certain supplements appeared to contain unlabelled pseudo-ephedrine, at that time a prohibited substance. This issue was brought to a head by sprinter Linford Christie, who tested positive for pseudo-ephedrine during the Olympic Games of 1988, but (as a rare exception) was not sanctioned because the likely source was a cup of ginseng tea. Contamination of ginseng is often cited as a potential hazard. Christie also tested positive for nandrolone in 1999. In the UK, the number of nandrolone positives jumped from an average of 3.4 in the years 1994–1998 to 17 in 1999; an increase from 0.08 percent to 0.29 percent of all the samples analysed. A possible cause of this increase was the ingestion of contaminated nutritional supplements. A few years later, it was concluded that this statistical increase appeared to have been exceptional and was only present within the UK in 1999, but from 2000 onwards the subject of nutritional supplements and doping entered the limelight. In subsequent years, more and more studies were published that confirmed the hypothesis that supplements could indeed cause unintentional doping infractions. Other publications showed that unlabeled doping substances can be found in a variety of products and thoroughly discussed the risks for elite athletes. The information on this issue came mainly from the WADA-accredited laboratory in Cologne that conducted an IOC-sponsored study in 2004. This study showed that 15 percent of 634 freely available substances contained anabolic agents that were not declared on the label. These products were partly selected because the producers of these substances also sold pro-hormone containing products. The risk of buying a contaminated supplement is about twice as high in products from such companies. The amounts that were found varied from 10 ng/g or parts per billion (ppb) to 190 microg/g or parts per million (ppm). Later studies found even higher and profoundly dangerous amounts of anabolic agents, up to 17 mg of unlabeled metandienone per tablet.

The fact that nutritional supplements can lead to a positive urine test has been consistently found in various studies. The risk of producing a positive doping test can be present for hours to days after the ingestion of one single supplement, depending on the substance, dose, and individual variation in metabolism. The difficulty of finding possible contaminations of a nutritional supplement was shown in one of the very first studies addressing this problem. A group from an anti-doping laboratory in Los Angeles, California, USA proved the existence of tablet-to-tablet variation in contaminations. This variation was confirmed later that year and is still likely to exist. The experiences from the laboratories show that contaminations can be present in the raw materials that are used, both in the active ingredients and in the
substances used to make tablets or capsules. This type of contamination is often referred to as “cross-contamination”. A second source of contamination might result from a lack of sufficient hygiene in the machinery that is being used during the production process. Contamination problems in nutritional supplements can be found in any country. It concerns all types of nutritional supplements and all forms, including powders, pills, capsules, and liquids. Likewise, experience shows that contaminations can occur with a multitude of doping substances. Examples of nutritional supplements that have been contaminated with doping substances are branched-chain amino acids (BCAAs), creatine, glutamine, guarana, minerals, ornithine-alpha-ketoglutarate (OKG), proteins, pyruvate, ribose, saw palmetto, Tribulus terrestris, vitamins, zinc, 4-androsten-3,17-diol, 4-androsten-3,17-dion, 5-androsten-3,17-diol, 19-nor-4-androsten-3,17-diol, 19-nor-4-androsten-3,17-dion, 19-nor-5-androsten-3,17-diol, 19-nortestosterone (nandrolone), benzylpiperazine, caffeine (off the WADA doping list since 1 January 2004), dehydroepiandrosterone (DHEA), ephedrine, methandienone, methylenedioxymethylamphetamine (MDMA or XTC), nor-pseudo-ephedrine, sibutramine, stanozolol, and testosterone. Even though these lists might not be complete, the variety of substances found indicates the magnitude of the problem. It also shows that contaminations in nutritional supplements are most likely to occur with substances that are part of the groups of anabolic agents or stimulants. The problems surrounding nutritional supplements that contain unlabeled doping substances have often been attributed to the Dietary Supplement Health Education Act (DSHEA) that was passed in the USA in 1994. The DSHEA has often been accused of introducing a system where quality control is lacking. This Act has undoubtedly played a large role in creating the problem of contaminated substances, because of the strong influence of the USA on the global market and the consequent spread of (traces of) anabolic agents and strong stimulants. But this problem does not only originate from the USA. Any facility that is part of the production or storage process of nutritional supplements, or that handles doping substances in addition to doping-free products, could be a source of the eventual downfall of an ignorant athlete. Globally there is a great difference in the quality procedures surrounding pharmacological medications and nutritional supplements, but the difference between these two groups is not always as clear as it should be. Based on the published facts that a precursor of an anabolic steroid in an amount between 1 and 10 microg can cause a positive doping test, and based on the fact that athletes easily use 50 g of supplements per day or more, a reporting threshold value of 10 ng/g or 10 ppb for all anabolic steroids is used in all tests. This value also allows for individual variations in metabolism. Excretion studies for stimulants are rare, but similar considerations led to the conclusion that for stimulants, a reporting threshold value of 100 ppb is opportune. However, the only way athletes are able to enjoy a 100 percent guarantee is when they decide not to take any supplements at all. But there are certainly some circumstances when dietary supplements provide an added benefit to diet and, in the world of elite sport where the ultimate goal is to reach one's best, it is not fair to deny athletes the use of legal substances that could improve their health, such as anti-oxidants and multivitamins. Although there are some studies that suggest that there is a relationship between (legal) supplement use and (illegal) doping use, these are only based on epidemiological data and causality has never been established [07025].

Even athletes who are careful can test positive for doping because of a contaminated nutritional supplement. This is a disconcerting thought, but an unavoidable consequence of the current situation in the nutritional supplement industry. However, years after the sudden rise in nandrolone positives in the UK (around 1998-1999) and the wealth of experience with this issue in the meantime, ignorance is no excuse for today's elite athletes. Two types of contamination can be identified. The first type is from malpracticing producers who do not care about consumer health or even deliberately spike products with known effective substances such as anabolic steroids or their precursors. Generally, such companies change
identity quickly and most often sell their products over the Internet. Occasionally, the products might emerge in regular shops, but a country’s health directorate is highly likely to pick up such products and take them off the market. Most of the time this type of company uses advertisements with unrealistic claims, and athletes and their support personnel should be able to avoid this type of supplement easily. The second type of contamination is more subtle and more difficult to detect, and thus more of a concern to athletes with good intentions. The nature of the origin of such contaminations (mostly cross-contamination from other products, frequently not in the facility where the end-product is made and packed and therefore always unexpected) makes it very difficult to pick up such contaminations, even for well-intentioned producers who follow strict quality procedures. Experience shows that such supplements can contain doping substances despite these extra efforts. Even though the level of such contaminations might be low, even very low amounts of doping substances can suffice to cause a positive urine sample for a window of several hours after the consumption of such a product [07025].

The Cologne study, performed in 2001, showed that the Netherlands faced one of the biggest contamination issues in Europe. In November 2001, the athletes nominated to go to the Winter Olympics in Salt Lake City 2002 were given an opportunity to have their supplements tested for doping substances. They were asked to buy a supply of the nutritional supplements they were going to use during their preparation for the Olympics from a controlled sample of one batch. From this supply, a random selection of supplements was tested for several anabolic steroids, their precursors, and several stimulants. The results of this preliminary study gave a clear insight of the seriousness, size, and scope of the problem. Of the 69 supplements that were submitted (mainly vitamins, minerals and creatine), 13 (19%) contained unlabeled doping substances. Most products showed traces of caffeine and/or ephedrine, one product contained a small amount of 3,4-methylenedioxymethamphetamine (better known as MDMA or XTC), and five products contained anabolic steroids. By pure chance, two different batches of one single product were tested as well, yielding one positive and one negative finding [07025].

Despite ongoing improvements to regulatory and manufacturing guidelines, the potential for contaminated nutritional supplements to cause a failed doping test for an athlete remains a concern. Several surveys of supplements available through the internet and at retail have confirmed that many are contaminated with steroids and stimulants that are prohibited for use in elite sport. Suggested responses to this issue include the complete avoidance of all supplements. However, this approach seems to be unrealistic as many athletes use nutritional supplements for very different reasons. In addition, the number of publications describing trials that demonstrate the benefit of certain nutritional products has also increased over the last decade or so. This ensures that for many sports the use of supplements will remain a common practice. In response to the issue of contamination in nutritional supplements, many reputable manufacturers have their products rigorously tested by sports anti-doping laboratories to help ensure as far as possible that the risks to an athlete remain minimal. In this chapter we review the issue of supplements and contamination, and look at how this might be addressed through effective quality control procedures at the manufacturing facility and through the highly sensitive testing of finished products using appropriately accredited tests [12372].

Previously developed estrogen and androgen mammalian reporter gene assays (RGAs) were assessed for their potential use as a quantitative screening method in the detection of estrogenic and androgenic endocrine disruptors (EDs) in sport supplements. The validation of both RGAs coupled with dispersive solid phase extraction (dSPE) was performed in accordance with European Commission Decision EC/2002/6579 for biological screening methods. Decision limits (CC-alpha) and detection capabilities (CC-beta) were established
for both the estrogen and androgen RGAs. All samples were compliant with CC-alpha and CC-beta in both bioassays. Recovery rates were 96 percent for 17beta-estradiol and 115 percent for dihydrotestosterone as obtained in their corresponding RGA. Both estrogens and androgens were stable in samples for more than 3 weeks, when stored at -20 °C. Specificity, good repeatability (coefficients of variation (CV), 12-25 %), reproducibility and robustness of both bioassays were also observed. Four different ED modes of action were determined for estrogens and androgens in 53 sport supplements, using the validated RGAs. This study revealed that 89 percent of the investigated sport supplements contained estrogenic EDs and 51 percent contained androgenic compounds. In conclusion, both bioassays are suitable for sport supplement screening of estrogenic and androgenic EDs [12373].

**Anabolic steroids**

Nineteen different dietary supplements, ordered through the internet and intercepted by the Belgian pharmaceutical inspection at the post office, were analyzed by means of liquid chromatography-tandem mass spectrometry (LC-MS/MS) for the presence of anabolic steroids. After a methanolic extraction the samples were screened for the presence of 49 compounds. This resulted in almost 60 percent of the samples being suspected of containing one of these 49 anabolic compounds and being subjected to a confirmatory product ion scan. In all of these suspected samples we were able to confirm at least one anabolic steroid with concentrations between 0.01 and 2.5 mg/unit (unit: one capsule or tablet or for liquids: the prescribed dose). The anabolic steroids that was mostly encountered was testosterone (50 %) followed by beta-boldenone (25 %). These results once more confirm the dubious reputation of over-the-counter dietary supplements [07245].

Several studies have highlighted that nutritional supplements may contain undeclared substances that are banned by the International Olympic Committee (IOC)/World Anti-Doping Agency (WADA). This paper describes a qualitative liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) method to detect anabolic androgenic steroids (4-androsten-3,17-dione, 4-oestrin-3,17-dione, 5alpha-androsten-17beta-ol-3-one, boldenone, nandrolone, nandrolone decanoate, testosterone, and testosterone decanoate) and ephedrine in food supplements. The products are dissolved in methanol and analysed by gas chromatography-mass spectrometry (GC-MS). The methanolic solution was added to testosterone-d(3), evaporated to dryness, mixed with NaOH and extracted with n-pentane:diethyl ether (9:1). LC-MS/MS analyses were performed in selected reaction monitoring (SRM) on an ion-trap equipped with an atmospheric pressure chemical ionization (APCI) probe operating in positive-ion mode. The method was applied to 64 nutritional supplements. A total of 13 percent of the nutritional supplements analysed contained banned substances not declared on the label (anabolic steroids and ephedrine). Detection limits were in the range 1-25 ng/g [07246].

Nineteen different dietary supplements, ordered through the internet and intercepted by the Belgian pharmaceutical inspection at the post office, were analyzed by means of liquid chromatography-tandem mass spectrometry (LC-MS/MS) for the presence of anabolic steroids. After a methanolic extraction the samples were screened for the presence of 49 compounds. The anabolic steroids that was mostly encountered was testosterone (50 %) followed by beta-boldenone (25 %). These results once more confirm the dubious reputation of over-the-counter dietary supplements [06244].
**Androgens on the nutritional supplement market**

During recent years, the nutritional supplement market has expanded and in 2006, the worldwide market was estimated to be worth more than US dollar 60 billion. The use of supplements is popular in the general population; however, athletes corner the market with 44-100 percent prevalence, dependent on age, gender, level of competition and the type of sport. Whilst vitamins, minerals, proteins and creatine, are not prohibited by WADA, the problem arises when supplements contain additives that are not on their label. This can occur inadvertently through cross-contamination from a production line and/or transport in unclean containers or it can occur through direct addition. This level of contamination can be sufficient to create a positive doping test. For example, 634 nutritional supplements purchased from 13 different countries were analyzed with mass spectrometric methods (GC/MS, LC/MS/MS) for undeclared doping substances and 15 percent of these minerals, vitamins, creatine or protein supplements contained androgens (mostly prohormones) that were not declared on the label. In another example, bioassays were used to screen a range of nutritional supplements for hormonal activity and found that for 63 supplements, only 13 were negative for estrogenic activity and that only 18 were negative for androgenic activity. All of the other supplements showed agonistic, partial agonistic and/or antagonistic hormone activities, indicating that these health food products contain hormonally active constituents. Since 2002, nutritional supplements have been found to be intentionally spiked with androgens at concentrations higher than 1 mg/g. The androgens found include metandienone, stanozolol, boldenone, oxandrolone and dehydrochloromethyltestosterone. These androgens were either not declared, or were declared but with non-approved names on the labels. The nutritional supplements can be purchased without restriction by telephone order or internet purchase and are delivered by ordinary mail. This allows easy access by the general population for non-medical reasons. Not only do sport nutritional supplements face the problem of androgen spiking, either deliberate or accidental, but “natural” products have also been found to contain hormonally active substances. For example, a herbal product used for the treatment of high level prostate-specific antigen (PSA) was found to contain an estrogenic substance, diethylstilbestrol (DES) using a yeast estrogen bioassay, together with nuclear magnetic resonance (NMR) and liquid chromatography/ time-of-flight MS (LC/TOFMS). This was identifiable clinically because of the development of gynecomastia. Therefore, it is evident that the intentional or unintentional addition of hormonally active substances is an ongoing problem. It is important then that methods are available for the exquisite detection of these hormonally active substances, especially those that are androgenic [13084].

**Methylstenbolone**

The use of "nutritional supplements" containing unapproved substances has become a regular practice in amateur and professional athletes. This represents a dangerous habit for their health once no data about toxicological or pharmacological effects of these supplements are available. Most of them are freely commercialized online and any person can buy them without medical surveillance. Usually, the steroids intentionally added to the "nutritional supplements" are testosterone analogues with some structural modifications. In this study, the analyzed product was bought online and a new anabolic steroid known as methylstenbolone (2,17alpha-dimethyl-17beta-hydroxy-5alpha-androst-1-en-3-one) was detected, as described on label. Generally, anabolic steroids are extensively metabolized, thus in-depth knowledge of their metabolism is mandatory for doping control purposes. For this reason, a human excretion study was carried out with four volunteers after a single oral dose to determine the urinary metabolites of the steroid. Urine samples were submitted to enzymatic hydrolysis of glucuron conjugated metabolites followed by liquid-liquid extraction and analysis of the trimethylsilyl derivatives by gas chromatography coupled to tandem mass spectrometry. Mass spectrometric data allowed the proposal of two plausible metabolites:
2,17α-dimethyl-16ε,17β-dihydroxy-5α-androst-1-en-3-one (S1), 2,17α-dimethyl-3α,16ε,17β-trihydroxy-5α-androst-1-ene (S2). Their electron impact mass spectra are compatible with 16-hydroxylated steroids O-TMS derivatives presenting diagnostic ions such as m/z 231 and m/z 218. These metabolites were detectable after one week post administration while unchanged methylstenbolone was only detectable in a brief period of 45 h [13605].

**Anabolic steroids and stimulants**

The purpose of one study was to analyze the composition of 103 dietary supplements bought on the internet. The supplements were dispatched in four different categories according to their announced contents [creatine, prohormones, "mental enhancers" and branched chain amino acids, BCAA]. All the supplements were screened for the presence of stimulants and main anabolic steroids parent compounds. At the same time, the research was focused on the precursors and metabolites of testosterone and nandrolone. The study pointed out three products containing an anabolic steroid, metandienone, in a very high amount. The ingestion of such products induced a high quantity of metandienone metabolites in urines that would be considered as a positive antidoping test. The results have also shown that one creatine product and three "mental enhancers" contained traces of hormones or prohormones not claimed on the labels and 14 prohormone products contained substances other than those indicated by the manufacturer. The oral intake of the creatine product revealed the presence of the two main nandrolone metabolites (19-norandrosterone and 19-noretiocholanolone) in urine [06245].

**Ephedrine**

Several studies have highlighted that nutritional supplements may contain undeclared substances that are banned by the International Olympic Committee (IOC)/World Anti-Doping Agency (WADA). One paper described a qualitative liquid chromatography coupled with tandem mass spectrometry detection (LC-MS/MS) method to detect anabolic androgenic steroids (4-androst-3,17-dion, 4-oestren-3,17-dion, 5α-androst-17β-ol-3-one, boldenone, nandrolone, nandrolone decanoate, testosterone, and testosterone decanoate) and ephedrine in food supplements. The products are dissolved in methanol and analysed by gas chromatography-mass spectrometry (GC-MS). The methanolic solution was added to testosterone-d(3), evaporated to dryness, mixed with NaOH and extracted with n-pentane:diethyl ether (9:1). LC-MS/MS analyses were performed in selected reaction monitoring (SRM) on an ion-trap equipped with an atmospheric pressure chemical ionization (APCI) probe operating in positive-ion mode. The method was applied to 64 nutritional supplements. A total of 13 percent of the nutritional supplements analysed contained banned substances not declared on the label (anabolic steroids and ephedrine). Detection limits were in the range 1-25 ng/g [07247].

**Hepatotoxicity**

The aim of one article was to re-emphasize the hepatotoxicity associated with the use of anabolic androgenic steroids and to highlight the marketing and sale of anabolic androgenic steroids as dietary supplements. It was a case series of two patients who developed a cholestatic liver panel after consumption of anabolic androgenic steroids. It was presented two young men who developed significant cholestatic liver injury after consumption of anabolic androgenic steroids. This was associated with considerable morbidity, although both patients recovered without the need for a liver transplant. Both of these anabolic androgenic steroids were being marketed as dietary supplements. It was concluded that despite being classified as class III controlled substances, anabolic androgenic steroids are
still a cause for serious hepatotoxicity. Some of these anabolic androgenic steroids are being marketed as dietary supplements. Increased vigilance is required from the medical profession [07248].

*How to deal with supplements in the field of practice*

Many athletes tend to take supplements for a variety of reasons. The first rule in any educational effort regarding supplements is that athletes should be cautioned against their indiscriminate use. Supplements can play a role in an athlete's diet, but confirmation of their added benefit should be sought with an appropriate expert before using them. The second step is to try and identify those supplements that have the slimmest chance of being contaminated with doping substances. Companies that sell products containing doping substances should definitely be avoided, and it is prudent to disregard companies with unrealistic claims in their advertisements. This includes advertisements that mention "IOC approved" or "WADA tested" on their label, as no such approvals exist. The basic anti-doping rule remains that at all times athletes are responsible for the substances that are within their bodies, and a simple appeal based on an advertisement does not lift this rule of strict liability. Athletes and their support personnel should be aware that no system is able to provide a 100% guarantee of doping free supplements. Contaminations can occur in many ways, which leads to possible package-to-package or even tablet-to-tablet variation. No sampling protocol is able to cater for all these possibilities. However, there are protective systems that can be used to bring down the chances of ingesting contaminated supplements to very close to 0 percent. Such athlete-friendly systems should address the problems surrounding possible contaminations mentioned in this article, and well intentioned producers should acknowledge that contaminations can occur outside their control. Generally speaking, any system that ensures that the particular product is produced in a "doping-free environment", meaning that all parts of the production process are free of any substances prohibited by WADA, will provide an athlete with a trustworthy product. But as the NZVT experience has shown, even quality systems that are foolproof on paper cannot prevent contaminations with doping substances. Therefore, the best available option for athletes is to only use supplements that have been analysed in a knowledgeable laboratory on a batch-by-batch basis [07025].

*Recovery time after sports*

To study the effects of a single soccer game on indices of performance, muscle damage, and inflammation during a 6-day recovery period an investigation was done. In 24 players a single soccer game induces short-term muscle damage and marked but transient inflammatory responses. Anaerobic performance seems to deteriorate for as long as 72-hour post-game. The acute phase inflammatory response in soccer appears to follow the same pattern as in other forms of exercise [08384].

*Self-reported recovery*

The aims of one study were to assess the dietary intake and monitor self-reported recovery quality and clinical symptomology of a male ultra-endurance runner who completed a multi-day ultra-endurance running challenge covering 4254 km from North Scotland to the Moroccan Sahara desert over 78 consecutive days. Food and fluid intakes were recorded and analysed through dietary analysis software. Body mass (BM) was determined before and after running each day, and before sleep. Clinical symptomology and perceived recovery quality were recorded each day. Whole blood haemoglobin and serum ferritin were
determined before and after the challenge. Total daily energy (mean ± SD: 23.2 ±3.2 MJ/day) and macronutrient intake (182 ± 31 g/day; protein, 842 ± 115g /day carbohydrate, 159 ± 55 g/day fat) met consensus nutritional guidelines for endurance performance. Total daily water intake through foods and fluids was 4.8 ± 2.0 L/day. Water and carbohydrate intake rates during running were 239 ± 143 ml/h and 56 ± 19 g/h, respectively. Immediately after running, carbohydrate and protein intakes were 1.3 ± 1.0 g/kg BM and 0.4 ± 0.2 g/kg BM, respectively. Daily micronutrient intakes ranged from 109-662 % of UK RNIs. Pre-running BM was generally maintained throughout. Overall exercise-induced BM loss averaged 0.8 ± 1.0 PERCENT, although BM losses of ≥2 PERCENT occurred in the latter stages, a reflection of the warmer climate. Varying degrees of self-reported perceived recovery quality and clinical symptomology occurred throughout the challenge. This case study highlights oscillations in dietary habits along 78 consecutive days of ultra-endurance running, dependent on changes in ambient conditions and course topography. Nevertheless, nutrition and hydration status were maintained throughout the challenge. Despite dietary iron intake above RNI and iron supplementation, this alone did not prevent deficiency symptoms [13602].

**Practical nutritional recommendations**

The aim of training is to achieve optimum performance on the day of competition via three processes or paradigms; training hard to create the required training stimulus, training smart to maximize adaptations to the training stimulus, and training specifically to fine-turn the behaviors or physiology needed for competition strategies. Dietary strategies for competition must target the factors that would otherwise cause fatigue during the event, promoting an enhancement of performance by reducing or delaying the onset of these factors. In some cases, the nutritional strategies needed to achieve these various paradigms are different, and even opposite to each other, so athletes need to periodize their nutrition, just as they periodize their training program. The evolution of new knowledge from sports nutrition research, such as presented in this book, usually starts with a stark concept that must be further refined; to move from individual nutrients to food, from "one size fits all" to the individual needs and practices of different athletes, and from single issues to an integrated picture of sports nutrition. The translation from science to practice usually requires a large body of follow-up studies as well as experimentation in the field [12366].

**Adolescents’ nutrition**

Athletics is a popular sport among young people. To maintain health and optimize growth and athletic performance, young athletes need to consume an appropriate diet. Unfortunately, the dietary intake of many young athletes follows population trends rather than public health or sports nutrition recommendations. To optimize performance in some disciplines, young athletes may strive to achieve a lower body weight or body fat content and this may increase their risk for delayed growth and maturation, amenorrhoea, reduced bone density, and eating disorders. Although many of the sports nutrition principles identified for adults are similar to those for young athletes, there are some important differences. These include a higher metabolic cost of locomotion and preferential fat oxidation in young athletes during exercise. Young athletes, particularly children, are at a thermoregulatory disadvantage due to a higher surface area to weight ratio, a slower acclimatization, and lower sweating rate. An appropriate dietary intake rather than use of supplements (except when clinically indicated) is recommended to ensure young athletes participate fully and safely in athletics [07236].
Athletics is a popular sport among young people. To maintain health and optimize growth and athletic performance, young athletes need to consume an appropriate diet. Unfortunately, the dietary intake of many young athletes follows population trends rather than public health or sports nutrition recommendations. To optimize performance in some disciplines, young athletes may strive to achieve a lower body weight or body fat content and this may increase their risk for delayed growth and maturation, amenorrhea, reduced bone density, and eating disorders. Although many of the sports nutrition principles identified for adults are similar to those for young athletes, there are some important differences. These include a higher metabolic cost of locomotion and preferential fat oxidation in young athletes during exercise. Young athletes, particularly children, are at a thermoregulatory disadvantage due to a higher surface area to weight ratio, a slower acclimatization, and lower sweating rate. An appropriate dietary intake rather than use of supplements (except when clinically indicated) is recommended to ensure young athletes participate fully and safely in athletics [07237].

Self-regulation concepts

To test self-regulation concepts in relation to dietary intake and physical activity patterns in adolescence, which we predicted to be influenced by components of a self-control model a survey was conducted with a multiethnic sample of 9th grade public school students in a metropolitan area (n=539). Confirmatory analysis tested the measurement structure of self-control. Structural equation modeling tested the association of self-control constructs with measures of fruit and vegetable intake, saturated fat intake, physical activity, and sedentary behavior. Confirmatory analysis of 14 indicators of self-control showed best fit for a two-factor structure, with latent constructs of good self-control (planfulness) and poor self-control (impulsiveness). Good self-control was related to more fruit and vegetable intake, more participation in sports, and less sedentary behavior. Poor self-control was related to more saturated fat intake and less vigorous exercise. These effects were independent of gender, ethnicity, and parental education, which themselves had relations to diet and exercise measures. Multiple-group modeling indicated that effects of self-control were comparable across gender and ethnicity subgroups. Self-control concepts are relevant for patterns of dietary intake and physical activity among adolescents. Attention to self-control processes may be warranted for prevention programs to improve health behaviors in childhood and adolescence [07238].

Adolescents aged 11-14 years (n=326), belonging to organized sports federations in the Federal District, Brazil were interviewed. Subjects (n=107) provided four non-consecutive days of food consumption and 219 subjects provided two non-consecutive days of intake. The objective was to assess their nutrient and water intake according to dietary reference intake values and their energy and macronutrient intake by sex and sports groups they were engaged in: endurance, strength-skill or mixed, according to the guidelines established by the American College of Sport Medicine (ACSM). Dietary data were corrected for intra-individual variation. Total energy expenditure was higher among endurance athletes following their higher training time when compared to adolescents engaged in strength-skill or mixed sports. Total energy intake was only significantly higher among endurance-engaged females. Protein intake of males was above the guidelines established by the ACSM for all sports groups. All male sport groups fulfilled the intake levels of carbohydrate per kg body weight but only females engaged in endurance sports fulfilled carbohydrate guidelines. Intakes of micronutrients with low prevalence of adequate intake were: vitamins B1, E and folate, magnesium and phosphorus. Few adolescents presented adequate intake for calcium, fibre, drinking water and beverages. For micronutrients, prevalence of adequacies were
lower for females than males, except for liquids and water. Nutrition guidance is needed to help adolescents fulfil specific guidelines of macronutrient intake for their sports and to improve their intake of micronutrients and water. Special attention should be given to female adolescent athletes [07239].

**Food preferences**

To assess the influence of preferences on food and nutritional intake in a group of adolescent high-level athletes, 22 male soccer players (14-16 years) were recruited. Individuals were asked to fill in a specific questionnaire including 15 food groups that had to be ranked according to their preferences. Three categories were established: “Like” (ranked 1-5), “Indifferent” (6-10), and “Dislike” (11-15). Dietary intake was assessed using the weighed food method (for nutrient intake) and a quantitative open-ended food frequency questionnaire (for the number of standard portions of each food group ingested daily). The main preferences were meat, poultry and derivates (ranked 1-5 in 83 % of individuals) and pasta (58 %), while vegetables (ranked 11-15 in 82 %) and fish (64 %) were the main dislikes. The most frequently consumed food groups were fruits and fruit juices (3.9 portions/day), Bread (3.0), and biscuits, confecionery and sweets (3.0). No statistical differences were found in food consumption between preference groups, and no relation was found between preferences and nutritional intake, except for those individuals who especially like bread, which had statistically higher energy and carbohydrate intake. Food preferences and food and nutritional intake of adolescent high-level soccer players were, effectively, unrelated [07240].

**Excess of protein and fat**

The purpose of one study was to determine whether 34 young Spanish males belonging to a cyclist team, follows the optimal macronutrients intake based on the recommended dietary guidelines. The deficits in nutrition jeopardise the sportive performances, but what about the diets with excessive intake of macronutrients? Furthermore, is there an association between their sports achievements and the psychological profile? Surely, but the problem is to determine which psychological variables are involved. Nutritional evaluation based on a questionnaire of 7 consecutive days. Cyclists consume an excessive quantity of proteins and lipids in their diets. The average consumption of proteins is 16 percent of their caloric intake (the recommended quantity is less than 10 %). The average consumption of fats is 39 percent (the recommended is less than 30 %). The same tendency is found in the homologous Spanish young people of the enKID study, where the percentage of energy from fat and saturated fat is much higher than the recommended one. The cyclists consume insufficient quantities of carbohydrates (average is 45 % of their caloric intake, the recommended is more than 60 %), therefore the reload of their glycogen stores may not be complete on each competition stage. No association has been found between the excessive intake of referred macronutrients and the achieved sports performances. This work contributes to the knowledge of the diets of very active young cyclists. Excessive intake of proteins and fats do not jeopardise their sportive performances. The commonly studied psychological variables in sport, are not determinant of sports achievements of young cyclists; additional work is needed to determine the psychological profile playing a determinant role in success of young cyclists [07241].

**Female needs in nutrition and hydration**

In general, differences in nutritional needs between males and females are smaller than differences between individuals, so that principles developed for male players also apply to
women. There is a need to address energy balance and body composition: prolonged energy deficits cannot be sustained without harm to health and performance. Published reports show mean carbohydrate intakes for female players of about 5 g/kg/day, and this seems to be too low to sustain consistent intensive training. The timing of protein intake may be as important as the amounts consumed, provided that the total intake is adequate. Dehydration adversely affects skill and stamina in women as it does in men, so an individualised hydration strategy should be developed. The prevalence of iron deficiency in women generally is high, but it seems to be alarmingly high in female players. All players should adopt dietary habits that ensure adequate iron intake. Football training seems to increase bone mass in the weight-bearing limbs, with positive implications for bone health in later life, but some players may be at risk from inadequate calcium dietary intake. An extensive series of reviews on all aspects of nutrition for football has been published. It is immediately evident from these reviews that there are abundant experimental data relating to the nutrition and hydration practices of male football players, but information on female players is less easy to find. There are many reasons for this, but the growing popularity of the women's game means that the nutritional needs of the female player need to be urgently considered. Owing to the shortage of gender-specific information, nutrition and hydration guidelines developed for male players are often applied to the female player. This is sometimes appropriate, but for many reasons this may not always be so. There are gender-related differences in the physical demands of training and match play, and also some differences in the nutrition needs of men and women generally, and of male and female athletes in particular. It is important to recognise at the outset, though, that the differences between the nutritional needs of men and women are generally small in comparison with the wide range of nutritional needs of the population as a whole. In addition to the physiological and metabolic demands that shape nutritional needs and eating habits, players are subject to many of the societal issues that affect the general population. Female football players are not immune to these external pressures. The women's game is generally less well developed – at least in most countries – than the men's game. This may mean that less emphasis is placed on training, nutrition and other means of enhancing performance. It may also mean that there is more scope for the committed player to gain an advantage by exploiting these opportunities. Most of the world's football players take part for enjoyment: only a few are professionals. The nutritional strategies of the elite player, who trains most days of the week and perhaps competes more than once most weeks of the year, will be different from those of the player who trains no more than once a week. The general nutritional principles are the same, however, and are aimed at promoting health, fitness and match performance [07242].

A triad

The female athlete triad (Triad) refers to the interrelationships among energy availability, menstrual function, and bone mineral density, which may have clinical manifestations including eating disorders, functional hypothalamic amenorrhea, and osteoporosis. With proper nutrition, these same relationships promote robust health. Athletes are distributed along a spectrum between health and disease, and those at the pathological end may not exhibit all these clinical conditions simultaneously. Energy availability is defined as dietary energy intake minus exercise energy expenditure. Low energy availability appears to be the factor that impairs reproductive and skeletal health in the Triad, and it may be inadvertent, intentional, or psychopathological. Most effects appear to occur below an energy availability of 30 kcal/kg of fat-free mass per day. Restrictive eating behaviors practiced by girls and women in sports or physical activities that emphasize leanness are of special concern. For prevention and early intervention, education of athletes, parents, coaches, trainers, judges, and administrators is a priority. Athletes should be assessed for the Triad at the preparticipation physical and/or annual health screening exam, and whenever an athlete
presents with any of the Triad's clinical conditions. Sport administrators should also consider rule changes to discourage unhealthy weight loss practices. A multidisciplinary treatment team should include a physician or other health-care professional, a registered dietitian, and, for athletes with eating disorders, a mental health practitioner. Additional valuable team members may include a certified athletic trainer, an exercise physiologist, and the athlete's coach, parents and other family members. The first aim of treatment for any Triad component is to increase energy availability by increasing energy intake and/or reducing exercise energy expenditure. Nutrition counseling and monitoring are sufficient interventions for many athletes, but eating disorders warrant psychotherapy. Athletes with eating disorders should be required to meet established criteria to continue exercising, and their training and competition may need to be modified. No pharmacological agent adequately restores bone loss or corrects metabolic abnormalities that impair health and performance in athletes with functional hypothalamic amenorrhea [07243].

Energy need

From a review of energy intake of male and female athletes in different sports it was concluded that the energy intake of female athletes, expressed relative to body mass, is about 70 percent of that of their male counterparts. This can be explained by the lower intensity, frequency and duration of the training programmes of most female athletes. Many studies, however, report that some athletes seem to be in negative energy balance, and such observations seem to apply more often to female athletes than to their male counterparts: these observations and the potential explanations have been reviewed in detail. It does seem that some female athletes are in precarious energy balance, and maintain a low body mass and low body fat content by prolonged energy restriction, including some periods of negative energy balance. This is not unique to female athletes, in many societies women are under greater pressure to maintain a low body fat content. At a time when the prevalence of obesity is increasing rapidly, some parts of the population are moving in the opposite direction. There seem to be rather few data on the energy intakes of female players, and most of those are based on short-term measurements (typically three days) using household measures to estimate portion sizes that were then recorded in a food diary. In one study it was used a seven-day food record: indirect calorimetry was used to assess resting metabolic rate and a physical activity diary was used to estimate energy expenditure. The mean estimated energy expenditure (9.42 MJ/day) was not different from the mean estimated energy intake (8.97 MJ/day). It is interesting to note that the estimated energy intake was also equal to energy expenditure in a control group in this study, but a group of gymnasts recorded energy expenditure that was more than 3 MJ/day higher than the estimated energy intake. Any restriction of energy intake with the aim of reducing body fat content requires careful attention if injury and illness are to be avoided. This is because of the potential for adverse effects of prolonged energy restriction, including delayed recovery from exercise, impairment of adaptation to the training stimulus, suppression of immune function, and disruption of reproductive function [07242].

Women football

There is little information on the nutritional habits of female football players at any level of the game. There is also a shortage of information on the nutrition and hydration strategies that players should adopt. In general, differences in nutritional needs between males and females are smaller than differences between individuals, so that principles developed for male players also apply to women. There is a need to address energy balance and body composition: prolonged energy deficits cannot be sustained without harm to health and performance. Published reports show mean carbohydrate intakes for female players of about 5 g/kg/day, and this seems to be too low to sustain consistent intensive training. The timing
of protein intake may be as important as the amounts consumed, provided that the total intake is adequate. Dehydration adversely affects skill and stamina in women as it does in men, so an individualised hydration strategy should be developed. The prevalence of iron deficiency in women generally is high, but it seems to be alarmingly high in female players. All players should adopt dietary habits that ensure adequate iron intake. Football training seems to increase bone mass in the weight-bearing limbs, with positive implications for bone health in later life, but some players may be at risk from inadequate calcium dietary intake [07244].

**Women endurance running**

The aim of one case study was to describe the race nutrition practices of a female runner who completed her first 100-km off-road ultraendurance running event in 12 hr 48 min 55 s. Food and fluid intake during the race provided 10,890 kJ (736 kJ/hr) and 6,150 ml (415 ml/hr) of fluid. Hourly reported carbohydrate intake was 44 g, with 34 percent provided by sports drink. Hourly carbohydrate intake increased in the second half (53 g/hr) compared with the first half (34 g/hr) of the race, as the athlete did not have access to individualized food and fluid choices at the early checkpoints and felt satiated in the early stages of the race after consuming a prerace breakfast. Mean sodium intake was 500 mg/hr (52 mmol/L), with a homemade savory broth and sports drink (Gatorade Endurance®) being the major contributors. The athlete consumed a variety of foods of varying textures and tastes with no complaints of gastrointestinal discomfort. Despite thinking she would consume sweet foods exclusively, as she had done in training, the athlete preferred savory foods and fluids at checkpoints during the latter stages of the race. This case study highlights the importance of the sports nutrition team in educating athletes about race-day nutrition strategies and devising a simple yet effective system to allow them to manipulate their race-day food and fluid intake to meet their nutritional goals [11380].

**Carbohydrate need**

Carbohydrate, in the form of glycogen stores in liver and skeletal muscle, is an essential fuel during training and match play, and carbohydrate availability is a limiting factor during prolonged fatiguing exercise. In male players, the glycogen content of the active muscles substantially decreases during training and match play, but the muscle glycogen content at the end of a game remains much higher than the values found in typical laboratory studies in which subjects run to fatigue. However, studies (on male players) have shown that an inadequate intake of dietary carbohydrate in the days before a match will impair running performance, reducing both the distance covered and the speed of running, especially during the second half of a game. This last finding suggests that, even though there is no good understanding of why players slow down and show signs of fatigue late in a game, it seems prudent to ensure that the muscle glycogen stores have been replenished since the last training session or game. This can be a problem for elite players when the fixture list becomes congested. However, it is less of a problem for those who play only once a week and can adjust training to ensure sufficient recovery prior to games. It is no longer appropriate to think of carbohydrate needs as a fraction of total energy intake: rather they should be expressed as an amount of carbohydrate relative to body mass. It was considered primarily male players, recommended that daily carbohydrate intake during periods of moderate training, periods of energy restriction to achieve fat loss, and for less mobile players, should be about 5-7 g/kg body mass. For more mobile players and during periods of twice-daily training or in preparation for match play, they recommended increasing this to 7-12 g/kg. This is a wide range, and it has important implications for overall energy balance and also raises practical issues relating to the amount of food that must be consumed. From the limited data available, it seems that female players typically consume rather less than
these recommendations. Although most of the players may be able to cope at this level of intake, those at the lower end might well benefit from an increased intake while remaining within their total energy budget. There are, however, consistent with data suggesting that early reports of women being less able than men to achieve supercompensation of muscle glycogen stores by manipulation of diet and exercise were the result of inadequate carbohydrate intake of the female subjects [07242].

Protein need

If the diet does not supply sufficient protein, and more particularly enough essential amino acids, the functional capacity of muscles and of all other tissues will eventually decline. An adequate intake of protein is essential for muscle growth and repair, and also for a healthy immune system and a whole range of other physiological functions. However, what constitutes an adequate protein intake has been widely debated. More recent investigations suggest that besides the amount of protein, the timing of intake and the presence or absence of other nutrients can affect the ability of an athlete to adapt to a training stimulus. The aim of training is to promote changes in tissue structure and function that lead to improved performance. This requires a constant turnover of protein molecules with a net breakdown of those proteins that are not required and a net synthesis of proteins that are required. These changes require the application of an appropriate exercise stimulus; the nature of the adaptation is specific to the type of training stimulus, and the extent of adaptation is a function of the training load. It is now known that the nutritional and hormonal environment will modulate these changes, making training either more or less effective. Whereas it was formerly thought that the main role of nutrition was to enhance recovery, thus allowing athletes to train harder, it is now recognised that a good dietary strategy can perhaps allow the same training adaptations with a reduced training load. This is important in reducing the risk of chronic fatigue and injury, and may allow more time and effort to be devoted to technical training rather than to strength and endurance training. There is some increase in the protein requirement during periods of stress, including those imposed by exercise training and competition. The protein requirement, assuming that the diet provides mixed proteins containing all of the essential amino acids, is about 0.6 g/kg/day. However, a safety margin is added to this to account for variations in the composition of the protein ingested as well as individual variation in the requirement, so that the recommended intake is usually set at about 0.8 g/kg/day for both men and women. This is easily achieved with normal levels of intake. Even a player eating a diet that provides only 2200 kcal/day (8.8 MJ/day) with 10-15 percent of total energy from protein will have an intake of 55-82 g/day. Assuming a body mass of 60 kg, this will give a daily protein intake of about 0.9-1.4 g/kg/day. Recommendations for football players have been set at various levels, but are commonly in the range of 1.4-1.7 g/kg/day. It is difficult not to reach this value with a typical Western diet if energy demand is met, but some players with restrictive eating practices and limited food choices may not. Millward's Adaptive Metabolic Demands model for protein says that a protein balance can be sustained on a wide range of protein intakes, but that sudden changes in intake are accommodated only slowly. The athlete on a high protein intake (3-4 g/kg/day) who suddenly reduces this will experience a loss of muscle during the process of accommodation but will eventually adapt to the new lower intake [07242].

Hydration during sports

Sweat rates in women are lower than in men across most activities for which data are available. In female football players sweat rates (mean 0.8 L/h in training, 0.8 L/h in a match) and drinking rates (0.4 L/h in training, 0.4 L/h in a match) tended to be lower than those observed in elite male players in training. This reflects in part the smaller mass of female
participants but is largely a consequence of the lower rates of metabolic heat production. Losses in sweat electrolytes in both England U21 female players (n=14) during training and England senior international players (n=25) during a friendly match were less than those of their male counterparts, but this was solely due to smaller volume losses: the sodium concentrations were similar (mean 44 mmol/L). Where sweat losses are small, there is little need for fluid replacement during training or match play. Performance, however, is impaired when the sweat-induced loss of body mass reaches about 1-2 percent of the pre-exercise body mass, and sufficient fluid should be consumed to prevent net loss exceeding this amount. Drinking fluids containing small amounts of carbohydrate and electrolytes may be better than drinking plain water. Water is adequate when sweat losses are small or when activity levels are not high. Where large sweat losses are anticipated as in games or hard training in the heat, players should be careful to ensure they are well hydrated beforehand. Self-monitoring by attention to the frequency, volume and colour of urine may be helpful when fluid balance is stressed – for example, in tournament situations in warm climates [07242].

**Calcium**

Most of the body's store of calcium is found in the bones, and the amount of calcium deposited there as calcium phosphate reaches a peak in young adulthood before beginning to decline thereafter. After the age of 40, bone mass is lost typically at a rate of about 0.5 to 1.0 percent a year. Anyone who reaches adult life with a low peak bone mass, or who experiences a high rate of loss, is at risk of increased bone fragility: a third of women who reach the age of 90 will have fractured a hip, about twice the rate in men. Estrogen has a major role in calcium homoeostasis in women, so women with late menarche and early menopause are more likely to have osteoporosis and associated weakening of the bone structure. An adequate intake of calcium is essential for bone health, but so too is vitamin D, either ingested as the preformed vitamin or synthesised in the skin on exposure to sunlight. Imposed stress, in the form of weight-bearing exercise, stimulates bone formation, while bedrest promotes bone loss. Female football players have higher bone mineral density than sedentary women. Lean players who experience amenorrhoea should be especially conscious of the risk of problems in later life. Dairy produce is the best source of dietary calcium, but it is often avoided by weight-conscious athletes because of the fat content. All players should be encouraged to consume adequate low fat dairy produce [07242].

**Iron**

Iron is a key component of hemoglobin, the protein responsible for transport of oxygen from the lungs to the active tissues, and low levels of haemoglobin are associated with reduced exercise performance. Iron deficiency affects both men and women: the consequences are probably the same for both genders, but it seems that more women are at risk. The prevalence of iron deficiency in the general population is higher in women than it is in men, so it is not surprising that female athletes also show a higher prevalence than their male counterparts. It is difficult to compare studies as many different criteria have been used, and generalisations are also fraught with difficulties. Data from Australia suggest that the prevalence of deficiency, defined as abnormal serum ferritin and/or transferrin saturation with or without anemia, is about 8 percent in women and 2 percent in men: in the vegetarian population, however, this rises to 27 percent of females and 5 percent of males. Data from the USA show an increased prevalence in women from minority populations and from lower socioeconomic groups. This high prevalence in disadvantaged populations is a particular concern, but in the USA the prevalence of iron deficiency has been estimated to be up to 20 percent in young women. This figure may increase to 25-35 percent or even more in women.
competing in a variety of sports. Of 28 players in the Swedish national squad, 59 percent were found to have iron deficiency and 29 percent iron deficiency anaemia six months prior to the Fédération Internationale de Football Association (FIFA) Women's World Cup. These values are alarmingly high, and although iron deficiency without anaemia has little effect on exercise performance, it may be the prelude to a fall in circulating haemoglobin concentration and lead to a fall in aerobic capacity. All individuals diagnosed as having iron deficiency anaemia should take iron supplements in the form of ferrous sulphate in an appropriate dose. The treatment will probably take months rather than weeks to be effective, and dietary changes should be started concurrently. Strategies should include:

- an increased intake of iron-rich foods, such as red meat that contain haem iron
- use of fortified foods, such as breakfast cereals
- use of nutrients that promote iron intake, such as vitamin C and meat with the iron-rich meals
- a reduction in the intake of inhibitors of iron absorption, such as fibre and tannin.

Note that supplementation should not be started on a “just in case” basis, but should follow a full investigation that includes blood parameters. The routine use of iron supplementation is common, but is probably not wise as it may do more harm than good [07242].

*Creatine*

Creatine has attracted enormous attention over recent years, and there is a solid body of evidence showing that some individuals may benefit by an increased ability to perform repeated sprints and an increased lean body mass. Studies that have used performance tasks that simulate football have not been entirely convincing. Equally, there is no evidence of harm, so players may feel inclined to see whether they experience a benefit. Any player adopting this approach must be aware that a large fraction of the dietary supplements on sale to athletes may contain agents that will cause a positive doping test, even though these are not declared on the label [07242].

*Nutrition in the aged athletes*

To evaluate the evidence for dietary recommendations in older adult athletes a review of the literature was performed. Regarding resistance training, a protein intake of slightly more than 0.8 g/kg/d is required to optimize gains in muscle strength. The early provision of protein and carbohydrate following a weight training session can enhance resultant strength and fat-free mass gains. Supplementation with creatine monohydrate (approximately 5 g/d) can potentiate some of the gains in strength and fat free mass attained through resistance exercise training. Regarding endurance exercise training, there are no studies evaluating carbohydrate loading, during-event, or postexercise carbohydrate/nutritional replacement in older adults. It was concluded that the amount and timing of dietary protein is important to maximize strength and gains in fat-free mass during resistance exercise training. Creatine monohydrate supplementation can potentiate some of these gains during the first 4 to 6 months of training. Older adults should consume adequate carbohydrates during endurance training (6-8 g/kg/d) and may benefit from the provision of carbohydrate and protein in the early recovery phase following endurance exercise to maximize glycogen re-synthesis for a subsequent exercise bout. There is no scientific reason to assume that older athletes will respond differently to the pre- and during-race fluid and carbohydrate replacement strategies suggested for younger athletes. The consensus guidelines outlined by the American College of Sports Medicine should therefore be followed for all athletes, regardless of their age.
Dietary recommendation

Impact of dietary recommendations

The aim of one study was to evaluate the nutritional trends in young elite male soccer players, attending national soccer league at RFC Bruges over the last two decades. At the start of each season, players and parents are instructed about normal healthy nutrition and fluid intake by dieticians. Since 1983, dieticians perform dietary habit surveys in the adolescent player groups. They instruct players and parents how to record all food and fluid intake during 3 days, a training-day, a match-day and an off -day. It is asked to do the recordings when players and parents are together and parents are asked to supervise the recording. Intakes are calculated using the Becel institute nutrition A significant decrease of energy intake/m² is observed over the last 20 years. Body composition, measured as age-matched body mass index remained at median levels for the population during this period. An important modification of dietary content towards the recommended daily intakes is observed. Fat, saturated fat and cholesterol intake decreased dramatically. Carbohydrate intake increased. It was concluded that a positive evolution towards the recommended dietary composition is observed over the years. However, the decrease in caloric intake without influence on the body mass index could suggest that these elite male footballers have a decreased physical activity as compared to 20 years ago [11378].

Energy intake

Previous intervention studies suggest that leptin, insulin, insulin-like growth factor 1 (IGF-1), and triiodothyronine (T3) are sensitive markers of inadequate energy intake in relation to exercise expenditures. Because of limitations in metabolic hormone measurements, self-reported energy availability (EA) based on food and activity records may present an alternative for characterizing energy status in young athletes. The purpose of one study was to assess whether self-reported EA is related to leptin, insulin, IGF-1, and T3 in 352 young athletes. Sex, body composition, sport participation, and acute weight changes were considered as confounding variables. Multiple linear regression revealed that EA was negatively associated with leptin but not with insulin, IGF-1, or T3. Female athletes with low EA (<30 kcal/kg fat-free mass (FFM)) had higher leptin concentrations (5.0 ± 4.7 ng/mL) and more body fat (18.3 % ± 5.1 %) than did females with normal EA (leptin, 3.1 ± 2.4 ng/mL; body fat, 15.8 % ± 4.2 %; both). Athletes reporting acute weight loss (>1 kg/week) had a lower EA (18.9 ± 7.4 kcal/kg FFM) than did weight-stable athletes (30.0 ± 11.2 kcal/kg FFM) or athletes reporting weight gain (>1 kg; 49.7 ± 13.1 kcal/kg FFM). IGF-1 and T3 were also significantly reduced in athletes who lost weight. This cross-sectional study reveals a lack of association between self-reported EA and metabolic hormones indicative of energy status in young athletes. Further studies are needed to investigate whether self-reported EA and metabolic hormones are in better agreement when measured repeatedly [13589].

Chewing gum

Although chewing gum has been considered a potential method for reducing energy intake, little empirical data exist to support this idea. The purpose of one study was to test the hypothesis that chewing gum before eating reduces motivation to eat, hunger, and energy intake. In order to test this hypothesis, we conducted two experiments in which participants chewed gum prior to completing a food reinforcement task or before all eating occasions for two of three weeks. In Experiment 1, we found that chewing gum had no influence on the
reinforcing value of food, but chewing mint gum reduced liking of and energy intake from fruit. In addition, chewing gum reduced self-reported hunger immediately after gum chewing and after eating compared with the no gum condition. In Experiment 2, gum chewing had no significant effect on total energy intake, but participants consumed fewer meals, consumed more energy per meal, and had a lower nutrient adequacy ratio during the gum chewing weeks. These studies provide no evidence that acute or chronic gum chewing reduces hunger or energy intake. In fact, chewing mint-flavored gum may deter consumption of fruit and reduce diet quality [13590].

For team sports

Abstract Implementation of a nutrition programme for team sports involves application of scientific research together with the social skills necessary to work with a sports medicine and coaching staff. Both field and court team sports are characterized by intermittent activity requiring a heavy reliance on dietary carbohydrate sources to maintain and replenish glycogen. Energy and substrate demands are high during pre-season training and matches, and moderate during training in the competitive season. Dietary planning must include enough carbohydrate on a moderate energy budget, while also meeting protein needs. Strength and power team sports require muscle-building programmes that must be accompanied by adequate nutrition, and simple anthropometric measurements can help the nutrition practitioner monitor and assess body composition periodically. Use of a body mass scale and a urine specific gravity refractometer can help identify athletes prone to dehydration. Sports beverages and caffeine are the most common supplements, while opinion on the practical effectiveness of creatine is divided. Late-maturing adolescent athletes become concerned about gaining size and muscle, and assessment of maturity status can be carried out with anthropometric procedures. An overriding consideration is that an individual approach is needed to meet each athlete's nutritional needs [11374].

For power sports

Contemporary training for power sports involves diverse routines that place a wide array of physiological demands on the athlete. This requires a multi-faceted nutritional strategy to support both general training needs – tailored to specific training phases – as well as the acute demands of competition. Elite power sport athletes have high training intensities and volumes for most of the training season, so energy intake must be sufficient to support recovery and adaptation. Low pre-exercise muscle glycogen reduces high-intensity performance, so daily carbohydrate intake must be emphasized throughout training and competition phases. There is strong evidence to suggest that the timing, type, and amount of protein intake influence post-exercise recovery and adaptation. Most power sports feature demanding competition schedules, which require aggressive nutritional recovery strategies to optimize muscle glycogen resynthesis. Various power sports have different optimum body compositions and body weight requirements, but increasing the power-to-weight ratio during the championship season can lead to significant performance benefits for most athletes. Both intra- and extracellular buffering agents may enhance performance, but more research is needed to examine the potential long-term impact of buffering agents on training adaptation. Interactions between training, desired physiological adaptations, competition, and nutrition require an individual approach and should be continuously adjusted and adapted [11375].

For endurance sports

Endurance sports are increasing in popularity and athletes at all levels are looking for ways to optimize their performance by training and nutrition. For endurance exercise lasting
30 min or more, the most likely contributors to fatigue are dehydration and carbohydrate depletion, whereas gastrointestinal problems, hyperthermia, and hyponatraemia can reduce endurance exercise performance and are potentially health threatening, especially in longer events (>4 h). Although high muscle glycogen concentrations at the start may be beneficial for endurance exercise, this does not necessarily have to be achieved by the traditional supercompensation protocol. An individualized nutritional strategy can be developed that aims to deliver carbohydrate to the working muscle at a rate that is dependent on the absolute exercise intensity as well as the duration of the event. Endurance athletes should attempt to minimize dehydration and limit body mass losses through sweating to 2-3 percent of body mass. Gastrointestinal problems occur frequently, especially in long-distance races. Problems seem to be highly individual and perhaps genetically determined but may also be related to the intake of highly concentrated carbohydrate solutions, hyperosmotic drinks, as well as the intake of fibre, fat, and protein. Hyponatraemia has occasionally been reported, especially among slower competitors with very high intakes of water or other low sodium drinks [11376].

For young soccer players

Limited data exist concerning the dietary practices of young professional soccer players that compete within the United Kingdom. Therefore, the purpose of this study was to investigate the nutritional and activity habits of professional male soccer players (n=10; age: 17 ± 1 years, height: 172 ± 5 m, mass: 68 ± 2 kg, estimated maximal aerobic capacity: 58 ± 1 mL/kg/min) who played for the youth team of a UK-based Championship club. All players recorded their 7-day dietary intake and activity habits during a competitive week that included a match day, 4 training days, and 2 rest days in the first half of the 2009/2010 playing season. The intake of carbohydrates (5.9 ± 0.4 g/kg/d), proteins (1.7 ± 0.1 g/kg/d), and fats (1.5 ± 0.1 g/kg/d) represented 56 ± 1, 16 ± 1, and 31 ± 1 percent of the mean daily energy intake respectively. The intake of fiber was found to be significantly lower than Recommended Nutrient Intake (RNI) values (67 % of RNI), whereas all other analyzed micronutrients met or exceeded recommended values. A mean daily energy deficit of 788 ± 174 kcal existed because daily energy expenditures exceeded that of intake (3,618 ± 61 vs. 2831 ± 164 kcal). The mean daily fluid intake was 3.2 ± 0.3 L. Consequently, the nutritional practices of the sampled group of professional youth soccer players were inadequate to sustain optimized performance throughout training and match play. Youth soccer players should therefore seek to ensure that their diets contain adequate energy through increased total caloric intake, while also optimizing the proportion of energy derived from carbohydrates and ensuring that enough fiber-rich foods are consumed [11377].

Response to long distance running (energy needed)

Marathoners are at an increased risk of developing upper respiratory tract infections following races and periods of hard training, which are associated with temporary changes in the immune system. The majority of the reported changes are decreases in function or concentration of certain immune cells. During this period of immune suppression, by some referred to as an “open window” in immune function, it has been hypothesized that viruses and bacteria might gain a foothold, which would increase the risk of infections. In light of this, nutritional interventions that can enhance immune function and reduce the risk of upper respiratory tract infections have been sought. One paper focused on the effect of glutamine, vitamin C, bovine colostrum and glucose. Although, some of these supplements can affect the physiological and immune changes associated with marathon racing, none of the supplements discussed have consistently been shown to reduce the risk of upper respiratory
tract infections and therefore cannot be recommended for use as enhancers of immune function in marathon runners [08426].

Many components of the immune system exhibit adverse change after marathon-type exertion. These immune changes occur in several compartments of the immune system and body (e.g. the skin, upper respiratory tract mucosal tissue, lung, peritoneal cavity, blood and muscle). Of all immune cells, natural killer (NK) cells, neutrophils and macrophages (of the innate immune system) exhibit the greatest changes in response to marathon competition, both in terms of numbers and function. Many mechanisms appear to be involved, including exercise-induced changes in stress hormone and cytokine concentrations, body temperature changes, increases in blood flow and dehydration. During this “open window” of immune dysfunction (which may last between 3 and 72 hours, depending on the immune measure), viruses and bacteria may gain a foothold, increasing the risk of subclinical and clinical infection. Of the various nutritional and pharmacological countermeasures to marathon-induced immune perturbations that have been evaluated thus far, ingestion of carbohydrate beverages during intense and prolonged exercise has emerged as the most effective. However, carbohydrate ingestion during a marathon attenuates increases in plasma cytokines and stress hormones, but is largely ineffective against changes in other immune components including suppression of NK and T-cell function, and salivary IgA output. Other countermeasures, such as glutamine, antioxidant supplements and ibuprofen, have had disappointing results and thus the search for companion agents to carbohydrate continues [08427].

It was investigated the nutritional habits of ultra-endurance runners before, during and after the Deutschlandlauf 2006 in Germany, from the north (Kap Arkona-Rügen) to the south (Lörrach), over 1,200 km and 17 stages. Twenty male ultra-runners completed a questionnaire about their nutrition before, during and after the race. In the 4 weeks, and the day before the race, 70 percent of the runners followed no special diet. In the morning before the start of a stage, the main nutrients were buns with jam, butter and cheese and the preferred drink was coffee. During the stages, the athletes preferred to consume bread, bananas and chocolate and preferably drank pure water, Apfelschorle and Coca Cola. In the evening, the athletes preferred to consume meat, noodles, pure water and beer. During the run, 40 percent of the athletes had a special desire for salty and fatty food and 10 percent a particular reluctance for sweet and carbohydrate-rich products. After the race, the runners preferred apples, vegetables, rice, bread, pure water, Apfelschorle and beer. Multi-vitamin products, multi-mineral products as well as magnesium were the preferred supplements before, during and after the race. It was conclude that 70 percent of the ultra-endurance runners in the Deutschlandlauf 2006 followed no special diet before the race. Multi-vitamins, multi-minerals and magnesium were preferably consumed as ergogenic supplements. Before the start of a stage they ate a normal breakfast; during a stage they preferred carbohydrate-rich products and water; and in the evening after a stage they preferred to consume meat with a carbohydrate-rich nutrition and drank water as well as beer [08428].

The objective of the study was to describe the food intake of adventure racers during a competition simulated in the laboratory. Ten male athletes with international experience in adventure races took part in the study. The experiment lasted 67 hr (total distance covered 477 km), but 3 athletes did not finish the race. Food intake was recorded throughout the simulation. Athletes’ total energy expenditure was greater than their total energy intake (24,516 vs. 14,738 kcal), and the athletes obtained significantly more energy from food than from supplements. Carbohydrate intake was below the recommendation of 0.5-1.0 g per kg and hour. These results indicate that guidelines for multiday adventure races are needed [08429].
Food provision during Olympic Games

The history of food provision at the summer Olympic Games over the past century (1896-2008) provides insight into the evolution of sports nutrition research and the dietary strategies of athletes. Early research favoring protein as the main fuel for exercise was reflected in Olympic Games menus from 1932 to 1968. Despite conclusive research from the 1960s demonstrating the clear benefit of carbohydrate on exercise performance, a specific emphasis on carbohydrate-rich foods was not noted until the 1970s. Athlete food preferences and catering complexity evolved rapidly between 1970 and 2000, driven predominantly by a dramatic expansion of the Olympic Games and the emergence of systematic sports nutrition research. Nutritional advice by experts and sponsorship by food companies became increasingly important beginning with the 1984 Los Angeles Olympic Games. More recent developments include nutritional labeling of menu items and provision of a nutrition information desk (Barcelona 1992), demand for a "high-starch, low-fat menu" (Atlanta 1996), the addition of a dedicated menu website and the systematic gathering of information on athletes' apparent consumption (Sydney 2000), and appointment of the first international dietetic review committee (Beijing 2008). The history of catering at the Olympic Games tracks the evolution of sports nutrition practice from anecdotes and myth towards an established specialty in nutrition and dietetics grounded in evidence-based science [11243].

General recommendations

It is the position of the American Dietetic Association, Dietitians of Canada, and the American College of Sports Medicine that physical activity, athletic performance, and recovery from exercise are enhanced by optimal nutrition. These organizations recommend appropriate selection of foods and fluids, timing of intake, and supplement choices for optimal health and exercise performance. This updated position paper couples a rigorous, systematic, evidence-based analysis of nutrition and performance-specific literature with current scientific data related to energy needs, assessment of body composition, strategies for weight change, nutrient and fluid needs, special nutrient needs during training and competition, the use of supplements and ergogenic aids, nutrition recommendations for vegetarian athletes, and the roles and responsibilities of sports dietitians. Energy and macronutrient needs, especially carbohydrate and protein, must be met during times of high physical activity to maintain body weight, replenish glycogen stores, and provide adequate protein to build and repair tissue. Fat intake should be sufficient to provide the essential fatty acids and fat-soluble vitamins, as well as contribute energy for weight maintenance. Although exercise performance can be affected by body weight and composition, these physical measures should not be a criterion for sports performance and daily weigh-ins are discouraged. Adequate food and fluid should be consumed before, during, and after exercise to help maintain blood glucose concentration during exercise, maximize exercise performance, and improve recovery time. Athletes should be well hydrated before exercise and drink enough fluid during and after exercise to balance fluid losses. Sports beverages containing carbohydrates and electrolytes may be consumed before, during, and after exercise to help maintain blood glucose concentration, provide fuel for muscles, and decrease risk of dehydration and hyponatremia. Vitamin and mineral supplements are not needed if adequate energy to maintain body weight is consumed from a variety of foods. However, athletes who restrict energy intake, use severe weight-loss practices, eliminate one or more food groups from their diet, or consume unbalanced diets with low micronutrient density, may require supplements. Because regulations specific to nutritional ergogenic aids are poorly enforced, they should be used with caution, and only after careful product evaluation for safety, efficacy, potency, and legality [09311, 09312].
Mineral nutrients, vitamins, and trace elements are essential for the growth and development of a multicellular organism. Today, an adequate supply of nutrients is often unattainable solely through a well-balanced diet, so a targeted, individually designed dietary supplement regime is necessary. Nutrient deficiency, which is impossible to detect through plasma levels alone, is reliably detected through the intracellular measurement of the nutrient levels in the blood. Two case studies presented here indicate the need for supplementation as improvement in nutritional behavior could not replenish already exhausted nutrient reservoirs. Only supplementation was able to significantly boost nutrient levels and confer beneficial effects on general welfare, physical performance, and resistance to infections. Therefore, it appears that nutritional supplements are advisable for everyone, but more research is needed, especially on an intracellular level, to corroborate these findings [07220].

Vitamins and minerals are necessary for many metabolic processes in the body and are important in supporting growth and development. Vitamins and minerals also are required in numerous reactions involved with exercise and physical activity, including energy, carbohydrate, fat and protein metabolism, oxygen transfer and delivery, and tissue repair. The vitamin and mineral needs of athletes have always been a topic of discussion. Some researchers state that athletes require more vitamins and minerals than their sedentary counterparts, whereas other researchers do not report greater micronutrient requirements. The intensity, duration, and frequency of the sport/workout and the overall energy and nutrient intakes of the individual all have an impact on whether or not micronutrients are required in greater amounts [07221].

**Nutrition for sprinters**

The primary roles for nutrition in sprints are for recovery from training and competition and influencing training adaptations. Sprint success is determined largely by the power-to-mass ratio, so sprinters aim to increase muscle mass and power. However, extra mass that does not increase power may be detrimental. Energy and protein intake are important for increasing muscle mass. If energy balance is maintained, increased mass and strength are possible on a wide range of protein intakes, so energy intake is crucial. Most sprinters likely consume ample protein. The quantity of energy and protein intake necessary for optimal training adaptations depends on the individual athlete and training demands; specific recommendations for all sprinters are, at best, useless, and are potentially harmful. However, if carbohydrate and fat intake are sufficient to maintain energy levels, then increased protein intake is unlikely to be detrimental. The type and timing of protein intake and nutrients ingested concurrently must be considered when designing optimal nutritional strategies for increasing muscle mass and power. On race day, athletes should avoid foods that result in gastrointestinal discomfort, dehydration or sluggishness. Several supplements potentially influence sprint training or performance. Beta-alanine and bicarbonate may be useful as buffering agents in longer sprints. Creatine may be efficacious for increasing muscle mass and strength and perhaps increasing intensity of repeat sprint performance during training [07222].

**Nutrition for runners**

The high prevalence of obesity in Western societies has been attributed in part to high-fat low-CHO food consumption. However, people have also become less active, and inactivity may have increased the risk for weight gain from poor dietary choices. Analyses were performed to test whether diet-weight relationships were attenuated by vigorous exercise. Age- and education-adjusted cross-sectional regression analyses of 62,042 men and 44,695
women recruited for the National Runners’ Health Study were conducted. Reported meat and fruit intakes were analyzed separately and as indicators of high-risk diets. The runners were generally lean as measured by body mass index (BMI), and middle-aged, who ran 5.30 ± 3.23 km/day if male and 4.79 ± 3.00 km/day if female. Running significantly attenuated BMI’s relationship to reported meat and fruit intakes in men and women. Specifically, compared with running <2 km/day running >8 km/day reduced the apparent BMI increase per serving of meat by 43 percent in men and 55 percent in women and reduced the apparent BMI reduction per serving of fruit by 75 percent in men and 94 percent in women. Running also significantly attenuated the concordant relationship between reported meat intake and waist and chest circumferences in men and women and the concordant relationship between meat intake and hip circumference in women. It was concluded that vigorous exercise may mitigate diet-induced weight gain, albeit not guaranteeing protection from poor dietary choices [11515].

Nutrition for triathlon and marathon

Triathlon is a sport consisting of sequential swimming, cycling and running. The main diversity within the sport of triathlon resides in the varying event distances, which creates specific technical, physiological and nutritional considerations for athlete and practitioner alike. The purpose of this article is to review physiological as well as nutritional aspects of triathlon and to make recommendations on ways to enhance performance. Aside from progressive conditioning and training, areas that have shown potential to improve triathlon performance include drafting when possible during both the swim and cycle phase, wearing a wetsuit, and selecting a lower cadence (60-80 rpm) in the final stages of the cycle phase. Adoption of a more even racing pace during cycling may optimise cycling performance and induce a “metabolic reserve” necessary for elevated running performance in longer distance triathlon events. In contrast, drafting in swimming and cycling may result a better tactical approach to increase overall performance in elite Olympic distance triathlons. Daily energy intake should be modified to reflect daily training demands to assist triathletes in achieving body weight and body composition targets. Carbohydrate loading strategies and within exercise carbohydrate intake should reflect the specific requirements of the triathlon event contested. Development of an individualised fluid plan based on previous fluid balance observations may assist to avoid both dehydration and hyponatremia during prolonged triathlon racing [07223].

Muscle glycogen provides a key fuel for training and racing a marathon. Carbohydrate “loading” can enhance marathon performance by allowing the competitor to run at their optimal pace for a longer period before fatiguing. For the well trained runner, this may be achieved by tapering exercise over the final days before the marathon and ensuring carbohydrate intakes of 10-12 g/kg/day over the 36-48 hours prior to the race. Sports nutrition guidelines recommend that the runner consumes sufficient carbohydrate to promote restoration of muscle glycogen between training sessions. This strategy should allow the runner to ‘train harder’ and recover optimally between workouts. A recent hypothesis suggests that runners might ‘train smarter’ by training with low glycogen stores, since this might promote greater stimulation of the training response. However, there is no evidence that a low carbohydrate diet enhances the outcomes of training or provides benefits as a depletion phase prior to carbohydrate loading. In fact, a low carbohydrate diet may even impair performance if carried out for extended periods. If there are benefits to manipulating glycogen stores for some workouts, this is likely to happen as the natural outcome of the periodisation of the high-volume programme of an elite runner [07224].
The energy required to run a marathon is mainly provided through oxidative phosphorylation in the mitochondria of the active muscles. Small amounts of energy from substrate phosphorylation are also required during transitions and short periods when running speed is increased. The three inputs for adenosine triphosphate production in the mitochondria include oxygen, free adenosine diphosphate and inorganic phosphate, and reducing equivalents. The reducing equivalents are derived from the metabolism of fat and carbohydrate (CHO), which are mobilised from intramuscular stores and also delivered from adipose tissue and liver, respectively. The metabolism of fat and CHO is tightly controlled at several regulatory sites during marathon running. Slower, recreational runners run at 60-65 percent maximal oxygen uptake ($\text{VO}_2\text{max}$) for approximately 3:45:00 and faster athletes run at 70-75 percent for approximately 2:45:00. Both groups rely heavily on fat and CHO fuels. However, elite athletes run marathons at speeds requiring between 80 and 90 percent $\text{VO}_2\text{max}$, and finish in times between 2:05:00 and 2:20:00. They are highly adapted to oxidise fat and must do so during training. However, they compete at such high running speeds, that CHO oxidation (also highly adapted) may be the exclusive source of energy while racing. Further work with elite athletes is needed to examine this possibility [07225].

**Nutrition for football players**

The physical demands in soccer have been studied intensively, and the aim of the present review is to provide an overview of metabolic changes during a game and their relation to the development of fatigue. Heart-rate and body-temperature measurements suggest that for elite soccer players the average oxygen uptake during a match is around 70 percent of maximum oxygen uptake ($\text{VO}_2\text{max}$). A top-class player has 150 to 250 brief intense actions during a game, indicating that the rates of creatine-phosphate (CP) utilization and glycolysis are frequently high during a game, which is supported by findings of reduced muscle CP levels and severalfold increases in blood and muscle lactate concentrations. Likewise, muscle pH is lowered and muscle inosine monophosphate (IMP) elevated during a soccer game. Fatigue appears to occur temporarily during a game, but it is not likely to be caused by elevated muscle lactate, lowered muscle pH, or change in muscle-energy status. It is unclear what causes the transient reduced ability of players to perform maximally. Muscle glycogen is reduced by 40 to 90 PERCENT during a game and is probably the most important substrate for energy production, and fatigue toward the end of a game might be related to depletion of glycogen in some muscle fibers. Blood glucose and catecholamines are elevated and insulin lowered during a game. The blood free-fatty-acid levels increase progressively during a game, probably reflecting an increasing fat oxidation compensating for the lowering of muscle glycogen. Thus, elite soccer players have high aerobic requirements throughout a game and extensive anaerobic demands during periods of a match leading to major metabolic changes, which might contribute to the observed development of fatigue during and toward the end of a game [07226].

**General recommendatons regarding the use of dietary supplements**

Many athletes continue to take supplements to try and improve recovery from training or to gain a performance edge in competition or are advised that supplements are necessary for health maintenance. Dietary supplement use by high-level athletes is estimated at 65-95 percentage. Supplement commercialization is a multibillion dollar industry where many claims are made with little scientific evidence; regulation for purity or side effects is still lacking in many countries. Members of the athletes' entourage often push substances without sufficiently understanding physiology or nutrition. There is a very limited number of dietary supplements which are permitted and considered ergogenic. Athletes need to focus
on proper training, optimal recovery practices and wholesome nutrition regimens before they even consider supplements. Some education programmes appear to be resulting in decreased supplement use among Olympic athletes. If an athlete truly believes he/she should take a dietary supplement, everything should be done to minimise the risk [13015]:

1. Do not rely on advice from friends, fellow athletes or coaches but undergo a proper evaluation by a qualified physician and/or sports nutrition professional familiar with sport and anti-doping rules. It is quite likely that dietary supplements are not necessary and nutrient deficiencies may be corrected from food sources.
2. Avoid any product making claims of performance enhancement or any exaggerated claims or uses the words: “stimulant, energy or muscle booster, enhancer, legal or alternate steroid, extreme, blast, weight lost”. Even if no prohibited substance is listed on the label, the product may be spiked with one.
3. Herbal stimulants and prohormones are especially high risk. Use of the terms herbal or natural does not in any way mean that the product does not contain a prohibited substance.
4. Some companies offer guarantees of purity or are certified by other companies that do quality control. Verify the third party testing system reputation and remember there are no absolute guarantees.
5. Avoid any company that states their products are WADA approved. WADA or its accredited laboratories never test supplements or any products when not part of a doping control process. WADA cannot recommend any company or quality control system. In order to guarantee purity, each product batch would have to be tested for all prohibited substances.
6. Avoid products containing multiple ingredients as there is a higher risk of contamination. Vitamins and minerals (often classified as supplements) should be from reputable pharmaceutical companies and should not be mixed with other products.
7. Seek guidance from your anti-doping organisation about recent information on contaminated or dangerous products in your part of the world.

Although athletes must exhibit utmost caution when using supplements due to risk of contamination, governmental authorities also have a duty to endeavour to ensure proper regulation and quality control within the supplement industry. Some initiatives are trying to improve this situation. According to Article 10, UNESCO International Convention against Doping in Sport, governments must encourage producers and distributors of dietary or nutritional supplements to establish marketing best practices, including accurate labelling, quality assurance and avoidance of false marketing. In a survey (UNESCO Conference of Parties 2011), only 43 percent of governments responded that they implemented extensive or substantial measures to address these issues [13015].

Furthermore, a more systematic approach is needed for analyzing risks and benefits of dietary supplements. The real risks to health of ingesting potentially dangerous substances contained in poorly regulated supplements are occasionally lost in the discussion of inadvertent doping. Anti-doping regulations were developed over many years to promote fairness in sport and to protect the health of the athlete. Athletes are keen to improve their performance and nutrition may play an integral part in their overall plan. However, when athletes embark upon using performance-enhancing supplements, the risks often outweigh the benefits. Improved regulation of the dietary supplement industry would go a long way towards reducing the risks, but the onus remains on the athlete to make the right choices [13015].
Recommendation of the International Society for Sports Nutrition

Sports nutrition is a constantly evolving field with hundreds of research papers published annually. For this reason, keeping up to date with the literature is often difficult. One paper was a five year update of the sports nutrition review article published as the lead paper to launch the ISSN in 2004 and presents a well-referenced overview of the current state of the science related to how to optimize training and athletic performance through nutrition. More specifically, the paper provides an overview of:

- the definitional category of ergogenic aids and dietary supplements
- how dietary supplements are legally regulated
- how to evaluate the scientific merit of nutritional supplements
- general nutritional strategies to optimize performance and enhance recovery
- an overview of our current understanding of the ergogenic value of nutrition and dietary supplementation in regards to weight gain, weight loss, and performance enhancement

The association also categorized nutritional supplements into “apparently effective”, “possibly effective”, “too early to tell”, and “apparently ineffective” as well a description of the general approach into educating athletes about sports nutrition. Over the last five years there have been many changes to the original categorization of supplements. In addition, a number of new supplements have been introduced to the market. Their classifications are based on current available scientific evidence and have been well received within the broader scientific community [10218].

It was first stated that an ergogenic aid is any training technique, mechanical device, nutritional practice, pharmacological method, or psychological technique that can improve exercise performance capacity and/or enhance training adaptations. This includes aids that may help prepare an individual to exercise, improve the efficiency of exercise, and/or enhance recovery from exercise. Ergogenic aids may also allow an individual to tolerate heavy training to a greater degree by helping them recover faster or help them stay injury-free and/or healthy during intense training. Although this definition seems rather straightforward, there is considerable debate regarding the ergogenic value of various nutritional supplements. Some sports nutrition specialists only consider a supplement ergogenic if studies show that the supplement significantly enhances exercise performance (e.g. helps you run faster, lift more weight, and/or perform more work during a given exercise task). On the other hand, some feel that if a supplement helps prepare an athlete to perform or enhances recovery from exercise, it has the potential to improve training adaptations and therefore should be considered ergogenic. In the view of the ISSN, one should take a broader view about the ergogenic value of supplements. According to the Food and Drug Administration (FDA), dietary supplements were regulated in the same manner as food prior to 1994 [4]. Consequently, the FDA monitored the manufacturing processes, quality, and labeling of dietary supplements. Products sold as dietary supplements must be clearly labeled as a dietary supplement, and dietary supplements are not drugs [10218].

One of the most common questions raised by athletes, parents, and professionals regarding dietary supplements relates to how they are manufactured and consumer awareness of supplement quality. In a number of cases, reputable companies who develop dietary supplements have research teams who scour the medical and scientific literature looking for potentially effective nutrients. These research teams often attend scientific meetings and review the latest patents, research abstracts presented at scientific meetings, and research
publications. They may also consult with leading researchers to discuss ideas about dietary supplements that can be commercialized. Leading companies invest in basic research on nutrients before developing their supplement formulations. Others wait until research has been presented in patents, research abstracts, or publications before developing nutritional formulations featuring the nutrient. Once a new nutrient or formulation has been identified, the next step is to contact raw ingredient suppliers to see if the nutrient can be obtained in a highly pure source and/or if it's affordable. Sometimes, companies develop and patent new processing and purification processes because the nutrient has not yet been extracted in a pure form or is not available in large quantities. Reputable raw material manufacturers conduct extensive tests to examine purity of their raw ingredients. If the company is working on a new ingredient, they often conduct toxicity studies on the new nutrient once a purified source has been identified [10218].

**Energy need**

Dietary supplements may contain carbohydrate, protein, fat, minerals, vitamins, herbs, enzymes, metabolic intermediates (like amino acids), and/or various plant/food extracts. Supplements can generally be classified as convenience supplements (e.g. energy bars, meal replacement powders, ready to drink supplements) designed to provide a convenient means of meeting caloric needs and/or managing caloric intake, weight gain, weight loss, and/or performance enhancement. The first component to optimize training and performance through nutrition is to ensure the athlete is consuming enough calories to offset energy expenditure. People who participate in a general fitness program (e.g. exercising 30-40 minutes per day, 3 times per week) can typically meet nutritional needs following a normal diet (e.g. 1,800-2,400 kcals/day or about 25-35 kcals/kg/day for a 50-80 kg individual) because their caloric demands from exercise are not too great (e.g. 200-400 kcals/session). However, athletes involved in moderate levels of intense training (e.g. 2-3 hours per day of intense exercise performed 5-6 times per week) or high volume intense training (e.g. 3-6 hours per day of intense training in 1-2 workouts for 5-6 days per week) may expend 600-1,200 kcals or more per hour during exercise. For this reason, their caloric needs may approach 50-80 kcals/kg/day (2,500-8,000 kcals/day for a 50-100 kg athlete). For elite athletes, energy expenditure during heavy training or competition may be enormous. For example, energy expenditure for cyclists to compete in the Tour de France has been estimated as high as 12,000 kcals/day (150-200 kcals/kg/d for a 60-80 kg athlete). Additionally, caloric needs for large athletes (i.e. 100-150 kg) may range between 6,000-12,000 kcals/day depending on the volume and intensity of different training phases [10218].

Although some argue that athletes can meet caloric needs simply by consuming a well-balanced diet, it is often very difficult for larger athletes and/or athletes engaged in high volume/intense training to be able to eat enough food in order to meet caloric needs. Maintaining an energy deficient diet during training often leads to significant weight loss (including muscle mass), illness, onset of physical and psychological symptoms of overtraining, and reductions in performance. Nutritional analyses of athletes' diets have revealed that many are susceptible to maintaining negative energy intakes during training. Susceptible populations include runners, cyclists, swimmers, triathletes, gymnasts, skaters, dancers, wrestlers, boxers, and athletes attempting to lose weight too quickly. Additionally, female athletes have been reported to have a high incidence of eating disorders. Consequently, it is important for the sports nutrition specialist working with athletes to ensure that athletes are well-fed and consume enough calories to offset the increased energy demands of training, and maintain body weight. Although this sounds relatively simple, intense training often suppresses appetite and/or alters hunger patterns so that many athletes do not feel like eating. Some athletes do not like to exercise within several hours after eating because of sensations of fullness and/or a predisposition to cause
gastrointestinal distress. Further, travel and training schedules may limit food availability and/or the types of food athletes are accustomed to eating. This means that care should be taken to plan meal times in concert with training, as well as to make sure athletes have sufficient availability of nutrient dense foods throughout the day for snacking between meals (e.g. drinks, fruit, carbohydrate/protein bars, etc). For this reason, sports nutritionists’ often recommend that athletes consume 4-6 meals per day and snacks in between meals in order to meet energy needs. Use of nutrient dense energy bars and high calorie carbohydrate/protein supplements provides a convenient way for athletes to supplement their diet in order to maintain energy intake during training [10218].

Carbohydrate

The second component to optimizing training and performance through nutrition is to ensure that athletes consume the proper amounts of carbohydrate (CHO), protein (PRO) and fat in their diet. Individuals engaged in a general fitness program can typically meet macronutrient needs by consuming a normal diet (i.e. 45-55 % CHO, 3-5 grams/kg/day) 10-15 % PRO, 0.8-1.0 gram/kg/day, and 25-35 % fat, 0.5-1.5 grams/kg/day). However, athletes involved in moderate and high volume training need greater amounts of carbohydrate and protein in their diet to meet macronutrient needs. For example, in terms of carbohydrate needs, athletes involved in moderate amounts of intense training (e.g. 2-3 hours per day of intense exercise performed 5-6 times per week) typically need to consume a diet consisting of 55-65 % carbohydrate (i.e. 5-8 grams/kg/day or 250-1,200 grams/day for 50-150 kg athletes) in order to maintain liver and muscle glycogen stores. Research has also shown that athletes involved in high volume intense training (e.g. 3-6 hours per day of intense training in 1-2 workouts for 5-6 days per week) may need to consume 8-10 grams/day of carbohydrate (i.e. 400-1,500 grams/day for 50-150 kg athletes) in order to maintain muscle glycogen levels. This would be equivalent to consuming 0.5-2.0 kg of spaghetti. Preferably, the majority of dietary carbohydrate should come from complex carbohydrates with a low to moderate glycemic index (e.g. whole grains, vegetables, fruit, etc). However, since it is physically difficult to consume that much carbohydrate per day when an athlete is involved in intense training, many nutritionists and the sports nutrition specialist recommend that athletes consume concentrated carbohydrate juices/drinks and/or consume high carbohydrate supplements to meet carbohydrate needs [10218].

It should also be noted that exogenous carbohydrate oxidation rates have been shown to differ based on the type of carbohydrate consumed because they are taken up by different transporters. For example, oxidation rates of disaccharides and polysaccharides like sucrose, maltose, and maltodextrins are high while fructose, galactose, trehalose, and isomaltulose are lower. Ingesting combinations of glucose and sucrose or maltodextrin and fructose have been reported to promote greater exogenous carbohydrate oxidation than other forms of carbohydrate. These studies generally indicate a ratio of 1-1.2 for maltodextrin to 0.8-1.0 fructose. For this reason, it was recommended that care should be taken to consider the type of carbohydrate to ingest prior to, during, and following intense exercise in order to optimize carbohydrate availability [10218].

Protein

There has been considerable debate regarding protein needs of athletes. For people involved in a general fitness program, protein needs can generally be met by ingesting 0.8-1.0 grams/kg/day of protein. Older individuals may also benefit from a higher protein intake (e.g. 1.0-1.2 grams/kg/day of protein) in order to help prevent sarcopenia. It is recommended that athletes involved in moderate amounts of intense training consume 1-1.5 grams/kg/day of protein (50-225 grams/day for a 50-150 kg athlete) while athletes involved in high volume
intense training consume 1.5-2.0 grams/kg/day of protein (75-300 grams/day for a 50-150 kg athlete). This protein need would be equivalent to ingesting 3-11 servings of chicken or fish per day for a 50-150 kg athlete. Although smaller athletes typically can ingest this amount of protein in their normal diet, larger athletes often have difficulty consuming this much dietary protein. Additionally, a number of athletic populations have been reported to be susceptible to protein malnutrition (e.g. runners, cyclists, swimmers, triathletes, gymnasts, dancers, skaters, wrestlers, boxers, etc). Therefore, care should be taken to ensure that athletes consume a sufficient amount of quality protein in their diet in order to maintain nitrogen balance (e.g. 1.5-2 grams/kg/day) [10218].

However, it should be noted that not all protein is the same. Proteins differ based on the source that the protein was obtained, the amino acid profile of the protein, and the methods of processing or isolating the protein. These differences influence availability of amino acids and peptides that have been reported to possess biological activity (e.g. alpha-lactalumin, beta-lactoglobulin, glycomacropeptide, immunoglobulins, lactoperoxidases, lactoferrin, etc). Additionally, the rate of digestion and/or absorption and metabolic activity of the protein also are important considerations. For example, different types of proteins (e.g. casein and whey) are digested at different rates, which directly affect whole body catabolism and anabolism. Therefore, care should be taken not only to make sure the athlete consumes enough protein in their diet but also that the protein is high quality. The best dietary sources of low fat, high quality protein are light skinless chicken, fish, egg white and skim milk (casein and whey). The best sources of high quality protein found in nutritional supplements are whey, colostrum, casein, milk proteins and egg protein. Although some athletes may not need to supplement their diet with protein and some sports nutrition specialists may not think that protein supplements are necessary, it is common for a sports nutrition specialist to recommend that some athletes supplement their diet with protein in order to meet dietary protein needs and/or provide essential amino acids following exercise in order to optimize protein synthesis. The timing of protein intake in the time period encompassing the exercise session has several benefits including improved recovery and greater gains in fat free mass. Protein residues such as branched chain amino acids have been shown to be beneficial for the exercising individual, including increasing the rates of protein synthesis, decreasing the rate of protein degradation, and possibly aiding in recovery from exercise [10218].

**Fat**

The dietary recommendations of fat intake for athletes are similar to or slightly greater than those recommended for non-athletes in order to promote health. Maintenance of energy balance, replenishment of intramuscular triacylglycerol stores and adequate consumption of essential fatty acids are of greater importance among athletes and allow for somewhat increased intake. This depends on the athlete’s training state and goals. For example, higher-fat diets appear to maintain circulating testosterone concentrations better than low-fat diets. This has relevance to the documented testosterone suppression which can occur during volume-type overtraining. Generally, it is recommended that athletes consume a moderate amount of fat (approximately 30 % of their daily caloric intake), while increases up to 50 percent of kcal can be safely ingested by athletes during regular high-volume training. For athletes attempting to decrease body fat, however, it has been recommended that they consume 0.5 to 1 g/kg/d of fat. The reason for this is that some weight loss studies indicate that people who are most successful in losing weight and maintaining the weight loss are those who ingest less than 40 g/d of fat in their diet although this is not always the case. Certainly, the type of dietary fat (e.g. n-6 versus n-3; saturation state) is a factor in such research and could play an important role in any discrepancies [10218].

**Strategic eating and refueling**
In addition to the general nutritional guidelines described above, research has also demonstrated that timing and composition of meals consumed may play a role in optimizing performance, training adaptations, and preventing overtraining. In this regard, it takes about 4 hours for carbohydrate to be digested and begin being stored as muscle and liver glycogen. Consequently, pre-exercise meals should be consumed about 4 to 6 h before exercise. This means that if an athlete trains in the afternoon, breakfast is the most important meal to top off muscle and liver glycogen levels. Research has also indicated that ingesting a light carbohydrate and protein snack 30 to 60 min prior to exercise (e.g. 50 g of carbohydrate and 5 to 10 g of protein) serves to increase carbohydrate availability toward the end of an intense exercise bout. This also serves to increase availability of amino acids and decrease exercise-induced catabolism of protein [10218].

When exercise lasts more than one hour, athletes should ingest glucose/electrolyte solution drinks in order to maintain blood glucose levels, help prevent dehydration, and reduce the immunosuppressive effects of intense exercise. Following intense exercise, athletes should consume carbohydrate and protein (e.g. 1 g/kg of carbohydrate and 0.5 g/kg of protein) within 30 min after exercise as well as consume a high carbohydrate meal within two hours following exercise. This nutritional strategy has been found to accelerate glycogen resynthesis as well as promote a more anabolic hormonal profile that may hasten recovery. Finally, for 2 to 3 days prior to competition, athletes should taper training by 30 to 50 percent and consume 200 to 300 g/d of extra carbohydrate in their diet. This carbohydrate loading technique has been shown to supersaturate carbohydrate stores prior to competition and improve endurance exercise capacity. During intense exercise, regular consumption (10-15 fl oz.) of a carbohydrate/electrolyte solution delivering 6-8 percent CHO (6-8 g CHO/100 ml fluid) should be consumed every 15-20 min to sustain blood glucose levels. Glucose, fructose, sucrose and other high-glycemic CHO sources are easily digested, but fructose consumption should be minimized as it is absorbed at a slower rate and increases the likelihood of gastrointestinal problems. The addition of protein (0.15-0.25 g PRO/kg/day) to CHO at all time points, especially post-exercise, is well tolerated and may promote greater restoration of muscle glycogen when carbohydrate intakes are suboptimal. Ingestion of 6-20 grams of essential amino acids (EAA) and 30 - 40 grams of high-glycemic CHO within three hours after an exercise bout and immediately before exercise has been shown to significantly stimulate muscle PRO synthesis. Milk PRO sources (e.g. whey and casein) exhibit different kinetic digestion patterns and may subsequently differ in their support of training adaptations. Addition of creatine monohydrate to a CHO + PRO supplement in conjunction with regular resistance training facilitates greater improvements in strength and body composition as compared with when no creatine is consumed. Irrespective of timing, regular ingestion of snacks or meals providing both CHO and PRO (3:1 CHO: PRO ratio) helps to promote recovery and replenishment of muscle glycogen when lesser amounts of carbohydrate are consumed [10218].

**Vitamins**

Vitamins are essential organic compounds that serve to regulate metabolic processes, energy synthesis, neurological processes, and prevent destruction of cells. There are two primary classifications of vitamins: fat and water soluble. The fat soluble vitamins include vitamins A, D, E, and K. The body stores fat soluble vitamins and therefore excessive intake may result in toxicity. Water soluble vitamins are B vitamins and vitamin C. Since these vitamins are water soluble, excessive intake of these vitamins are eliminated in urine, with few exceptions (e.g. vitamin B6, which can cause peripheral nerve damage when consumed in excessive amounts). Although research has demonstrated that specific vitamins may possess some health benefit (e.g. Vitamin E, niacin, folic acid, vitamin C, etc), few have been
reported to directly provide ergogenic value for athletes. However, some vitamins may help athletes tolerate training to a greater degree by reducing oxidative damage (Vitamin E, C) and/or help to maintain a healthy immune system during heavy training (Vitamin C). Theoretically, this may help athletes tolerate heavy training leading to improved performance. The remaining vitamins reviewed appear to have little ergogenic value for athletes who consume a normal, nutrient dense diet. Since dietary analyses of athletes have found deficiencies in caloric and vitamin intake, many sports nutritionists' recommend that athletes consume a low-dose daily multivitamin and/or a vitamin enriched post-workout carbohydrate/protein supplement during periods of heavy training. Suggestions that there is no benefit of vitamin supplementation for athletes and/or it is unethical for an sports nutrition specialist to recommend that their clients take a one-a-day multi-vitamin and/or suggest taking other vitamins that may raise HDL cholesterol levels and decrease risk of heart disease (niacin), serve as antioxidants (Vitamin E), preserve musculoskeletal function and skeletal mass (vitamin D), or may help maintain a health immune system (Vitamin C) is not consistent with current available literature [10218].

Minerals

Minerals are essential inorganic elements necessary for a host of metabolic processes. Minerals serve as structure for tissue, important components of enzymes and hormones, and regulators of metabolic and neural control. Some minerals have been found to be deficient in athletes or become deficient in response to training and/or prolonged exercise. When mineral status is inadequate, exercise capacity may be reduced. Dietary supplementation of minerals in deficient athletes has generally been found to improve exercise capacity. Additionally, supplementation of specific minerals in non-deficient athletes has also been reported to affect exercise capacity. Of the minerals reviewed, several appear to possess health and/or ergogenic value for athletes under certain conditions. For example, calcium supplementation in athletes susceptible to premature osteoporosis may help maintain bone mass. There is also recent evidence that dietary calcium may help manage body composition. Iron supplementation in athletes prone to iron deficiencies and/or anaemia has been reported to improve exercise capacity. Sodium phosphate loading has been reported to increase maximal oxygen uptake, anaerobic threshold, and improve endurance exercise capacity by 8 to 10 percent. Increasing dietary availability of salt (sodium chloride) during the initial days of exercise training in the heat has been reported to help maintain fluid balance and prevent dehydration. ACSM recommendations for sodium levels (340 mg) represent the amount of sodium in less than 1/8 teaspoon of salt and meet recommended guidelines for sodium ingestion during exercise (300-600 mg per hour or 1.7-2.9 grams of salt during a prolonged exercise bout). Finally, zinc supplementation during training has been reported to decrease exercise-induced changes in immune function. Consequently, somewhat in contrast to vitamins, there appear to be several minerals that may enhance exercise capacity and/or training adaptations for athletes under certain conditions. However, although ergogenic value has been purported for remaining minerals, there is little evidence that boron, chromium, magnesium, or vanadium affect exercise capacity or training adaptations in healthy individuals eating a normal diet [10218].

Water

The most important nutritional ergogenic aid for athletes is water. Exercise performance can be significantly impaired when 2 percent or more of body weight is lost through sweat. For example, when a 70-kg athlete loses more than 1.4 kg of body weight during exercise (2 %), performance capacity is often significantly decreased. Further, weight loss of more than 4 percent of body weight during exercise may lead to heat illness, heat exhaustion, heat stroke, and possibly death. For this reason, it is critical that athletes consume a sufficient
amount of water and/or carbohydrates and electrolyte sports drinks during exercise in order to maintain hydration status. The normal sweat rate of athletes ranges from 0.5 to 2.0 L/h depending on temperature, humidity, exercise intensity, and their sweat response to exercise. This means that in order to maintain fluid balance and prevent dehydration, athletes need to ingest 0.5 to 2 L/h of fluid in order to offset weight loss. This requires frequent ingestion of 6-8 oz of cold water or sports drink every 5 to 15-min during exercise. Athletes should not depend on thirst to prompt them to drink because people do not typically get thirsty until they have lost a significant amount of fluid through sweat. Additionally, athletes should weigh themselves prior to and following exercise training to ensure that they maintain proper hydration. The athlete should consume 3 cups of water for every pound lost during exercise in order adequately rehydrate themselves. Athletes should train themselves to tolerate drinking greater amounts of water during training and make sure that they consume more fluid in hotter/humid environments. Preventing dehydration during exercise is one of the most effective ways to maintain exercise capacity. Finally, inappropriate and excessive weight loss techniques (e.g. cutting weight in saunas, wearing rubber suits, severe dieting, vomiting, using diuretics, etc) are extremely dangerous and should be prohibited [10218].

Convenience supplements

Convenience supplements are meal replacement powders (MRP’s), ready to drink supplements (RTD’s), energy bars, and energy gels. They currently represent the largest segment of the dietary supplement industry representing 50-75 percent of most company’s sales. They are typically fortified with vitamins and minerals and differ on the amount of carbohydrate, protein, and/or fat they contain. They may also vary based whether they are fortified with various nutrients purported to promote weight gain, enhance weight loss, and/or improve performance. Most people view these supplements as a nutrient dense snack and/or use them to help control caloric intake when trying to gain and/or lose weight. In our view, MRP’s, RTD’s, and energy bars/gels can provide a convenient way for people to meet specific dietary needs and/or serve as good alternatives to fast food other foods of lower nutritional value. Use of these types of products can be particularly helpful in providing carbohydrate, protein, and other nutrients prior to and/or following exercise in an attempt to optimize nutrient intake when an athlete doesn't have time to sit down for a good meal or wants to minimize food volume. However, they should be used to improve dietary availability of macronutrients, not as a replacement for a good diet. Care should also be taken to make sure they do not contain any banned or prohibited nutrients [10218].

Muscle building supplements

One of the most common means athletes have employed to increase muscle mass is to add extra calories to the diet. Most athletes "bulk up" in this manner by consuming extra food and/or weight gain powders. In order to increase skeletal muscle mass, there must be adequate energy intake (anabolic reactions are endergonic and therefore require adequate energy intake). Studies have consistently shown that simply adding an extra 500-1,000 calories per day to your diet in conjunction with resistance training will promote weight gain. However, only about 30-50 percent of the weight gained on high calorie diets is muscle while the remaining amount of weight gained is fat. Consequently, increasing muscle mass by ingesting a high calorie diet can help build muscle but the accompanying increase in body fat may not be desirable for everyone. Therefore, it is not recommend this type of weight gain approach [10218].

Creatine
The most effective nutritional supplement available to athletes to increase high intensity exercise capacity and muscle mass during training is creatine monohydrate. Numerous studies have indicated that creatine supplementation increases body mass and/or muscle mass during training. Gains are typically 2-5 pounds greater than controls during 4-12 weeks of training. The gains in muscle mass appear to be a result of an improved ability to perform high intensity exercise enabling an athlete to train harder and thereby promote greater training adaptations and muscle hypertrophy. The only clinically significant side effect occasionally reported from creatine monohydrate supplementation has been the potential for weight gain. Although concerns have been raised about the safety and possible side effects of creatine supplementation, recent long-term safety studies have reported no apparent side effects and/or that creatine monohydrate may lessen the incidence of injury during training [10218].

It was concluded that creatine monohydrate is the most effective ergogenic nutritional supplement currently available to athletes in terms of increasing high-intensity exercise capacity and lean body mass during training. There is no compelling scientific evidence that the short- or long-term use of creatine monohydrate has any detrimental effects on otherwise healthy individuals. If proper precautions and supervision are provided, supplementation in young athletes is acceptable and may provide a nutritional alternative to potentially dangerous anabolic drugs. The addition of carbohydrate or carbohydrate and protein to a creatine supplement appears to increase muscular retention of creatine, although the effect on performance measures may not be greater than using creatine monohydrate alone. The quickest method of increasing muscle creatine stores appears to be to consume ~0.3 grams/kg/day of creatine monohydrate for at least 3 days followed by 3-5 g/d thereafter to maintain elevated stores. Ingesting smaller amounts of creatine monohydrate (e.g. 2-3 g/d) will increase muscle creatine stores over a 3-4 week period, however, the performance effects of this method of supplementation are less supported [10218].

**Essential amino acids (EAA)**

Recent studies have indicated that ingesting 3 to 6 g of EAA prior to and/or following exercise stimulates protein synthesis. Theoretically, this may enhance gains in muscle mass during training. Because EAA's include branch chain amino acids (BCAA) it is probable that positive effects on protein synthesis from EAA ingestion are likely due to the BCAA content. It was thus concluded that BCAAs have been shown to acutely stimulate protein synthesis, aid in glycogen resynthesis, delaying the onset of fatigue, and help maintain mental function in aerobic-based exercise. It was concluded that consuming BCAAs (in addition to carbohydrates) before, during, and following an exercise bout would be recommended safe and effective [10218].

**Beta-hydroxy beta-methylbutyrate (HMB)**

HMB is a metabolite of the amino acid leucine. Leucine and metabolites of leucine have been reported to inhibit protein degradation. Supplementing the diet with 1.5 to 3 g/d of calcium HMB during training has been typically reported to increase muscle mass and strength particularly among untrained subjects initiating training and the elderly. Gains in muscle mass are typically 0.5 to 1 kg greater than controls during 3-6 weeks of training. There is also evidence that HMB may lessen the catabolic effects of prolonged exercise and that there may be additive effects of co-ingesting HMB with creatine. However, the effects of HMB supplementation in athletes are less clear. Most studies conducted on trained subjects have reported non-significant gains in muscle mass possibly due to a greater variability in response of HMB supplementation among athletes [10218].
Amino acids such as leucine and its metabolite alpha-ketoisocaproate (KIC), are returning to be the focus of studies, mainly because of their anti-catabolic properties, through inhibition of muscle proteolysis and enhancement of protein synthesis. It is clear that these effects may counteract catabolic conditions, as well as enhance skeletal muscle mass and strength in athletes. Moreover, beta-hydroxy-beta-methylbutyrate (HMB) has been shown to produce an important effect in reducing muscle damage induced by mechanical stimuli of skeletal muscle. One review aimed to describe the general scientific evidence of KIC and HMB supplementation clinical relevance, as well as their effects (e.g. increases in skeletal muscle mass and/or strength), associated with resistance training or other sports. Moreover, the possible mechanisms of cell signaling regulation leading to increases and/or sparing (during catabolic conditions) of skeletal muscle mass were discussed in detail [10415].

Beta-hydroxy-beta-methylbutyrate (HMBeta) is a metabolite of leucine widely used for improving sports performance. Although HMB is recognized to promote anabolic or anti-catabolic effects on protein metabolism, the impact of its long-term use on skeletal muscle and/or genes that control the skeletal protein balance is not fully known. This study aimed to investigate whether chronic HMBeta treatment affects the activity of GH/IGF-I axis and skeletal muscle IGF-I and myostatin mRNA expression. Rats were treated with HMBeta (320mg/kg BW) or vehicle, by gavage, for 4 weeks, and killed by decapitation. Blood was collected for evaluation of serum insulin, glucose and IGF-I concentrations. Samples of pituitary, liver, extensor digitorum longus (EDL) and soleus muscles were collected for total RNA or protein extraction to evaluate the expression of pituitary growth hormone (GH) gene (mRNA and protein), hepatic insulin-like growth factor I (IGF-I) mRNA, skeletal muscle IGF-I and myostatin mRNA by Northern blotting/real time-PCR, or Western blotting. Chronic HMBeta treatment increased the content of pituitary GH mRNA and GH, hepatic IGF-I mRNA and serum IGF-I concentration. No changes were detected on skeletal muscle IGF-I and myostatin mRNA expression. However, the HMBeta-treated rats although normoglycemic, exhibited hyperinsulinemia. The data presented herein extend the body of evidence on the potential role of HMBeta-treatment in stimulating GH/IGF-I axis activity. In spite of this effect, HMBeta supplementation also induces an apparent insulin resistance state which might limit the beneficial aspects of the former results, at least in rats under normal nutritional status and health conditions [11236].

The use of ergogenic nutritional supplements is becoming inseparable from competitive sports. beta-Hydroxy-beta-methylbutyric acid (HMB) has recently been suggested to promote fat-free mass (FFM) and strength gains during resistance training in adults. In this prospective randomized, double-blind, placebo-controlled study, it was studied the effect of HMB (3 g/day) supplementation on body composition, muscle strength, anaerobic and aerobic capacity, anabolic/catabolic hormones and inflammatory mediators in elite, national team level adolescent volleyball players (14-18 years, 14 males, 14 females, Tanner stage 4-5) during the first 7 weeks of the training season. HMB led to a significant greater increase in FFM by skinfold thickness. HMB led to a significant greater increase in both dominant and non-dominant knee flexion isokinetic force/FFM, measured at fast (180°/sec) and slow (60°/sec) angle speeds, but had no significant effect on knee extension and elbow flexion and extension. HMB led to a significant greater increase in peak and mean anaerobic power determined by the Wingate anaerobic test (peak power and mean power), with no effect on fatigue index. HMB had no significant effect on aerobic fitness or on anabolic (growth hormone, IGF-I, testosterone), catabolic (cortisol) and inflammatory mediators (IL-6 and IL-1 receptor antagonist). HMB supplementation was associated with greater increases in muscle mass, muscle strength and anaerobic properties with no effect on aerobic capacity suggesting some advantage for its use in elite adolescent volleyball players during the initial phases of the training season. These effects were not accompanied by hormonal and
beta-Hydroxy-beta-methylbutyrate (HMBeta) supplementation is used to treat cancer, sepsis and exercise-induced muscle damage. However, its effects on animal and human health and the consequences of this treatment in other tissues (e.g. fat and liver) have not been examined. The purpose of one study was to evaluate the effects of HMBeta supplementation on skeletal muscle hypertrophy and the expression of proteins involved in insulin signalling. Rats were treated with HMBeta (320 mg/kg body weight) or saline for one month. The skeletal muscle hypertrophy and insulin signalling were evaluated by western blotting, and hormonal concentrations were evaluated using ELISAs. HMBeta supplementation induced muscle hypertrophy in the extensor digitorum longus (EDL) and soleus muscles and increased serum insulin levels, the expression of the mammalian target of rapamycin (mTOR) and phosphorylation of p70S6K in the EDL muscle. Expression of the insulin receptor was increased only in liver. Thus, the results suggest that HMBeta supplementation can be used to increase muscle mass without adverse health effects [11238].

beta-Hydroxy-beta-methylbutyrate (HMBeta) is a metabolite of leucine widely used for improving sports performance. Although HMBeta is recognized to promote anabolic or anti-catabolic effects on protein metabolism, the impact of its long-term use on skeletal muscle and/or genes that control the skeletal protein balance is not fully known. One study aimed to investigate whether chronic HMBeta treatment affects the activity of GH/IGF-I axis and skeletal muscle IGF-I and myostatin mRNA expression. Rats were treated with HMBeta (320 mg/kg BW) or vehicle, by gavage, for 4 weeks, and killed by decapitation. Blood was collected for evaluation of serum insulin, glucose and IGF-I concentrations. Samples of pituitary, liver, extensor digitorum longus (EDL) and soleus muscles were collected for total RNA or protein extraction to evaluate the expression of pituitary growth hormone (GH) gene (mRNA and protein), hepatic insulin-like growth factor I (IGF-I) mRNA, skeletal muscle IGF-I and myostatin mRNA by Northern blotting/real time-PCR, or Western blotting. Chronic HMBeta treatment increased the content of pituitary GH mRNA and GH, hepatic IGF-I mRNA and serum IGF-I concentration. No changes were detected on skeletal muscle IGF-I and myostatin mRNA expression. However, the HMBeta-treated rats although normoglycemic, exhibited hyperinsulinemia. The data presented extend the body of evidence on the potential role of HMB-treatment in stimulating GH/IGF-I axis activity. In spite of this effect, HMBeta supplementation also induces an apparent insulin resistance state which might limit the beneficial aspects of the former results, at least in rats under normal nutritional status and health conditions [11239].

Amino acids such as leucine and its metabolite alpha-ketoisocaprate (KIC), are returning to be the focus of studies, mainly because of their anti-catabolic properties, through inhibition of muscle proteolysis and enhancement of protein synthesis. It is clear that these effects may counteract catabolic conditions, as well as enhance skeletal muscle mass and strength in athletes. Moreover, beta-hydroxy-beta-methylbutyrate (HMB) has been shown to produce an important effect in reducing muscle damage induced by mechanical stimuli of skeletal muscle. One review aimed to describe the general scientific evidence of KIC and HMB supplementation clinical relevance, as well as their effects (e.g. increases in skeletal muscle mass and/or strength), associated with resistance training or other sports. Moreover, the possible mechanisms of cell signaling regulation leading to increases and/or sparing (during catabolic conditions) of skeletal muscle mass are discussed in detail based on the recent literature [11240].

HMB is a metabolite of the essential branched chain amino acid leucine, via alpha-ketoisocaprate, the transamination product of leucine. Approximately 2-10 percent of leucine oxidation proceeds to HMB. Much initial research on HMB focused on animals,
assessing effects on immune function, morbidity and mortality, colostral milk fat content, growth rates, safety and toxicity. Despite unconvincing results in animal research, HMB supplementation was used in humans in the mid-1990s on the presumption that it might enhance gains in muscle size and strength while reducing muscle damage and soreness associated with resistance training, and possibly also enhance aerobic capacity. Supplementation with either 1.5 or 3.0 g/day of HMB had a favourable impact on indirect indices of muscle protein breakdown and muscle damage, with concomitant trends for enhanced strength and skeletal muscle hypertrophy. Consequently, the popularity of HMB supplementation increased dramatically, becoming one of the top supplements used by athletes in the late 1990s. More recently, interest in HMB supplementation among athletes has probably declined. Despite this, HMB research reports within the sports environment continue to emerge. There are several recent HMB reviews, with results of resistance training research from 2001 to 2007 consolidated into two meta-analyses. It was concluded that HMB supplementation augmented lean mass and strength gains associated with resistance training, although the magnitude of effect was trivial (0.28% increase in lean mass gain per week). It was also identified similar small benefits from HMB supplementation in untrained males but effects were trivial for strength and non-existent for body composition in trained lifters. This disparity in responsiveness to HMB supplementation relative to resistance training status might be expected, given the suppression in skeletal muscle protein breakdown as a consequence of resistance training adaptations. Furthermore, if HMB does enhance net protein balance following resistance training as a consequence of reducing protein degradation, any effect on adaptations is likely to be blunted compared with interventions that enhance protein synthesis as the protein synthetic response is many times more sensitive to nutrition interventions than degradation. An exception may be in clinical conditions such as cancer in which skeletal muscle atrophy results from an elevation in skeletal muscle protein breakdown. Short-term HMB supplementation appears to be safe, with daily doses equivalent to approximately 6 g/day (76 mg/kg) having no impact on indices of hepatic, renal or immune function. Based on current available reports, the potential for HMB supplementation to enhance strength training adaptations appears to be small in previously untrained individuals and negligible in resistance-trained athletes. Given that the protein synthetic response is much more sensitive to nutrition interventions than protein breakdown, the resistance-trained athlete is advised to focus on proven strategies such as post-exercise ingestion of high biological value proteins rich in leucine to maximise adaptation to the resistance training stimulus [11241].

There is a huge market for ergogenic supplements for athletes. However, only a few products have been proven to have ergogenic effects and to be effective at improving muscle strength and body composition. One such supplement is beta-hydroxy beta-methylbutyrate (HMB). Derived from the amino acid leucine and its keto acid alpha-ketoisocaproate (KIC), HMB has been well documented as an oral ergogenic supplement commonly used by athletes. Several studies have shown that combining exercise training with HMB supplementation leads to increased muscle mass and strength, and there is some anecdotal evidence of aerobic improvement. However, HMB supplementation has been found to be effective mainly for untrained individuals. While previous reviews have emphasized three main pathways for HMB's mode of action, i.e. enhancement of sarcolemmal integrity via cytosolic cholesterol, inhibition of protein degradation via proteasomes, and increased protein synthesis via the mTOR pathway, more recent studies have suggested additional possible mechanisms for its physiological effects. These include decreased cell apoptosis and enhanced cell survival, increased proliferation, differentiation and fusion via the MAPK/ERK and PI3K/Akt pathways, and enhanced IGF-I transcription [10416].
Branched chain amino acids (BCAA)

BCAA supplementation has been reported to decrease exercise-induced protein degradation and/or muscle enzyme release (an indicator of muscle damage) possibly by promoting an anti-catabolic hormonal profile. Theoretically, BCAA supplementation during intense training may help minimize protein degradation and thereby lead to greater gains in fat-free mass. There is some evidence to support this hypothesis. Although more research is necessary, findings suggest that BCAA supplementation may have some impact on body composition [10218].

alpha-Ketoglutarate (alpha-KG)

alpha-KG is an intermediate in the Krebs cycle that is involved in aerobic energy metabolism. There is some clinical evidence that alpha-KG may serve as an anticitabolotic nutrient after surgery. However, it is unclear whether alpha-KG supplementation during training may affect training adaptations [10218].

alpha-Ketoisocaproate (KIC)

KIC is a branched-chain keto acid that is a metabolite of leucine metabolism. In a similar manner as HMB, leucine and metabolites of leucine are believed to possess anticitabolotic properties. There is some clinical evidence that KIC may spare protein degradation in clinical populations [10218].

Ecdysterones

Ecdysterones (also known as ectysterone, 20 Beta-Hydroxyecdysterone, turkesterone, ponasterone, ec dysone, or ec dys tene) are naturally derived phytoecdysteroids (i.e. insect hormones). They are typically extracted from the herbs Leuza raptonticum sp., Rhaponticum carthamoides, or Cyanotis vaga. They can also be found in high concentrations in the herb Suma (also known as Brazilian Ginseng or Pfaffia). Research from Russia and Czechoslovakia conducted over the last 30 years indicates that ecdysterones may possess some potentially beneficial physiological effects in insects and animals. It is too early to tell whether phytoecdysteroids serve as a safe and effective nutritional supplement for athletes [10218].

Growth hormone releasing peptides (GHRP) and secretagogues

Research has indicated that growth hormone releasing peptides (GHRP) and other non-peptide compounds (secretagogues) appear to help regulate growth hormone (GH) release. These observations have served as the basis for development of nutritionally-based GH stimulators (e.g. amino acids, pituitary peptides, "pituitary substances", Macuna pruriens, broad bean, alpha-GPC, etc). Although there is clinical evidence that pharmaceutical grade GHRP's and some non-peptide secretagogues can increase GH and IGF-1 levels at rest and in response to exercise, it has not been demonstrated that such increases lead to an increase in skeletal muscle mass [10218].

Ornithine-alpha-ketoglutarate (OKG)

OKG (via enteral feeding) has been shown to significantly shorten wound healing time and improve nitrogen balance in severe burn patients. Because of its ability to improve nitrogen
balance, OKG may provide some value for athletes engaged in intense training. However, additional research is needed before conclusions can be drawn [10218].

**Zinc/Magnesium aspartate (ZMA)**

The main ingredients in ZMA formulations are zinc monomethionine aspartate, magnesium aspartate, and vitamin B-6. The rationale of ZMA supplementation is based on studies suggesting that zinc and magnesium deficiency may reduce the production of testosterone and insulin-like growth factor (IGF-1). ZMA supplementation has been theorized to increase testosterone and IGF-1 leading to greater recovery, anabolism, and strength during training. More research is needed to further evaluate the role of ZMA on body composition and strength during training before definitive conclusions can be drawn [10218].

**Glutamine**

Glutamine is the most plentiful non-essential amino acid in the body and plays a number of important physiological roles. Glutamine has been reported to increase cell volume and stimulate protein and glycogen synthesis. Despite its important role in physiological roles, there is no compelling evidence to support glutamine supplementation in terms of increasing lean body mass [10218].

**Isoflavones**

Isoflavones are naturally occurring non-steroidal phytoestrogens that have a similar chemical structure as ipriflavone (a synthetic flavonoid drug used in the treatment of osteoporosis). For this reason, soy protein (which is an excellent source of isoflavones) and isoflavone extracts have been investigated in the possible treatment of osteoporosis. Results of these studies have shown promise in preventing declines in bone mass in post-menopausal women as well as reducing risks to side effects associated with estrogen replacement therapy. However, there are currently no peer-reviewed data indicating that isoflavone supplementation affects exercise, body composition, or training adaptations in physically active individuals [10218].

**Sulfo-polysaccharides (myostatin inhibitors)**

Myostatin or growth differentiation factor 8 (GDF-8) is a transforming growth factor that has been shown to serve as a genetic determinant of the upper limit of muscle size and growth. Recent research has indicated that eliminating and/or inhibiting myostatin gene expression in mice and cattle promotes marked increases in muscle mass during early growth and development. The result is that these animals experience what has been termed as a "double-muscle" phenomenon apparently by allowing muscle to grow beyond its normal genetic limit. In agriculture research, eliminating and/or inhibiting myostatin may serve as an effective way to optimize animal growth leading to larger, leaner, and a more profitable livestock yield. In humans, inhibiting myostatin gene expression has been theorized as a way to prevent or slow down muscle wasting in various diseases, speed up recovery of injured muscles, and/or promote increases in muscle mass and strength in athletes. While these theoretical possibilities may have great promise, research on the role of myostatin inhibition on muscle growth and repair is in the very early stages, particularly in humans. Though the research is limited, there is currently no published data supporting the use of sulfo-polysaccharides as a muscle building supplement [10218].

**Boron**
Boron is a trace mineral proposed to increase testosterone levels and promote anabolism. Several studies have evaluated the effects of boron supplementation during training on strength and body composition alterations. These studies (conducted on male bodybuilders) indicate that boron supplementation (2.5 mg/d) appears to have no impact on muscle mass or strength [10218].

**Chromium**

Chromium is a trace mineral that is involved in carbohydrate and fat metabolism. Clinical studies have suggested that chromium may enhance the effects of insulin particularly in diabetic populations. Since insulin is an anti-catabolic hormone and has been reported to affect protein synthesis, chromium supplementation has been theorized to serve as an anabolic nutrient. Theoretically, this may increase anabolic responses to exercise. Although some initial studies reported that chromium supplementation increased gains in muscle mass and strength during training particularly in women, most well-controlled studies that have been conducted since then have reported no benefit in healthy individuals taking chromium (200-800 mcg/d) for 4 to 16-weeks during training [10218].

**Conjugated linoleic acids (CLA)**

Animal studies indicate that adding CLA to dietary feed decreases body fat, increases muscle and bone mass, has anti-cancer properties, enhances immunity, and inhibits progression of heart disease. Consequently, CLA supplementation in humans has been suggested to help manage body composition, delay loss of bone, and provide health benefit. Although animal studies are impressive and some studies suggests benefit over time at some but not all dosages, there is little current evidence that CLA supplementation during training can affect lean tissue accretion [10218].

**Gamma oryzanol (Ferulic acid)**

Gamma oryzanol is a plant sterol theorized to increase anabolic hormonal responses during training. Although data are limited, one study reported no effect of 0.5 g/d of gamma oryzanol supplementation on strength, muscle mass, or anabolic hormonal profiles during 9-weeks of training [10218].

**Prohormones**

Testosterone and growth hormone are two primary hormones in the body that serve to promote gains in muscle mass and strength while decreasing muscle breakdown and fat mass. Prohormones (androstenedione, 4-androstenediol, 19-nor-4-androstenedione, 19-nor-4-androstenediol, 7-keto DHEA, and DHEA, etc) are naturally derived precursors to testosterone or other anabolic steroids. Prohormones have become popular among body builders because they believe they are natural boosters of anabolic hormones. Consequently, a number of over-the-counter supplements contain prohormones. While there is some data indicating that prohormones increase testosterone levels, there is virtually no evidence that these compounds affect training adaptations in younger men with normal hormone levels. In fact, most studies indicate that they do not affect testosterone and that some may actually increase estrogen levels and reduce HDL-cholesterol. Consequently, although there may be some potential applications for older individuals to replace diminishing androgen levels, it appears that prohormones have no training value. Since prohormones are "steroid-like compounds", most athletic organizations have banned their use. Use of nutritional supplements containing prohormones will result in a positive drug test for anabolic
steroids. Use of supplements knowingly or unknowingly containing prohormones have been believed to have contributed to a number of recent positive drug tests among athletes. Consequently, care should be taken to make sure that any supplement an athlete considers taking does not contain prohormone precursors particularly if their sport bans and tests for use of such compounds. Rather than provide the body with a precursor to testosterone, a more recent technique to enhance endogenous testosterone has been to inhibit aromatase activity. Two studies have investigated the effects of aromatase inhibitors (androst-4-ene-3,6,17-trione) and (hydroxyandrost-4-ene-6,17-dioxo-3-THP ether and 3,17-diketo-androst-1,4,6-triene]). In both of these investigations, it was reported that free testosterone and dihydrotestosterone levels were significantly increased. Muscle mass/fat free mass was not measured in one investigation and no changes were observed in fat free mass in the other investigation [10218].

Tribulus terrestris

Tribulus terrestris (also known as puncture weed/vine or caltrops) is a plant extract that has been suggested to stimulate leutinizing hormone (LH) which stimulates the natural production of testosterone. Consequently, Tribulus has been marketed as a supplement that can increase testosterone and promote greater gains in strength and muscle mass during training. Several recent studies have indicated that Tribulus supplementation appears to have no effects on body composition or strength during training [10218].

Vanadyl sulfate (Vanadium)

In a similar manner as chromium, vanadyl sulfate is a trace mineral that has been found to affect insulin-sensitivity and may affect protein and glucose metabolism. For this reason, vanadyl sulfate has been purported to increase muscle mass and strength during training. Although there may be some clinical benefits for diabetics (with a therapeutic dose of at least 50 mg vanadyl sulfate twice daily, vanadyl sulfate supplementation does not appear to have any effect on strength or muscle mass during training in non-diabetic, weight training individuals [10218].

Green tea extract

Green tea is now one of the most common herbal supplements that is being added to thermogenic products because it has been suggested to affect weight loss and is now the fourth most commonly used dietary supplement in the US. Green tea contains high amounts of caffeine and catechin polyphenols. The primary catechin that is associated to the potential effects on weight loss through diet induced thermogenesis is the catechin epigallocatechin gallate, also known as EGCG. Research suggests that catechin polyphenols possess antioxidant properties and the intake of tea catechins is associated with a reduced risk of cardiovascular disease. However, it must be noted that both human and animal studies have not supported positive findings and have reported that supplementation of these extracts does not affect weight loss [10218].

Phosphatidyl choline (Lecithin)

Choline is considered an essential nutrient that is needed for cell membrane integrity and to facilitate the movement of fats in and out of cells. It is also a component of the neurotransmitter acetylcholine and is needed for normal brain functioning, particularly in infants. For this reason, phosphatidyl choline has been purported as a potentially effective supplement to promote fat loss as well as improve neuromuscular function. However, despite
these alleged benefits of lecithin supplementation, there are no clinical trials in humans to support a potential role of lecithin supplementation affecting weight loss [10218]

*Dehydroepiandrosterone (DHEA) and 7-Keto DHEA*

Dehydroepiandrosterone (DHEA) and its sulfated conjugate DHEAS represent the most abundant adrenal steroids in circulation. Although, DHEA is considered a weak androgen, it can be converted to the more potent androgens testosterone and dihydrotestosterone in tissues. In addition, DHEAS can be converted into androstenedione and testosterone. DHEA levels have been reported to decline with age in humans. The decline in DHEA levels with aging has been associated with increased fat accumulation and risk to heart disease. Since DHEA is a naturally occurring compound, it has been suggested that dietary supplementation of DHEA may help maintain DHEA availability, maintain and/or increase testosterone levels, reduce body fat accumulation, and/or reduce risk to heart disease as one ages. Although animal studies have generally supported this theory, the effects of DHEA supplementation on body composition in human trials have been mixed [10218].
NUTRITIONAL SUPPLEMENTS: WATER, CARBOHYDRATE, PROTEIN, AND FAT

Studies failing to show a negative effect of rapid weight loss (RWL) on performance have been conducted in athletes who have been cycling weight for years. It has been suggested that chronic weight cycling could lead combat athletes to become resistant to the stresses associated with weight loss. To investigate the effects of RWL up to 5 percent of body mass on high-intensity intermittent performance in weight cyclers (WC) and non-weight cyclers (non-WC). Eighteen male combat athletes (WC: n=10; non-WC: n=8) reduced up to 5 percent of their body mass in 5 days. Body composition, high-intensity performance and plasma lactate were assessed preweight loss and postweight loss. Athletes had 4 h to refeed and rehydrate following the weigh-in. Food intake was recorded during the weight loss and the recovery periods. Athletes significantly decreased body mass, lean body mass (most likely due to fluid loss) and fat mass following weight loss. No significant changes in performance were found from preweight loss to postweight loss in both groups. Plasma lactate was significantly elevated after exercise in both groups, but no differences were found between groups and in response to RWL. For all these variables no differences were observed between groups. Athletes from both groups ingested high amounts of energy and carbohydrates during the recovery period after the weigh-in. Thus, chronic weight cycling does not protect athletes from the negative impact of RWL on performance. The time to recover after weigh-in and the patterns of food and fluid ingestion during this period is likely to play the major role in restoring performance to baseline levels [13591].

The purpose of one study was to compare fluid balance between a resistance and aerobic training session, in elite rugby players. It is hypothesised that resistance exercise will result in a higher prevalence of over-drinking whereas during the aerobic session under-drinking will be more prevalent. As with previous fluid balance studies, this was an observational study. Twenty-six players completed the resistance training session and twenty players completed the aerobic training session. All players were members of an elite rugby union squad competing in the southern hemisphere’s premier competition. For both sessions players provided a pre-exercise urine sample to determine hydration status, pre- and post-exercise measures of body mass and blood sodium concentration were taken and the weight of drinks bottles were recorded to calculate sweat rates and fluid intake rates. Sweat patches were positioned on the shoulder of the players and these remained in place throughout each training session, and were later analysed for sodium concentration. The percentage of sweat loss replaced was higher in the resistance (196 ± 130 %) than the aerobic training session (56 ± 17 %). Despite this, no cases of hyponatremia were detected. The results also indicated that over 80% of players started training in a hypohydrated state. Fluid intake appears to differ depending on the nature of the exercise session. In this group of athletes, players did not match their fluid intakes with their sweat loss, resulting in over-drinking during resistance training and under-drinking in aerobic training. Therefore, hydration strategies and education need to be tailored to the exercise session. Furthermore, given the large number of players arriving at training hypohydrated, improved hydration strategies away from the training venue are required [13592].

High temperature environment causes detrimental effects on health. In the present study, the effects of intake of several kinds of beverage on blood components during exercise under the high temperature environment were evaluated. The 10 subjects were student of the H University. Exercise intensity was 50-60 percent $O_{2max}$ and treadmill exercise was continued for 1 h. The kinds of beverage were water, ion beverage, cucumber drink. Blood sampling was performed before the exercise, immediately finishing exercise, and 30 min after rest. In
the present results, glucose concentration was increased by intake of water, ion beverage, and cucumber drink immediately after exercise. In the water intake group, glucose concentration was decreased 30 min after rest. Free fatty acid concentration was increased by intake of water, ion beverage, and cucumber drink 60 min after exercise. In the ion beverage and cucumber drink intake groups, free fatty acid concentration was decreased 30 min after rest. Insulin concentration was increased by intake of water, ion beverage, and cucumber drink 60 min after exercise. In the water intake group, insulin concentration was decrease 30 min after rest. There was no difference in the efficacy among water, ion beverage, and cucumber drink, but ion beverage and cucumber drink showed more potent effect on metabolic parameters [13593].

Hydration

It has now been established that exercise performed under various environmental conditions may affect acute energy intake and appetite-related hormones. Long-term maintenance of a healthy body weight (BW) is becoming increasingly important as rates of obesity and obesity-related comorbidities continue to rise. While the "energy balance equation" is understood to underpin long-term weight maintenance, several studies have shown that, without an accompanying conscious reduction in energy intake, weight loss is not maintained during the longer-term through exercise alone. The exact mechanism linking acute energy intake and exercise remains unknown, although indirect evidence suggests a possible role for hydration status. External factors such as the ambient temperature during exercise and the exercise intensity may also affect short-term energy intake. Of particular interest, an acute bout of exercise performed at 36°C resulted in lower relative energy intake (REI) in the subsequent meal as well as an increased circulating concentration of peptide YY (PYY; appetite-suppressing peptide) when compared to a resting control trial, whereas an equivalent bout of exercise in a temperate environment (25°C) did not. The reduced REI after exercise in the heat raises the possibility that dehydration may play a role in modulating energy intake after exercise. That hydration levels may reduce appetite and feeding behavior in animals has long been acknowledged, and indeed, the term dehydration-induced anorexia is commonly used in animal-based research. Therefore, the purpose of one study was to investigate the interaction of exercise and hydration status on subsequent energy intake and appetite-related hormones. In a randomized, counterbalanced design, 10 physically active males completed three experimental trials in a fasted state: exercise when hydrated (0 % to 1 % of body mass), exercise when dehydrated (-1 % to -2 % of body mass), and a hydrated resting control. Exercise consisted of treadmill running for 45 min at 70 percent V·O$_2$peak. Participants were then given access to a buffet-style breakfast from which they could consume ad libitum. Blood was sampled regularly during trials for appetite-related hormones. There were no significant differences in total energy intake between trials, however, relative energy intake was significantly higher in the control (4839 ± 415 kJ) compared to hydrated (1749 ± 403 kJ) and dehydrated exercise (1656 ± 413 kJ) conditions. Exercise performed in a dehydrated state resulted in significantly lower concentrations of ghrelin compared with control and hydrated exercise conditions. Exercise significantly decreased relative energy intake compared with resting control; however, energy intake (relative and total) was no different between the exercise conditions (dehydrated vs hydrated). Despite similar energy intake between trials, exercise in a dehydrated state resulted in a significantly lower concentration of ghrelin, a hormone responsible for stimulating appetite [11379].

People perform physical activity throughout a range of environmental conditions (humidity, temperature, sun, wind exposure). Depending upon the metabolic rate, environmental conditions and clothing worn, exercise can induce significant elevations in body (core and
skin) temperatures. Body temperature elevations elicit heat loss responses of increased skin blood flow and increased sweat secretion. Sweat evaporation provides the primary avenue of heat loss during vigorous exercise in warm hot weather; therefore sweat losses can be substantial. Besides containing water, sweat contains electrolytes that are lost. If not appropriately replaced, water and electrolytes imbalances (dehydration and hyponatremia) can develop and adversely impact on the individuals exercise performance and perhaps health. One “Position Stand” provides guidance on fluid replacement to sustain appropriate hydration of individuals performing physical activity. Throughout the position stand, the term “euhydration” refers to “normal” body water content, while the terms “hypohydration” and “hyperhydration” refer to body water content deficits and excesses beyond the normal fluctuation in body water content, respectively. The term “dehydration” refers to the loss of body water. The hypohydration that occurs during exercise is usually characterized as hyperosmotic hypovolemia (because sweat is hypotonic to plasma), although iso-osmotic hypovolemia can occur when taking some medications (e.g., diuretics) or exposure to cold and hypoxia. For simplicity, the term dehydration will be used to describe both the process of body water loss and hypohydration in this position statement, unless stated otherwise. The goal of prehydrating is to start the activity euhydrated and with normal plasma electrolyte levels. Prehydrating with beverages, in addition to normal meals and fluid intake, should be initiated when needed at least several hours before the activity to enable fluid absorption and allow urine output to return to normal levels. The goal of drinking during exercise is to prevent excessive (>2 % body weight loss from water deficit) dehydration and excessive changes in electrolyte balance to avert compromised performance. Because there is considerable variability in sweating rates and sweat electrolyte content between individuals, customized fluid replacement programs are recommended. Individual sweat rates can be estimated by measuring body weight before and after exercise. During exercise, consuming beverages containing electrolytes and carbohydrates can provide benefits over water alone under certain circumstances. After exercise, the goal is to replace any fluid electrolyte deficit. The speed with which rehydration is needed and the magnitude of fluid electrolyte deficits will determine if an aggressive replacement program is merited [07249].

Water is the largest single component of the human body. It is obtained from food and beverage consumption and by metabolic production in the body. One study investigated water consumption in adults living in the UK. Forty males and 40 females (mean ± SD age 34 ± 13 years, body mass 72 ± 19 kg, height 169 ± 10 cm, body mass index 25 ± 6 kg/m², mean arterial blood pressure 97 ± 13 mm Hg) completed a three consecutive day dietary record for 1 weekend and 2 week days. Every item consumed (food and drinks), the eating occasion (meal or snack), time, food preparation method, brand of product, location of consumption and details of any people with them were recorded. Females tended to consume more water than males (2402 ± 827 ml/day, 2056 ± 911 mL/day respectively. More water was consumed via nonwater beverages than food and plain water, equivalent to 27 ± 11 percent of total daily water intake from food, 45 ± 20 percent from nonwater beverages and 28 ± 21 percent from plain water. There was no difference in total water intake on weekend days compared to week days for females 2488 ± 1041 ml, 2446 ± 831 ml and 2272 ± 9 21 mL or for males 2132 ±1 353 ml, 2101 ± 1295 ml and 1934 ± 876 mL. There was no difference in total water intake among females and males relative to weekend days and week day 1 and week day 2 [10506].

Research into exercise and hydration is not new. Twenty-five years ago, White and Ford1 reported on the voluntary dehydration (hypohydration) during a competitive cycling road race; subjects' mean body mass losses were greater than 3 percent, and there were low rates of fluid ingestion despite fluid being freely available. It is notable that there was no relationship between fluid intake and finishing position. The British Journal of Sports Medicine published one of the first consensus statements on fluid replacement2 during and after exercise. It has
now been challenged the common belief that (full) fluid replacement is necessary to maintain/improve high-intensity exercise performance in moderate and warm conditions. Data show neuromuscular adjustments according to hydration status allowing the attainment of similar peak and terminal core body temperatures and heart rates, and performance times. Therefore, subjects performed equally well during 60 min of cycling at 20°C when fully hydrated, as at 33°C without any hydration (with body mass losses of 2.1 %). Interestingly, this is not the first study to demonstrate this occurrence. In another study it was utilised a similar 60 min cycling protocol performed at 20°C and reported no benefit of replacing fluid losses during exercise when compared to complete fluid restriction (2.2 % body mass loss); in fact, when receiving fluid, subjects actually performed worse! So, why does the sports medicine and exercise science community advocate that “during prolonged exercise the ingestion of appropriate fluids will improve performance” and “dehydration >2% body weight degrades aerobic exercise”, when fluid restriction or ad libitum ingestion has been shown to exert no deleterious performance effect? Substantial literature demonstrates that prolonged exercise can cause considerable body water deficit (dehydration), which adversely affects blood (plasma) volume and therefore cardiac stroke volume and output, osmolality, mean arterial pressure, body temperature(s), perception of effort and exercise duration; fluid replacement can attenuate these effects. Heat stress usually accelerates this exercise-induced dehydration and therefore exacerbates the forementioned consequences. Most, if not all, of these observations were made employing fixed-intensity exercise protocols – an experimental model that controls numerous confounding factors. Ideally then, the investigators can confidently conclude that independent variable x (e.g. fluid intake) exerts an effect on dependent variable y (e.g. exercise performance). While “as fast as possible” not “as long as possible” is reasonable, and one on which much of our understanding of physiological responses to exercise has been built, there is one area where this model is falling out of favour – exercise “performance”. Traditionally, exercising to exhaustion, that is, volitional fatigue, has been the performance measure of choice, yet the ecological validity of such a test is low as most “real-life” sporting situations require us to complete a set distance as quickly as possible rather than for as long as possible. Importantly, exercise is usually self-paced – the athlete can adjust “pace” or workload as desired. Thus, while fixed-intensity exercise to exhaustion only allows an all-or-none response (exercise continuance vs termination), self-paced exercise of a set load (distance/work/time) allows continual behavioural adjustments that may affect performance. This explains the need to re-examine the literature on hydration and exercise performance, such as the improved exercise duration with adequate hydration observed by the same group who 1 year later observed no such performance improvement. One study is an innovative foray into studies of self-paced exercise performance and its determinants, such as hydration. Importantly, this new study suggests that previous conclusions, based on fixed-intensity exercise models, cannot be assumed to apply to the more realistic setting of self-paced competition [10507].

Twelve adolescent athletes underwent, in a crossover-design study, 3 separate 90-min training sessions in the following conditions: no fluid ingestion allowed (NF), ad libitum ingestion of water (W), and ad libitum ingestion of a commercial 8 percent carbohydrate-electrolyte sports beverage (CSB). After each session athletes performed a set of basketball drills (2-point, 3-point, and free-throw shootout, suicide sprints, and defensive zigzags). Body weight (before and after sessions), rating of perceived exertion (RPE), urine color, and beverage acceptability were determined in each session. Athletes also completed a survey about their knowledge and behaviors regarding hydration and fluid replacement. The percentage of weight loss was significantly higher in NF than in the other 2 conditions but also higher in W than CSB. RPE was higher in NF than in the W and CSB trials. Athletes' fluid intake was positively correlated with proper self-reported behaviors and knowledge about fluid and hydration. In conclusion, fluid restriction during exercise was associated with a greater level of dehydration and increased perceived exertion but had no impact on
basketball performance compared with ad libitum drinking of water or a CSB. Athletes with more knowledge about hydration and better self-reported hydration behaviors ingested more fluids during training sessions [11247].

The field of research examining the link between dehydration and endurance performance is at the dawn of a new era. This article reviews the latest findings describing the relationship between exercise-induced dehydration and endurance performance and provides the knowledge necessary for competitive, endurance-trained athletes to develop a winning hydration strategy. Acute, pre-exercise body weight loss at or above 3 percent may decrease subsequent endurance performance. Therefore, endurance athletes should strive to start exercise well hydrated, which can be achieved by keeping thirst sensation low and urine color pale and drinking approximately 5-10 mL/kg body weight of water 2 h before exercise. During exercise lasting 1 h or less, dehydration does not decrease endurance performance, but athletes are encouraged to mouth-rinse with sports drinks. During exercise lasting longer than 1 h, in which fluid is readily available, drinking according to the dictates of thirst maximizes endurance performance. In athletes whose thirst sensation is untrustworthy or when external factors such as psychological stress or repeated food intake may blunt thirst sensation, it is recommended to program fluid intake to maintain exercise-induced body weight loss around 2 to 3 percent [12376].

Another review also presented recommendations for fluid needs and hydration assessment for recreational activity. Fluid needs are based on sweat losses, dependent on intensity and duration of the activity, and will vary among individuals. Prolonged aerobic activity is adversely influenced by dehydration, and heat exposure will magnify this effect. Fluid needs predicted for running 5-42 km at recreational paces show that fluid losses are <2 percent body mass; thus, aggressive fluid replacement may not be necessary. Competitive paces result in greater fluid losses and greater fluid needs. Fluid needs for recreational activity may be low; however, carbohydrate consumption (sport drinks, gels, bars) can benefit high-intensity (≤ 1 h) and less-intense, long-duration activity (≥ 1 h). Spot measures of urine color or urine-specific gravity to assess hydration status have limitations. First morning urine concentration and body mass with gross thirst perception can be simple ways to assess hydration status [12377].

Loss of body water, if sufficiently severe, impairs most physiological functions, but the body water content fluctuates over the course of a normal day with no implications for physical or mental performance. The point at which an effect of dehydration becomes apparent has been the subject of much debate, in part, at least, because of the different tests that have been applied, differences in the methodologies used to induce dehydration and also because of differences in the fitness and other physiological characteristics of the subjects studied. The act of drinking itself and the conscious denial of access to water will also have implications for subjective responses to the exercise task. In many published studies, it is difficult to separate the effects of ingestion of water from those of carbohydrate, electrolytes, and other drink components. Nevertheless, there is good evidence that drinking appropriate amounts of water, especially cold water, can enhance exercise performance in many situations [12378].

In adolescents

There is a lack of studies concerning hydration status of young athletes exercising in the heat. To assess pre-exercise hydration status in young soccer players during a summer sports camp and to evaluate body water balance after soccer training sessions initial hydration status was assessed in 107 young male soccer players (age: 11-16 years) during the 2nd day of the camp. Seventy two athletes agreed to be monitored during two more
training sessions (3rd and 5th day of the camp) in order to calculate dehydration via changes in body weight, while water drinking was allowed ad libitum. Hydration status was assessed via urine specific gravity (USG), urine color and changes in total body weight. Mean environmental temperature and humidity were 27 ± 2°C and 57 ± 9 percent, respectively. According to USG values, 95 out of 107 of the players were hypohydrated (USG≥1.020), prior to practice. The prevalence of dehydration observed was maintained in both days, with 96 and 97 percent of the players being dehydrated, after the training sessions in the 3rd and 5th day, respectively. Despite fluid availability, 54 out of the 66 (82 %) dehydrated players reduced their body weight (-0.35 ± 0.04 kg) as a response to training, while 75 percent (47 out of the 63) reduced further their body weight (-0.22 ± 0.03 kg) after training in the 5th day. It was concluded that approximately 90 percent of the young soccer players who began exercising under warm weather conditions were hypohydrated; while drinking ad libitum during practice, did not prevent further dehydration in already dehydrated players [12379].

The purpose of one study was to determine the hydration status, fluid intake, and electrolyte losses of 21 male professional youth soccer players (age 17 years) training in a cool environment. Pretraining and posttraining measurements of body mass, urine (freezing-point osmolality method), and sweat concentration (flame-emission spectroscopy) were collected. Fourteen players were found to be hypohydrated before training. The amount of fluid lost due to exercise equated to a 2 percent loss in body mass, which equated to a gross dehydration loss of 0.5 percent. Overall, the soccer players replaced 46 ± 88 percent of sweat loss during training, and only 4 remained hypohydrated after training. No significant correlations between sweat loss and sweat concentrations of Na⁺ or K⁺ were found, but there was a significant correlation with Mg²⁺. The study found large variability in pretraining hydration status that the players were able to rehydrate during the training sessions. However, given the numbers starting training in a hypohydrated state, adequate hydration status before training should be considered by youth players, coaches, and sports-science support staff [12380].

Effects on environment and persons around for drinking habits

People tend to drink and eat more when others are present than when alone [De Castro. Physiol Behav 1994; 56: 445-55]. One study investigated the influence of the presence of other people on water consumption in adults living in the UK. Eight females and 11 males who consumed 74 ± 12 percent (Mean ± SD) of their meals and snacks alone (1) and 8 females and 11 males who had 80 ± 17 percent of their meals and snacks with other people present (2+) completed a 3-consecutive day dietary record for 1 weekend and 2 week days. Every item consumed, eating occasion (meal/snack), time, food preparation method, product brand, location of consumption and details of any people with them were recorded. Characteristics of subjects 1 and 2+ are: 31 ± 13 year, 41 ± 15 year; body mass 74 ± 17 kg, 75 ± 14 kg; height 171 ± 11 cm, 172 ± 8 cm; BMI 26 ± 7 kg/m², 25 ± 4 kg/m²; environmental temperature 10 ± 5°C, 10 ± 4°C, respectively. Comparisons between groups were determined by unpaired t-tests. Group 2+ consumed more water than group 1 subjects (2482 ± 691 mL/ day, 1681 ± 630 mL/day. This was because they consumed more water via drinks (non-water beverages: 1143 ± 565 mL, 731 ± 559 mL respectively, plain water: 791 ± 432 mL, 383 ± 347 mL respectively) as there was no difference between groups in total water intake from food (1; 506 ± 270 mL, 2+; 608 ± 152 mL respectively. There was a strong and significant correlation between water intake and other people present. The amount of water ingested with other people present increase by over 801 mL/ day than alone. This is similar to previous research [De Castro et al. Physiol Behav 1991; 51: 121-5] which found that eating alone decreased intake by 200 kcal/day [11516].

Effect of warm and cold climate
Olympic class sailing poses physiological challenges similar to other endurance sports such as cycling or running, with sport specific challenges of limited access to nutrition and hydration during competition. As changes in hydration status can impair sports performance, examining fluid consumption patterns and fluid/electrolyte requirements of Olympic class sailors is necessary to develop specific recommendations for these elite athletes. The purpose of one study was to examine if Olympic class sailors could maintain hydration status with self-regulated fluid consumption in cold conditions and the effect of fixed fluid intake on hydration status in warm conditions. In a cold condition study (CCS), 11 elite Olympic class sailors were provided ad libitum access to three different drinks. Crystal Light (control, C); Gatorade (experimental control, G); and customized sailing-specific Infinit (experimental, IN) (1.0:0.22 CHO:PRO), were provided on three separate training days in cold 7.1°C. A warm condition study (WCS) examined the effect of fixed fluid intake (11.5 mL/kg/h) of C, G and heat-specific experimental Infinit (INW)(1.0:0.074 CHO:PRO) on the hydration status of eight elite Olympic Laser class sailors in 19.5°C. Both studies used a completely random design. In CCS, participants consumed 802 ± 91, 924 ± 137 and 707 ± 152 mL of fluid in each group respectively. This did not change urine specific gravity, but did lead to a main effect for time for body mass, blood sodium, potassium and chloride with all groups lower post-training. In WCS, fixed fluid intake increased participant's body mass post-training in all groups and decreased urine specific gravity post-training. There was a main effect for time for blood sodium, potassium and chloride concentration, with lower values observed post-training. C blood sodium concentrations were lower than the INW group post-training with a trend towards significance in the G group. It was concluded that ad libitum fluid consumption in cold conditions was insufficient in preventing a decrease in body mass and blood electrolyte concentration post-training. However, when a fixed volume of 11.5 mL/kg/L was consumed during warm condition training, hydration status was maintained by preventing changes in body mass and urine specific gravity [13599].

Sweating

Participation in physical activity exposes individuals to a variety of factors that influence sweat losses; these include the duration and intensity of exercise, the environmental conditions and the type of clothing/equipment worn. Sometimes, these factors are standardized for a specific activity or event within a sport (e.g. the temperature of an air conditioned indoor stadium or the uniform worn by a sporting team). In other cases, these factors occur in a predictable manner (e.g. running speeds in a 10,000 m race are higher than in a marathon, Nordic skiing, and other outdoor winter sports are undertaken in colder environments than summer sports). Nevertheless, in most activities, there is considerable variability in exposure to the factors that contribute to sweat rates between participants. Individual characteristics, such as body weight, genetic predisposition, heat acclimatization state, and metabolic efficiency (economy at undertaking a specific exercise task) will influence sweat rates for a given activity. As a result, there is a large range in sweat rates and total sweat losses of individuals between and within activities, and in some cases even in the same event on a given day. For example, elite marathon runners may have higher sweating rates but similar total sweat losses (run for shorter duration) as recreational runners who finish the race at the rear of the field. In a soccer match, sweat rates will vary between players according to their position and playing style as well as the total time spent on the field. Likewise, American football players (large body mass and wearing protective clothing) will have markedly greater daily sweat losses than cross country runners training in the same hot environmental for the same duration. Individuals often achieve sweating rates from 0.5 to 2.0 L/h. The differences in sweat rates between individuals, different sports and climatic season demonstrate the difficulties in providing a single one size fits all recommendation [07249].
Muscular contractions produce metabolic heat that is transferred from the active muscles to blood and then the body core. Subsequent body core temperature elevations elicit physiologic adjustments that facilitate heat transfer from within the body core to the skin where it can be dissipated to the environment. Heat exchange between the skin and the environment is governed by biophysical properties dictated by the surrounding temperature, humidity and air motion, sky and ground radiation, and clothing. In temperate and cooler environments, the high capacity for dry heat loss (radiation and convection) reduces evaporative cooling requirements, so sweat losses are relatively small. As the environmental heat stress increases, there is a greater dependence on sweating for evaporative cooling. The wearing of heavy or impermeable clothing, such as a football uniform, greatly increases the heat stress and evaporative cooling requirements while exercising in temperate to hot environments. Likewise, wearing heavy or impermeable clothing while exercising in cold weather can elicit unexpectedly high sweat rates. If the exercise task is 20 percent efficient, then 80 percent of metabolic energy is converted to heat in the body. Therefore, high intensity exercise will require about 800 W (11.5 kcal/min) of metabolic energy to be dissipated to avoid heat storage. If secreted sweat drips from the body and is not evaporated, higher sweating will be needed to achieve the evaporative cooling requirements. Conversely, increased air motion (wind, movement velocity) will facilitate evaporation and minimize wasted (dripping) sweat. Heat acclimatization enhances an individual to achieve higher and more sustained sweating rates, if needed. Similarly, aerobic exercise training has a modest effect on enhancing sweating rate responses. Other factors, such as wet skin (e.g. from high humidity) and dehydration can act to suppress the sweating rate response [07249].

Sweat electrolyte losses depend on the total sweat losses and sweat electrolyte concentrations. Sweat sodium concentration averages about 35 mEq/L (range 10-70 mEq/L) but varies depending upon genetic predisposition, diet, sweating rate, and heat acclimatization state. Sweat concentrations of potassium averages 5 mEq/L (range 3-15 mEq/L), calcium averages 1 mEq/L (range 0.3-2 mEq/L), magnesium average 0.8 mEq/L (range 0.2-1.5 mEq/L), and chloride averages 30 mEq/L (range 5-60 mEq/L). Neither gender, maturation, nor aging appear to have marked effects on sweat electrolyte concentrations; although dehydration can increase the sweat concentrations of sodium and chloride. Sweat glands reabsorb sodium and chloride, but the ability to reabsorb these electrolytes does not increase proportionally with the sweating rate. As a result, the concentration of sweat sodium and chloride increases as a function of sweating rate. Heat acclimatization improves the ability to reabsorb sodium and chloride, thus heat acclimatized individuals usually have lower sweat sodium concentrations for any given sweating rate [07249].

Hydration assessment

Water gain occurs from consumption (liquids and food) and production (metabolic water), while water losses occur from respiratory, gastrointestinal, renal, and sweat losses. The volume of metabolic water produced during cellular metabolism (about 0.13 g/kcal) is approximately equal to respiratory water losses (about 0.12 g/kcal), so this results in water turnover with no net change in total body water. Gastrointestinal tract losses are small (100-200 mL/d) unless the individual has diarrhea. Sweating provides the primary avenue of water loss during exercise-heat stress. The kidneys regulate water balance by adjusting urine output, with minimum and maximum urine outputs of approximately 20 and 1000 mL/h, respectively. During exercise and heat stress, both glomerular filtration and renal blood flow are markedly reduced, resulting in decreased urine output. Therefore, when fluids are over consumed during exercise (hyperhydration), there may be a reduced ability to produce urine to excrete the excess volume. With intermittent activities these effects may not be as strong.
on reducing urine production. Over a protracted period (e.g. 8-24 h), if adequate fluid and electrolytes are consumed, the water losses will usually be fully replaced to reestablish the "normal" total body water (TBW). TBW is regulated within 0.2 to 0.5 percent of daily body mass. TBW averages about 60 percent of body mass, with a range from approximately 45 to 75 percent. These differences are primarily due to body composition; fat-free mass is about 70 to 80 percent water, while adipose tissue contains about 10 percent water. These water content relationships are independent of age, sex and race. Therefore, an average 70-kg person has approximately 42 L of total body water, with a range of 31–51 L. Trained athletes have relatively high TBW values by virtue of having a high muscle mass and low body fat and a small aerobic training effect. Additionally, individuals who load glycogen may experience a small increase in TBW, but this is not always observed. Furthermore, the surplus water associated with typical muscle glycogen increases is minor (about 200 mL) when considering the small absolute muscle mass involved and assuming 3 mL water per gram glycogen. The precise fate of water liberated as glycogen is utilized is unknown, but the fact that any water bound to glycogen is part of the starting TBW pool suggests it is of little potential consequence to fluid intake recommendations [07249].

When assessing an individual’s hydration status, there is no one TBW that represents euhydration, and determinations need to be made of body water fluctuations beyond a range that have functional consequences. Ideally, the hydration biomarker should be sensitive and accurate enough to detect body water fluctuations of about 3 percent of TBW (or water content change sufficient to detect fluctuations of 2 percent body weight for the average person). In addition, the biomarker should also be practical (time, cost, and technical expertise) to be used by individuals and coaches. Individuals can determine their hydration status by using several simple biomarkers (urine and body weight) that by themselves have marked limitations; but when these indicators are used together in the proper context, they can provide valuable insight. The use of first morning body weight measurement after voiding, in combination with a measure of urine concentration should allow sufficient sensitivity (low false negative) to detect deviations in fluid balance. Urine biomarkers of hydration status can allow discrimination of whether an individual is euhydrated or dehydrated. Urine specific gravity (USG) and osmolality are quantifiable, whereas urine color and urine volume are often subjective and might be confounded. USG of > 1.020 is indicative of being euhydrated. Osmolality is more variable, but values > 700 mOsmol/kg are indicative of being euhydrated. However, urine values can provide misleading information regarding hydration status if obtained during rehydration periods. For example, if dehydrated persons consume large volumes of hypotonic fluids, they will have copious urine production long before euhydration is reestablished. Urine samples collected during this period will be light in color and have USG and osmolality values that reflect euhydration when in fact the person remains dehydrated. This emphasizes the need to use either first morning urine samples, or samples after several hours of stable hydration status, to allow valid discrimination between euhydration and dehydration. Body weight (BW) measurements provide another simple and effective tool to assess fluid balance. For well-hydrated persons, who are in energy balance, a first morning (after urinating) nude BW will be stable and fluctuate by < 1 percent. At least three consecutive morning nude BW measurements should be made to establish a baseline value, which approximates euhydration, in active men consuming food and fluid ad libitum. Women may need more BW measurements to establish a baseline value, because their menstrual cycle influences body water status. For example, luteal phases can increase body water and BW by >2 kg. Lastly, first morning BW is influenced by changes in eating and bowel habits [07249].

Acute changes in BW during exercise can be used to calculate sweating rates and perturbations in hydration status that occur in different environments. This approach assumes that 1 mL of sweat loss represents a 1-g loss in body weight (i.e. specific gravity of
sweat is 1.0 g/mL). The before-exercise BW measures are used with the postexercise BW corrected for urine losses and drink volume. When possible, nude weights should be used to avoid corrections for sweat trapped in the clothing. Other nonsweat factors contributing to BW loss during exercise include respiratory water and carbon exchange. Ignoring those two factors will over estimate sweat rate modestly (5-15 %) but generally do not require correction for exercise durations <3 h. If proper controls are made, BW changes can provide a sensitive estimate of acute TBW changes to access hydration changes during exercise [07249].

Hydration status is not easily measured, but acute changes in hydration status are often estimated from body mass change. Changes in body mass are also often used as a proxy measure for sweat losses. There are, however, several sources of error that may give rise to misleading results, and the aim in one paper was to quantify these potential errors. Respiratory water losses can be substantial during hard work in dry environments. Mass loss also results from substrate oxidation, but this generates water of oxidation which is added to the body water pool, thus dissociating changes in body mass and hydration status: fat oxidation actually results in a net gain in body mass as the mass of carbon dioxide generated is less than the mass of oxygen consumed. Water stored with muscle glycogen is presumed to be made available as endogenous carbohydrate stores are oxidized. Fluid ingestion and sweat loss complicate the picture by altering body water distribution. Loss of hypotonic sweat results in increased osmolality of body fluids. Urine and faecal losses can be measured easily, but changes in the water content of the bladder and the gastrointestinal tract cannot. Body mass change is not always a reliable measure of changes in hydration status and substantial loss of mass may occur without an effective net negative fluid balance [07250].

It was evaluated the change in body mass including fat mass and skeletal muscle mass in one ultracyclist whilst cycling 1,000 km in 48 hours at a constant intensity of about 48 percent VO\text{2}\text{max}, corresponding to a heart rate frequency of 105 ± 5 bpm. A 1 kg fat mass decrease resulted, with the largest decrease occurring between the 12th and the 24th hour. No steady state in metabolism was observed and no regular decrease of subcutaneous adipose tissue resulted. This result is backed up by the nuclear magnetic resonance (NMR) urine analysis. Body water increase with simultaneous dehydration is possibly due to endocrine-induced renal water retention, in order to maintain metabolism processes that are required for energy supply and blood flow during very prolonged exercise. Both applied methods, the anthropometric and the bioelectrical impedance analysis, analyse fluid accumulation – especially in the skinfolds of the lower extremities – apparently incorrectly as an increase in body mass and not as an increase in fluids [11381].

**Dehydration**

For the past 30 years, these have been two of the basic tenets of sports nutrition. Recently, however, both these universally regarded “truths” have been challenged. Firstly, it is now know that excessive intake of fluid during endurance events can lead to exercise-associated hyponatraemic encephalopathy (EAHE) or “water intoxication.” There have been a number of deaths reported from this syndrome. Drinking too much water can lead to fluid retention and EAHE in those who also have the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Endurance athletes have been encouraged for the past three decades to not wait until they were thirsty, but to drink large amounts of water or sports drinks to prevent dehydration and heat illness. However, excessive fluid overload is the major danger in endurance exercise, not dehydration and heat stroke, and that the old adage of drink when you are thirsty is actually correct [13596].
It is purported that exercise-induced dehydration (EID), especially if \( \geq 2 \) percent of body-weight, impairs endurance performance (EP). The recommendation to limit dehydration to 2 percent bodyweight during exercise is based from results of studies that used exercise protocols where athletes were forced to exercise at fixed-work rates until exhaustion or at least during part of the exercise protocols. These research designs have a poor reliability or possess a very low ecological validity, thereby suggesting that they should not be used in the establishment of fluid intake guidelines, especially those designed for athletes. In fact, several studies have shown that athletes’ exercise intensity during racing conditions never remains constant but rather constantly varies throughout either on a macro- or micro-scale. There is no sporting event where athletes are required to exercise until exhaustion. Finally, optimal endurance performance can only be achieved when the knowledge of the distance or time to be completed during an exercise bout is known. Using the meta-analytic procedure, one study compared the findings of laboratory-based studies that examined the impact of EID upon EP using either ecologically valid (EV) (timetrial exercise) or non-ecologically valid (NEV) (clamped-intensity exercise) exercise protocols. EP outcomes were put on the same scale and represent percentage changes in power output between euhydrated and dehydrated exercise tests. Random effects model meta-regressions and weighted mean effect summaries, mixed-effects model analogue to the ANOVAs and magnitude-based effect statistics were used to delineate treatment effects. Fifteen research articles were included, producing 28 effect estimates, representing 122 subjects. Compared with euhydration, EID increased \((0.09 \pm 2.60 \% )\), not statistically significant, EP under time-trial exercise conditions, whereas it significantly reduced it \((1.91 \pm 1.53 \% )\) with NEV exercise protocols. Only with NEV exercise protocols did EID \( \geq 2 \) percent body weight impair EP. Evidence thus indicates that exercise-induced dehydration \( \leq 4 \) percent bodyweight is very unlikely to impair EP under real-world exercise conditions (time-trial type exercise) and; under situations of fixed-exercise intensity, which may have some relevance for military and occupational settings, EID \( \geq 2 \) percent bodyweight is associated with a reduction in endurance capacity. The 2 percent bodyweight loss rule has been established from findings of studies using NEV exercise protocols and does not apply to out-of-doors exercise conditions. Athletes are therefore encouraged to drink according to thirst during exercise [13597].

To determine the effects of exercise heat-induced two percent dehydration (DEH) and euhydration (EUH) with a six percent carbohydrate-electrolyte solution (CES) compared with placebo EUH (P EUH) on basketball skills in skilled young players. Fifteen 12- to 15-year-old boys underwent three separate 2-h exercise heat exposures (double blind, random order): 2 percent DEH by limiting fluid intake during exercise in the heat and basketball skill drills, EUH (no net weight change) with a 6 percent CES, and EUH with a flavored water placebo (P EUH). After recovery, subjects performed an orchestrated sequence of continuous basketball drills designed to simulate a game (12-min quarters + a 10-min halftime). Performance measures and component drills inherent to basketball included various individual and combined shooting percentages (3-point, 15-foot, free-throw shots), sprint (suicides, court widths), lateral movement (zigzags, lane slides), and defensive drill (combining lateral and front-to-back movement) times. Compared with P EUH, combined shooting percentage was improved by 2 percent DEH and improved by CES intake. Total sprint times showed a similar effect. Total lateral movement times were impaired by 2 percent DEH. CES improved total defensive drill times compared with 2 percent DEH. It was concluded that deterioration in basketball skill performance accompanies two percent dehydration in skilled 12- to 15-year-old basketball players. Additionally, EUH with a 6 percent CES significantly improves shooting performance and on-court sprinting over EUH with water [06252].

Individuals often start an exercise task with normal total body water and dehydrate over an extended duration; however, in some sports the person might initiate the exercise task
dehydrated such as when the interval between exercise sessions is inadequate for full rehydration or when initial body weight is an issue. For example, in weight-class sports (e.g. boxing, power lifting, wrestling) individuals may purposely dehydrate to compete in lower weight classes. In addition, some individuals undertaking twice a day training, or prolonged daily sessions of exercise in hot conditions, may also carry a fluid deficit from their previous workout into the next. Water deficit without proportionate sodium chloride loss is the most commonly seen form of dehydration during exercise in the heat. If large sodium chloride deficits occur during exercise then the extracellular fluid volume will contract and cause “salt depletion dehydration.” Regardless of the dehydration method, for any water deficit, there is similarity in altered physiologic function and performance consequences. Dehydration increases physiologic strain as measured by core temperature, heart rate and perceived exertion responses during exercise-heat stress. The greater the body water deficit, the greater the increase in physiologic strain for a given exercise task. Dehydration >2 percent of body weight degrades aerobic exercise and cognitive/mental performance in temperate-warm-hot environments. Greater levels of dehydration will further degrade aerobic exercise performance. The critical water deficit (>2 % BW for most individuals) and the magnitude of performance decrement are likely related to the environmental temperature, exercise task, and the individual’s unique biological characteristics (e.g. tolerance to dehydration). Therefore, some individuals will be more or less tolerant to dehydration. Dehydration (3 % BW) has marginal influence on degrading aerobic exercise performance when cold stress is present. Dehydration (3-5 % BW) probably does not degrade either muscular strength or anaerobic performance. Physiologic factors that contribute to dehydration-mediated aerobic exercise performance decrements include increased body core temperature, increased cardiovascular strain, increased glycogen utilization, altered metabolic function, and perhaps altered central nervous system function. Though each factor is unique, evidence suggests that they interact to contribute in concert, rather than in isolation, to degrade aerobic exercise performance. The relative contribution of each factor may differ depending on the specific activity, environmental conditions, heat acclimatization status and athlete prowess, but elevated hyperthermia probably acts to accentuate the performance decrement. Cognitive/mental performance, which is important where concentration, skilled tasks and tactical issues are involved, is also degraded by dehydration and hyperthermia. The evidence is stronger for a negative effect of hyperthermia than that of mild dehydration on degrading cognitive/mental performance, but the two are closely linked when performing exercise in warm-hot weather [07249].

To determine the effect of a 48-h period of either fluid restriction (FR), energy restriction (ER), or fluid and energy restriction (F + ER) on 30-min treadmill time trial (TT) performance in temperate conditions. Thirteen males participated in four randomized 48-h trials (mean 21 years). Control (CON) participants received their estimated energy and water requirements. For FR, participants received their energy requirements and 193 mL/day water to drink, and for ER, participants received their water requirements and 290 kcal/day. F + ER was a combination of FR and ER. After 48 h, participants performed a 30-min treadmill TT in temperate conditions. A separate investigation (n=10) showed the TT to be highly reproducible (CV 1.6 %). Body mass loss (BML) was 0.6 percent (CON), 3.2 percent (FR), 3.4 percent (ER), and 3.6 percent (F + ER). Compared with CON less distance was completed on ER (10.3 %) and F + ER (15.0 %). Although less distance was completed on FR (2.8 %), this was not significantly different from CON. These results show a detrimental effect of a 48-h period of ER but no significant effect of FR on 30-min treadmill TT performance in temperate conditions. Therefore, these results do not support the popular contention that modest hypohydration (2-3 % BML) significantly impairs endurance performance in temperate conditions [07251].
One article summarizes a case of ischemic colitis suffered by a triathlete during an Ironman competition. Exercise results in a significant reduction in splanchnic blood flow to help maintain cardiovascular function. When dehydration and heat stress accompany exercise, blood flow to the splanchnic vasculature is further reduced, increasing the risk of local ischemia and tissue injury. Right hemicolectomy involving a 16-cm segment of ischemic large intestine and appendectomy the day following the race. The case study highlights one of the risks associated with dehydration during prolonged exercise in the heat. Of particular interest are practical interventions to reduce health and performance issues. Poor hydration and nutrition practices during intense exercise can affect gut function, impair performance, and jeopardize health. Optimal intake of fluid, carbohydrate, and salt will enhance performance and reduce risk to health [07252].

To determine the effect of 1, 2, 3, and 4% dehydration (DEH) versus euhydration (EUH) on basketball performance in adult male players 17-17 to 28-year-old male basketball players completed 3 h of interval treadmill walking (40 degrees C and 20 % relative humidity) with or without fluid replacement. Subjects completed six trials in random order: EUH with a carbohydrate-electrolyte solution (CES), EUH control (flavored water with 0 percent carbohydrate and 18 mM sodium), 1 percent DEH, 2 percent DEH, 3 percent DEH, and 4 percent DEH. After a 70-min recovery period, subjects performed a sequence of continuous basketball drills designed to simulate a fast-paced game. Measures of overall skill performance during the 80-min game included total time to complete basketball-specific movement drills (sprinting, defensive slides, sprinting-defensive slides combination, and repetitive jumping drills) and 2) total number of shots (foul-line and baseline jump shots, layups, three-point, 15-ft, free throws) made per game. Performance during all timed and shooting drills declined progressively as % DEH increased. Total time to complete basketball-specific movement drills was significantly slower and fewer shots were made during DEH versus EUH control. There were no significant differences in performance between CES and EUH control. It was concluded that basketball players experienced a progressive deterioration in performance as DEH progressed from 1 to 4 percent. The threshold, or percent DEH at which the performance decrement reached statistical significance, was 2 percent for combined timed and shooting drills [07253].

While in vitro work has revealed that dehydration and hyperthermia can elicit increased cellular and oxidative stress, in vivo research linking dehydration, hyperthermia, and oxidative stress is limited. The purpose of one study was to investigate the effects of exercise-induced dehydration with and without hyperthermia on oxidative stress. Seven healthy male, trained cyclists (power output (W) at lactate threshold (LT): 199 ± 19 W) completed 90 min of cycling exercise at 95 percent LT followed by a 5-km time trial (TT) in 4 trials: (i) euhydration in a warm environment (EU-W, control), (ii) dehydration in a warm environment (DE-W), (iii) euhydration in a thermoneutral environment (EU-T), and (iv) dehydration in a thermoneutral environment (DE-T). Oxidized glutathione (GSSG) increased significantly postexercise in dehydration trials only, and while not significant, total glutathione (TGSH) and thiobarbituric acid reactive substances (TBARS) tended to increase postexercise in dehydration trials. Monocyte heat shock protein 72 (HSP72) concentration was increased while lymphocyte HSP32 concentration was decreased for all trials. Exercise-induced dehydration led to an increase in GSSG concentration while maintenance of euhydration attenuated these increases regardless of environmental condition. Additionally, we found evidence of increased cellular stress (measured via HSP) during all trials independent of hydration status and environment. Finally, both 90-min and 5-km TT performances were reduced during only the DE-W trial, likely a result of combined cellular stress, hyperthermia, and dehydration. These findings highlight the importance of fluid consumption during exercise to attenuate thermal and oxidative stress during prolonged exercise in the heat [11517].
Exercise-associated collapse

Exercise-associated collapse (EAC) commonly occurs after the completion of endurance running events. EAC is a collapse in conscious athletes who are unable to stand or walk unaided as a result of light headedness, faintness and dizziness or syncope causing a collapse that occurs after completion of an exertional event. Although EAC is perhaps the most common aetiology confronted by the medical provider attending to collapsed athletes in a finish-line tent, providers must first maintain vigilance for other potential life-threatening aetiologies that cause collapse, such as cardiac arrest, exertional heat stroke or exercise-associated hyponatraemia. Previously, it has been believed that dehydration and hyperthermia were primary causes of EAC. On review of the evidence, EAC is now believed to be principally the result of transient postural hypotension caused by lower extremity pooling of blood once the athlete stops running and the resultant impairment of cardiac baroreflexes. Once life-threatening aetiologies are ruled out, treatment of EAC is symptomatic and involves oral hydration and a Trendelenburg position – total body cooling, intravenous hydration or advanced therapies is generally not needed [11518].

To investigate which of two commonly used treatment protocols for exercise-associated postural hypotension (EAPH) resulted in earlier discharge from the medical facility a randomised clinical field trial was undertaken at two Ironman Triathlon competitions and one ultra-distance footrace. All collapsed athletes admitted to the medical facilities were considered for the trial. Following clinical assessment and special investigations to confirm the diagnosis of EAPH, 28 athletes were randomly assigned to an oral fluid and Trendelenburg position (OT=14) or an intravenous fluid (IV=14) treatment group. Following admission fluid intake was recorded, and all athletes were assessed clinically (blood pressure, heart rate, level of consciousness) every 15 min until discharge criteria were met. The main measure of outcome was the time to discharge (min). On admission, subjects in the OT and IV groups were similar with respect to age, systolic blood pressure, heart rate and serum sodium concentration. There were no significant differences in heart rate, systolic and diastolic blood pressure between groups and over time until discharge. The fluid intake during the treatment period was significantly greater in the IV group (IV 1045 ± 185 mL, OT 204 ± 149 ml). The average time to discharge for the OT group (58 ± 23 min) was similar to that of the IV group (52.5 ± 18 min). It was concluded that endurance athletes with EAPH can be treated effectively using the Trendelenburg position and oral fluids and the administration of intravenous fluids does not reduce the time to discharge. The findings of this study support the hypothesis that EAPH is a result of venous pooling due to peripheral vasodilatation, rather than dehydration [11519].

Hyperhydration

Hyperhydration can be achieved by overdrinking combined with an agent that “binds” water within the body. These binding agents include glycerol and hypertonic drinks that can induce hyperhydration for varied durations. Simple overdrinking will usually stimulate urine production and body water will rapidly return to euhydration within several hours, however, this compensatory mechanism (urine production) is less effective during exercise and there is a risk of dilutional hyponatremia. Likewise, overconsumption of fluids with most hyperhydration binding agents will still elevate urine output well above normal levels. Hyperhydration does not provide any thermoregulatory advantages, but can delay the onset of dehydration, which may be responsible for any small performance benefits that are occasionally reported [07249].

Muscle problems in hypohydration
Skeletal muscle cramps are believed associated with dehydration, electrolyte deficits and muscle fatigue, and are common in non-heat-acclimatized football players, tennis matches, long cycling races, late in tropical triathlons, soccer and beach volleyball. Muscle cramps can also occur in winter activities-in cross-country ski-racers and icehockey goalies. Persons susceptible to muscle cramps are believed to be often profuse sweaters with large sweat sodium losses. Triathlon athletes experiencing muscle cramps, however, have been reported to not have clinically significant different serum electrolyte concentrations than counterparts without cramps [07249].

Rhabdomyolysis (syndrome causing release of skeletal muscle contents) is most often observed with novel, strenuous, overexertion and clinical evidence suggests that dehydration can increase the consequences of rhabdomyolysis. For example, it appears that dehydration increases the likelihood or severity of acute renal failure associated with rhabdomyolysis. A cluster of exertional rhabdomyolysis cases provides evidence that dehydration, combined with heat stress and novel training, can induce serious health problems [07249].

Exercise associated hyponatremia was first reported at the comrades marathon. Later, exercise-associated hyponatremia was reported in endurance runners, and since that time a number of participants from a variety of occupational and recreational activities have been hospitalized for this condition, with several having died. Symptomatic hyponatremia can occur when plasma sodium rapidly drops to about 130 mmol/L and below. The lower the plasma sodium falls, the faster it falls, and the longer it remains low, the greater the risk of dilutional encephalopathy and pulmonary edema. Some individuals have survived plasma sodium levels as low as 109 mmol/L and others have died with initial (in hospital) levels over 120 mmol/L. With plasma sodium <125 mmol/L and falling, symptoms become increasingly severe and include headache, vomiting, swollen hands and feet, restlessness, undue fatigue, confusion and disorientation (due to progressive encephalopathy), and wheezy breathing (due to pulmonary edema). When plasma sodium falls well below 120 mmol/L, the chances increase for severe cerebral edema with seizure, coma, brainstem herniation, respiratory arrest, and death. Contributing factors to exercise-associated hyponatremia include overdrinking of hypotonic fluids and excessive loss of total body sodium. In marathoners, symptomatic hyponatremia is more likely to occur in smaller and less lean individuals who run slowly, sweat less, and drink heavily-water and other hypotonic fluids-before, during, and after the race. In tropical triathlons, some participants may have been both dehydrated and hyponatremic based upon clinical observations. In general, symptomatic hyponatremia in events that last >4 h is from overdrinking before, during and sometimes even after the event. In longer ultraendurance events, sodium losses can induce hyponatremia to levels associated with the onset of symptoms regardless if the individual is over- or underdrinking, so replacing some of the sodium losses is warranted. Exercise-associated hyponatremia occurs occasionally in tennis players who drink too much water to treat or try to prevent heat cramps, or when a cramping player is given hypotonic fluid intravenously [07249].

**Modifying factors for hypohydration**

Women typically have lower sweating rates and electrolyte losses than men. The lower sweating rates are primarily because they have smaller body size and lower metabolic rates when performing a given exercise task. In addition, women seem to have less wasted sweat when their skin is wet. Gender differences in renal water and electrolyte retention are subtle and probably not of consequence. The diuretic response to a water load can be greater in women than men, suggesting that women turn water over more quickly than men. Women show reduced arginine vasopressin (AVP) responses to osmotic stimuli, which should result
in elevated renal water and electrolyte losses. Paradoxically, within women, both endogenous estrogens and exogenously administered estrogens appear to increase AVP release and both estrogens and progesterone enhance renal water and electrolyte retention. Women appear to be at greater risk than men to develop symptomatic hyponatremia when competing in marathon and ultra marathon races. While the explanation for this increased risk may be due to a number of biological and psychosocial factors, the cause for greater risk for hyponatremia has not been established with certainty. Although the kidney is important in the pathogenesis of hyponatremia, the target organs for morbidity and mortality are the brain and lungs. During AVP-induced hyponatremia, animal studies have shown significantly greater sodium transport in the male rat versus the female rat brain, suggesting impairment of the Na⁺-K⁺-ATPase pump activity in the female brain. Therefore, this might aggravate hyponatremia induced cerebral edema. Likewise, sex hormones have been suggested to impair Na⁺-K⁺-ATPase pump activity in the female brain and account for women having increased morbidity and mortality from postoperative hyponatremia [07249].

Older (ages >65 years) persons are generally adequately hydrated. However, there is an age-related blunting of thirst response to water deprivation, making older persons more susceptible to becoming dehydrated. Older adults have an age-related increase in resting plasma osmolality and are slower to restore body fluid homeostasis in response to water deprivation and exercise than younger adults. If given sufficient time and access to water and sodium, older adults will adequately restore body fluids, indicating appropriate, albeit sluggish, control of body fluids. Older persons are also slower to excrete water following fluid loads. This slower water and sodium excretion increases sodium retention and can lead to increases in blood pressure. While thirst sensitivity to a given extracellular fluid loss is reduced in older adults, osmoreceptor signaling remains intact. The osmotic and volume stimuli that results from dehydrating, impart important drives for thirst and drinking in older adults. Thus, older adults should be encouraged to rehydrate during or after exercise, but they should also consider the risks of excess water (i.e. hyponatremia) or sodium ingestion (i.e. hypertension) because they may be slower to excrete both the water and electrolytes. Prepubescent children have lower sweating rates than adults, and with values rarely exceeding 400 mL/h. These lower sweating rates are probably the result of smaller body mass and thus lower metabolic rate. Sweat electrolyte content is similar or slightly lower in children than adults [07249].

Carbohydrate-electrolyte solution (CES)
One study examined the effects of a carbohydrate-electrolyte drink on voluntary fluid intake, affect and self-selected intensity during recreational exercise after fluid restriction. In a randomised counterbalanced design, ten physically active adults were dehydrated via a 24-h period of fluid restriction before completing two 20-min bouts of cardiovascular exercise, 20-min of resistance exercise and 20 min on a cycle ergometer at a self-selected intensity with ad libitum access to water (W) or a carbohydrate-electrolyte solution (CES). Fluid restriction induced hyponatremia of about 1.2 percent initial body mass. Fluid intake during exercise was greater with CES and resulted in more adequate hydration. Plasma glucose concentrations and pleasure ratings were greater with CES than W. Mean power output during exercise performed at a self-selected intensity was 5.6 percent greater with CES. In physically active adults performing a “real-life” recreational exercise simulation, CES resulted in more adequate hydration and an enhanced affective experience that corresponded with an increase in self-selected exercise intensity [13595].

Diet
Meal consumption is critical to ensure full hydration on a day-to-day basis. Eating food
promotes fluid intake and retention. Sweat electrolyte (e.g. sodium and potassium) losses need to be replaced to reestablish total body water and this can be accomplished during meals with most persons. Diet macronutrient composition has a minor influence on urine losses during rest and probably has even a smaller influence during exercise. Therefore, diet macronutrient composition does not measurably alter daily fluid needs for individuals [07249].

Caffeine is contained in many beverages and foods and recent evidence suggests if consumed in relatively small doses (<180 mg/d) it will likely not increase daily urine output or cause dehydration. The influence of caffeine consumption on urine output during exercise or in dehydrated individuals is not well documented, but urine production is already decreased by dehydration, exercise and heat stress. Therefore, it is doubtful that caffeine consumption during exercise would elevate urine output and induce dehydration during exercise. Since alcohol can act as a diuretic (particularly at high doses) and increase urine output, it should be consumed in moderation, particularly during the postexercise period when rehydration is a goal [07249].

**Fluid replacement before exercise**

The goal of prehydrating is to start the physical activity euhydrated and with normal plasma electrolyte levels. If sufficient beverages are consumed with meals and a protracted recovery period (8-12 h) has elapsed since the last exercise session, then the person should already be close to being euhydrated. However, if the person has suffered substantial fluid deficits and has not had adequate time or fluids/electrolytes volumes to reestablish euhydration, then an aggressive prehydration program may be merited. The prehydration program will help ensure that any previously incurred fluid-electrolyte deficit is corrected prior to initiating the exercise task. When hydrating prior to exercise the individual should slowly drink beverages (for example, 5-7 mL/kg per body weight) at least 4 h before the exercise task. If the individual does not produce urine, or the urine is dark or highly concentrated, she or he should slowly drink more beverage (for example, another 3-5 mL/kg) about 2 h before the event. By hydrating several hours prior to exercise there is sufficient time for urine output to return towards normal before starting the event. Consuming beverages with sodium (20-50 mEq/L) and/or small amounts of salted snacks or sodium-containing foods at meals will help to stimulate thirst and retain the consumed fluids. Attempting to hyperhydrate with fluids that expand the extra- and intracellular spaces (e.g. water and glycerol solutions) will greatly increase the risk of having to void during competition and provides no clear physiologic or performance advantage over euhydration. In addition, hyperhydration can substantially dilute and lower plasma sodium before starting exercise and therefore increase the risk of dilutional hyponatremia, if fluids are aggressively replaced during exercise. Enhancing palatability of the ingested fluid is one way to help promote fluid consumption, before, during, or after exercise. Fluid palatability is influenced by several factors including temperature, sodium content and flavoring. The preferred water temperature is often between 15 and 21 °C, but this and flavor preference varies greatly between individuals and cultures [07249].

**Fluid replacement during exercise**

The goal of drinking during exercise is to prevent excessive dehydration (92 % BW loss from water deficit) and excessive changes in electrolyte balance to avert compromised exercise performance. The amount and rate of fluid replacement depends upon the individual sweating rate, exercise duration, and opportunities to drink. Individuals should periodically drink (as opportunities allow) during exercise, if it is expected they will become excessively dehydrated. Care should be taken in determining fluid replacement rates, particularly in
prolonged exercise lasting greater than 3 h. The longer the exercise duration the greater the cumulative effects of slight mismatches between fluid needs and replacement, which can excessive dehydration or dilutional hyponatremia. It is difficult to recommend a specific fluid and electrolyte replacement schedule because of different exercise tasks (metabolic requirements, duration, clothing, equipment), weather conditions, and other factors (e.g. genetic predisposition, heat acclimatization and training status) influencing a person’s sweating rate and sweat electrolyte concentrations. It is recommended that individuals should monitor body weight changes during training/competition sessions to estimate their sweat lost during a particular exercise task with respect to the weather conditions. This allows customized fluid replacement programs to be developed for each person’s particular needs; however, this may not always be practical. Fluid and electrolyte replacement strategies will be vastly different for a large football player in early season summer practice when contrasted with a petite marathoner running at a 6-h pace. A possible starting point suggested for marathon runners (who are euhydrated at the start) is they drink ad libitum from 0.4 to 0.8 L/h, with the higher rates for faster, heavier individuals competing in warm environments and the lower rates for the slower, lighter persons competing in cooler environments. For smaller runners, drinking at 0.8 L/h resulted in over-consumption (weight gain, light shaded areas), and for larger runners, drinking at 0.4 L/h resulted in excessive dehydration (3 % body weight loss). The composition of the consumed fluids can be important. It has been recommended that these types of fluid replacement beverages might contain about 20-30 meq/L sodium (chloride as the anion), about 2-5 meq/L potassium and 5-10 percent carbohydrate. The need for these different components (carbohydrate and electrolytes) will depend on the specific exercise task (e.g. intensity and duration) and weather conditions. The sodium and potassium are to help replace sweat electrolyte losses, while sodium also helps to stimulate thirst, and carbohydrate provides energy. These components also can be consumed by nonfluid sources such as gels, energy bars, and other foods. Carbohydrate consumption at a rate of 30-60 g/h has been demonstrated to maintain blood glucose levels and sustain exercise performance. The greatest rates of carbohydrate delivery are achieved with a mixture of sugars (e.g. glucose, sucrose, fructose, maltodextrine). If both fluid replacement and carbohydrate delivery are going to be met with a single beverage, the carbohydrate concentration should not exceed 8 percent, or even be slightly less, as highly concentrated carbohydrate beverages reduce gastric emptying. Finally, caffeine consumption might help to sustain exercise performance and likely will not alter hydration status during exercise [07249].

Drinking pattern during different parts of activity

Energy drinks are intended for people who work hard, both physically and mentally, particularly young people engaged in an active lifestyle. To assess the intake of energy drinks in a student group, during examinations and throughout an academic year a survey was performed on 92 students attending the Faculty of Human Nutrition and Consumer Sciences and those from the Faculty of Physical Education in Warsaw. Students consumed many more energy drinks during examinations (1424 ± 1577 mL/week) than during the rest of the academic year (441 ± 579 mL/week). About 30 percent more subjects from UPE drank such drinks, throughout both examinations and the academic year, compared to those from WULS. On average, most students drunk less than one can per day. During exams, only 49 percent students consumed an average of less than 125 ml of energy drinks per day, whereas this rose to 84 percent during the academic year. The most popular brands were Tiger, Red Bull and Burn. It is important that due care and attention is exercised in consuming high amounts of energy drinks as they contain bioactive substances, including caffeine, inositol, taurine, glucuronolactone and vitamins of the group B. These all have specific effects on the body and can be a cause for concern if their intake is high [13601].

1630
Different commercial available sport drinks

To determine the effectiveness of 3 commonly used beverages in restoring fluid and electrolyte balance, 8 volunteers dehydrated by 1.9 ± 0.2 percent of body mass by intermittent exercise in the heat, then ingested a carbohydrate-electrolyte solution (Gatorade), carbonated water/apple-juice mixture (Apfelschorle), and San Benedetto mineral water in a volume equal to 150 percent body-mass loss. These drinks are all are perceived to be effective rehydration solutions, and their effectiveness was compared with the rehydration effectiveness of Evian mineral water, which is not perceived in this way by athletes. Four hours after rehydration, the subjects were in a significantly lower hydration status than the pretrial situation on trials with two but were in the same hydration status as before the dehydrating exercise on Gatorade. Sodium balance was negative on all trials throughout the study; only with Apfelschorle did subjects remain in positive potassium balance. In this scenario, recovery of fluid balance can only be achieved when significant, albeit insufficient, quantities of sodium are ingested after exercise. There is a limited range of commercially available products that have a composition sufficient to achieve this, even though the public thinks that some of the traditional drinks are effective for this purpose [07254].

The purpose of one study was to identify and to compare the effects of ingesting liquids during a 16-km military march under moderate environmental conditions. Twenty-six volunteer male subjects were randomly divided into two groups. Group GW received water (n=12), and group GP received an electrolytic carbohydrate solution (n=14). Blood and urine samples were obtained immediately before and after the march. No significant differences between the drinks were found for any of the measured variables. However, important results (p < 0.05) were observed by comparing variables before and after exercise. The variables included sodium, hematocrit, red blood cell, hemoglobin, and lactic acid levels and body weight (group GW) and sodium, potassium, hematocrit, red blood cell, hemoglobin, and lactic acid levels (group GP). Under the environmental conditions and hydration procedures applied, the results of this study showed similarities in the behavior of the variables, regardless of the kind of beverage consumed [07255].

Sports drinks versus water

Sports drinks are often used before, during and after tennis tournaments, but their ability to influence physiological and psychological variables and the characteristics of tennis match play remains uncertain. The objective of this study was to evaluate the impact of ingesting specially formulated pre-exercise, endurance and recovery sports drinks on glycaemia and performance indices during a simulated tennis tournament. Eight well-trained male tennis players performed two 3-match round-robin tennis tournaments while ingesting sports drinks (SPDs) or placebos (PLAs) before, during and after each match (crossover study design). Before the first tournament, match and drink order were randomized (SPDs or PLAs first) and players were placed under controlled nutritional and hydration conditions. Glycaemia, heart rate response, rate of perceived exertion and notational/match analysis were assessed during each match. SPDs maintained higher glycaemia levels during match 2 and 3 of the tennis tournament compared with PLAs. Moreover, higher mean heart rates and stroke frequencies concomitantly with lower rates of perceived exertion were recorded throughout the duration of the tournament, when players used the SPDs. During a 3-match tennis tournament, SPDs allow higher stroke frequency during play, with decreased rates of perceived exertion [13598].

Effect of osmolality

It was investigated the effects of two carbohydrate-based sports drinks on fluid intake and immunoendocrine responses to cycling. Six well-trained male cyclists completed trials on three separate days that involved cycling at 60 percent VO_{2peak} for 90 min in hot conditions.
During each trial, the subjects consumed ad libitum an isotonic sports drink (osmolality 317 mOsm/kg), a hypotonic sports drink (osmolality 193 mOsm/kg) or plain water. The cyclists consumed significantly more of the isotonic drink and hypotonic drink compared with water. Compared with water, body mass decreased significantly less after consuming the hypotonic drink but not the isotonic drink. Blood glucose concentration was significantly higher at the end of the isotonic and hypotonic drink trials compared with the water trial. Neutrophil count and the plasma concentrations of catecholamines, interleukin 6 (IL-6), myeloperoxidase, calprotectin and myoglobin increased significantly during all three trials. IL-6 and calprotectin were significantly lower following the hypotonic drink trial compared with the water trial. In conclusion, hypotonic sports drinks are appealing for athletes to drink during exercise, and may help to offset fluid losses and attenuate some inflammatory responses to exercise [13600].

**Dehydration despite favorable conditions for fluid intake**

Study investigated the relationship between runners' perceptions of fluid needs and drinking behavior under conditions of compensable heat stress (ambient temperature 21 degrees C; relative humidity 77 %). Eighteen experienced runners (15 men, 41 years, and 3 women, 42 years) were given ad libitum access to a sports drink (6 % carbohydrate-electrolyte solution) at miles 2, 4, 6, and 8. After the run (76 min), subjects completed questionnaires that required them to estimate their individual fluid intake and sweat loss. Dehydration averaged 1.9 ± 0.8 percent of initial body weight (a mean sweat loss of 22 ± 5 mL/kg and h). Subjects replaced only 31 percent of sweat loss and underestimated their sweat loss by 43 percent. Subjects' self-estimations of fluid intake were not significantly different from actual fluid intake and were significantly correlated. The data indicate that even under favorable conditions, experienced runners voluntarily dehydrate possibly because they are unable to accurately estimate sweat loss and consequently cannot subjectively judge how much fluid to ingest to prevent dehydration. This conclusion suggests that runners should not depend on self-assessment to maintain adequate hydration, underscores the need for runners to enhance their ability to self-assess sweat losses, and suggests that a predetermined regimen of fluid ingestion might be necessary if they wish to maintain more optimal hydration [07256].

**Gastric emptying**

This study examined gastric emptying, core temperature, and sprint performance during prolonged intermittent shuttle running in 30 degrees C when ingesting a carbohydrate-electrolyte solution (CES) or flavored water (FW). Nine male soccer players performed 60 min of shuttle running, ingesting fluid before exercise and every 15 min during exercise. Gastric emptying was measured using a double-sampling aspiration technique, and intestinal temperature was monitored via ingested capsules. There were no differences between trials in the total fluid volume emptied from the stomach during each exercise period (P = 0.054). The volume emptied every 15 min was 244 ± 67 mL in the CES trial and 273 ± 66 mL in the FW trial. Intestinal temperature was significantly higher during exercise in the CES trial, and cumulative sprint time was shorter. Sprint performance was enhanced by the ingestion of a CES, which resulted in elevated core temperatures, and the rate of gastric emptying remained similar between solutions [07257].

**Fluid restriction increases GI permeability**

The purpose of one study was to determine gastrointestinal (GI) permeability during prolonged treadmill running (60 min at 70 % VO2max) with and without fluid intake (3 ml/kg body mass/10 min). Twenty runners (11 males, 9 females; age 22 years) completed four
experiments: 1) rest, 2) running with no fluid (NF), 3) running with ingestion of a 4% glucose solution (GLU), and 4) running with ingestion of a water placebo (PLA). To determine GI permeability, subjects also drank a solution containing 5 g sucrose (S), 5 g lactulose (L), and 2 g rhamnose (R) immediately prior to each trial. Gastroduodenal permeability was determined by urinary S excretion, while small intestinal permeability was determined by the L/R excretion ratio. Percent body mass loss (i.e. dehydration) was negligible during rest, GLU and PLA, while NF resulted in a 1.5 percent loss of body mass. Gastroduodenal and intestinal permeability were significantly increased in NF compared to rest. There were no other differences in GI permeability. These results indicate that fluid restriction during 1 h of steady-state running increases GI permeability above resting levels [07264].

Effects of hypohydration on performance

Although many studies have attempted to examine the effect of hypohydration on strength, power, and high-intensity endurance, few have successfully isolated changes in total body water from other variables that alter performance (e.g., increased core temperature), and none have documented the influence of hypohydration on an isotonic, multiset, multirepetition exercise bout typical of resistance exercise training. Further, no investigations document the effect of hypohydration on the ability of the central nervous system to stimulate the musculature, despite numerous scientists suggesting this possibility. The purposes of one study were to examine the isolated effect of hydration state on strength, power, and the performance of acute resistance exercise, and central activation ratio (CAR). Seven healthy resistance-trained males (age 23 years) completed three resistance exercise bouts in different hydration states: euhydrated (EU), hypohydrated by approximately 2.5 percent body mass (HY25), and hypohydrated by approximately 5.0 percent body mass (HY50). Investigators manipulated hydration status via exercise-heat stress and controlled fluid intake 1 d preceding testing. Body mass decreased 2.4 ± 0.4 and 4.8 ± 0.4 percent during HY25 and HY50, respectively. No significant differences existed among trials in vertical jump height, peak lower-body power (assessed via jump squat), or peak lower-body force (assessed via isometric back squat). CAR tended to decrease as hypohydration increased. When evaluated as a function of the percentage of total work completed during a six-set back squat protocol, hypohydration significantly decreased resistance exercise performance during sets 2-3 and 2-5 for HY25 and HY50, respectively. These data indicate that hypohydration attenuates resistance exercise performance; the role of central drive as the causative mechanism driving these responses merits further research [07258].

Drinking pattern during sports

Although expert groups have developed guidelines for fluid intake during sports, there is debate about their real-world application. It was reviewed the literature on self-selected hydration strategies during sporting competitions to determine what is apparently practical and valued by athletes. It was found few studies of drinking practices involving elite or highly competitive athletes, even in popular sports. The available literature revealed wide variability in fluid intake and sweat losses across and within different events with varied strategies to allow fluid intake. Typical drinking practices appear to limit body mass (BM) losses to about 2 percent in non-elite competitors. There are events, however, in which mean losses are greater, particularly among elite competitors and in hot weather, and evidence that individual participants fail to meet current guidelines by gaining BM or losing >2 percent BM over the competition activity. Substantial (>5%) BM loss is noted in the few studies of elite competitors in endurance and ultra-endurance events; while this may be consistent with winning outcomes, such observations cannot judge whether performance was optimal for that individual. A complex array of factors influence opportunities to drink during continuous
competitive activities, many of which are outside the athlete's control: these include event rules and tactics, regulated availability of fluid, need to maintain optimal technique or speed, and gastrointestinal comfort. Therefore, it is questionable, particularly for top competitors, whether drinking can be truly ad libitum (defined as "whenever and in whatever volumes chosen by the athlete"). While there are variable relationships between fluid intake, fluid balance across races, and finishing times, in many situations it appears that top athletes take calculated risks in emphasizing the costs of drinking against the benefits. However, some non-elite competitors may need to be mindful of the disadvantages of drinking beyond requirements during long events. Across the sparse literature on competition hydration practices in other sports, there are examples of planned and/or ad hoc opportunities to consume fluid, where enhanced access to drinks may allow situations at least close to ad libitum drinking. However, this situation is not universal and, again, the complex array of factors that influence the opportunity to drink during an event is also often beyond the athletes' control. Additionally, some competition formats result in athletes commencing the event with a body fluid deficit because of their failure to rehydrate from a previous bout of training/competition or weight-making strategies. Finally, since fluids consumed during exercise may also be a source of other ingredients (e.g., carbohydrate, electrolytes, or caffeine) or characteristics (e.g., temperature) that can increase palatability or performance, there may be both desirable volumes and patterns of intake that are independent of hydration concerns or thirst, as well as benefits from undertaking a "paced" fluid plan. Further studies of real-life hydration practices in sports including information on motives for drinking or not, along with intervention studies that simulate the actual nature of real-life sport, are needed before conclusions can be made about ideal drinking strategies for sports. Different interpretations may be needed for elite competitors and recreational participants [13594].

**Hydration in marathon**

There is a large and growing body of scientific evidence that documents the benefits of ingesting salt and glucose (carbohydrates) during prolonged exercise. Those benefits include maintenance of cardiovascular function, enhanced carbohydrate oxidation, blunted decline in plasma sodium concentration and improved performance. The consumption of approximately 1 g of carbohydrate per kilogram of bodyweight per hour appears sufficient to improve performance in prolonged exercise. Research also indicates that approximately 450 mg of sodium per hour is the minimum amount required to maintain plasma volume and slow the decline in plasma sodium concentration that can accompany prolonged exercise in some runners. Adequate carbohydrate and electrolyte intake can be achieved by consuming a well formulated sports drink at regular intervals during exercise, in volumes designed to minimise dehydration. For marathon runners, this could range from approximately 400 mL to >1.5 L per hour, depending upon individual sweating rates [07259].

**Water and carbohydrates**

One study investigated water absorption and blood volume changes after drinking water and 3 percent and 6 percent carbohydrate drinks. Nine healthy male volunteers completed this crossover study after giving informed consent to participate. On three separate occasions they consumed 500 ml of Evian water (W), a 3 percent carbohydrate drink (3 % CHO) or a 6 percent carbohydrate drink (6 % CHO) to which had been added 10.00 ± 0.01 g of deuterium oxide. Blood samples were collected 10 and 5 min before drink ingestion and at 2, 5, 10, 15, 20, 30, 45 and 60 min after drink ingestion. In addition, subjective feeling questionnaires were completed at intervals throughout and subjects urinated before and after the study period. Blood samples were analysed for hematocrit and haemoglobin, glucose and deuterium concentrations. There was a significant increase in blood glucose concentration...
after consumption of both the 3 percent CHO and 6 percent CHO drinks, with the increase being greater after consumption of the 6 percent CHO drink. Both the 3 percent CHO and 6 percent CHO drinks promoted a significant blood and plasma volume expansion after their consumption whereas there was no change in blood and plasma volumes when water was consumed. Blood deuterium enrichment increased after consumption of all three drinks, but there was no significant difference between drinks. The results suggest that when a significant expansion of blood volume is desired, this can be achieved by consumption of the 3 percent CHO or 6 percent CHO drink rather than with plain water consumption. This is likely to be due to the sodium and carbohydrate content of these drinks [10508].

Carbohydrate (CHO) ingestion results in positive effects on exercise capacity, repeated sprint speed and sport-specific skill performance during intermittent exercise. One study evaluated the effects of lower concentrations of CHO on performance during intermittent exercise. Ten healthy males completed four 15-min periods of intermittent running, consisting of maximal sprinting interspersed with periods of running and walking. This was followed by the multistage shuttle-running fitness test to volitional exhaustion. Subjects consumed 3 ml/kg body mass of plain water, a 3 percent CHO solution or a 6 percent CHO solution before exercise and a further 1.5 ml/kg body mass of the appropriate drink after each 15-min block. A trial with no fluid ingestion was also completed. Sprint time, heart rate, core temperature, perceived exertion and thermal stress were recorded at regular intervals. Cognitive function was assessed using a computer-based test battery. Time to exhaustion in the multistage shuttle-running fitness test was 9.9 ± 2.0 min, 10.2 ± 2.0 min, 10.9 ± 1.9 min and 11.2 ± 1.8 min in the no fluid, water, 3 percent and 6 percent CHO trials, respectively. Core temperature reached 38.9 ± 0.4°C during the no fluid trial, 38.5 ± 0.4°C in the water trial and 38.6 ± 0.3°C at the end of the CHO trials. There was no change in response times to a visual search task in the no fluid and water trials, but CHO ingestion improved response times after exercise (3 % CHO; 6 % CHO). These data suggest that drinks containing lower CHO concentrations can produce improvements in exercise capacity and motor response times similar to those observed with the ingestion of the amounts of CHO found in many sports drinks. The study was carried out in relation to the product Powerade and was funded in part by The Coca-Cola Company [10509].

**Water and electrolytes**

The purpose of one study was to summarize water, carbohydrate (CHO), and electrolyte absorption from carbohydrate-electrolyte (CHO-E) solutions based on all of the triple-lumen-perfusion studies in humans since the early 1960s. The current statistical analysis included 30 reports from which were obtained information on water absorption, CHO absorption, total solute absorption, CHO concentration, CHO type, osmolality, sodium concentration, and sodium absorption in the different gut segments during exercise and at rest. Mean differences were assessed using independent-samples t tests. Exploratory multiple-regression analyses were conducted to create prediction models for intestinal water absorption. The factors influencing water and solute absorption are carefully evaluated and extensively discussed. The authors suggest that in the human proximal small intestine, water absorption is related to both total solute and CHO absorption; osmolality exerts various impacts on water absorption in the different segments; the multiple types of CHO in the ingested CHO-E solutions play a critical role in stimulating CHO, sodium, total solute, and water absorption; CHO concentration is negatively related to water absorption; and exercise may result in greater water absorption than rest. A potential regression model for predicting water absorption is also proposed for future research and practical application. In conclusion, water absorption in the human small intestine is influenced by osmolality, solute absorption, and the anatomical structures of gut segments. Multiple types of CHO in a CHO-E solution
facilitate water absorption by stimulating CHO and solute absorption and lowering osmolality in the intestinal lumen [10433].

The aim of one study was to determine the effects of postexercise ingestion of different-molecular-weight glucose polymer solutions on subsequent high-intensity interval-running capacity. In a repeated-measures design, 6 men ran for 60 min in the morning at 70 percent VO$_2$max. Immediately post- and at 1 and 2 hr postexercise, participants consumed a 15 percent low-molecular-weight (LMW) or high-molecular-weight (HMW) carbohydrate solution, at a rate of 1.2 g of carbohydrate/kg body mass, or an equivalent volume of flavored water. After recovery, participants performed repeated 1-min intervals at 90 percent VO$_2$max interspersed with 1 min active recovery (walking) until volitional exhaustion. Throughout the 3-hr recovery period, plasma glucose concentrations were significantly higher during the HMW and LMW conditions than with flavored water, although there was no difference between HMW and LMW conditions. Exercise capacity was 13 and 11 min longer with HMW and LMW solutions, respectively, than with flavored water (30 ± 9 min). There was no substantial difference in exercise capacity between LMW and HMW solutions. Although this magnitude of difference is most likely trivial in nature, the uncertainty allows for a possible small substantial enhancement of physiological significance, and further research is required to clarify the true nature of the effect [10510].

Solutions containing multiple carbohydrates utilizing different intestinal transporters (glucose and fructose) show enhanced absorption, oxidation, and performance compared with single-carbohydrate solutions, but the impact of the ratio of these carbohydrates on outcomes is unknown. In a randomized double-blind crossover, 10 cyclists rode 150 min at 50 percent peak power, then performed an incremental test to exhaustion, while ingesting artificially sweetened water or one of three carbohydrate-salt solutions comprising fructose and maltodextrin in the respective following concentrations: 4.5 and 9 percent (0.5-Ratio), 6 and 7.5 percent (0.8-Ratio), and 7.5 and 6 percent (1.25-Ratio). The carbohydrates were ingested at 1.8 g/min and naturally $^{13}$C-enriched to permit evaluation of oxidation rate by mass spectrometry and indirect calorimetry. Mean exogenous carbohydrate oxidation rates were 1.04, 1.14, and 1.05 g/min (coefficient of variation 20 %) in 0.5-, 0.8-, and 1.25-Ratios, respectively, representing likely small increases in 0.8-Ratio of 11 percent and 10 percent relative to 0.5- and 1.25-Ratios, respectively. Comparisons of fat and total and endogenous carbohydrate oxidation rates between solutions were unclear. Relative to 0.5-Ratio, there were moderate improvements to peak power with 0.8- and 1.25-Ratio but unclear with water Increases in stomach fullness, abdominal cramping, and nausea were lowest with the 0.8-followed by the 1.25-Ratio solution. At high carbohydrate-ingestion rate, greater benefits to endurance performance may result from ingestion of 0.8- to 1.25-Ratio fructose-maltodextrin solutions. Small perceptible improvements in gut comfort favor the 0.8-Ratio and provide a clearer suggestion of mechanism than the relationship with exogenous carbohydrate oxidation [10511].

Alcoholic beverage for treatment of dehydration

Beer for water replacement
To investigate the effect of manipulating the alcohol and sodium content of beer on fluid restoration following exercise 7 male volunteers exercised on a cycle ergometer until 1.96 ± 0.25 percent body mass (mean ± SD) was lost. Participants where then randomly allocated a different beer to consume on four separate occasions. Drinks included a low alcohol beer (2.3 % ABV) [LightBeer], a low alcohol beer with 25 mmol/L of added sodium [LightBeer+25], a full strength beer (4.8 % ABV) [Beer] or a full strength beer with 25 mmol/L of added sodium [Beer+25]. Volumes consumed were equivalent to 150 percent of body mass loss.
during exercise and were consumed over a 1h period. Body mass and urine samples were obtained before and hourly for 4h after beverage consumption. Significantly enhanced net fluid balance was achieved following the LightBeer+25 trial (-1.02 ± 0.35 kg) compared to the Beer (-1.59 ± 0.32 kg) and Beer+25 (-1.64 ± 0.28 kg) treatments. Accumulated urine output was significantly lower in the LightBeer+25 trial (1477 ± 485 mL) compared to the Beer+25 (2101 ± 482 mL) and Beer (2175 ± 372 mL) trials. It was concluded that a low alcohol beer with added sodium offers a potential compromise between a beverage with high social acceptance and one which avoids the exacerbated fluid losses observed when consuming full strength beer [13603].

**Dehydration plus alcohol**

One study investigated the impact of mild-moderate dehydration on alcohol-induced deteriorations in cognitive functions. Sixteen healthy males participated in a single-blind, placebo-controlled cross-over design study involving 4 experimental trials (separated by ≥7 d). In each trial, participants were dehydrated by 2.5 percent body mass through exercise. After 1 h recovery in a thermo-neutral environment (22 ± 2°C, 60-70 % relative humidity) 4 tasks from the Cambridge Neuropsychological Test Automated Battery (CANTAB) were administered to the participants (test 1). In two of the trials, participants were provided with water equivalent to either 50 or 150 percent body mass loss and given salt (NaCl) capsules (50 mmol/L). A set volume of alcohol or placebo was then consumed in each trial, incorporating the conditions: dehydration-placebo (DP), dehydration-alcohol (DA), partial rehydration-alcohol (PA), and full rehydration-alcohol (FA). The same 4 CANTAB tasks were then re-administered (test 2). Subjective ratings of mood and estimates of alcohol intoxication and driving impairment were also recorded in each trial. Alcohol consumption caused deterioration on 3 of the 4 CANTAB measures (e.g. choice reaction time, executive function and response inhibition). This reduction in performance was exacerbated when participants were dehydrated compared to trials where full rehydration occurred. Subjective ratings of impairment and intoxication were not significantly different between any of the trials where alcohol was consumed; however ratings for alcohol trials were significantly higher than in the placebo trial. These findings suggest that rehydration after exercise that causes fluid loss can attenuate alcohol-related deterioration of cognitive functions. This may pose implications for post match fluid replacement if a moderate amount of alcohol is also consumed [13604].

**Oral salt supplementation**

During long-distance exercise, it can become difficult to continue to provide good nutrition support. The aim was to evaluate the potential of sausage “Saucisport” (water: 71 %, proteins: 17 %, carbohydrates: 3 %, fat: 6 %, other: 3 %) to maintain metabolic balance and performance during long-distance exercise. Ten male long-distance runners (mean ± SD: age 34 ± 14 years, height 177 ± 6 cm, weight 71 ± 6 kg, VO2max 56 ± 8 ml/min/kg) performed two sessions on treadmill (4 h at 65-70 % VO2 max). These two exercises were separated by 10 days. Subjects were randomized to receive “standard” or oral salt supplementation. During rectangular test, different parameters were recorded every hour (T0, T1, T2, T3, T4) and 1 h postexercise (T5): ventilation, respiratory quotient, oxygen consumption, heart rate, insulin, glucose and free fatty acids. Analysis of respiratory and cardiovascular parameters did not show any difference between salt and sugar supplementation, although in general the values observed in sweet supplementation are slightly higher than those in salt supplementation. Evolution of insulin during the stress test was comparable in both types of supplementation. Blood glucose values were higher after 3 h and 4 h of effort under “standard” supplementation, but were not different at the end of the exercise test. The study
shows that the sausage Saucisport® does not alter the physiological parameters, metabolic balance or performance during long-distance exercise [11520].

Exercise-associated hyponatremia

Exercise-associated hyponatremia has been described after sustained physical exertion during marathons, triathlons, and other endurance athletic events. As these events have become more popular, the incidence of serious hyponatremia has increased and associated fatalities have occurred. The pathogenesis of this condition remains incompletely understood but largely depends on excessive water intake. Furthermore, hormonal (especially abnormalities in arginine vasopressin secretion) and renal abnormalities in water handling that predispose individuals to the development of severe, life-threatening hyponatremia may be present. Studies have shown that endurance athletes not uncommonly develop hyponatremia at the end of the race, usually in the absence of clear central nervous system symptoms. For example, in the 2002 Boston Marathon, it was found that 13 percent of 488 runners studied had hyponatremia (defined as a serum sodium concentration of 135 mmol/L or less) and 0.6 percent had critical hyponatremia (serum sodium concentration of 120 mmol/L or less). In another study it was investigated 330 athletes who finished an ultramarathon race. In this study, 58 (18 %) were hyponatremic (defined as a serum sodium <135 mmol/L) and 11 had severe hyponatremia (serum sodium <130 mmol/L). Studies of other endurance events have reported the incidence of hyponatremia to be up to 29 percent. These incidence rates may be overestimations as a result of sampling biases. The majority of these athletes are asymptomatic or mildly symptomatic (nausea, lethargy). However, severe manifestations such as cerebral edema, noncardiogenic pulmonary edema, and death can occur. There have been at least 8 reported deaths from EAH (exercise-associated hyponatremia). Many of these reports relate to a series of fatalities in the military between 1989 and 1996. During this period, military recruits were encouraged to ingest 1.8 L of fluid for every hour they were exposed to temperatures above 30°C. Several risk factors have been linked with the development of EAH. The major risk factor seems to be overhydration or excessive fluid consumption during activity. This first was suggested by Noakes et al. in their original publication in 1985 and confirmed in this group’s later studies. The chronological history of the incidence of EAH also points to the primary role of overhydration in the pathogenesis. Before 1981, athletes were encouraged to drink heavily during exertion to avoid dehydration. With the description of EAH in South Africa and New Zealand in 1985, new fluid consumption guidelines that restricted overzealous fluid intake for endurance events in these countries were promoted. Concomitant with these recommendations, the incidence of EAH fell in both of these regions. Similar observations were made after the US military revised its guidelines for fluid consumption during training activities after the incidence of EAH increased. With an upper limit of fluid consumption set at 1.0 to 1.5 L/h, the incidence of EAH in the US military fell. In a study of runners in the Boston Marathon, it was found significant correlations between fluid intake and the incidence of hyponatremia. Specifically, a fluid intake of >3 L, a postrace weight greater than prerace weight, self-reported water loading (increased fluid consumption above baseline in preparation for the marathon), and self-reported fluid intake during the race all were found to be significant predictors for the development of hyponatremia. Substantial weight gain during the duration of the activity seemed to be the most important predictor of hyponatremia and correlated well with increased fluid intake. Also in another study it was found correlations between intrarace weight gain and hyponatremia: 73 percent of patients who were found to be severely hyponatremic had either gained or maintained weight during the race. In a large study it was investigated the changes in serum sodium concentration associated with changes in body weight in 2135 endurance athletes. The mean ± SD serum sodium was 136 ± 6 mmol/L for
athletes who gained weight during the race, 141 ± 4 mmol/L for those with minimal weight gain, and 141 ± 4 mmol/L for those who lost weight during the race. The authors estimated that athletes who gained >4 percent body weight during exercise had a 45 percent probability of developing hyponatremia. Importantly, 70 percent of individuals who gained weight during exercise did not develop hyponatremia, pointing to other important factors in the pathogenesis. It has not been possible to find a correlation in the type of fluids consumed (water versus electrolyte-containing solutions) and the subsequent development of hyponatremia. Other studies also have shown that the consumption of a carbohydrate/electrolyte-containing sports drink does not protect against the development of hyponatremia. This likely reflects the relative hypotonicity of most of the commercial sports drinks in which the sodium concentration typically is 18 mmol/L. Gender likely plays a role in the risk for development of EAH, with female athletes more likely than male athletes to develop hyponatremia during endurance events. Of 26 cases of EAH reported after the San Diego Marathon, 23 occurred in women. Hyponatremia was three times more common in women than in men in the 1997 New Zealand Ironman triathlon. It was also found that hyponatremia developed more commonly in women in the Boston Marathon. However, in that study, when these results were corrected for body mass index, racing time, and weight change, the difference did not reach statistical significance, suggesting that body size and duration of exercise may explain the gender differences. Furthermore, the incidence of hyponatremia in US military recruits reflects the gender distribution of this cohort and is not skewed to women. Some investigators also have suggested that women adhere more stringently to hydration recommendations during exercise and therefore consume more fluids. The finding of a gender association for the risk for symptomatic hyponatremia also has been seen in the postoperative state. The development of hyponatremia also has been correlated with the number of marathons run, the training pace, and the race duration. Those who have run fewer marathons (less experienced runners), have slower training paces, and have longer race times (especially >4 h) each were shown independently to have a significantly higher risk for developing hyponatremia. Longer race times likely correlate with increased water consumption and increased sodium losses. For example, participants who developed hyponatremia in the 1998 and 1999 San Diego Marathons had an average finishing time of 5 h and 38 min, and many of these individuals admitted to drinking as much fluid as possible during and after the event. A low body mass index also was shown to be a significant risk factor, perhaps as a result of the ingestion of larger amounts of fluid in proportion to size and total body water (TBW) [07260].

It has been suggested recently that financial links between manufacturers of sports drinks and professional Sports Science organisations in North America have suppressed information on the existence and ways of preventing an epidemic of exercise-associated hyponatraemia (EAH). One article reviewed evidence for the prevalence of both biochemical and clinical hyponatraemia. It concludes that a limited number of cases of EAH occur after ultra-long distance events, particularly when performed under cold and wet conditions, and that some eight deaths have been associated with EAH since 1985. However, this information has been widely reported, both in North America and in other parts of the world. Claims of an “epidemic” seem unwarranted, and there is no solid evidence supporting the claim that information has been suppressed because of ties between sports scientists and sports drink manufacturers [11521].

_Use of NSAID_

Medications also may play a significant role in the hyponatremia that is found in endurance athletes, but this largely is unproved. Nonsteroidal anti-inflammatory drug (NSAID) use is common among marathon runners, being used in 50 to 60 percent of men and women,
respectively. NSAID are known to potentiate the effects of arginine vasopressin (AVP) by inhibiting renal prostaglandin synthesis via the COX-2 isoform of cyclo-oxygenase. Furthermore, NSAID decrease the GFR when given to those with effective volume depletion, such as exercising endurance athletes. These effects may impair the urine-diluting capacity of the kidney. Despite these theoretical considerations, it has not been possible to associate the use of NSAID with the development of hyponatremia in the runners who were studied in the 2002 Boston Marathon. Other studies also have not been able to ascribe conclusively to NSAID use the development of hyponatremia, although several of these studies were underpowered to do so. However, one study in 330 triathletes demonstrated a significant association of NSAID use and the development of hyponatremia. In this study, the incidence of NSAID use in athletes was 30 percent, and NSAID use was highly associated with the development of hyponatremia, as well as higher plasma potassium and creatinine levels. Several other, smaller studies and case reports also have suggested a potentiating role for NSAID use. Therefore, the role of NSAID in the development of EAH remains controversial but in some runners likely is a potentiating factor. Whether other medications, such as selective serotonin reuptake inhibitors or thiazide diuretics, that are associated with hyponatremia in nonathletes can potentiate the development of EAH is not known. It is important to recognize that these risk factors do not suggest causation or even an independent association with the development of hyponatremia. However, they do offer important clues to the pathogenesis of the condition [07260].

Pathophysiology

Normally, renal and hormonal systems maintain the plasma osmolality within tight limits with variability of no more than 1 to 2 percent. These tight limits reflect the physiologic importance of osmolality regulation on cell volume and function. The development of hyponatremia (usually, in the setting of hypo-osmolality) reflects either defects in these hormonal and renal control mechanisms or water ingestion that overwhelms them. In the specific instance of EAH, defects in renal diluting mechanisms, hormonal control of water excretion, excessive sodium losses, and excessive water intake all contribute to the development of hypo-osmolality. Current evidence strongly supports that EAH is, in large part, dilutional in nature. In the majority of athletes who develop hyponatremia, there is an increase in TBW relative to that of total body exchangeable sodium. This seems to occur by the ingestion of hypotonic fluids (water or sports drinks) in excess of sweat, urine, and insensible (mainly respiratory and gastrointestinal) losses. In a seminal study, it was described a linear relationship with a negative slope between the serum sodium after racing and the degree of weight change in 2135 athletes. The primary cause of this weight gain during exercise must be the consumption of fluids during exercise. This consumption of fluids during exercise can be driven by thirst or through conditioned behavior. Some have hypothesized that in some athletes, the thirst drive may be excessive, but, more likely, the excessive fluid intake during exercise reflects conditioned behavior that is based on recommendations to drink fluid during exercise to avoid dehydration as well as the wide availability of fluids along the race course. This hypothesis is supported by data, that the incidence of EAH was rare or nonexistent before 1981, when recommendations for fluid intake during exercise were conservative. EAH was seen only after recommendations for more aggressive hydration were promulgated. Occasionally, some athletes may drink up to 3 L/h in an attempt to produce dilute urine to escape detection of banned drugs in the urine. Finally, some athletes may drink large volumes of fluid in the days leading up to a marathon in an attempt to ward off dehydration. This was the case for one female runner who drank 10 L of fluid on the evening before a marathon and then experienced postrace hyponatremia. However, excessive fluid consumption is not the sole explanation for the development of EAH. In one study hyponatremia did not develop in 70 percent of the athletes who overconsumed fluids and had an increase in TBW. This indicates that other important factors must be operational in the
pathogenesis of EAH. The importance of other factors also is highlighted by the fact that the maximum water excretory capacity of the kidneys is between 750 and 1500 mL/h. In combination with fluid losses from sweating and insensible losses (which may be in excess of 500 mL/h), most athletes should be able to consume fluids in excess of 1500 mL/h before retaining weight and increasing TBW. This amount of fluid consumption is at the upper limit of what most athletes would consume during an activity. Therefore, either defects in renal water excretion and/or significant sodium losses or failure to mobilize exchangeable sodium stores may occur in athletes who develop EAH. Furthermore, some athletes develop hyponatremia without appreciable gains in total body weight. These athletes may have significant sodium losses or also may have gained net body free water as a result of the metabolism of glycogen and triglycerides and not as a result of ingestion. However, the contribution of fuel metabolism or metabolic water production to TBW likely is small. During treadmill running at 74 percent of maximal oxygen consumption, metabolic water production averages 144 g/h (in contrast, sweat loss during this time was 1200 g/h). There is a possibility that water that is stored with glycogen can be released with glycogen breakdown. This may be an important component in the cause of hyponatremia that occurs without weight gain because each kilogram of glycogen can contain upwards of 3 kg of associated water.

Arginine vasopressin (AVP)

Data on the levels of AVP during exercise are conflicting. Unfortunately, systematic measurement of AVP levels or free water clearances in athletes who present with hyponatremia has not been done except in isolated cases. There are several potential pathways for stimulation of AVP release in exercising athletes. Controlled laboratory studies have demonstrated that as exercise intensity increases above 60 percent of maximal oxygen consumption, there are concomitant increases in AVP levels. Nonspecific stresses that are experienced by athletes and caused by factors such as pain, emotion, or physical exercise have been thought to cause nonosmotic release of AVP. However, it is difficult to determine whether this effect is mediated by a specific pathway or is due to a secondary stimulus, such as hypotension or nausea, that may occur in exercising athletes. AVP production also may be stimulated appropriately in athletes who develop volume depletion. However, the level of volume depletion that is required to stimulate AVP production in the absence of hyperosmolality is in excess of 7 to 8 percent of body volume. These levels of volume depletion typically are not seen in athletes (e.g., in the 2001 South African Ironman Triathlon, only 7 percent of finishers had a net body weight loss >5%). Furthermore, the majority of athletes with EAH finish events with an increase in body weight and possibly an expanded plasma volume. Exposure to heat also can lead to the secretion of AVP. However, this effect of temperature may be influenced secondarily by changes in effective arterial volume that occur with heat-induced vasodilation. Despite these considerations, in some athletes during prolonged exercise, plasma AVP levels may not be suppressed maximally despite maintenance or even excess of plasma volume. This has been described in studies of hikers who developed hyponatremia in the Grand Canyon and in an army recruit during a prolonged field march. In one study it was also described median AVP levels that were significantly higher in athletes who developed hyponatremia in the 1997 New Zealand Ironman Triathlon. An intriguing link between exercise and the nonosmotic stimulation of AVP release may be related to the release of inflammatory cytokines by the exercising and injured skeletal muscle. As glycogen stores are depleted, rhabdomyolysis or lesser degrees of muscle injury can occur with the release of inflammatory cytokines such as IL-6. Independent of rhabdomyolysis, studies have shown that exercise primes an array of pro- and anti-inflammatory and growth factor expressions within circulating leukocytes. A particular athlete may be predisposed to EAH on the basis of the single-nucleotide polymorphism profile and specific inflammatory response to exercise. Conversely, IL-6 in a rat sepsis model has been
shown to reduce the expression of aquaporin-2, the downstream target of AVP and ultimate regulator of water diuresis. How these factors interact to cause EAH is not known but should be an avenue of research. Consistent with the probable role of AVP in EAH, athletes who have finished races with hyponatremia have also been demonstrated, in some cases, to have inappropriately elevated urine osmolality. In this setting, even small increases in plasma AVP levels can cause significant water retention and hyponatremia, especially in combination with excessive water intake. Furthermore, gastrointestinal blood flow and water absorption from the stomach and intestine may be impaired during exercise. When the athlete stops activity, water absorption may increase rapidly and significantly. In the setting of elevated AVP levels, this rapid absorption of large quantities of water or hypotonic fluids can lead to significant falls in serum sodium.

**Sweating**

Although overdrinking clearly is the most important causative factor in the development of EAH, there is a variable and important contribution of sodium loss from sweating. The concentration of sodium in sweat varies widely but is usually 15 to 65 mEq/L, with highly fit athletes generally excreting sweat with sodium concentrations <40 mEq/L. The volume of sweat during exercise also varies widely, from approximately 250 ml/h to >2 L/h, again being less in more fit athletes. This loss of a substantial amount of hypotonic fluid may seem to protect against the development of hyponatremia. However, these losses are replaced by the ingestion of more hypotonic fluids (water or sports drinks), and the extracellular volume loss in sweat may serve as a stimulus for antidiuretic hormone (ADH) secretion. In fact, mathematical models demonstrate that the magnitude of sweat sodium loss is insufficient to produce EAH. For example, in a 90-km ultramarathon race, an athlete may lose approximately 8.6 L of sweat. Assuming sweat sodium concentrations of either 25 or 50 mmol/L and that all fluid losses were replaced by water, the resulting sodium deficits would be 215 and 430 mmol, respectively. For a 70-kg athlete, the resulting serum sodium concentration would be either 135 or 130 mmol/L, respectively. However, for longer duration events and for those with high sweat sodium concentrations (>75 mmol/L), a sufficient sweat sodium deficit can occur for athletes to finish the race both dehydrated and hyponatremic. This is supported by the finding that some athletes finish races with net weight loss and hyponatremia. Furthermore, one case report of a patient who had cystic fibrosis (patients with cystic fibrosis excrete large amounts of sodium in their sweat) and developed EAH points to the possibility that some people may be genetically predisposed to EAH as a result of high sweat sodium.

**Clinical features**

The clinical manifestations of EAH range from no or minimal symptoms to severe encephalopathy, seizures, respiratory distress, and death. In general, the degree of clinical symptoms is related not to the absolute measured level of serum sodium but to both the rate and the extent of the drop in extracellular tonicity. However, individual variability in the clinical manifestations of hyponatremia is great. It seems that the majority of runners with EAH have mild (weakness, dizziness, headache, nausea/vomiting) or no symptoms (usually associated with serum sodium values ranging from 134 to 128 mmol/L). In athletes with serum sodium values <126 mmol/L, there is a higher likelihood of severe clinical manifestations such as cerebral edema, altered mental status, seizures, pulmonary edema, coma, and death. It was examined the clinical manifestations of 21 hyponatremic runners who finished the Houston Marathon in 2000. These clinical manifestations were compared with those of runners who did not have hyponatremia and presented to the medical tent at the conclusion of the race. The only symptom that was more common in the hyponatremic group was vomiting. Other
symptoms such as headache, nausea, dizziness, and lightheadedness could not distinguish hyponatremia from other causes, attesting to the nonspecific nature of signs and symptoms that are associated with hyponatremia. A common scenario for medical personnel who staff endurance athletic events is the care of the “collapsed athlete.” Several studies have examined the incidence of hyponatremia in this cohort, and a range of 6 to 30 percent of these athletes had serum sodium values below normal. The wide range of incidence likely reflects differences in fluid replacement guidelines that were prevalent at the time and place of the study. It is critically important to realize that a postrace venous serum sodium measurement may underestimate significantly the severity of hyponatremia. This occurs for three reasons:

1. Water may be retained in the gastrointestinal tract during the athletic event only to be absorbed rapidly in the postrace period. If AVP levels are elevated, this retained water can lower rapidly the serum sodium when reabsorbed into the circulation.
2. Arterial sodium concentration can be significantly lower than the venous sodium concentration, with this difference being accentuated with more rapid absorption of water (there may be as much as a 4-mM difference between arterial and venous sodium concentrations when water is ingested rapidly). Because it is the arterial sodium concentration that determines the risks for acute central nervous system symptoms, runners with a large amount of retained water in the gastrointestinal tract may be at higher risk for cerebral edema than their venous serum sodium concentration would indicate. Therefore, in athletes with low body mass, mildly depressed venous sodium concentrations, and recent large water intakes, the risk for deterioration secondary to worsening hyponatremia may go unrecognized.
3. There may be transient rises in venous sodium concentration at the end of a race (especially if sprinting) as muscle lactic acid accumulates and leads to a shift of water intracellularly. This transient rise in serum sodium can be as high as 10 mM and may mask significant hyponatremia.

Prevention of EAH

Because EAH primarily develops by consumption of fluid in excess of urinary and sweat losses, most efforts at prevention have been focused on education about the risks of the overconsumption of fluids. In many respects, EAH can be viewed as an iatrogenic condition because of the prevailing view that exercising athletes should drink as much fluid as tolerable during a race. Given that there is a wide variation of sweat production and renal water excretory capacity both between individual athletes and in the same individual depending on ambient conditions during the race, universal guidelines for prevention are not feasible. However, several general recommendations for the prevention of EAH have been made. The first is to drink only according to thirst and no more than 400 to 800 ml/h. The higher rates of fluid intake would be recommended for runners with higher rates of exertion (e.g., heavier runners, warmer conditions, longer times of exertion). This rate of fluid intake is well below the levels of intake that are seen in athletes who develop EAH (up to 1.5 L/h water) but above the level that would be associated with dehydration. The second recommendation is to use the USA Track and Field guidelines or other methods to estimate hourly sweat losses during exercise and avoid consuming amounts that are greater than this amount during endurance events. This is facilitated by serial measurements of weights during and after exercise with the goal to maintain weight or even finish exercise with a slighter lower weight. However, this is difficult, time-consuming, and less likely to be followed by casual athletes. Currently, there is insufficient evidence to support the suggestion that ingestion of sodium prevents or decreases the risk for EAH; neither is there any evidence that consumption of sports drinks (electrolyte-containing hypotonic fluids) can prevent the development of EAH. Again, most commercial sports drinks are hypotonic with a sodium content of 10 to 20
mmol/L (230 to 460 mg/L). Overconsumption of such fluids may decrease the rate of serum sodium decline but is unlikely to prevent EAH. Currently, the American College of Sports Medicine recommends an intake of 0.5 to 0.7 g sodium/L of water as the appropriate level of sodium intake to replace the sodium that is lost in sweat during endurance events [07260].

**Therapy of EAH**

Ideally, medical facilities at endurance events should be able to measure serum or plasma sodium concentrations in any athlete who manifests symptoms that are compatible with EAH or EAHE. However, this may not be universally feasible, and caregivers may have to act empirically on the suspicion of EAH or EAHE as the cause of symptoms. It is crucial for on-site caregivers to be vigilant for the possibility of EAH and not diagnose incorrectly volume depletion and implement a reflex therapy of normal saline infusion. In 2005, a consensus panel made specific recommendations for the treatment of EAH and EAHE. The specific treatment recommended depends on the level of symptoms that the athlete is exhibiting at the time of presentation. Most forms of mild hyponatremia (serum sodium 130 to 135 mmol/L) will be asymptomatic and found only by laboratory testing. Most athletes with mild, asymptomatic hyponatremia will require only fluid restriction and observation until spontaneous diuresis occurs. It is important that hydration with intravenous 0.9 percent sodium chloride be used with utmost caution because this therapy runs the potential risk for further decreasing the serum sodium if AVP levels remain elevated in some athletes. Furthermore, the absorption of large amounts of retained hypotonic fluids in the gastrointestinal tract may continue to lower the serum sodium for some time after the event is finished. Therefore, intravenous hydration with sodium should be reserved for athletes who manifest clear clinical signs of volume depletion and used cautiously with mandatory monitoring of serum sodium levels. Furthermore, cases of pulmonary edema have been described in individuals who received aggressive hydration with 0.9 percent sodium Monitoring of urinary sodium and potassium concentrations and calculation of the urinary free water excretion rate can be helpful in this situation. Athletes who are excreting free water can be monitored safely without need for intravenous fluids, whereas athletes with a negative free water clearance should not receive 0.9 percent sodium because this may worsen the hyponatremia. The treatment of severe (serum natrium <120 mmol/L) or symptomatic EAH requires the administration of hypertonic saline. There are some important considerations when deciding to treat EAH with hypertonic saline. First is the assumption that all EAH is acute (<48 h). This allows the correction of the hyponatremia to be done rapidly and safely. The second consideration is that no cases of osmotic demyelination syndrome have been reported with the treatment of EAH. However, there is no general consensus on the amount of hypertonic saline to be given in athletes with EAH. In the field, it has been suggested that experienced medical staff may give 100 ml of 3 percent saline over 10 min...m This has been suggested to be safe, raising the serum sodium concentration 2 to 3 mmol/L in a short period of time, and should be used in athletes who exhibit symptoms of severe hyponatremia (confusion, vomiting, respiratory insufficiency). The use of hypertonic saline has been shown to induce a greater-than-expected increase in the serum sodium, likely as a result of a decrease in AVP, and the restoration of a dilute urine; therefore, it is imperative that all athletes who receive therapy for EAH or EAHE be transported to a medical center where the serum sodium can be monitored closely. Use of hypertonic saline should be continued in the hospital to correct the hyponatremia using standard protocols. In general, 3 percent hypertonic saline can be given at 1 to 2 ml/kg per h with close monitoring of both serum electrolytes and urinary sodium and potassium excretion. In cases of severe antidiuresis, the rate of infusion may need to be increased to 3 to 4 ml/kg per h. Once significant water diuresis begins, the rate of infusion can be decreased or stopped. Special mention should be made of the patient who presents with severe EAHE and pulmonary edema. It is imperative that these patients receive emergent therapy with 3 percent
hypertonic saline despite evidence of volume overload. The addition of a loop diuretic can be considered in two circumstances: significant volume overload and significant antidiuresis with a very elevated urinary osmolality, sodium, and/or potassium level. Hypokalemia can develop during athletic events especially after the event is completed. It is important that the potential for hypokalemia be appreciated because it can have important implications for treatment. First, hypokalemia is a risk factor for the development of osmotic demyelination that is associated with correction of chronic hyponatremia. Whether hypokalemia is a risk factor for poor neurologic outcomes that are associated with therapy for acute hyponatremia is not known. Second, replacement of potassium deficits will increase the serum sodium as sodium shifts out of cells. With concomitant potassium repletion, the serum sodium may rise faster than anticipated, and correction of hyponatremia should be less aggressive [07260].

Exercise-associated hyponatremia (EAH), as defined by a blood sodium concentration less than 135 mmol/L, may lead to hypotonic encephalopathy with fatal cerebral edema. Understanding the pathogenetic role of antidiuresis may lead to improved strategies for prevention and treatment. Normonatremic marathon runners were tested pre- and post-race for creatine kinase, interleukin-6, cortisol, prolactin, and arginine vasopressin. Similar testing also was carried out in runners with encephalopathy caused by EAH, including 2 cases with fatal cerebral edema. Normonatremic runners (n=33; 2001) with a mean 3 percent decrease in body weight showed a 40-fold increase in interleukin-6, which was significantly correlated with increases in creatine kinase, cortisol, and prolactin but not arginine vasopressin. Collapsed runners with EAH (n=22; 2004) showed a mean blood urea nitrogen less than 15 mg/dL with measurable plasma levels of arginine vasopressin (>0.5 pg/mL) in 43 percent of cases. Two marathon runners with fatal cerebral edema additionally showed less than maximally dilute urines (>100 mmol/kg/H₂O) and urine sodium concentration greater than 25 mEq/L. Cases of EAH fulfill the essential diagnostic criteria for the syndrome of inappropriate antidiuretic hormone secretion (SIADH). Runners with hypotonic encephalopathy at subsequent races were treated with intravenous hypertonic (3 %) saline on the basis of this paradigm, which resulted in rapid clinical improvement without adverse effects. Release of muscle-derived interleukin-6 may play a role in the nonosmotic secretion of arginine vasopressin, thereby linking rhabdomyolysis to the pathogenesis of EAH [07261].

Exercise-associated hyponatraemia (EAH) is an acute-onset imbalance in the tonicity of extracellular fluids during or after endurance exercise which results in a blood sodium concentration <135 mmol/L. Both excessive fluid intake and a concurrent decrease in urine formation contribute to this rapid-onset, predominantly dilutional, decrease in serum sodium, which can result in life-threatening pulmonary and cerebral edema. Marathon runners with hypotonic encephalopathy related to EAH, including two cases with fatal cerebral oedema, demonstrated non-osmotic secretion of arginine vasopressin and fulfilled the essential diagnostic criteria for the syndrome of inappropriate antidiuretic hormone secretion (SIADH). The pathophysiology of SIADH as the proximate cause of EAH accounts for otherwise puzzling clinical observations such as cases occurring after only moderate fluid intake or presenting hours after races. This formulation provides a framework for enhancing prevention by monitoring weight changes during races to detect positive fluid balance before the onset of mental status changes. Most importantly, SIADH supports a strategy for use of oral and intravenous hypertonic solutions, including 3 percent sodium chloride, for the emergent treatment of moderate and life-threatening symptoms of hypotonic encephalopathy, respectively [07262].

Over the past 2 decades, exercise-associated hyponatraemia (EAH) has emerged as an important complication of prolonged endurance physical activities. Data collected since the first reports of EAH have strongly implicated a dilutional hyponatraemia from inappropriate retention of body water as the primary cause of EAH. Although high rates of fluid
consumption clearly contribute to the pathogenesis of EAH, a review of the available data does not support the view that EAH can be ascribed solely to excess drinking. Because the kidney is exquisitely sensitive to low plasma levels of the antidiuretic hormone arginine vasopressin (AVP) and because many non-osmotic stimuli to AVP secretion normally occur during prolonged endurance exercise activity, it is more likely that a combination of higher than normal fluid intakes in the setting of modest elevations of plasma AVP levels from a variety of potential stimuli during prolonged physical activity accounts for the majority of cases of EAH. In any individual, the degree to which AVP secretion is stimulated and whether it can be suppressed with sufficient fluid ingestion, will determine their susceptibility to EAH as a result of fluid ingestion both before and after physical activity, accounting for the high degree of individual variability in the occurrence of this potentially life-threatening metabolic disorder [07263].

**Bicarbonate**

Although a considerable amount of published literature exists on the ergogenic potential of ingesting sodium bicarbonate (NaHCO₃) prior to short-term, high intensity exercise, very little exists on optimal loading times prior to exercise. The purpose of this study was to determine the influence of NaHCO₃ supplementation timing on repeated sprint ability (RSA). Eight males completed three (randomized and counter balanced) trials of ten, 10 s sprints separated by 50 seconds of active recovery (1:5 work-to-rest) on a non-motorized treadmill (NMT). Prior to each trial, subjects ingested 0.3 g/kg BW of NaHCO₃ at 60 (H1), 120 (H2) or 180 (H3) min prior to exercise. Additionally, subjects assessed any side effects (gastrointestinal (GI) discomfort) from the NaHCO₃ ingestion via a visual analog scale (VAS). Blood buffering was assessed using a two-way ANOVA with repeated measures, while repeated sprint performance and GI discomfort was assessed via a one-way ANOVA with repeated measures. Blood-buffering capacity was not different at pre exercise times. Average speed (AS), average power (AP) and total distance (TD) covered progressively declined over the ten sprints, however there was no difference between conditions. Incidence of GI discomfort was significantly higher from pre ingestion at all time points with the exception of 180 min, while severity was only different between 90 and 180 min. Ingestion times (between 60 and 180 min) did not influence the blood buffering or ergogenic potential of NaHCO₃ as assessed by RSA. However, VAS scores indicated that at 180 min post ingestion an individual is less prone to experience significant GI discomfort [11408].

Lactate (La) and H⁺-ions are unequally distributed in the blood between plasma and red blood cells (RBCs). There is no data concerning the effects of an oral ingestion of bicarbonate (HCO₃⁻) on repeated high intensity sprint exercise and La and H⁺ distribution between plasma and RBCs. Since an oral ingestion of bicarbonate leads to a higher efflux of La from the working skeletal muscle to the plasma, as it was shown by previous studies, this would lead to a higher gradient of La between plasma and RBCs. Although a higher gradient leads to a higher uptake, it is even more difficult for the RBCs to take up La fast enough, due to the more stressed transport system. Since RBCs function to transport La from the working muscle and help to maintain a concentration difference between plasma and muscle, this potentially increases performance during repeated sprint exercise (e.g. 4 × 30 s). The major goal of one investigation was to test this hypothesis. Eleven male participants ingested either a solution of sodium bicarbonate (NaHCO₃) or placebo (CaCO₃). Thereafter all performed four maximal 30 s sprints with 5 min of passive rest. During the resting periods concentrations of bicarbonate La and H⁺ where measured in both blood compartments (plasma and RBCs). There were no significant differences in the La-ratios between plasma and RBCs between both interventions. These results indicate that the La/H⁺ co-transport is
Metabolic acidosis is associated with skeletal muscle proteolysis, and alkali supplementation has shown improvements in lean body mass and urinary nitrogen wasting in several studies. However, the association of acidosis with functional outcomes has not been examined on a population-based level. 2,675 nationally representative adults 50 years or older in the National Health and Nutrition Examination Survey 1999-2002. Serum bicarbonate level <23 mEq/L was present in 23 percent of the cohort. Compared with participants with bicarbonate levels ≥23 mEq/L, those with bicarbonate levels <23 mEq/L had higher body mass index and serum albumin levels; were more likely to have low socioeconomic status, a diagnosis of diabetes mellitus, or glomerular filtration rate <60 mL/min/1.73 m²; and were less likely to use diuretics. Serum bicarbonate level <23 mEq/L compared with ≥23 mEq/L was associated with low gait speed (odds ratio 1.43) and low peak torque (odds ratio 1.36) after multivariable adjustment. The association with low peak torque was modified by race/ethnicity in women, but not men. Lower serum bicarbonate levels are associated with slower gait speed and decreased quadriceps strength in older adults. Further studies should examine the effect of alkali therapy on functional outcomes [11410].

The aim of one study was to determine the effect and reliability of acute and chronic sodium bicarbonate ingestion for 2000-m rowing ergometer performance (watts) and blood bicarbonate concentration [HCO₃⁻]. In a crossover study, 7 well-trained rowers performed paired 2000-m rowing ergometer trials under 3 double-blinded conditions: (1) 0.3 grams per kilogram of body mass (g/kg BM) acute bicarbonate; (2) 0.5 g/kg BM daily chronic bicarbonate for 3 d; and (3) calcium carbonate placebo, in semi-counterbalanced order. For 2000-m performance and bicarbonate amount it was examined differences in effects between conditions via pairwise comparisons, with differences interpreted in relation to the likelihood of exceeding smallest worthwhile change thresholds for each variable. There were only trivial differences in 2000-m performance between placebo (277 ± 60 W), acute bicarbonate (280 ± 65 W) and chronic bicarbonate (282 ± 65 W); however, [HCO₃⁻] was substantially greater after acute bicarbonate, than with chronic loading and placebo. Typical error for 2000-m mean power was 2.1 percent for acute bicarbonate, 3.6 percent for chronic bicarbonate, and 1.6 percent for placebo. It was concluded that performance in 2000-m rowing ergometer trials may not substantially improve after acute or chronic bicarbonate loading. However, performances will be reliable with both acute and chronic bicarbonate loading protocols [12456].

The aim of one study was to examine the effects of sodium bicarbonate (NaHCO₃) administration on lower-body, hypertrophy-type resistance exercise (HRE). Using a double-blind randomized counterbalanced design, 12 resistance-trained male participants (mean age 20 years) ingested 0.3 g/kg of NaHCO₃ or placebo 60 min before initiation of an HRE regimen. The protocol employed multiple exercises: squat, leg press, and knee extension, utilizing four sets each, with 10-12 repetition-maximum loads and short rest periods between sets. Exercise performance was determined by total repetitions generated during each exercise, total accumulated repetitions, and a performance test involving a fifth set of knee extensions to failure. Arterialized capillary blood was collected via fingertip puncture at four time points and analyzed for pH, [HCO₃⁻], base excess (BE), and lactate [Lac(-)]. NaHCO₃ supplementation induced a significant alkaline state. NaHCO₃ administration resulted in significantly more total repetitions than placebo after the exercise protocol. These findings demonstrate ergogenic efficacy for NaHCO₃ during HRE and warrant further investigation into chronic training applications [13606].

At rest, administration of the short-chain fatty acid acetate suppresses fat oxidation without
affecting carbohydrate utilization. The combined effect of increased acetate availability and exercise on substrate utilization is, however, unclear. With local ethics approval, it was studied the effect of ingesting either sodium acetate (NaAc) or sodium bicarbonate (NaHCO$_3$) at a dose of 4 mmol/kg body mass 90 min before completing 120 min of exercise at 50 percent VO$_{2\text{peak}}$. Six healthy young men completed the trials after an overnight fast and ingested the sodium salts in randomized order. As expected NaAc ingestion decreased resting fat oxidation (mean ± SD; 0.09 ± 0.02 vs. 0.07 ± 0.02 g/min pre- and post-ingestion respectively) with no effect upon carbohydrate utilization. In contrast, NaHCO$_3$ ingestion had no effect on substrate utilization at rest. In response to exercise, fat and CHO oxidation increased in both trials, but fat oxidation was lower (0.16 ± 0.10 vs 0.29 ± 0.11 g/min) and carbohydrate oxidation higher (1.67 ± 0.35 vs 1.44 ± 0.22 g/min) in the NaAc trial compared with the NaHCO$_3$ trial during the first 15 min of exercise. Over the final 75 min of exercise an increase in fat oxidation and decrease in carbohydrate oxidation was observed only in the NaAc trial. These results demonstrate that increasing plasma acetate concentration suppresses fat oxidation both at rest and at the onset of moderate-intensity exercise [13607].

During intensive anaerobic exercise with a large glycolytic component, one major cause of fatigue is believed to be acidosis caused by high levels of hydrogen ions (H$^+$) in the muscle fibers. The increase in (H$^+$) corresponds to a decrease in muscle and blood pH, can slow glycolysis, interfere with calcium release from the endoplasmic reticulum and calcium ion binding, and increase the perception of fatigue after some types of exercises. A number of buffers can be used by the body, but the primary method for buffering the H$^+$ is thought to be either bicarbonate or hemoglobin. For the past 35 years, several studies have investigated the use of sodium bicarbonate (SB) as an ergogenic aid. The participants have typically been men, and efficacy (improved performance and a decrease in H$^+$ concentration after exercise) has generally been seen at doses of at least 0.3 g/kg body mass. A meta-analysis by suggests that ingestion of SB at 0.3-0.5 g/kg body mass improves mean power by 1.7 ± 2.0 percent during high-intensity races of short duration (1–10 min). Timing of ingestion ranging from 60 min - 180 min before exercise did not influence buffering capacity or the ergogenic potential of SB (0.3 g/kg body mass) as assessed by repeated sprint ability. However, visual analog scale scores indicated that at 180 minutes post-ingestion, an individual is less prone to experiencing significant gastrointestinal discomfort. It has also been demonstrated that swimmers ingesting 0.3 g/kg body mass of SB can enhance blood buffering potential and positively influence interval swim performance. One study examined the effect of simultaneous supplementation of extracellular buffer sodium bicarbonate (SB) and intracellular buffer beta-alanine (BA) on maximal sprint swimming. Thirteen competitive male swimmers completed 4 different treatments (placebo [PL], SB, BA + PL, and BA + SB) in a crossover procedure. PL or SB supplementation (0.3 g/kg body weight) was ingested 60 min before two maximal 100-m freestyle swims that were performed with a passive recovery of 12-min between each swim. Because of the known long washout period for carnosine, four weeks of BA supplementation (4.8 g per day) was started after the first week of PL or SB supplementation and performance testing. The first maximal swims were similar, but the increase in time of the second versus the first 100-m swimming time was 1.5 s more in PL than in SB. Blood pH values were significantly (p < 0.05) greater in the SB and in the BA + SB groups compared to the PL and BA + PL values. There were no differences in peak blood lactate between the treatments. It was concluded that supplementing with SB prior to performing maximal sprint swimming with repetitions under 60 s improves performance. However, co-supplementation with SB and BA did not confer any added benefit on maximal swim performance [13608].

One study examined the acute effects of NaHCO$_3$ ingestion on repetitions to failure and rating of perceived exertion (RPE) in the back squat and bench press in trained males. Eight resistance trained males took part in this double-blind, randomized cross-over experimental
study whereby they ingested NaHCO$_3$ (0.3 g/kg body mass) or placebo (sodium chloride NaCl: 0.045 g/kg body mass) solution 60 mins before completing a bout of resistance exercise (3 sets of bench press and back squat exercise to failure at an intensity of 80 percent 1 repetition maximum). Experimental conditions were separated by at least 48 hours. Participants completed more repetitions to failure in the back squat following NaHCO$_3$ ingestion but not for bench press. Mean ± SD of total repetitions was 31.3 ± 15.3 and 24.6 ± 16.2 for back squat and 28.7 ± 12.2 and 26.7 ± 10.2 for bench press in NaHCO$_3$ and placebo conditions respectively. Repetitions to failure decreased as set increased for the back squat and bench press. RPE significantly increased with set for the back squat and bench press. There was no significant change in blood lactate across time or between conditions. There were however treatment X time interactions for blood pH and blood HCO$_3$ concentration. Following ingestion blood pH and HCO$_3$ concentration were greater for the NaHCO$_3$ condition compared to the placebo condition. The results of this study suggest that sodium bicarbonate ingestion can enhance resistance exercise performance using a repetition to failure protocol in the first exercise in a resistance exercise session [13609].

**Physiology**

Defense of extracellular pH constancy against lactic acidosis can be estimated from changes (Delta) in lactic acid ([La]), HCO$_3^-$, pH and PCO$_2$ in blood plasma because it is equilibrated with the interstitial fluid. These quantities were measured in earlobe blood during and after incremental bicycle exercise in 13 untrained (UT) and 21 endurance-trained (TR) males to find out if acute and chronic exercise influence the defense. During exercise the capacity of non-bicarbonate buffers ($\beta$(nbi) = -Delta[La] . DeltapH(-1) - Delta[HCO$_3^-$] . DeltapH(-1)) available for the extracellular fluid (mainly hemoglobin, dissolved proteins and phosphates) amounted to 32 ± 2 and 20 ± 2 mmol/L in UT and TR, respectively, which was a significant difference. During recovery $\beta$(nbi) decreased to significantly in both groups corresponding to values previously found at rest by in vivo CO$_2$ titration. Bicarbonate buffering ($\beta$(bi)) amounted to 44-48 mmol/L during and after exercise. The large exercise $\beta$(nbi) seems to be mainly caused by an increasing concentration of all buffers due to shrinking of the extracellular volume, exchange of small amounts of HCO$_3^-$ or H$^+$ with cells and delayed HCO$_3^-$ equilibration between plasma and interstitial fluid. Increase of concentration of HCO$_3^-$ during titration by these mechanisms augments total $\beta$ and thus the calculated $\beta$(nbi) more than $\beta$(bi) because it reduces DeltapH and Delta[HCO$_3^-$] at constant Delta[La]. The smaller rise in exercise $\beta$(nbi) in TR than UT may be caused by an increased extracellular volume and an improved exchange of lactic acid, bicarbonate and H$^+$ between trained muscles and blood [07265].

**Effect on exercise**

Bicarbonate loading is a popular ergogenic aid used primarily by athletes in short-duration, high-intensity sporting events and competitions. Controlled experimental trials have shown that small (worthwhile) benefits can obtained from acute doses of bicarbonate taken before exercise. Gastrointestinal problems encountered by some athletes limit the widespread use of this practice, however. The transfer of positive research findings to the competitive environment has proved problematic for some individuals. More recent applications involve serial ingestion of bicarbonate over several days before competition or during high-intensity training sessions over a few weeks. A number of research questions need to be addressed to enhance applications of bicarbonate loading in the elite sport environment. One commentary examined some of research and practical issues of bicarbonate loading used to enhance both training and competitive performance [07266].
Sodium bicarbonate ingestion has been shown to improve performance in single-bout, high intensity events, probably due to an increase in buffering capacity, but its influence on single-bout swimming performance has not been investigated. The effects of sodium bicarbonate supplementation on 200 m freestyle swimming performance were investigated in elite male competitors. Following a randomised, double blind counterbalanced design, 9 swimmers completed maximal effort swims on 3 separate occasions: a control trial (C); after ingestion of sodium bicarbonate (SB: NaHCO₃ 300 mg/kg body mass); and after ingestion of a placebo (P: CaCO₃ 200 mg/kg body mass). The SB and P agents were packed in gelatine capsules and ingested 90-60 min prior to each 200 m swim. Mean 200 m performance times were significantly faster for SB than C or P. Base excess, pH and blood bicarbonate were all elevated pre-exercise in the SB compared to C and P trials. Post-200 m blood lactate concentrations were significantly higher following the SB trial compared with P and C. It was concluded that SB supplementation can improve 200 m freestyle performance time in elite male competitors, most likely by increasing buffering capacity.

The effects of exercise on energy substrate metabolism persist into the postexercise recovery period. It was sought to derive bicarbonate retention factors (k) to correct for carbon tracer oxidized, but retained from pulmonary excretion before, during, and after exercise. Ten men and nine women received a primed-continuous infusion of ¹³C-bicarbonate (sodium salt) under three different conditions: before, during, and 3 h after 90 min of exercise at 45 percent peak oxygen consumption (VO₂peak); before, during, and 3 h after 60 min of exercise at 65 percent VO₂peak and during a time-matched resting control trial, with breath samples collected for determination of ¹³CO₂ excretion rates. Throughout the resting control trial, k was stable and averaged 0.83 in men and women. During exercise, average k in men was 0.93 at 45 percent VO₂peak and 0.94 at 65 percent VO₂peak and in women k was 0.91 at 45 percent VO₂peak and 0.92 at 65 percent VO₂peak with no significant differences between intensities or sexes. After exercise at 45 percent VO₂peak k returned rapidly to control values in men and women, but following exercise at 65 percent VO₂peak k was significantly less than control at 30 and 60 min postexercise in men (0.74 and 0.72, respectively) and women (0.75 and 0.76, respectively) with no significant postexercise differences between men and women. We conclude that bicarbonate retention is transiently increased in men and women for the first hour of postexercise recovery following endurance exercise bouts of hard but not moderate intensity.

Ingestion of agents that modify blood buffering action may affect high-intensity performance. Here we present a meta-analysis of the effects of acute ingestion of three such agents – sodium bicarbonate, sodium citrate and ammonium chloride – on performance and related physiological variables (blood bicarbonate, pH and lactate). A literature search yielded 59 useable studies with 188 observations of performance effects. To perform the mixed-model meta-analysis, all performance effects were converted into a percentage change in mean power and were weighted using standard errors derived from exact p-values, confidence limits (CLs) or estimated errors of measurement. The fixed effects in the meta-analytic model included the number of performance-test bouts (linear), test duration (log linear), blinding (yes/no), competitive status (athlete/nonathlete) and sex (male/female). Dose expressed as buffering mmoL/kg/body mass (BM) was included as a strictly proportional linear effect interacted with all effects except blinding. Probabilistic inferences were derived with reference to thresholds for small and moderate effects on performance of 0.5 and 1.5 percent, respectively. Publication bias was reduced by excluding study estimates with a standard error >2.7 percent. The remaining 38 studies and 137 estimates for sodium bicarbonate produced a possibly moderate performance enhancement of 1.7 percent with a typical dose of 3.5 mmoL/kg/BM (about 0.3 g/kg/BM) in a single 1-minute sprint, following blinded consumption by male athletes. In the 16 studies and 45 estimates for sodium citrate, a typical dose of 1.5 mmoL/kg/BM (about 0.5 g/kg/BM) had an unclear effect on performance.
of 0.0 percent, while the five studies and six estimates for ammonium chloride produced a possibly moderate impairment of 1.6 percent with a typical dose of 5.5 mmol/kg/BM (about 0.3 g/kg/BM). Study and subject characteristics had the following modifying small effects on the enhancement of performance with sodium bicarbonate: an increase of 0.5 percent with a 1 mmol/kg/BM increase in dose; an increase of 0.6 percent with five extra sprint bouts; a reduction of 0.6 percent for each 10-fold increase in test duration (e.g. 1-10 minutes); reductions of 1.1 percent with nonathletes and 0.7 percent with females. Unexplained variation in effects between research settings was typically ±1.2 percent. The only noteworthy effects involving physiological variables were a small correlation between performance and pre-exercise increase in blood bicarbonate with sodium bicarbonate ingestion, and a very large correlation between the increase in blood bicarbonate and time between sodium citrate ingestion and exercise. The approximate equal and opposite effects of sodium bicarbonate and ammonium chloride are consistent with direct performance effects of pH, but sodium citrate appears to have some additional metabolic inhibitory effect. Important future research includes studies of sodium citrate ingestion several hours before exercise and quantification of gastrointestinal symptoms with sodium bicarbonate and citrate. Although individual responses may vary, it was recommended ingestion of 0.3-0.5 g/kg/BM sodium bicarbonate to improve mean power by 1.7 percent in high-intensity races of short duration [11586].

Decrease in peripheral oxygen delivery may impact exercise performance in athletes with exercise-related arterial oxygen desaturation (ERD). It was evaluated whether sodium bicarbonate ingestion would be effective to reduce ERD and what is the consequences upon exercise performance. Seventy highly trained athletes performed an incremental treadmill cardiopulmonary exercise test (incCPX) and a high intensity constant speed test (ctCPX) on separate days. Subjects who developed ERD by pulse oximetry were randomly allocated to oral sodium bicarbonate or placebo during 5 days. At the end of treatment subjects repeated both tests. ERD prevalence was 33 percent during the incCPX (17 % severe, 48% moderate and 35 % mild) and 34 percent (5 % severe, 37 % moderate and 58 % mild) in the ctCPX. Athletes who developed ERD by pulse oximetry were randomly allocated to oral sodium bicarbonate or placebo during 5 days. At the end of treatment subjects repeated both tests. ERD prevalence was 33 percent during the incCPX (17 % severe, 48% moderate and 35 % mild) and 34 percent (5 % severe, 37 % moderate and 58 % mild) in the ctCPX. Active treatment, but not placebo, reduced ERD during ctCPX (P<0.05). However, there were no significant positive effects on main parameters of aerobic function and endurance exercise capacity. It was concluded that sodium bicarbonate was effective in lessening ERD during ctCPX in athletes. However, this intervention failed to improve maximal and submaximal exercise capacity in these subjects [13610].

Effect on symptoms from the stomach

Sodium bicarbonate (NaHCO₃) is often ingested at a dose of 0.3 g/kg body mass (BM), but ingestion protocols are inconsistent in terms of using solution or capsules, ingestion period, combining NaHCO₃ with sodium citrate (Na₃C₆H₅O₇), and coingested food and fluid. To quantify the effect of ingesting 0.3 g/kg NaHCO₃ on blood pH, [HCO₃⁻], and gastrointestinal (GI) symptoms over the subsequent 3 hr using a range of ingestion protocols and, thus, to determine an optimal protocol in a crossover design, 13 physically active subjects undertook 8 NaHCO₃ experimental ingestion protocols and 1 placebo protocol. Capillary blood was taken every 30 min and analyzed for pH and [HCO₃⁻]. GI symptoms were quantified every 30 min via questionnaire. Statistics used were pairwise comparisons between protocols; differences were interpreted in relation to smallest worthwhile changes for each variable. A likelihood of >75% was a substantial change. [HCO₃⁻] and pH were substantially greater than in placebo for all other ingestion protocols at almost all time points. When NaHCO₃ was coingested with food, the greatest [HCO₃⁻] (30.9 mmol/kg) and pH (7.49) and lowest incidence of GI symptoms were observed. The greatest incidence of GI side effects was
observed 90 min after ingestion of 0.3 g/kg NaHCO₃ solution. It was concluded that the changes in pH and [HCO₃⁻] for the 8 NaHCO₃-ingestion protocols were similar, so an optimal protocol cannot be recommended. However, the results suggest that NaHCO₃ coingested with a high-carbohydrate meal should be taken 120-150 min before exercise to induce substantial blood alkalosis and reduce GI symptoms [11248].

**Sodium bicarbonate and sodium citrate**

Athletes utilise many different strategies to enhance performance. Among the more popular ergogenic aids are sodium bicarbonate (NaHCO₃) or sodium citrate, collectively recognised as “buffers.” These substances, permitted for use by the World Anti-Doping Agency code, potentially provide the body with improved resistance to the fatigue caused by changes in acid-base balance. Typically, resting human arterial blood pH is approximately pH 7.4, slightly alkalotic, but after strenuous exercise may fall to about 7.1, while muscle pH decreases to about 6.8. Buffers such as NaHCO₃ and sodium citrate will increase the buffering capacity by increasing, for example, the amount of bicarbonate that can be utilised, say, by increasing the pH to 7.5. Studies in the 1980s on intense running using NaHCO₃ as a buffer suggested that ingesting this substance could enhance performance in elite athletes running 400-800 m. An ergogenic benefit in 200 m freestyle swimming performance after NaHCO₃ ingestion has also been reported. Researchers found that, after ingesting an acute load of 0.3 g/kg bw of NaHCO₃ and undergoing a loading sequence of creatine, swimmers who undertook an interval protocol (2×100 m freestyle with 10 min passive rest between bouts) experienced an improvement in time to complete the second swim. A recent study has suggested that, in order to overcome the gastrointestinal upset often associated with buffering, a progressive intake of 600 mg/kg bodyweight, split into several doses over the day, can be used as an alternative to the acute dose protocol. More conclusive, perhaps, is the ergogenic potential observed in recreational team sport participants during repeated sprints (5×6 s) or multiple effort bouts. Similar to earlier studies, it was observed a lower blood [H⁺] and higher [HCO₃⁻] after supplementing with 0.3 g/kg bw NaHCO₃. No differences were reported in total work or percentage fatigue, but improvements in sprints were observed. NaHCO₃ provision also resulted in significantly higher post-test muscle lactate values, attributed by the authors to a high rate of glycolytic flux in the muscle. However, another study failed to find any evidence of improved repeated sprint ability in college wrestlers. A NaHCO₃ dose of 0.3 g/kg body weight was used in a randomised controlled trial on 10 well-trained male cyclists undertaking 1 h maximal effort cycle ergometry. The cyclists performed, on average, 13 and 14 percent greater total with NaHCO₃ than control and placebo, respectively. More recently, no difference in NaHCO₃ (0.3 g/kg body weight) and control trials lasting about 60 min in total was observed. It was concluded that both NaHCO₃ and sodium citrate are effective, the optimal amount being 0.3 g/kg body weight. Users should test the response to buffer ingestion to improve their own performance prior to any competitive event, as both buffers can contribute to GI upset. It appears that short- and long-term high-intensity exercise, and possibly high-intensity longer-duration performance, can benefit from the ergogenic effects of these buffers. Loading sequences and timing of pre-exercise doses tend to be different in most studies, leading to confusion regarding effectiveness of the various buffering substances [09343].

**Energy need**

It has been demonstrated that athletes' dietary intake was relatively well-balanced according to the recommended dietary allowances (RDAs). In contrast, other studies have shown that athletes may have low energy intake or imbalance of protein and fat and insufficient minerals
and vitamins. Nonetheless, it was hypothesized that practicing a sport may allow young adults to have a nutritional status closer to recommended values. The purpose of one experiment was to study the nutritional status of young French adults, particularly to compare the nutritional status of trained young male and female athletes to those of young sedentary control subjects, and to national RDAs. A total of 85 young adults were recruited and filled a 4-day food and physical activity record. Dietary intake, energy expenditure, energy balance, carbohydrate, protein, fat, water, vitamins, and minerals were recorded. Energy intake values were $9874 \pm 3050$ kJ for the athletes and $7506 \pm 1845$ kJ for control subjects. Athletes' nutritional status was closer to French RDAs than those of sedentary subjects who present a lower energy intake, a greater percentage of the energy intake from fat and lower values for minerals and vitamins. In conclusion, practicing a sport may allow athletes to balance their energy intake and expenditure and could be a good way to have a nutritional status closer to RDAs. Educational programs for students on proper food selection, eating habits and physical activity are needed to improve the nutritional status of these young French adults, particularly in sedentary students [09322].

**Meal frequency**

Admittedly, research to date examining the physiological effects of meal frequency in humans is somewhat limited. More specifically, data that has specifically examined the impact of meal frequency on body composition, training adaptations, and performance in physically active individuals and athletes is scant. Until more research is available in the physically active and athletic populations, definitive conclusions cannot be made. However, within the confines of the current scientific literature, it can be asserted that:

- increasing meal frequency does not appear to favorably change body composition in sedentary populations
- if protein levels are adequate, increasing meal frequency during periods of hypoenergetic dieting may preserve lean body mass in athletic populations
- increased meal frequency appears to have a positive effect on various blood markers of health, particularly LDL cholesterol, total cholesterol, and insulin
- increased meal frequency does not appear to significantly enhance diet induced thermogenesis, total energy expenditure or resting metabolic rate
- increasing meal frequency appears to help decrease hunger and improve appetite control

Although athletic and physically active populations have not been independently studied in this domain, given the beneficial outcomes that increasing meal frequency exerts on a variety of health markers in non-athletic populations, it appears as if increasing meal frequency in athletic populations is warranted in terms of improving blood markers of health. Nutrient timing research has demonstrated the importance of protein ingestion before, during, and following physical activity. Social and cultural definitions of an actual "meal" (vs snack) vary greatly and time between "meals" is arbitrary. In other words, if the "time-lag" is very short, it may increase the number of feedings as opposed to a study with a greater "time-lag". Taking all of this into account, it appears from the existing (albeit limited) body of research that increased meal frequency may not play a significant role in weight loss/gain when under-reporting, restrained eating, and exercise are accounted for in the statistical analyses. Furthermore, most, but not all of the existing research, fails to support the effectiveness of increased meal frequency on the thermic effect of food, resting metabolic rate, and total energy expenditure. However, when energy intake is limited, increased meal frequency may likely decrease hunger, decrease nitrogen loss, improve lipid oxidation, and improve blood markers such as total and LDL cholesterol, and insulin. Nonetheless, more well-designed research studies involving various meal frequencies, particularly in physically active/athletic populations are warranted [11246].
Carbohydrates

One review considered aspects of the optimal nutritional strategy for recovery from prolonged moderate to high intensity exercise. Dietary carbohydrate represents a central component of post-exercise nutrition. Therefore, carbohydrate should be ingested as early as possible in the post-exercise period and at frequent (i.e. 15- to 30-minute) intervals throughout recovery to maximize the rate of muscle glycogen resynthesis. Solid and liquid carbohydrate supplements or whole foods can achieve this aim with equal effect but should be of high glycaemic index and ingested following the feeding schedule described above at a rate of at least 1 g/kg/h in order to rapidly and sufficiently increase both blood glucose and insulin concentrations throughout recovery. Adding ≥0.3 g/kg/h of protein to a carbohydrate supplement results in a synergistic increase in insulin secretion that can, in some circumstances, accelerate muscle glycogen resynthesis. Specifically, if carbohydrate has not been ingested in quantities sufficient to maximize the rate of muscle glycogen resynthesis, the inclusion of protein may at least partially compensate for the limited availability of ingested carbohydrate. Some studies have reported improved physical performance with ingestion of carbohydrate-protein mixtures, both during exercise and during recovery prior to a subsequent exercise test. While not all of the evidence supports these ergogenic benefits, there is clearly the potential for improved performance under certain conditions, e.g. if the additional protein increases the energy content of a supplement and/or the carbohydrate fraction is ingested at below the recommended rate. The underlying mechanism for such effects may be partly due to increased muscle glycogen resynthesis during recovery, although there is varied support for other factors such as an increased central drive to exercise, a blunting of exercise-induced muscle damage, altered metabolism during exercise subsequent to recovery, or a combination of these mechanisms [10434].

During postexercise recovery, optimal nutritional intake is important to replenish endogenous substrate stores and to facilitate muscle-damage repair and reconditioning. After exhaustive endurance-type exercise, muscle glycogen repletion forms the most important factor determining the time needed to recover. Postexercise carbohydrate (CHO) ingestion has been well established as the most important determinant of muscle glycogen synthesis. Coingestion of protein and/or amino acids does not seem to further increase muscle glycogen synthesis rates when CHO intake exceeds 1.2 g/kg per hour. However, from a practical point of view it is not always feasible to ingest such large amounts of CHO. The combined ingestion of a small amount of protein (0.2-0.4 g/kg per hour with less CHO (0.8 g/kg per hour) stimulates endogenous insulin release and results in similar muscle glycogen-repletion rates as the ingestion of 1.2 g/kg per hour CHO. Furthermore, postexercise protein and/or amino acid administration is warranted to stimulate muscle protein synthesis, inhibit protein breakdown, and allow net muscle protein accretion. The consumption of about 20 g intact protein, or an equivalent of about 9 g essential amino acids, has been reported to maximize muscle protein-synthesis rates during the first hours of postexercise recovery. Ingestion of such small amounts of dietary protein 5 or 6 times daily might support maximal muscle protein-synthesis rates throughout the day. Consuming CHO and protein during the early phases of recovery has been shown to positively affect subsequent exercise performance and could be of specific benefit for athletes involved in multiple training or competition sessions on the same or consecutive days [10512].

Consuming carbohydrate-rich meals before continuous endurance exercise improves performance, yet few studies have evaluated the ideal preexercise meal for high-intensity intermittent exercise, which is characteristic of many team sports. Now it was the purpose to investigate the effects of low- and high-glycemic-index (GI) meals on metabolism and
performance during high-intensity, intermittent exercise. Sixteen male participants completed three 90-min high-intensity intermittent running trials in a single-blinded random order, separated by about 7 d, while fasted (control) and 2 hr after ingesting an isoenergetic low-GI (lentil), or high-GI (potato and egg white) preexercise meal. Serum free fatty acids were significantly higher and insulin lower throughout exercise in the fasted condition, but there were no differences in blood glucose during exercise between conditions. Distance covered on a repeated-sprint test at the end of exercise was significantly greater in the low-GI and high-GI conditions than in the control. Rating of perceived exertion was lower in the low-GI condition than in the control. In a subsample of 5 participants, muscle glycogen availability was greater in the low-and high-GI conditions versus fasted control before the repeated-sprint test, with no differences between low and high GI. When exogenous carbohydrates are not provided during exercise both low- and high-GI preexercise meals improve high-intensity, intermittent exercise performance, probably by increasing the availability of muscle glycogen. However, the GI does not influence markers of substrate oxidation during high-intensity, intermittent exercise [10513].

Ingesting carbohydrate plus protein during prolonged variable intensity exercise has demonstrated improved aerobic endurance performance beyond that of a carbohydrate supplement alone. The purpose of one study was to determine if a supplement containing a mixture of different carbohydrates (glucose, maltodextrin, and fructose) and a moderate amount of protein given during endurance exercise would increase time to exhaustion (TTE), despite containing 50 percent less total carbohydrate than a carbohydrate-only supplement. We also sought post priori to determine if there was a difference in effect based on percentage of ventilatory threshold (VT) at which the subjects cycled to exhaustion. Fifteen trained male and female cyclists exercised on 2 separate occasions at intensities alternating between 45 and 70 percent VO$_{2\text{max}}$ for 3 hours, after which the workload increased to 74-85 percent VO$_{2\text{max}}$ until exhaustion. Supplements (275 mL) were provided every 20 minutes during exercise, and these consisted of a 3 percent carbohydrate/1.2% protein supplement (MCP) and a 6 percent carbohydrate supplement (CHO). For the combined group (n=15), TTE in MCP did not differ from CHO. However, for subjects cycling at or below VT (n=8), TTE in MCP was significantly greater than for CHO. There were no significant differences in TTE for the above VT group (n=7). The results suggest that, compared to a traditional 6% percentCHO supplement, a mixture of carbohydrates plus a moderate amount of protein can improve aerobic endurance at exercise intensities near the ventilatory threshold, despite containing lower total carbohydrate and caloric content [10514].

Rowing is an endurance sport with an important skill component. One study evaluated the effects of carbohydrate (CHO) solution ingestion on rowing technique before and after 60 min of ergometer rowing. On two occasions, eight male rowers rowed as a group in an indoor rowing tank for 6 min at 18 strokes per minute before and after 60 min of ergometer rowing at 60 percent of VO$_{2\text{max}}$. Participants ingested either a 6 percent CHO solution or a flavoured placebo in a randomised, counterbalanced fashion. Physiological and technical measures were analysed using a repeated measures analysis of variance. There were no differences in heart rate or rating of perceived exertion between the treatments, indicating similar physiological strain. There were no changes in stroke length over the 60-min period with either treatment. Oar handle velocity decreased from 49.7 ± 3.6 to 47.4 ± 2.8 °/s over the 60-min period in placebo group but did not change in CHO (48.9 ± 2.2 to 48.2 ± 1.9 °/s). Oar handle curves did not differ between CHO and placebo. Maximum blade depth declined similarly by 20 ± 16 placebo in both groups. This change is likely to decrease the resistance of the water upon the oar blade during the drive phase of the rowing stroke. In conclusion, selected measures of rowing tank technique deteriorated in response to 60 min of ergometer rowing in both placebo and CHO. Ingestion of CHO may help to maintain velocity of movement as rowers fatigue [10509].
Health care professionals advocate that athletes who are susceptible to exercise-associated muscle cramps (EAMCs) should moderately increase their fluid and electrolyte intake by drinking sport drinks. Some clinicians have also claimed drinking small volumes of pickle juice effectively relieves acute EAMCs, often alleviating them within 35 seconds. Others fear ingesting pickle juice will enhance dehydration-induced hypertonicity, thereby prolonging dehydration. To determine if ingesting small quantities of pickle juice, a carbohydrate-electrolyte (CHO-e) drink, or water increases plasma electrolytes or other selected plasma variables a crossover study was performed. Nine euhydrated, healthy men completed the study. Mean fluid intake was 86 ± 17 mL. Plasma sodium concentration, plasma magnesium concentration, plasma calcium concentration, plasma osmolality, and plasma volume did not change during the 60 minutes after ingestion of each fluid. Water ingestion slightly decreased plasma potassium concentration at 60 minutes. At these volumes, ingestion of pickle juice and CHO-e drink did not cause substantial changes in plasma electrolyte concentrations, plasma osmolality, or plasma volume in rested, euhydrated men. Concern that ingesting these volumes of pickle juice might exacerbate an athlete’s risk of dehydration-induced hypertonicity may be unwarranted. If EAMCs are caused by large electrolyte loss due to sweating, these volumes of pickle juice or CHO-e drink are unlikely to restore any deficit incurred by exercise [09325].

The purpose of one study was to examine the influences of a carbohydrate (CHO) mouth rinse on self-selected running speeds during a 30-min treadmill run. Ten endurance-trained men performed 2 trials, each involving a 10-min warm-up at 60 percent VO2max followed by a 30-min run. The run was performed on an automated treadmill that allowed the spontaneous selection of speeds without manual input. Participants were asked to run at speeds that equated to a rating of perceived exertion of 15, mouth rinsing with either a 6 percent CHO or taste-matched placebo solution. In addition to recording self-selected speeds and total distance covered the authors assessed the runners’ subjective feelings. The total distance covered was significantly greater during the CHO than during the placebo trial. Faster speeds selected during the first 5 min of exercise corresponded with enhanced feelings of pleasure when mouth rinsing with the CHO solution. Mouth rinsing with a CHO solution increased total distance covered during a self-selected 30-min run in comparison with mouth rinsing with a color- and taste-matched placebo [09326].

The aim of one study was to investigate the pre- and during-race nutritional intake of cyclists competing in a 210-km 1-day ultraendurance cycle race. Forty-five endurance-trained male cyclists participated in this dietary survey and completed a 3-day dietary record. Mean reported carbohydrate (CHO) intake over the 3 days before the race (5.6 ± 1.7 g/kg) was below the recommended guidelines of 7-10 g/kg. Although 57 percent of participants indicated that they CHO loaded 1-3 days before the race, only 23 percent of these participants achieved CHO intakes of ≥ 7 g/kg over the 3-day period before the race, demonstrating a discrepancy between perceived and actual intakes of CHO. Most participants indicated the use of CHO supplements before (84 %) and during (98 %) the race and achieved a CHO intake of 63 ± 23 g/hr during the race. Although most cyclists failed to meet recommended prerace CHO intakes, most achieved the recommended CHO intakes during the race [09327].

One study investigated the effects of short-term dietary changes on metabolism and duathlon performance. Eleven men underwent a high-fat (HF; >65% fat from energy) or a high-carbohydrate (HC) diet (>60 % carbohydrate from energy). Energy intake was individualized, and commercially available foods were prepared and packaged for each participant 48 hr before they completed a laboratory-based duathlon (5-km run, 30 km cycling, and 10-km run). Blood samples were obtained before, immediately after, and 1 and 2 hr after the
duathlon for determination of glucose, insulin, and glucagon. Oxygen consumption, ratings of perceived exertion, and respiratory-exchange ratio were assessed, and fat and carbohydrate oxidation were estimated before, during, and after the duathlon. Dietary records indicated a significant difference in fat content ingested before the duathlons. Time to complete the duathlon did not differ between the HC- and the HF-diet trials. Carbohydrate-oxidation rate was significantly higher during the HC-diet trial than during the HF-diet trial. Fat-oxidation rates were also significantly higher in the HF-diet trial than in the HC-diet trial. No differences in of perceived exertion were found between dietary trials. Blood glucose concentration was significantly higher immediately after the duathlon in the HC-diet trial than in the HF-diet trial and remained higher 1 and 2 hr after the duathlon. It was concluded that Duathlon performance was not altered by short-term changes in dietary fat or carbohydrate composition despite higher blood glucose concentrations under the HC condition [09328].

The aim of one study was to determine if the carbohydrate (CHO) availability alters the rate of increase in the rating of perceived exertion (RPE) during high intensity exercise and whether this would be associated with physiological changes. Six males performed high intensity exercise after 48 h of controlled, high CHO (80 %) and low CHO (10 %) diets. Time to exhaustion was lower in the low compared to high CHO diet. The rate of increase in RPE was greater and the VO$_2$ slow component was lower in the low CHO diet than in the control. There was no significant condition effect for cortisol, insulin, pH, plasma glucose, potassium, or lactate concentrations. Multiple linear regression indicated that the total amplitude of VO$_2$ and perceived muscle strain accounted for the greatest variance in the rate of increase in RPE. These results suggest that cardiorespiratory variables and muscle strain are important afferent signals from the periphery for the RPE calculations [10396].

The aim of one study was to investigate the prerace and during-race carbohydrate intakes of elite-level triathletes contesting draft-legal Olympic-distance triathlon (ODT) events. Self-reported prerace and during-race nutrition data were collected at 3 separate ODT events from 51 elite senior and under-23 triathletes. One hundred twenty-nine observations of food and fluid intake representing actual prerace (n=62) and during-race (n=67) nutrition practices from 36 male and 15 female triathletes were used in the final analysis of this study. Female triathletes consumed significantly more carbohydrate on the morning before race start when corrected for body mass and race start time than their male counterparts. Male and female triathletes consumed 26 percent more energy (kJ/kg) and 24 percent more carbohydrate (g/kg) when commencing a race after midday (1:00-1:30 p.m.) than for a late morning (11:00-11:15 a.m.) race start. During the race, triathletes consumed less than 60 g of carbohydrate on 66 percent of occasions, with average total race intakes of 48 ± 25 and 49 ± 25 g carbohydrate for men and women, respectively. Given average race times of 1:57:07 hr and 2:08:12 hr, hourly carbohydrate intakes were about 25 g and 23 g for men and women, respectively. Although most elite ODT triathletes consume sufficient carbohydrate to meet recommended prerace carbohydrate intake guidelines, during-race carbohydrate intakes varied considerably, with many failing to meet recommended levels [10397].

The effect of moderate dehydration and consequent fluid replenishment on short-duration maximal treadmill performance was studied in eight healthy, fit, young males. The study involved a within subject, blinded, crossover, placebo design. Initially, all subjects performed a baseline exercise test using an individualized treadmill protocol structured to induce exhaustion in 7 to 10 min. On each of the three subsequent testing days, the subjects exercised at 70-75 percent VO$_{2\text{max}}$ for 60 min at 29-33 degrees C, resulting in a dehydration weight loss of 1.8-2.1 percent body weight. After 60 min of rest and recovery at 22 C, subjects performed the same treadmill test to voluntary exhaustion, which resulted in a small reduction in VO$_{2\text{max}}$ and a decline in treadmill performance by 3% relative to the baseline results. Following another 60 min rest and recovery, subjects ingested the same amount of
fluid lost in the form of one of three lemon-flavored, randomly assigned commercial drinks, namely Crystal Light (placebo control), Gatorade® and Rehydrate Electrolyte Replacement Drink, and then repeated the treadmill test to voluntary exhaustion. VO₂max returned to baseline levels with Rehydrate, while there was only a slight improvement with Gatorade and Crystal Light. There were no changes in heart rate or ventilation with all three different replacement drinks. Relative to the dehydrated state, a 6.5 percent decrease in treadmill performance time occurred with Crystal Light, while replenishment with Gatorade, which contains fructose, glucose, sodium and potassium, resulted in a 2.1 percent decrease. In contrast, treatment with Rehydrate, which comprises fructose, glucose polymer, calcium, magnesium, sodium, potassium, amino acids, thiols and vitamins, resulted in a 7.3 percent increase in treadmill time relative to that of the dehydrated state. The results indicate that constituents other than water, simple transportable monosaccharides and sodium are important for maximal exercise performance and effective recovery associated with endurance exercise-induced dehydration [10398].

Carbohydrate is an essential part of the human diet and is the macronutrient that supplies the greatest fraction of total energy intake for most people. Because of its central role in energy metabolism during exercise, it plays a vital role in the athlete's diet. Though well-chosen foods can meet carbohydrate needs in many situations, carbohydrate supplements may be useful before, during and after exercise to help athletes achieve their nutrition goals. These supplements may be in solid, liquid or gel format and may or may not contain other nutrients. Judicious selection of carbohydrate-containing foods and supplements in the overall diet and around exercise sessions can help athletes to optimise training and competition performance. In this review, the authors have included two tables giving current recommendations for carbohydrate intakes for sport, as well as a range of products that can help to meet these goals [10223].

The term “carbohydrate” refers to members of a large family of organic compounds composed of carbon, hydrogen and oxygen with the general formula Cₘ(H₂O)ₙ. Carbohydrates can exist as single molecules (monosaccharides) such as glucose (a six-carbon hexose with the formula C₆H₁₂O₆), but these can polymerise to form chains that vary in length from two (disaccharides) to tens of thousands of glucose units (polysaccharides). ‘Sugars’ is the term used to refer to monosaccharides such as glucose (dextrose) and fructose (fruit sugar), and the disaccharides sucrose (table sugar: one molecule of glucose and one of fructose) and lactose (milk sugar: glucose plus galactose). Five carbon pentoses include the sugar ribose, which forms an important part of several key molecules such as the adenine nucleotides (ATP, ADP and AMP) and RNA. Glycogen, the storage form of carbohydrate in liver and in muscle, has a complex glucose polymer structure and is in many ways similar to starch, which acts as a storage form of carbohydrate in plants. The polymerised form occupies much less space but also, being almost insoluble, can be stored without large amounts of extra water being retained by the cells. The total amount of carbohydrate stored in the body is small, with a maximum of about 100 g in the liver and 400–500 g in the muscles: these amounts depend on the preceding diet, and will be reduced by fasting and by exercise. Liver glycogen can be broken down to glucose and released into the bloodstream where it is available to all tissues to act as a fuel. This is especially important for the brain, which relies heavily on blood glucose as a fuel, and for other tissues such as the red blood cells which use blood glucose as their only substrate. The muscle store of glycogen is more immediately available when the muscles are called on to do work, but it is not so readily available to other tissues. Resting muscle can meet the majority of its energy demand by the oxidation of any available fuels, including fat as well as carbohydrate. During exercise, the rate of carbohydrate utilisation, and its contribution to the total fuel mix, varies according to a range of factors including the intensity and duration of exercise, the training state of the athlete and the effects of carbohydrate intake prior to and during the
session. There are several ways in which body carbohydrate stores are critical for sports performance. Carbohydrate is the primary fuel for high-intensity work when the metabolic demand requires the recruitment of high glycolytic muscle fibres; inadequate muscle glycogen stores will limit the performance of single or repeated high-intensity bouts. At moderate exercise intensities of long duration, the depletion of muscle glycogen is associated with fatigue and reduction in work capacity as the muscle becomes more reliant on fat as an energy substrate. Reductions in blood glucose concentration can also occur during exercise due to a mismatch between liver glucose release and muscle glucose uptake. In some athletes or events, this may progress to frank hypoglycaemia and obvious signs of fatigue, disorientation and impaired work capacity. However, central fatigue (or sub-optimal performance) may occur with more subtle changes in blood glucose concentrations or carbohydrate availability to the central nervous system. This can become manifest in terms of sub-optimal work capacity via reductions in pacing strategies or muscle fibre recruitment or as impairments of the skill and concentration which underpin the outcomes in many sports. Total body carbohydrate stores are limited and often substantially less than the fuel requirements of intensive training and competition sessions. Athletes are therefore guided to consume dietary sources of carbohydrates to avoid or delay the depletion of body carbohydrate stores during exercise. It should be noted that sports nutrition guidelines no longer promote a “high carbohydrate” diet for all athletes. Instead, general targets are provided to allow athletes to meet the carbohydrate fuel requirements for their specific training and competition schedules, with suggestions for total amounts of carbohydrate that might be consumed over a day, as well as goals for intake before and during exercise, or in the recovery period between one session and the next. There is good evidence that carbohydrate intake strategies which maintain high carbohydrate availability during exercise and prevent carbohydrate depletion are associated with enhanced endurance and performance. Such strategies include glycogen supercompensation prior to endurance and ultraendurance events; ingesting a carbohydrate-rich meal in the hours before events of prolonged (>90 min) sustained or intermittent exercise; carbohydrate intake during sustained high-intensity exercise lasting about 60 min or prolonged sustained/intermittent exercise, and in the recovery period between two bouts of carbohydrate-demanding exercise. Carbohydrate is an essential ingredient of effective sports drinks; water and carbohydrate have independent and additive performance-enhancing effects when ingested during endurance exercise. The primary source of carbohydrate comes from the diet, and sugar-rich and starch-rich foods can contribute to energy and fuel needs as well as providing other useful nutrients for health and performance. However, special sports products containing substantial amounts of carbohydrate provide a valuable nutrition aid in some situations. The advantages of these products include taste appeal, provision of a known amount of carbohydrate to meet a specific sports nutrition goal, simultaneous provision of other important nutrients for sports nutrition goals, and gastrointestinal characteristics promoting quick digestion and absorption. Other benefits relate to characteristics that make the products practical to consume around exercise sessions (low-bulk, conveniently packaged) or in the athlete’s lifestyle (portable, non-perishable, minimal preparation). When these sports products are used by an athlete to meet the sports nutrition goals or guidelines, they are likely to enhance performance. In fact, the performance benefits achieved by addressing a situation that would otherwise result in low carbohydrate availability are robust, ranking carbohydrate supplements among the performance enhancers with the strongest evidence base in sports nutrition. In the sports world, where millions of products with special ingredients are marketed with claims of enhanced performance, it is ironic that sports foods containing an everyday nutrient (carbohydrate) may be best able to deliver on these claims. Although some of these sports foods – for example, sports drinks – have crossed into the general food supply and are consumed outside the context of sport, when they are used appropriately to support the carbohydrate needs of exercise or recovery they are likely to produce detectable benefits [10223].
The objective was to determine the effects of carbohydrate (CHO) supplementation on exercise-induced hormone responses and post-training intramyocellular lipid stores (IMCL). Twenty-four elite male athletes (28 ± 1 years) were randomized to receive CHO (maltodextrin solution) or zero energy placebo solution (control group). The high-intensity running protocol consisted of 10×800 m at 100 percent of the best 3000-m speed and 2×1000 m maximal bouts in the morning and a submaximal 10-km continuous easy running in the afternoon of day 9. IMCL concentrations were assessed by 1H-MRS before (-day 9) and after training (day 9) in soleus (SO) and tibialis anterior (TA) muscles. Blood hormones were also measured before, during, and post-exercise. The percent change in TA-IMCL was higher in the CHO group than in the control group. Insulin concentrations were higher in the CHO group post-intermittent running compared to control. Circulating levels of free fatty acids and GH were lower in the CHO group. The decline in performance in the 2nd 1000-m bout was also attenuated in this group compared to control. The hormonal milieu (higher insulin and lower GH levels) in the CHO group, together with unchanged free fatty acid levels, probably contributed to the increased IMCL stores. This greater energy storage capacity may have improved post-exercise recovery and thus prevented performance deterioration [12381].

Carbohydrate and fat are the two primary fuel sources oxidized by skeletal muscle tissue during prolonged (endurance-type) exercise. The relative contribution of these fuel sources largely depends on the exercise intensity and duration, with a greater contribution from carbohydrate as exercise intensity is increased. Consequently, endurance performance and endurance capacity are largely dictated by endogenous carbohydrate availability. As such, improving carbohydrate availability during prolonged exercise through carbohydrate ingestion has dominated the field of sports nutrition research. As a result, it has been well-established that carbohydrate ingestion during prolonged (>2 h) moderate-to-high intensity exercise can significantly improve endurance performance. Although the precise mechanism(s) responsible for the ergogenic effects are still unclear, they are likely related to the sparing of skeletal muscle glycogen, prevention of liver glycogen depletion and subsequent development of hypoglycemia, and/or allowing high rates of carbohydrate oxidation. Currently, for prolonged exercise lasting 2-3 h, athletes are advised to ingest carbohydrates at a rate of 60 g/h (1.0-1.1 g/min) to allow for maximal exogenous glucose oxidation rates. However, well-trained endurance athletes competing longer than 2.5 h can metabolize carbohydrate up to 90 g/h (1.5-1.8 g/min) provided that multiple transportable carbohydrates are ingested (e.g. 1.2 g/min glucose plus 0.6 g/min of fructose). Surprisingly, small amounts of carbohydrate ingestion during exercise may also enhance the performance of shorter (45-60 min), more intense (>75 % peak oxygen uptake; VO₂peak) exercise bouts, despite the fact that endogenous carbohydrate stores are unlikely to be limiting. The mechanism(s) responsible for such ergogenic properties of carbohydrate ingestion during short, more intense exercise bouts has been suggested to reside in the central nervous system. Carbohydrate ingestion during exercise also benefits athletes involved in intermittent/team sports. These athletes are advised to follow similar carbohydrate feeding strategies as the endurance athletes, but need to modify exogenous carbohydrate intake based upon the intensity and duration of the game and the available endogenous carbohydrate stores. Ample carbohydrate intake is also important for those athletes who need to compete twice within 24 h, when rapid repletion of endogenous glycogen stores is required to prevent a decline in performance. To support rapid post-exercise glycogen repletion, large amounts of exogenous carbohydrate (1.2 g/kg/h) should be provided during the acute recovery phase after exhaustive exercise. For those athletes with a lower gastrointestinal threshold for carbohydrate ingestion immediately post-exercise, and/or to support muscle re-conditioning, co-ingesting a small amount of protein (0.2-0.4 g/kg/h) with less carbohydrate (0.8 g/kg/h) may provide a feasible option to achieve similar muscle glycogen repletion rates [13611].
It is now well established that protein supplementation after resistance exercise promotes increased muscle protein synthesis, which ultimately results in greater net muscle accretion, relative to exercise alone or exercise with supplementary carbohydrate ingestion. However, it is not known whether combining carbohydrate with protein produces a greater anabolic response than protein alone. Recent recommendations have been made that the composition of the ideal supplement post-exercise would be a combination of a protein source with a high glycemic index carbohydrate. This is based on the hypothesis that insulin promotes protein synthesis, thus maximising insulin secretion will maximally potentiate this action. However, it is still controversial as to whether raising insulin level, within the physiological range, has any effect to further stimulate muscle protein synthesis. One commentary reviewed the evidence underpinning the recommendation to consume carbohydrates in addition to a protein supplementation after resistance exercise for the specific purpose of increasing muscle mass. The paucity of data will be discussed, thus our conclusions are that further studies are necessary prior to any conclusions that enable evidence-based recommendations to be made [13612].

There is a consensus claiming an ergogenic effect of carbohydrates ingested in the proximity of or during a performance bout. However, in performance studies, the protocols that are used are often highly standardized (e.g. fasted subjects, constant exercise intensity with time-to-exhaustion tests), and do not necessarily reflect competitive real-life situations. Therefore, we aimed at systematically summarizing all studies with a setting mimicking the situation of a real-life competition (e.g. subjects exercising in the postprandial state and with time-trial-like performance tests such as fixed distance or fixed time tests). We performed a PubMed search by using a selection of search terms covering inclusion criteria for sport, athletes, carbohydrates, and fluids, and exclusion criteria for diseases and animals. This search yielded 16,658 articles and the abstract of 16,508 articles contained sufficient information to identify the study as non-eligible for this review. The screening of the full text of the remaining 150 articles yielded 17 articles that were included in this review. These articles described 22 carbohydrate interventions covering test durations from 26 to 241 min (mostly cycling). It was observed no performance improvement with half of the carbohydrate interventions, while the other half of the interventions had significant improvement between 1 and 13 percent (improvement with one of five interventions lasting up to 68 min and with 10 of 17 interventions lasting between 70 and 241 min). Thus, when considering only studies with a setting mimicking real-life competition, there is a mixed general picture about the ergogenic effect of carbohydrates ingested in the proximity of or during a performance bout with an unlikely effect with bouts up to perhaps 70 min and a possible but not compelling ergogenic effect with performance durations longer than about 70 min [13613].

Carbohydrates are one of the two main fuels for sport activities, and their relevance for optimal sport performance is undisputed among experts. In general, there is a consensus claiming an ergogenic effect of carbohydrates ingested just before or during a performance bout. However, in scientifically aimed studies the subjects are often fasted overnight even in performance studies. The reason for this is probably that the metabolism in fasted subjects is in a more balanced state, which might be more easily reproduced than a postprandial state. However, the recommendation to athletes is not to compete in a fasted state because of potentially reduced liver glycogen stores and a subsequent negative effect on performance. While this concern might be unsubstantiated (overnight-fasted well-trained subjects can have more than twofold higher liver glycogen levels compared to overnight-fasted non-athletes, about 130 g versus about 50 g, respectively), athletes almost intuitively do not compete in a fasted state. Further, a test mode assessing how long a subject can exercise at a given intensity is common in “performance” studies (e.g. time-to-exhaustion tests). This is also does not reflect the real-life situation as usually a sporting event, at least in elite sports,
requires performing either as fast as possible for a given distance (e.g. races) or as well as possible within a given time (e.g. team sports) [13613].

The current consensus indicates that carbohydrates ingested in the proximity of or during a performance bout are ergogenic. However, the application of rigorous criteria to a systematic review, such as excluding fasted subjects and time-to-exhaustion test modes, led to a less convincing picture. It was observed no significant performance improvement with most of the performance bouts lasting less than 70 min, and the results with longer performance bouts indicated a significant improvement with 10 of 17 interventions. The absence of clear evidence is, nevertheless, not clear evidence of an absent effect. This is particularly true for the present review as we discarded many studies because relevant information was missing in the articles. As mentioned above, we encountered studies among other with missing information on age, gender, prandial state, or \( \text{VO}_{2\text{max}} \) of the subjects, missing information on the blinding or randomization of the interventions, or missing information on the drink volume ingested during the intervention. Thus, it cannot be excluded that some or even all of these discarded studies would have met the inclusion criteria if only the description were appropriate, and that then the outcome would have been a different one. Being conservative, however, it can be stated that with shorter duration events up to perhaps 70 min an ergogenic effect of carbohydrates ingested in the proximity of or during a performance bout is unlikely with trained (but not elite) male athletes in a real-life competition. The picture for longer durations is slightly more in favor than against the current consensus, but it is too heterogeneous for a solid conclusion [13613].

**Effects of carbohydrate loading**

The purpose of the present study was to examine the effects of a high- or low-carbohydrate (CHO) diet on performance, aerobic and anaerobic contribution, and metabolic responses during supramaximal exercise. Six physically-active men first performed a cycling exercise bout at 115 percent maximal oxygen uptake to exhaustion after following their normal diet for 48 h (about 50 % of CHO, control test). Seventy-two hours after, participants performed a muscle glycogen depletion exercise protocol, followed by either a high- or low-CHO diet (about 70 and 25 % of CHO, respectively) for 48 h, in a random, counterbalanced order. After the assigned diet period (48 h), the supramaximal cycling exercise bout (115 % maximal oxygen consumption) to exhaustion was repeated. The low-CHO diet reduced time to exhaustion when compared with both the control and the high-CHO diet (-19 and -32 %, respectively). The reduced time to exhaustion following the low-CHO diet was accompanied by a lower total aerobic energy contribution (-39 %) compared with the high-CHO diet. However, the aerobic and anaerobic energy contribution at the shortest time to exhaustion (isotime) was similar among conditions. The low-CHO diet was associated with a lower blood lactate concentration, with no effect on the plasma concentration of insulin, glucose and \( \text{K}^+ \). In conclusion, a low-CHO diet reduces both performance and total aerobic energy provision during supramaximal exercise. As peak \( \text{K}^+ \) concentration was similar, but time to exhaustion shorter, the low-CHO diet was associated with an earlier attainment of peak plasma \( \text{K}^+ \) concentration [13614].

**Glucose homeostasis in athletes**

The maintenance of normal blood glucose levels at rest and during exercise is critical. The maintenance of blood glucose homeostasis depends on the coordination and integration of several physiological systems, including the sympathetic nervous system and the endocrine system. During prolonged exercise increased demand for glucose by contracting muscle causes to increase glucose uptake to working skeletal muscle. Increase in glucose uptake by working skeletal muscle during prolonged exercise is due to an increase in the translocation
of insulin and contraction sensitive glucose transporter-4 (GLUT4) proteins to the plasma membrane. However, normal blood glucose level can be maintained by the augmentation of glucose production and release through the stimulation of liver glycogen breakdown, and the stimulation of the synthesis of glucose from other substances, and by the mobilization of other fuels that may serve as alternatives. Both feedback and feedforward mechanisms allow glycemia to be controlled during exercise. One review focused on factors that control blood glucose homeostasis during prolonged exercise [07297].

Physical activity is essential for weight control, for limiting onset and complications of chronic disorders and for preventing impaired insulin sensitivity. Little is known about the glycaemic adaptations of physically active subjects, especially elite and professional athletes. Thus, it was evaluated the glycaemic control in elite and professional cyclists by assessing fasting plasma glucose (FPG) and glycated haemoglobin (HbA1c). The study population consisted of 47 male professional road cyclists, 72 male elite road cyclists and 58 male sedentary blood donors. A significant difference was observed for FPG between sedentary controls and either elite or professional cyclists. Athletes showed a consistent trend towards higher HbA1c values, reaching statistical significance between sedentary individuals and professional cyclists. In multiple linear regression analysis, the intensity of physical exercise is inversely correlated with FPG and directly correlated with HbA1c. These results demonstrate a significant association between intensity of the training regimen and both FPG and HbA1c, highlighting the need for establishing the appropriate critical difference for the measurement of FPG and HbA1c according to the training and exercise workload [07298].

**Effect on perceived exertion**

The aim of this study was to determine if the carbohydrate (CHO) availability alters the rate of increase in the rating of perceived exertion (RPE) during high intensity exercise and whether this would be associated with physiological changes. Six males performed high intensity exercise after 48 h of controlled, high CHO (80 %) and low CHO (10 %) diets. Time to exhaustion was lower in the low compared to high CHO diet. The rate of increase in RPE was greater and the VO₂ slow component was lower in the low CHO diet than in the control. There was no significant condition effect for cortisol, insulin, pH, plasma glucose, potassium, or lactate concentrations. Multiple linear regression indicated that the total amplitude of VO₂ and perceived muscle strain accounted for the greatest variance in the rate of increase in RPE. These results suggest that cardiorespiratory variables and muscle strain are important afferent signals from the periphery for the RPE calculations [10399].

One study was designed to determine the effects of ingesting a carbohydrate (CHO) solution on affective states and rating of perceived exertion (RPE) during prolonged intermittent high-intensity exercise. Seventeen male soccer players completed a prolonged intermittent high-intensity exercise protocol for 90 min on two occasions, separated by at least 7 days. Participants consumed either a 6.4 percent CHO (0.6 g/kg body mass (BM)/h) or an artificially sweetened placebo (PLA) solution immediately before (8 mL/kg BM) and every 15 min (3 mL/kg BM) during exercise in a double-blind, counterbalanced design. Pleasure-displeasure, perceived activation, RPE and plasma glucose concentration was assessed. The results showed that compared with the CHO trial, perceived activation were lower in the placebo trial during the last 30 min of exercise and this was accompanied by lowered plasma glucose concentrations. In the CHO trial, RPE was maintained in the last 30 min of exercise but carried on increasing in the PLA trial. Therefore, CHO ingestion during prolonged high-intensity exercise appears to elicit an enhanced perceived activation profile that may impact upon task persistence and performance. This finding is in addition to the physiological and metabolic benefits of the exogenous energy supply [07270].
The purpose of one study was to examine the effect of carbohydrate supplementation on differentiated and undifferentiated ratings of perceived exertion (RPE) during prolonged intermittent exercise and recovery. Twelve male subjects cycled for 2.0 h at 64 percent $W_{\text{max}}$ and 73 percent $V_{\text{O2peak}}$ with 3-min rest intervals interspersed every 10 min (2.6 h of total exercise time, including rest intervals) with placebo (P) or carbohydrate (C) beverages. RPE was assessed during the last minute of each 10-min exercise interval and then every 30 s during the 3-min recovery period. The pattern of change in RPE over time was significantly different between C and P ingestion, with attenuated RPE responses found for both overall body (O) and legs (L). A significant main effect was found for recovery RPE-O between C and P ingestion, with attenuated RPE responses found in the later part of the 2-h run. C relative to P ingestion was associated with higher respiratory exchange ratios and plasma levels of glucose and with lower levels of plasma cortisol. These data indicate that carbohydrate supplementation attenuates perceived exertion during prolonged intermittent exercise and recovery [07271].

Effect on endurance exercise

The main aim of one study was to investigate the influence of consuming a 6 percent carbohydrate-electrolyte (CHO-E) solution on the intermittent, high-intensity endurance performance and capacity of adolescent team games players. Fifteen participants (mean age 13 years) performed two trials separated by 3-7 days. In each trial, they completed 60 min of exercise composed of four 15-min periods of part A of the Loughborough Intermittent Shuttle Test, followed by an intermittent run to exhaustion (part B). In a double-blind, randomised, counterbalanced fashion participants consumed either the 6 percent CHO-E solution or a non-carbohydrate (CHO) placebo (5 ml/kg BM) during the 5 min pre-trial and after each 15-min period of part A (2 ml/kg BM). Time to fatigue was increased by 25 percent during part B when CHO was ingested, with distance covered in part B also significantly greater in the CHO trial. No significant between-trials differences were observed for mean 15-m sprint time, peak sprint time, or heart rate during part A. These results demonstrate, for the first time, that ingestion of a CHO-E solution significantly improves the intermittent, high-intensity endurance running capacity of adolescent team games players during an exercise protocol designed to simulate the physiological demands of team games [10400].

The purpose of one study was to determine if the type of diet can influence blood glucose levels during a regular swimming training session. Twelve elite male swimmers were enrolled for this study. Swimmers were put on two isocaloric three-day diets, containing either a high percentage of carbohydrate (HCD-65 %) or a low percentage of carbohydrate (LCD-35 %) before performing the two 110 minutes training sessions (inter-spaced by 6-8 days) at an intensity of 75 percent of peak heart rates. Blood glucose was collected and analyzed at 0, 20, 60 and 110 minutes of exercise. Blood glucose under both dietary conditions initially dropped and thereafter rose again by the end of the 110 minute training session. The data revealed that blood glucose never dropped to hypoglycemic levels, but showed a different pattern of changes throughout training. The carbohydrate content of the diet followed for a period of three days prior to testing, does not appear to directly affect blood glucose levels throughout a swimming training session lasting over 90 minutes, in elite national level skimmers [08389].

Rapid and complete rehydration, or restoration of fluid spaces, is important when acute illness or excessive sweating has compromised hydration status. Many studies have investigated the effects of graded concentrations of sodium and other electrolytes in rehydration solutions; however, no study to date has determined the effect of carbohydrate on fluid retention when electrolyte concentrations are held constant. The purpose of one
study was to determine the effect of graded levels of carbohydrate on fluid retention following exercise-induced dehydration. Fifteen heat-acclimatized men exercised in the heat for 90 min with no fluid to induce 2-3 percent dehydration. After a 30-min equilibration period, they received, over the course of 60 min, one of five test beverages equal to 100 percent of the acute change in body mass. The experimental beverages consisted of a flavored placebo with no electrolytes (P), placebo with electrolytes (P + E), 3 percent, 6 percent, and 12 percent carbohydrate solutions with electrolytes. All beverages contained the same type and concentration of electrolytes (18 meq/l Na⁺, 3 meq/l K⁺, 11 meq/l Cl⁻). Subjects voided their bladders at 60, 90, 120, 180, and 240 min, and urine specific gravity and urine volume were measured. Blood samples were taken before exercise and 30, 90, 180, and 240 min following exercise and were analyzed for glucose, sodium, hemoglobin, hematocrit, renin, aldosterone, and osmolality. Body mass was measured before and after exercise and a final body mass was taken at 240 min. There were no differences in percent dehydration, sweat loss, or fluid intake between trials. Fluid retention was significantly greater for all carbohydrate beverages compared with P. P + E was not different from water, 3 percent or 6 percent but was significantly less than 12 percentretention of the ingested fluid. No difference was found between the carbohydrate beverages. Carbohydrate at the levels measured exerts a mild influence on fluid retention in postexercise recovery [09323].

One study examined the effect of consuming carbohydrate-(CHO) electrolyte solution on running performance after different-glycemic-index (GI) meals. Nine men completed 3 trials in a randomized counterbalanced order, with trials separated by at least 7 days. Two hours before the run after an overnight fast, each participant consumed a high-GI (GI=83) or low-GI (GI=36) CHO meal or low-energy sugar-free Jell-O (GI=0, control). The two isocaloric GI meals provided 1.5 g available CHO/kg body mass. During each trial, 2 ml/kg body mass of a 6.6 percent CHO-electrolyte solution was provided immediately before exercise and every 2.5 km after the start of running. Each trial consisted of a 21-km performance run on a level treadmill. The participants were required to run at 70 percent VO₂max during the first 5 km of the run. They then completed the remaining 16 km as fast as possible. There was no difference in the time to complete the 21-km run and there were no differences in total CHO and fat oxidation throughout the trials, despite differences in preexercise blood glucose, serum insulin, and serum free-fatty-acid concentrations. It was concluded that when a CHO-electrolyte solution is consumed during a 21-km run, the GI of the preexercise CHO meal makes no difference in running performance [09324].

There is a growing body of research on the influence of ingesting carbohydrate-electrolyte solutions immediately prior to and during prolonged intermittent, high-intensity exercise (team games exercise) designed to replicate field-based team games. One review presents the current body of knowledge in this area, and identifies avenues of further research. Almost all early work supported the ingestion of carbohydrate-electrolyte solutions during prolonged intermittent exercise, but was subject to methodological limitations. A key concern was the use of exercise protocols characterized by prolonged periods at the same exercise intensity, the lack of maximal- or high-intensity work components and long periods of seated recovery, which failed to replicate the activity pattern or physiological demand of team games exercise. The advent of protocols specifically designed to replicate the demands of field-based team games enabled a more externally valid assessment of the influence of carbohydrate ingestion during this form of exercise. Once again, the research overwhelmingly supports carbohydrate ingestion immediately prior to and during team games exercise for improving time to exhaustion during intermittent running. While the external validity of exhaustive exercise at fixed prescribed intensities as an assessment of exercise capacity during team games may appear questionable, these assessments should perhaps not be viewed as exhaustive exercise tests per se, but as indicators of the ability to maintain high-intensity exercise, which is a recognized marker of performance and fatigue during field-based team
games. Possible mechanisms of exercise capacity enhancement include sparing of muscle glycogen, glycogen resynthesis during low-intensity exercise periods and attenuated effort perception during exercise. Most research fails to show improvements in sprint performance during team games exercise with carbohydrate ingestion, perhaps due to the lack of influence of carbohydrate on sprint performance when endogenous muscle glycogen concentration remains above a critical threshold of 200 mmol/kg dry weight. Despite the increasing number of publications in this area, few studies have attempted to drive the research base forward by investigating potential modulators of carbohydrate efficacy during team games exercise, preventing the formulation of optimal carbohydrate intake guidelines. Potential modulators may be different from those during prolonged steady-state exercise due to the constantly changing exercise intensity and frequency, duration and intensity of rest intervals, potential for team games exercise to slow the rate of gastric emptying and the restricted access to carbohydrate-electrolyte solutions during many team games. The review highlights fluid volume, carbohydrate concentration, carbohydrate composition and solution osmolality; the glycaemic index of pre-exercise meals; fluid and carbohydrate ingestion patterns; fluid temperature; carbohydrate mouthwashes; carbohydrate supplementation in different ambient temperatures; and investigation of all of these areas in different subject populations as important avenues for future research to enable a more comprehensive understanding of carbohydrate ingestion during team games exercise [11436].

Effects of a carbohydrate beverage on the physiological responses to load carriage were examined. Ten fit male participants (age: 28 ± 9 years, body mass: 82 ± 11 kg, O2max: 55 ± 6 mL/kg/min) completed two test conditions in random order, walking on a treadmill (6.5 km/h)) for 120 min, carrying a 25-kg backpack. At 0 and 60 min of exercise participants consumed 250 mL of a placebo (flavoured water) (PLA) or 6.4 percent carbohydrate (CHO) beverage. There were no differences in O2max respiratory exchange ratio (RER), heart rate or EMG activity of m. rectus femoris, m. vastus lateralis, m. semitendinosus and m. biceps femoris between conditions at minute 5 of exercise. The increase in O2max between minutes 5 and 120 was less during CHO than PLA (8 ± 5 vs. 14 ± 6 %). RER decreased during PLA, from 0.96 ± 0.05 at minute 5 to 0.87 ± 0.04 at minute 120, but not during CHO. Heart rate increased between minutes 5 and 120 during PLA (16 ± 10 %) and CHO (12 ± 6 %), with no difference between conditions. EMG peak RMS did not change between minutes 7 and 107 during PLA or CHO for the leg muscles. However, individual responses in EMG were highly variable (i.e. both increases and decreases in RMS). It was concluded that carbohydrate intake during load carriage reduced the O2max drift, which could be partially attributed to higher carbohydrate oxidation rates. Despite muscle fatigue/damage previously being identified as a cause of O2max drift, it appears that carbohydrate had no effect on neuromuscular responses during load carriage [11384].

One study was a systematic review with meta-analysis examining the efficacy of carbohydrate (CHO) ingestion compared with placebo (PLA) on endurance exercise performance in adults. Relevant databases were searched to January 2011. Included studies were PLA-controlled, randomized, crossover designs in which CHO ingestion not exceeding 8 percent and between 30 and 80 g/h during exercise of ≥1 h was evaluated via time trial (TT) or exercise time to exhaustion (TTE). The between-trial standardized mean differences (effect size, ES) and pooled estimates of the effect of CHO ingestion were calculated. Of the 41,175 studies from the initial search, 50 were included. The ES for submaximal exercise followed by TT was significant as was the effect size for TT. The weighted mean improvement in exercise performance favored CHO ingestion. TTE and submaximal exercise followed by TTE also showed significant effects, with weighted mean improvements of 15 and 54 percent, respectively, with CHO ingestion. Similar trends were evident for subanalyses of studies using only male or trained participants, for exercise of 1-3 h duration, and where CHO and PLA beverages were matched for electrolyte content. The data support
that ingestion of CHO between 30 and 80 g/h enhances endurance exercise performance in adults [11250].

Effects of a carbohydrate beverage on the physiological responses to load carriage were examined. Ten fit male participants completed two test conditions in random order, walking on a treadmill for 120 min, carrying a 25-kg backpack. At 0 and 60 min of exercise participants consumed 250 mL of a placebo (flavoured water) (PLA) or 6.4 percent carbohydrate (CHO) beverage. There were no differences in respiratory exchange ratio (RER), heart rate or EMG activity of m. rectus femoris, m. vastus lateralis, m. semitendinosus and m. biceps femoris between conditions at minute 5 of exercise. The increase between minutes 5 and 120 was less during CHO than PLA. RER decreased during PLA, from 0.96 ± 0.05 at minute 5 to 0.87 ± 0.04 at minute 120, but not during CHO. Heart rate increased between minutes 5 and 120 during PLA and CHO, with no difference between conditions. EMG peak RMS did not change between minutes 7 and 107 during PLA or CHO for the leg muscles. However, individual responses in EMG were highly variable (i.e. both increases and decreases in RMS). It was concluded that carbohydrate intake during load carriage reduced the O₂ drift, which could be partially attributed to higher carbohydrate oxidation rates. Despite muscle fatigue/damage previously being identified as a cause of O₂ drift, it appears that carbohydrate had no effect on neuromuscular responses during load carriage [11251].

An athlete’s carbohydrate intake can be judged by whether total daily intake and the timing of consumption in relation to exercise maintain adequate carbohydrate substrate for the muscle and central nervous system (“high carbohydrate availability”) or whether carbohydrate fuel sources are limiting for the daily exercise programme (“low carbohydrate availability”). Carbohydrate availability is increased by consuming carbohydrate in the hours or days prior to the session, intake during exercise, and refuelling during recovery between sessions. This is important for the competition setting or for high-intensity training where optimal performance is desired. Carbohydrate intake during exercise should be scaled according to the characteristics of the event. During sustained high-intensity sports lasting about 1 h, small amounts of carbohydrate, including even mouth-rinsing, enhance performance via central nervous system effects. While 30-60 g/h is an appropriate target for sports of longer duration, events >2.5 h may benefit from higher intakes of up to 90 g/h. Products containing special blends of different carbohydrates may maximize absorption of carbohydrate at such high rates. In real life, athletes undertake training sessions with varying carbohydrate availability. Whether implementing additional “train-low” strategies to increase the training adaptation leads to enhanced performance in well-trained individuals is unclear [11252].

One study investigated the effects of high and low glycemic index (GI) 24 h recovery meals on the physiological responses and subsequent athletic performance, following a glycogen depleting protocol. Ten well trained cyclists participated in two trials in a randomized cross-over design. On day 1, subjects performed a glycogen depleting protocol after which they then consumed either high or low GI recovery diets over the next 24 h, which provided 8 g/kg BW of carbohydrate. On day 2, the subjects returned to the laboratory, 2-3 h postprandial, to perform a 40 km time trial (TT) on the Velotron cyclePro© ergometer. No difference was observed in TT performance times between the high GI trial and the low GI trial. Additionally, no differences in carbohydrate, fat oxidation or blood glucose concentration was observed. The results of the study suggest that the ingestion of a high GI carbohydrate 24 h recovery diet following glycogen depleting exercise, has no greater effect on endurance performance than consuming a low GI carbohydrate 24 h recovery diet. It may be concluded from these results that, provided enough carbohydrate is consumed during a 24 h recovery period, there is no difference in subsequent endurance performance [11254].
One study determined if recreational type of endurance exercise is limited by a short-term fast, such as an overnight fast or benefited by a carbohydrate supplement prior to and during endurance exercise. Six individuals ran at 70 percent VO₂max for 90 min under three dietary conditions (fed, fasted for 16 to 18 h, fasted plus CHO). RPE, RER, BG (blood glucose), and La (lactate) were similar between conditions throughout 90 min of exercise. FFA was higher only in the fed and fasted groups after exercise. It was concluded that the psychosomatic sensation, physiologic, and metabolic data all indicated that endurance exercise for up to 90 min for fit individuals is not limited by a short-term fast or enhanced by carbohydrate supplementation. These findings are of interest to persons who exercise to maintain and enhance health and are not concerned with elite performance [07272].

The purpose of one investigation was to determine the effects of 2.5 hours of cycling with and without carbohydrate supplementation on gross efficiency. Trained cyclists (n=15) were tested for VO₂max and lactate threshold during incremental tests to exhaustion. On 2 separate visits, cyclists performed 2.5 hours of cycling on an indoor trainer. A carbohydrate (C) or placebo (P) beverage was randomly provided and counterbalanced for each of the trials. Gross efficiency, cycling economy, power output, VO₂, lactate, and blood glucose were measured every 20 minutes during the 2.5-hour ride. Muscle glycogen was measured immediately before and after the ride from the vastus lateralis. Results indicated that power output and VO₂ decreased over time but were not different between trials. Relative gross efficiency and cycling economy during C were greater than P at 40 and 150 minutes. Blood glucose significantly decreased in P and was lower than C at all time points. Respiratory exchange ratio decreased over time in both trials, with a significant treatment effect at 40 and 150 minutes. Muscle glycogen decreased by 65 percent during both conditions but demonstrated no treatment effect. It was concluded that carbohydrate supplementation during 2.5 hours of cycling attenuated the decrease in gross efficiency possibly by maintaining blood glucose levels. This suggests that the positive effect of carbohydrate supplementation on endurance performance may be through the maintenance of metabolic efficiency [07269].

Curvilinear dose-response relationship of carbohydrate (0-120 g/h) and performance
There is a lack of consensus regarding the optimal range of carbohydrate (CHO) ingestion rates recommended for endurance athletes. One study investigated the relationship between CHO dose and cycling time trial performance to identify an optimal range of CHO ingestion rates for endurance performance. Fifty-one cyclists and triathletes (28 ± 7 years) across four research sites completed four trials. Each trial consisted of a 2-h constant load ride at 95 percent of the workload that elicited a 4-mmol/L blood lactate concentration immediately followed by a computer-simulated 20-km time trial, which subjects were asked to complete as quickly as possible. Twelve CHO electrolyte (18 mmol/L Na, 3 mmol/L K, and 11 mmol/L Cl) beverages (three at each site) were tested in a double-blind manner, providing subjects 10, 20, 30, 40, 50, 60, 70, 80, 90, 100, 110, and 120 g CHO (1:1:1 glucose-fructose-maltodextrin) per hour during the 2-h constant load ride at a fluid intake rate of 1 L/h. All subjects also consumed a noncaloric placebo on one counterbalanced test occasion. Data were natural log transformed, subjected to a mixed-model analysis, and are reported as adjusted treatment means. It was estimate incremental performance improvements of 1.0, 2.0, 3.0, 4.0, and 4.7 percent at 9, 19, 31, 48, and 78 g·h, respectively, with diminishing performance enhancement seen at CHO levels >78 g/h. It was concluded that CHO beverage ingestion and endurance (about 160 min) performance appear to be related in a curvilinear dose-response manner, with the best performance occurring with a CHO (1:1:1 glucose-fructose-maltodextrin) ingestion rate of 78 g/h [13615].

During exercise
Research on the performance effects of acute carbohydrate supplementation is comprehensive. Eighty-eight randomized crossover studies in which carbohydrate supplements were consumed with or without protein before and/or during exercise provided 155 estimates for performance effects in time-to-exhaustion tests or in time trials with or without a preload. For the mixed-model meta-analysis, all effects were converted into percentage changes in mean power in a non-preloaded time trial and weighted using percentage standard errors derived from exact p-values (in a minority of studies) or from estimated errors of measurement (in all other studies). Publication bias was assessed with a plot of t-values for the random-effect solutions versus standard errors. Probabilistic inferences were derived with reference to thresholds for small, moderate and large effects on performance of 0.5, 1.5 and 2.7 percent. Publication bias was reduced by excluding studies with a standard error >1.25 percent. In the remaining 73 studies and 122 estimates, the meta-analysed performance effects of carbohydrate supplements ranged from clear large improvements of >6 percent to clear moderate impairments of >2 percent. The best supplement inferred from the analysis consisted of a 3-10 percent carbohydrate-plus-protein drink providing 0.7 g/kg/h glucose polymers, 0.2 g/kg/h fructose and 0.2 g/kg/h protein. Substantial increases in the benefit of a supplement were probably small with an additional 9-hour fast and with the inclusion of 0.2 g/kg/h of protein, probably small to moderate with ingesting the first bolus not at the start of exercise but 1-4 hours before exercise, and possibly small with increasing the frequency of ingestion by three boluses per hour. Substantial reductions in the benefit of a supplement were possibly moderate with a supplement providing >0.25 g/kg/h fructose, and possibly small with an increase in ambient temperature of 10°C. The effect in subjects with maximal oxygen consumption higher by 10 mL/kg/min was probably trivial, and the effects of exercise duration were dependent on the concentration of carbohydrate plus protein in the supplement. The effect of including salt was unexpectedly trivial, and the effect of gender was unclear. Carbohydrate supplements with an appropriate composition and administration regimen can have large benefits on endurance performance. More research and better reporting are required to investigate the moderating effects of gender and salt [11437].

The effect of carbohydrate (CHO) consumption during prolonged endurance running on post-exercise inflammation and hepcidin levels was investigated. Eleven well-trained male endurance athletes completed a graded exercise test, followed by two experimental running trials in a randomized order. The two experimental trials consisted of a 90 min run at 75 percent of the peak oxygen uptake velocity (vO2peak), while consuming a solution with either 6 percent CHO or a placebo (PLA) equivalent at 3 ml/kg every 20 min. Serum interleukin-6 (IL-6), free hemoglobin (Hb), haptoglobin (Hp), hepcidin and iron parameters were assessed throughout the post-run recovery period. Serum iron and IL-6 were significantly elevated immediately post-run in both CHO and PLA, with no differences between trials. Serum-free Hb increased and Hp decreased significantly immediately post-run in both conditions. Serum soluble transferrin receptor levels were significantly below the baseline at 3 and 24 h post-run in both conditions. Serum hepcidin concentration recorded 3 h post-run in both conditions was significantly elevated, and had returned to the baseline by 24 h post-run. Thus, the use of a 6 percent CHO solution at 3 ml/kg/20 min during endurance running did not attenuate the inflammatory response and subsequent increase in serum hepcidin levels during the post-run recovery period [11413].

One study was designed to determine the effects of ingesting a carbohydrate (CHO) solution on affective states and rating of perceived exertion (RPE) during prolonged intermittent high-intensity exercise. Seventeen male soccer players completed a prolonged intermittent high-intensity exercise protocol for 90 min on two occasions, separated by at least 7 days. Participants consumed either a 6.4% CHO (0.6 g/kg body mass (BM)/h) or an artificially sweetened placebo (PLA) solution immediately before (8 mL/kg BM) and every 15 min (3
mL/kg BM) during exercise in a double-blind, counterbalanced design. Pleasure-displeasure, perceived activation, RPE and plasma glucose concentration was assessed. The results showed that compared with the CHO trial, perceived activation were lower in the placebo trial during the last 30 min of exercise and this was accompanied by lowered plasma glucose concentrations. In the CHO trial, RPE was maintained in the last 30 min of exercise but carried on increasing in the PLA trial. Therefore, CHO ingestion during prolonged high-intensity exercise appears to elicit an enhanced perceived activation profile that may impact upon task persistence and performance. This finding is in addition to the physiological and metabolic benefits of the exogenous energy supply [07282].

During and after sessions of high-intensity intermittent running exercise

One study evaluated the acute effects of carbohydrate supplementation on heart rate (HR), rate of perceived exertion (RPE), metabolic and hormonal responses during and after sessions of high-intensity intermittent running exercise. Fifteen endurance runners (26 years) performed two sessions of intermittent exercise under carbohydrate (CHO) and placebo (PLA) ingestion. The sessions consisted of 12 x 800 m separated by intervals of 1 min 30 s at a mean velocity corresponding to the previously performed 3-km time trial. Both the CHO and PLA sessions were concluded within approximately 28 min. Blood glucose was significantly elevated in both sessions and mean blood lactate was significantly higher in the CHO. The metabolic stress induced by the exercise model used was confirmed by the elevated HR (approximately 182 bpm) and RPE (approximately 18 on the 15-point Borg scale) for both conditions. No significant differences in plasma insulin, cortisol or free fatty acids were observed during exercise between the two trials. During the recovery period, free fatty acid and insulin concentrations were significantly lower in the CHO trial. Supplementation with CHO resulted in higher lactate associated with lipolytic suppression, but did not attenuate the cortisol, RPE or HR responses [06253].

Effect of pre-exercise carbohydrate-loading on endurance performance

One study examined the influence of 3-day isoenergetic carbohydrate (CHO) loading with different glycemic index (GI) and glycemic load (GL) meals on running performance and metabolic responses. With a randomized crossover design, nine male runners performed a 1-h run at 70 percent VO$_{2\text{max}}$ followed by a 10-km performance run after a 3-day diet adaptation, which involved different GI and GL meals (CHO intake (%), GI, and GL per day were 73%, 80, and 553 percent for the high GI and high GL (HH); 73%, 36, and 249 for the low GI and low GL (LL); and 31%, 79, and 227 for the high GI and low GL (HL), respectively). There were no differences in the time to complete the 10-km run between the two high-CHO trials; however, the performance in the LL trial was improved as compared to that in the HL trial. It appears that the amount, rather than the nature, of the CHO consumed during the 3-day isoenergetic CHO loading may be the most overriding factor on subsequent metabolism and endurance run performance [07274].
during the 3-day isoenergetic CHO loading may be the most overriding factor on subsequent metabolism and endurance run performance [07275].

The purpose of one study was to investigate the effect of pre-test carbohydrate (CHO) ingestion on anaerobic-threshold assessment using the lactate-minimum test (LMT). Fifteen competitive male distance runners capable of running 10 km in 33.5-43 min were used as subjects. LMT was performed following CHO (2x300 mL, 7 % solution) or comparable placebo (Pl) ingestion, in a double-blind, randomized order. The LMT consisted of two high-intensity 1 min treadmill runs (17-21 km/h), followed by an 8 min recovery period. Subsequently, subjects performed 5 min running stages, incremented by 0.6 km/h and separated by 1 min blood-sampling intervals. Tests were terminated after 3 consecutive increases in blood-lactate concentration (La) had been observed. Finger-tip capillary blood was sampled for lactate concentration and blood-glucose determination 30 min before the test's onset, during the recovery phase following the 2 high-intensity runs, and following each of the subsequent 5 min stages. Heart rate (HR) and rating of perceived exertion (RPE) were recorded after each stage. The lactate-minimum speed (LMS) was determined from the individual [La]-velocity plots and was considered reflective of the anaerobic threshold. Pre-test CHO ingestion had no effect on LMS, nor on concentration of lactate and glucose concentration at that speed, or on HR and RPE responses. Pre-test CHO ingestion therefore does not affect LMS or the LMT-estimated anaerobic threshold [07276].

One study compared effects of carbohydrate (CHO) and rest on oxidative stress during exercise. Cyclists (n=12) completed 4 randomized trials at 64 percent Wattsmax under 2 conditions (continuous cycling for 2 h [C] and cycling with 3-min rest every 10 min for 2.6 h [R]). Subjects cycled under each condition while receiving 6 percent CHO and placebo (PLA). CHO and PLA were given preexercise (12 mL/kg) and during exercise (4 mL/kg for 15 minutes). Blood was collected preexercise, postexercise, and 1 h postexercise and assayed for F2-isoprostanes, hydroperoxides (LH), nitrite, antioxidant capacity, glucose, insulin, cortisol, and epinephrine. F2-isoprostanes and LH were lower in CHO. Glucose, cortisol, and epinephrine exhibited significant effects, with postexercise levels of glucose higher and cortisol and epinephrine lower in CHO during the R condition. This pattern was identical in the C condition. Oxidative stress during cycling was unaffected by use of short rest intervals but was diminished by CHO [07277].

The purpose of this investigation was to determine the effects of 2.5 hours of cycling with and without carbohydrate supplementation on gross efficiency (GE). Trained cyclists (n=15) were tested for VO2max and lactate threshold during incremental tests to exhaustion. On 2 separate visits, cyclists performed 2.5 hours of cycling on an indoor trainer. A carbohydrate (C) or placebo (P) beverage was randomly provided and counterbalanced for each of the trials. Gross efficiency, cycling economy, power output, VO2, lactate, and blood glucose were measured every 20 minutes during the 2.5-hour ride. Muscle glycogen was measured immediately before and after the ride from the vastus lateralis. Results indicated that power output and VO2 decreased over time but were not different between trials. Relative GE and cycling economy during C were greater than P at 40 and 150 minutes. Blood glucose significantly decreased in P and was lower than C at all time points. Respiratory exchange ratio decreased over time in both trials, with a significant treatment effect at 40 and 150 minutes. Muscle glycogen decreased by 65 percent during both conditions but demonstrated no treatment effect. It was concluded that carbohydrate supplementation during 2.5 hours of cycling attenuated the decrease in GE possibly by maintaining blood glucose levels. This suggests that the positive effect of carbohydrate supplementation on endurance performance may be through the maintenance of metabolic efficiency [07278].
The purpose of one study was to investigate the effect of pre-test carbohydrate (CHO) ingestion on anaerobic-threshold assessment using the lactate-minimum test (LMT). Fifteen competitive male distance runners capable of running 10 km in 33.5-43 min were used as subjects. LMT was performed following CHO (2x300 mL, 7 % solution) or comparable placebo (Pl) ingestion, in a double-blind, randomized order. The LMT consisted of two high-intensity 1 min treadmill runs (17-21 km/h), followed by an 8 min recovery period. Subsequently, subjects performed 5 min running stages, incremented by 0.6 km/h and separated by 1 min blood-sampling intervals. Tests were terminated after 3 consecutive increases in blood-lactate concentration ([La]) had been observed. Finger-tip capillary blood was sampled for [La] and blood-glucose determination 30 min before the test's onset, during the recovery phase following the 2 high-intensity runs, and following each of the subsequent 5 min stages. Heart rate (HR) and rating of perceived exertion (RPE) were recorded after each stage. The lactate-minimum speed (LMS) was determined from the individual [La]-velocity plots and was considered reflective of the anaerobic threshold. Pre-test CHO ingestion had no effect on LMS, nor on [La] and glucose concentration at that speed, or on HR and RPE responses. Pre-test CHO ingestion therefore does not affect LMS or the LMT-estimated anaerobic threshold [07279].

Carbohydrate ingested 30-60 min before exercise may result in hypoglycaemia during exercise, a phenomenon often called rebound or reactive hypoglycaemia. There is considerable confusion regarding pre-exercise carbohydrate feeding with advice that ranges from “consume carbohydrate in the hour before exercise” to “avoid carbohydrate in the 60 min prior to exercise.” It was analysed the studies available in the literature to draw conclusions about the use of carbohydrate in the pre-exercise period. Without performing a meta-analysis, it is clear that the risk of reduced performance is minimal as almost all studies point towards unaltered or even improved performance. This is despite the rather large metabolic changes that occur in response to pre-exercise carbohydrate feeding. It can be concluded that advice to avoid carbohydrate feeding in the hour before exercise is unfounded. Nevertheless athletes may develop symptoms similar to those of hypoglycaemia, even though they are rarely linked to actual low glucose concentrations. An individual approach may therefore be necessary to minimize these symptoms even though they do not appear to be related to exercise performance [11249].

One study examined the effects of pre-exercise food on different glycemic indexes (GI) on exercise metabolism and endurance running capacity. Nine subjects performed 3 exercise trials on different days 15 min after ingesting: lentils (LGI), potatoes (HGI), and placebo. Each subject ingested an equal amount of each food (1 g/kg body mass) and ran on a level treadmill for 5 min at 60 percent, 45 min at 70 percent and then at 80 percent of VO\textsubscript{2max} until exhaustion. Serum glucose concentrations were higher 15 min after the HGI trial compared to the LGI and placebo trials. In addition, serum glucose levels were higher during the LGI trial at the time of exhaustion compared to the HGI and placebo trials. Plasma insulin levels, 15 min after ingestion, were higher in the HGI trial as compared to the LGI and placebo trials. Exercise time was longer during the LGI trial compared to the placebo, but the time to exhaustion in the HGI condition did not differ from the placebo. These results suggest that lentils, the LGI food, ingested 15 min before prolonged exercise maintained euglycemia during exercise and enhanced endurance running capacity [11253].

The effects of dietary factors such as carbohydrate (CHO) on endurance-running performance have been extensively studied under laboratory-based and simulated field conditions. Evidence from "real-life" events, however, is poorly characterized. The purpose of this observational study was to examine the associations between prerace and in-race nutrition tendencies and performance in a sample of novice marathoners. Forty-six college students (36 women and 10 men) age 21.3 ± 3.3 years recorded diet for 3 d before, the
morning of, and during a 26.2-mile marathon. Anthropometric, physiological, and performance measurements were assessed before the marathon so the associations between diet and marathon time could be included as part of a stepwise-regression model. Mean marathon time was 266 ± 42 min. A pre-marathon 2-mile time trial explained 73% of the variability in marathon time. Day-before + morning-of CHO was the only other significant predictor of marathon time, explaining an additional 4 percent of the variability in marathon time. Other factors such as age, body-mass index, gender, day-before + morning-of energy, and in-race CHO were not significant independent predictors of marathon time. In this sample of primarily novice marathoners, Day-before + morning-of CHO intake was associated with faster marathon time, independent of other known predictors. These results suggest that novice and recreational marathoners should consider consuming a moderate to high amount of CHO in the 24-36 hr before a marathon [13617].

Meal frequency of pre-exercise carbohydrate feedings
One study compared the effect of single and multiple carbohydrate feedings before exercise on biochemical and physiological responses during exercise. Eight males performed 3 runs for 1 h at 70 percent VO$_{2\text{max}}$ after consuming a meal containing 2.5 g carbohydrate per kg body mass in a single dose 3 h before exercise (SF), the same meal in 5 equal doses at 3, 2.5, 2, 1.5, and 1 h before exercise (MF), or a liquid placebo 3 h before exercise (P). RER and carbohydrate oxidation rates were higher in SF and MF compared to P trials, but there was no difference between SF and MF trials. Pre-exercise insulin was 2.0- and 3.4-fold higher in SF and MF, respectively, compared to P, and 1.7-fold higher in MF compared to SF. Glycerol and NEFA were higher in P compared to SF and MF trials before and at the end of exercise. In conclusion, a carbohydrate meal containing 2.5 g/kg ingested in doses over 3 h before running produced higher hyperinsulinemia pre-exercise than that produced when the meal was consumed in a single dose. Nevertheless, estimated carbohydrate utilization and adipose tissue lipolysis during exercise after multiple feedings seemed to be as high as after a single feeding [07284].

The day before
To investigate whether the “overnight second-meal effect” results in altered substrate oxidation during the postprandial period following breakfast and subsequent sub-maximal exercise in women. Seven recreationally active women were recruited for the study. In each trial, participants were provided with their evening meal on day 1, which was composed of either high glycaemic index (HGI) or low glycaemic index (LGI) carbohydrates (CHO). On day 2, participants were provided with a standard HGI breakfast and then performed a 60 min run at 65 percent VO$_{2\text{max}}$ 3 h later. The incremental area under the curve (IAUC) for plasma glucose concentrations during the postprandial period following breakfast was greater in the HGI trial compared to the LGI trial (P<0.01). Similarly, the IAUC for serum insulin concentrations was greater in the HGI trial than the LGI trial (P<0.05). No differences in plasma free-fatty acids (FFA) or plasma glycerol concentrations were found between trials during the postprandial period. During subsequent exercise, there were no significant differences in substrate metabolism. The glycaemic index of an evening meal does not alter substrate oxidation at rest following breakfast or during subsequent submaximal exercise in women. This study provides further evidence for the overnight second-meal effect on glycaemic responses following a LGI mixed evening meal [07280].

In women
The effect of different quantities of carbohydrate (CHO) intake on CHO metabolism during prolonged exercise was examined in endurance-trained females. On four occasions, eight females performed 2 h of cycling at approximately 60 percent VO$_{2\text{max}}$ with ingestion of beverages containing low (LOW, 0.5 g/min), moderate (MOD, 1.0 g/min), or high (HIGH, 1.5 g/min) amounts of CHO, or water only (WAT). Test solutions contained trace amounts of [U-
\[^{13}\text{C}]\) glucose. Indirect calorimetry combined with measurement of expired \[^{13}\text{C}]\text{CO}_2 \text{ and plasma }^{13}\text{C} \text{ enrichment enabled calculation of exogenous CHO, liver-derived glucose, and muscle glycogen oxidation during the last 30 min of exercise. The highest rates of exogenous CHO oxidation were observed in MOD, with no further increases in HIGH. Endogenous CHO oxidation was lowest in MOD. Compared with WAT, CHO ingestion reduced liver glucose oxidation during exercise by approximately 30 percent. Differential rates of muscle glycogen oxidation were observed with different CHO doses. It was concluded that in endurance-trained women, the highest rates of exogenous CHO oxidation and greatest endogenous CHO sparing was observed when CHO was ingested at moderate during exercise [07281].

**Effect on combat sports**

The purpose of the current study was to investigate elite female (n=21) and male (n=47) combat sports athletes' (n=68; mean age (± SD) 21 ± 4 years; mean height 177 ± 10 cm) dietary intake between weigh-in and the first bout in Olympic combat sports. The data were collected at 6 separate tournaments and measurements included estimated food records, time for recovery, and body weight (BW) at weigh-in and first match. In total, 33 athletes participated in wrestling and taekwondo, sports with extended recovery times, and 35 athletes in judo and boxing, sports with limited recovery time. The results displayed that despite a mean consumption of food and drinks corresponding to 4.2 kg, the athletes only regained an average of 1.9 kg BW during recovery. Water accounted for 86 percent of the total intake. For each litre of water consumed, athletes gained 0.57 kg BW, when excluding heavy weight athletes (n=5). Carbohydrate consumption was 5.5 g/kg BW, compared to the recommended 8-10 g/kg BW. In total, one-quarter of the consumed water originated from carbohydrate-rich drinks. Given the average recovery time of 18 (wrestling, taekwondo) versus 8 hours (judo, boxing), the former group consumed twice the amount of water, carbohydrates, protein, and fat as the latter group. In conclusion, a large proportion of the participants did not meet the recovery nutrition guidelines for carbohydrates. Also, the discrepancy between nutrient intake and weight gain points to the physiological barriers to retaining fluids during a limited recovery time after engaging in weight making practices [13618].

**Effect on tennis**

Carbohydrate supplementation is a popular nutritional practice used in tennis to enhance physical capacities, motor-skill performance, and delay fatigue. However, the effects of carbohydrate supplementation on physiological and perceptual responses during tennis match play are not established. A double blind, randomized, placebo-controlled crossover study was designed to determine the influence of carbohydrate supplementation (0.5g/kg/h) on glycemia, salivary hormones (cortisol and testosterone) concentration, salivary IgA concentration and ratings of perceived exertion (RPE) during 3 h of tennis match play in 12 well trained tennis players. The only significant difference between the two conditions was a lower salivary cortisol concentration post-match in the carbohydrate trial; however, there was a trend for higher glucose concentration and lower session-RPE following tennis match play in the carbohydrate condition, which may have some practical implications. There was no change in salivary testosterone, salivary IgA and RPE responses during tennis match play between conditions. These data indicate that carbohydrate ingestion during 3 h of competitive tennis match play helps to maintain glycemina and attenuates the increase in salivary cortisol concentration compared to placebo [0619].

**Effect on football**

1674
One study investigated how performance was affected after soccer players, in a postprandial state, ingested a 7 percent carbohydrate (CHO) solution compared to a placebo (0 % CHO) during a simulated soccer match. Using a double-blind placebo-controlled design, 22 trained male league soccer players (age: 24 ± 7 years, wt: 73 ± 12 kg, VO\textsubscript{2}max: 52 ± 4 mL O\textsubscript{2}/kg/min) completed two trials, separated by 7 days, during which they ingested, in random order, 700 mL of either a 7 percent CHO or placebo drink during a simulated soccer match. Ratings of perceived exertion (RPE), agility, timed and run to fatigue were measured during the trials. Change in agility times was not altered by CHO versus placebo ingestion. Timed runs to fatigue were 381 ± 267 s versus 294 ± 159 s for the CHO and placebo drinks, respectively. Body mass modified the relationship between time to fatigue and drink ingestion, such that lower body mass was associated with increased time to fatigue when the players ingested CHO, but not placebo. RPE values for the final stage of the simulated soccer match were 8.5 ± 1.7 and 8.6 ± 1.5 for the CHO and placebo drinks respectively. The group data showed that the 7 percent CHO solution (49 g CHO) did not significantly improve performance during a simulated soccer match in league soccer players who had normal pre-match nutrition. However, when adjusting for body mass, increasing CHO intake was associated with improved time to fatigue during the simulated soccer match [13620].

**Effect on sleep onset**

Dietary carbohydrate intake has been shown to increase the plasma concentration of tryptophan, a precursor of serotonin and sleep-inducing agent. To investigate the role of carbohydrate in sleep induction, it was explored the effect of glycemic index (GI) and meal time on sleep in healthy volunteers. It was compared the effect of high- and low-GI carbohydrate-based meals ingested 4 h before bedtime on sleep quality. It was also evaluated the effect of the timing of high-GI meals (4 h compared with 1 h) on sleep quality. Twelve healthy men (aged 18-35 year) were administered standard, isocaloric (3212 kJ; 8 % of energy as protein, 1.6 % of energy as fat, and 90.4 % of energy as carbohydrate) meals of either Mahatma (low GI = 50) or Jasmine (high GI = 109) rice 4 h before their usual bedtime. On another occasion, the high-GI meal was given 1 h before bedtime. The participants underwent a familiarization night followed by 3 test nights in random order 1 week apart. A significant reduction in the mean sleep onset latency was observed with a high-GI compared with a low-GI meal consumed 4 h before bedtime. The high-GI meal given 4 h before bedtime showed a significantly shortened sleep onset latency compared with the same meal given 1 h before bedtime. No effects on other sleep variables were observed. It was shown that a carbohydrate-based high-GI meal resulted in a significant shortening of sleep onset latency in healthy sleepers compared with a low-GI meal and was most effective when consumed 4 h before bedtime. The relevance of these findings to persons with sleep disturbance should be determined in future trials [07283].

**Mouth rinse with carbohydrate solutions**

Ingesting carbohydrate-electrolyte solutions during exercise has been reported to benefit self-paced time-trial performance. The mechanism responsible for this ergogenic effect is unclear. For example, during short duration (≤1 hour), intense (>70 % maximal oxygen consumption) exercise, euglycaemia is rarely challenged and adequate muscle glycogen remains at the cessation of exercise. The absence of a clear metabolic explanation has led authors to speculate that ingesting carbohydrate solutions during exercise may have a 'non-metabolic' or 'central effect' on endurance performance. This hypothesis has been explored by studies investigating the performance responses of subjects when carbohydrate solutions are mouth rinsed during exercise. The solution is expectorated before ingestion, thus removing the provision of carbohydrate to the peripheral circulation. Studies using this
method have reported that simply having carbohydrate in the mouth is associated with improvements in endurance performance. However, the performance response appears to be dependent upon the pre-exercise nutritional status of the subject. Furthermore, the ability to identify a central effect of a carbohydrate mouth rinse may be affected by the protocol used to assess its impact on performance. Studies using functional MRI and transcranial stimulation have provided evidence that carbohydrate in the mouth stimulates reward centres in the brain and increases corticomotor excitability, respectively. However, further research is needed to determine whether the central effects of mouth-rinsing carbohydrates, which have been seen at rest and during fatiguing exercise, are responsible for improved endurance performance [11256].

The aim of one study was to determine the effect of a carbohydrate mouthwash on running time-trial performance. On two separate occasions, seven recreationally active males completed a preloaded (15 min at 65 %VO$_{2\text{max}}$) time-trial of 45 min in duration on a motorized treadmill. At 6-min intervals during the preload and time-trial, participants were given either a 6 percent maltodextrin, 3 percent lemon juice solution (carbohydrate trial) or a 3 percent lemon juice placebo mouthwash (placebo trial) in a double-blind, randomized crossover design. Heart rate, oxygen consumption (VO$_2$), respiratory exchange ratio (RER), and ratings of perceived exertion (RPE) were measured during the preload, and blood glucose and lactate were measured before and after the preload and time-trial. There were no significant differences in distance covered between trials. Furthermore, there were no significant between-trial differences in heart rate and running speed during the time-trial, or VO$_2$, RER or RPE during the preload. Blood lactate and glucose increased as a result of the exercise protocol, with no between-trial differences. In conclusion, there was no positive effect of a carbohydrate mouthwash on running performance of approximately 1 h duration [07305].

It has been previously reported that carbohydrate (CHO) mouth rinse can improve exercise performance. The proposed mechanism involves increased activation of brain regions believed to be responsible for reward/motivation and motor control. Since strength-related performance is affected by central drive to the muscles, it seems reasonable to hypothesize that the positive CNS response to oral CHO sensing may counteract the inhibitory input from the muscle afferent pathways minimizing the drop in the central drive. The purpose of one study was to test if CHO mouth rinse affects maximum strength and strength endurance performance. Twelve recreationally strength-trained healthy males took part in the study. All of the tests were performed in the morning, after an 8 h overnight fasting. Subjects were submitted to a maximum strength test (1-RM) and a strength endurance test (six sets until failure at 70 % of 1-RM), in separate days under three different experimental conditions (CHO mouth rinse, placebo-PLA mouth rinse and control-CON) in a randomized crossover design. The CHO mouth rinse (25 mL) occurred before every attempt in the 1-RM test, and before every set in the endurance strength test. Blood glucose and lactate were measured immediately before and 5 min post-tests. There were no significant differences in 1-RM between experimental conditions. Furthermore, there were no significant between-trial differences in heart rate and running speed during the time-trial, or VO$_2$, RER or RPE during the preload. Blood lactate and glucose increased as a result of the exercise protocol, with no between-trial differences. In conclusion, there was no positive effect of a carbohydrate mouthwash on running performance of approximately 1 h duration [11257].

To investigate the influence of ingesting versus mouth rinsing a carbohydrate-electrolyte solution on 1-h running performance, after a 14- to 15-h fast, 10 endurance-trained male runners completed three 1-h performance runs separated by 1 week. In random order, runners ingested either a 8 mL/kg body mass of either a 6.4 percent carbohydrate-electrolyte solution (CHO) or a placebo solution (P) 30 min before or a 2 mL/kg body mass at 15 min
intervals throughout the 1 h run. On a separate occasion, runners mouth rinsed (R) a 6.4 percent CHO, i.e., without ingestion, at the same times as in the ingestion trials. A greater distance was covered after the mouth rinse and ingestion of a 6.4 percent CHO during a 1 h performance run than when mouth rinsing the same solution or mouth rinsing followed by the ingestion of the same volume of a placebo solution [11258].

Carbohydrate during exercise has been demonstrated to improve exercise performance even when the exercise is of high intensity (>75 % VO_{2max}) and relatively short duration (approximately 1 h). It has become clear that the underlying mechanisms for the ergogenic effect during this type of activity are not metabolic but may reside in the central nervous system. Carbohydrate mouth rinses have been shown to result in similar performance improvements. This would suggest that the beneficial effects of carbohydrate feeding during exercise are not confined to its conventional metabolic advantage but may also serve as a positive afferent signal capable of modifying motor output. These effects are specific to carbohydrate and are independent of taste. The receptors in the oral cavity have not (yet) been identified and the exact role of various brain areas is not clearly understood. Further research is warranted to fully understand the separate taste transduction pathways for simple and complex carbohydrates and how these differ between mammalian species, particularly in humans [10401].

It is well known that carbohydrate (CHO) supplementation can improve performance in endurance exercises through several mechanisms such as maintenance of glycemia and sparing endogenous glycogen as well as the possibility of a central nervous-system action. Some studies have emerged in recent years in order to test the hypothesis of ergogenic action via central nervous system. Recent studies have demonstrated that CHO mouth rinse can lead to improved performance of cyclists, and this may be associated with the activation of brain areas linked to motivation and reward. These findings have already been replicated in other endurance modalities, such as running. This alternative seems to be an attractive nutritional tool to improve endurance exercise performance [10402].

It was investigated the influence of ingesting versus mouth-rinsing a carbohydrate-electrolyte solution on 1 h running performance. Following a 14-15 h fast, ten endurance-trained male runners completed three 1 h performance runs separated by 1 week. In random order runners either ingested 8 ml/kg body mass of either a 6.4 percent carbohydrate-electrolyte solution (CHO) or placebo solution (P) 30 min prior to and 2 ml per kg body mass at 15 min intervals throughout the 1 h run. On a separate occasion runners mouth-rinsed (R) a 6.4 percent carbohydrate-electrolyte solution i.e. without ingestion, at the same times as in the ingestion trials. Total distances covered in the CHO, P and R trials were 14515 ± 756 m; 14190 ± 800 m and 14283 ± 758 m respectively. Runners covered 320 m more (during the CHO trial compared to the placebo trial and 230 m more in comparison to the mouth rinse trial. Thus, a greater distance was covered following the mouth-rinse and ingestion of a 6.4 percent carbohydrate-electrolyte solution during a 1 h performance run than when mouth-rinsing the same solution or mouth-rinsing followed by the ingestion of the same volume of a placebo solution [10403].

As the primary fuel for abiding sports, carbohydrate intake before, during, and after exercise, has a positive effect on endurance performance. Apart from being an energy substrate, the sight, smell, and taste of food may act as positive reinforcements. By generating promises for food intake, these senses play a role in reward prediction. As a result, the body starts to function as if it is going to receive food. Recent studies suggest that simple mouth rinses with a carbohydrate solution can improve endurance performance even for performances that last about an hour, that is, in conditions where glycogen stores should not be limiting. Both complex and simple sugars can elicit a mouth rinse effect. Intravenous infusion of glucose
with a similar effect on blood sugar regulation parameters, as compared to a swallowed glucose solution, did not affect performance in a about 1-hour-time trial. It seems that specific oropharyngeal receptors, linked to brain centers that are involved in motivation and reward, play a role in the ergogenic effect of carbohydrate mouth rinsing. Oropharyngeal receptors thus signal presence of carbohydrate to the brain. Mouth rinses with a carbohydrate solution facilitate corticomotor output and improve time-trial performance in well-trained subjects in a fasted state. It was tested for this effect in nonathletic subjects in fasted and nonfasted state. Thirteen healthy non-athletic males performed 5 tests on a cycle ergometer. After measuring maximum power output ($W_{\text{max}}$), the subjects cycled four times at 60 percent $W_{\text{max}}$ until exhaustion while rinsing their mouth every 5 minutes with either a 6.4 percent maltodextrin solution or water, one time after an overnight fast and another after a carbohydrate rich breakfast. Mouth rinsing with maltodextrin improved time-to-exhaustion in pre- and postprandial states. This was accompanied by reductions in the average and maximal rates of perceived exertion but no change in average or maximal heart rate was observed. It was concluded that carbohydrate mouth rinsing improves endurance capacity in both fed and fasted states in non-athletic subjects [11386].

The purpose of one study was to examine the effectiveness of carbohydrate and caffeine mouth rinses in enhancing repeated sprint ability. Previously, studies have shown that a carbohydrate mouth rinse (without ingestion) has beneficial effects on endurance performance that are related to changes in brain activity. Caffeine ingestion has also demonstrated positive effects on sprint performance. However, the effects of carbohydrate or caffeine mouth rinses on intermittent sprints have not been examined previously. Twelve males performed 5 × 6 s sprints interspersed with 24 s of active recovery on a cycle ergometer. Twenty-five milliliters of either a noncaloric placebo, a 6 percent glucose, or a 1.2 percent caffeine solution was rinsed in the mouth for 5 s prior to each sprint in a double-blinded and balanced cross-over design. Postexercise maximal heart rate and perceived exertion were recorded, along with power measures. A second experiment compared a combined caffeine-carbohydrate rinse with carbohydrate only. Compared with the placebo mouth rinse, carbohydrate substantially increased peak power in sprint 1, and both caffeine and carbohydrate improved mean power in sprint 1. Experiment 2 demonstrated that a combination of caffeine and carbohydrate improved sprint 1 power production compared with carbohydrate alone. It was concluded that carbohydrate and (or) caffeine mouth rinses may rapidly enhance power production, which could have benefits for specific short sprint exercise performance. The ability of a mouth-rinse intervention to rapidly improve maximal exercise performance in the absence of fatigue suggests a central mechanism [13621].

**Influence on testosterone levels**

One study examined the effect of dietary carbohydrate (CHO) consumption on the free testosterone to cortisol (fT/C) ratio during a short-term intense micro-cycle of exercise training. The fT/C ratio is a proposed biomarker for overreaching-overtraining (i.e. training stress or imbalance) in athletes. The ratio was studied in two groups, control-CHO (approximately 60 % of daily intake, n=12) and low-CHO (approximately 30 % of daily intake, n=8), of male subjects who performed three consecutive days of intensive training (approximately 70-75 % maximal oxygen consumption, 60 min per day) with a dietary intervention (on the day before and during training). Resting, pre-exercise blood samples were collected under standardized-controlled conditions before each day of training (pre 1, 2, 3) and on a fourth day after the micro-cycle (rest). Bloods were analyzed for free testosterone and cortisol via radioimmunoassay procedures. Subjects performed no additional physical activity other than prescribed training. Statistical analysis (ANCOVA) revealed the fT/C ratio decreased significantly from pre-study resting measurement (pre 1) to
the final post-study resting measurement (rest) in the low-CHO group (-43 %), but no change occurred in the control-CHO group (-3 %). Findings suggest if the fTC ratio is utilized as a marker of training stress or imbalance it is necessary for a moderately high diet of CHO to be consumed to maintain validity of any observed changes in the ratio value [10224].

Endurance performance and fuel selection while ingesting glucose (15, 30, and 60 g/h) was studied in 12 cyclists during a 2-h constant-load ride (approximately 77 % peak $O_2$ uptake) followed by a 20-km time trial. Total fat and carbohydrate (CHO) oxidation and oxidation of exogenous glucose, plasma glucose, glucose released from the liver, and muscle glycogen were computed using indirect respiratory calorimetry and tracer techniques. Relative to placebo, glucose ingestion increased the time trial mean power output. With 60 g/h glucose, mean power was 2.3, 0.4 to 4.2 percent higher, and 3.1, 0.5 to 5.7 percent higher than with 30 and 15 g/h, respectively, suggesting a relationship between the dose of glucose ingested and improvements in endurance performance. Exogenous glucose oxidation increased with ingestion rate, but endogenous CHO oxidation was reduced only with 30 and 60 g/h due to the progressive inhibition of glucose released from the liver (probably related to higher plasma insulin concentration) with increasing ingestion rate without evidence for muscle glycogen sparing. Thus ingestion of glucose at low rates improved cycling time trial performance in a dose-dependent manner. This was associated with a small increase in CHO oxidation without any reduction in muscle glycogen utilization [10225].

**Intake recommendations**

Carbohydrate intake during prolonged exercise has been shown to increase endurance capacity and improve performance. Until recently, the advice was to ingest 30-60 g of carbohydrate per hour. The upper limit was based on studies that demonstrated that intakes greater than 60-70 g/h would not result in greater exogenous carbohydrate oxidation rates. The lower limit was an estimated guess of the minimum amount of carbohydrate required for ergogenic effects. In addition, the advice was independent of the type, the duration or the intensity of the activity as well as the level of athlete. Since 2004, significant advances in the understanding of the effects of carbohydrate intake during exercise have made it possible to be much more prescriptive and individual with the advice. Studies revealed that oxidation rates can reach much higher values (up to 105 g/h) when multiple transportable carbohydrates are ingested (i.e. glucose:fructose). It has also been observed that carbohydrate ingested during shorter higher intensity exercise (1 h, 80 % $VO_2_{max}$) can improve performance, although mechanisms are distinctly different. These findings resulted in new recommendations that are dependent on the duration and intensity of exercise and not only specify the quantity of carbohydrate to be ingested but also the type [13616].

**Can low carbohydrate high fat provide fuel for sport?**

As for athletic performance, athletes have long been encouraged to load up with carbohydrates prior to and during endurance exercise because glycogen, the storage form of carbohydrate, was thought to be a more efficient fuel than fat. This has also been challenged of late by scientists who argue that fat provides more calories per gram and also has much larger body stores. After a week or two of carbohydrate deprivation, our bodies change from a carbohydrate metabolism to a fat metabolism with health and performance improvements. It would seem that fat is just as effective a fuel for endurance events. What is unclear is whether a high fat low carbohydrate diet is appropriate for athletes in intermittent high-intensity sports such as football or road cycling [13596].

**Carbohydrates and protein**
The incidence of heat illness and heat stroke is greater in older than younger people. In this context, exercise training regimens to increase heat tolerance in older people may provide protection against heat illness. Acute increases in plasma volume (PV) improve thermoregulation during exercise in young subjects, but there is some evidence that changes in PV in response to acute exercise are blunted in older humans. It was recently demonstrated that protein-carbohydrate (Pro-CHO) supplementation immediately after a bout of exercise increased PV and plasma albumin content (Albcont) after 23 h in both young and older subjects. It was also examined whether Pro-CHO supplementation during aerobic training enhanced thermoregulation by increasing PV and Albcont in older subjects. Older men aged 68 years exercised at moderate intensity, 60 min/day, 3 days/week, for 8 weeks, at 19 degrees C, and took either placebo (CNT; 0.5 kcal, 0 g protein/kg) or Pro-CHO supplement (Pro-CHO; 3.2 kcal, 0.18 g protein/kg) immediately after exercise. After training, it was found during exercise at 30 degrees C that increases in oesophageal temperature were attenuated more in Pro-CHO than CNT and associated with enhanced cutaneous vasodilatation and sweating. It was also confirmed similar results in young subjects after 5 days of training. These results demonstrate that post-exercise protein and CHO consumption enhance thermoregulatory adaptations especially in older subjects and provide insight into potential strategies to improve cardiovascular and thermoregulatory adaptations to exercise in both older and younger subjects [09329].

The purpose of one study was to determine whether an isocaloric beverage with added protein and vitamins would influence oxidative stress and inflammation after cycling to exhaustion as indicated by plasma protein carbonyls (PC), lipid hydroperoxides (LOOH), and interleukin-6 (IL-6). Twelve trained men (18-33 yr) volunteered and performed this randomized crossover study. Participants cycled at 70 percent of VO2peak until fatigue and at 80 percent VO2peak 22-24 hr later to fatigue with either carbohydrate or the special drink. Blood collected before the cycling at rest and 24, 48, and 72 hr after the exercise was analyzed for PC and LOOH spectrophotometrically and for IL-6 via an enzyme-linked immunosorbent assay. Protein carbonyls demonstrated significant treatment and time effects with no Treatment x Time interaction. PC was higher in the special drink treatment than with carbohydrate independent of time and increased at 24 (48 %), 48 (59 %), and 72 (67 %) hr after exercise compared with preexercise values. Resting LOOH and IL-6 did not have any significant changes with time or treatment. These data indicate that an isocaloric beverage with added protein and vitamins would drink after 2 cycling bouts to exhaustion will exacerbate the resting PC level compared with an isocaloric drink [09330].

It was examined whether protein-carbohydrate (CHO) supplementation immediately after exercise each day during aerobic training facilitated plasma volume (PV) expansion and thermoregulatory and cardiovascular adaptations in older men. Fourteen moderately active older men (68 ± 5 yr) were divided into two groups so as to have no significant differences in anthropometric measures, PV, and peak oxygen consumption rate (VO2peak)). Each group was provided with a mixture of protein and CHO (3.2 kcal, 0.18 g protein/kg body wt, Pro-CHO, n=7) or a non-protein and low-calorie placebo (0.5 kcal, 0 g protein/kg body wt, CNT, n=7) immediately after cycling exercise (60-75 % VO2peak), 60 min/day, 3 days/wk) each day for 8 wk at approximately 19 degrees C ambient temperature and approximately 43 percent relative humidity. Before and after training, we measured PV, cardiac stroke volume (SV), and esophageal temperature during 20-min exercise at 60 percent of pretraining VO2peak at 30 degrees C and 50 percent relative humidity. After training, PV significantly increased by approximately 6 percent in Pro-CHO, with an approximately 10 percent increase in SV during exercise. Thus postexercise protein-CHO supplementation during training caused PV expansion and facilitated thermoregulatory and cardiovascular adaptations, possibly providing a new training regimen for older men [09331].
This study examined whether increased plasma volume (PV) and albumin content in plasma for 23 h after exercise were attenuated in older subjects compared with in young adult subjects, and if this attenuation abated by supplementation with protein and carbohydrate (CHO) immediately after exercise. Eight moderately active older (approximately 68 yr) and 8 young (approximately 21 yr) men performed two trials: control and Pro-CHO in which subjects consumed placebo (0.5 kcal, 0 g protein, 0.5 mg Na⁺ in 3.2 ml total fluid volume/kg body wt) or protein and CHO mixture (3.2 kcal, 0.18 g protein, 0.5 mg Na⁺ in 3.2 ml total fluid volume/kg body wt) suppletions, respectively, immediately after high-intensity interval exercise for 72 min (8 sets of 4 min at 70-80 % peak oxygen consumption rate, VO₂peak, intemitted by 5 min at 20 percent VO₂peak). PV, albumin content, and plasma globulin content were measured before exercise, at the end of exercise, every hour from the 1st to the 5th hour after exercise, and at the 23rd hour after exercise. From 12 h before the start to the end of experiment, food intake was controlled to the age-matched recommended dietary allowances. It was found that during the first 4 h after exercise in controls, albumin content recovered less in the older than the young group by approximately 0.04 g/kg, which was a significant difference, while it generally recovered more with Pro-CHO than controls by approximately 0.09 and approximately 0.04 g/kg in the young and older group, respectively, accompanied by a greater increase in PV by approximately 1 and approximately 2 ml/kg, respectively, during the 23 h after exercise. Globulin content remained constant throughout the experiment in both trials for both age groups. Thus the attenuated responses of albumin content and plasma volume after exercise in older subjects were restored by protein and CHO supplementation immediately after exercise, similarly to young subjects [09332].

One study examined whether a carbohydrate (CHO) + casein hydrolysate beverage improved time-trial performance versus a CHO beverage delivering approximately 60 g CHO/hr. Markers of muscle disruption and recovery were also assessed. Thirteen male cyclists completed 2 computer-simulated 60-km time trials consisting of 3 laps of a 20-km course concluding with a 5-km climb (approximately 5 % grade). Participants consumed 200 ml of CHO (6 %) or carbohydrate + casein hydrolysate beverage (6 % + 1.8 % protein hydrolysate) every 5 km and 500 ml of beverage immediately postexercise. Beverage treatments were administered using a randomly counterbalanced, double-blind design. Plasma creatine phosphokinase (CK) and muscle-soreness ratings were assessed immediately before and 24 hr after cycling. All time differences between treatments occurred during the final lap, with protein hydrolysate ingestion explaining a significant proportion of between-trials differences over the final 20 km and final 5 km. Plasma CK levels and muscle-soreness ratings increased significantly after the CHO trial but not the CHO + casein hydrolysate trial. Late-exercise time-trial performance was enhanced with CHO + casein hydrolysate beverage ingestion compared with a beverage containing CHO provided at maximal exogenous oxidation rates during exercise. CHO casein hydrolysate ingestion also prevented increases in plasma CK and muscle soreness after exercise [09333].

Exercise-induced muscle damage (EIMD) leads to decrements in muscle performance and increases in intramuscular enzymes measured in the plasma, and to delayed onset of muscle soreness (DOMS), partly due to the activation of degradative pathways. It has been shown that milk-based carbohydrate-protein (CHO-P) can limit changes in markers of EIMD, possibly by attenuating protein degradation and (or) increasing protein synthesis. However, the timing of supplementation has received limited attention, and this may alter the response. One study examined the effects of acute milk-based CHO-P supplementation timing on the attenuation of EIMD. Four independent matched groups of 8 healthy males consumed milk-based CHO-P before (PRE), immediately after (POST), or 24 h after (TWENTY-FOUR) muscle-damaging exercise. Active DOMS, isokinetic muscle performance, reactive strength index (RSI), and creatine kinase (CK) were assessed immediately before and 24, 48, and 72
h after EIMD. POST and TWENTY-FOUR demonstrated a benefit in limiting changes in active DOMS, peak torque, and RSI over 48 h, compared with PRE. PRE showed a possible benefit in reducing increases in CK over 48 h and limiting changes in other variables over 72 h. Consuming milk-based CHO-P after muscle-damaging exercise is more beneficial in attenuating decreases in muscle performance and increases in active DOMS at 48 h than ingestion prior to exercise [10226].

The aim of one study was to determine whether adding protein to a CHO beverage would improve late-exercise cycle time-trial performance over CHO alone. Furthermore, it was examined the effects of coingesting protein with CHO during exercise on postexercise markers of sarcolemmal disruption and the recovery of muscle function. In a double-blind, crossover design, 12 trained male cyclists performed 120 min of steady-state (SS) cycling at approximately 55 percent VO_{2max} followed by a time trial lasting approximately 1 h. At 15-min intervals during SS exercise, participants consumed either a CHO or a CHO + protein (CHO + Pro) beverage (providing 65 g/h CHO or 65 g/h CHO plus 19 g/h protein). Twenty-four hours after the onset of the SS cycle, participants completed a maximum isometric strength test. At rest and 24 h postexercise, a visual analog scale was used to determine lower-limb muscle soreness, and blood samples were obtained for plasma creatine kinase concentration. Dietary control was implemented 24 h before and during the time course of each trial. Average power output sustained during time trial was similar for CHO and CHO + Pro, with no effect of treatment on the time to complete the time trial. Postexercise isometric strength significantly declined for CHO (15 %) and CHO + Pro (11 %) compared with baseline. Plasma creatine kinase concentrations, and visual analog scale soreness significantly increased at 24 h postexercise, with no difference between treatments. The present findings suggest that carbohydrate plus protein coingestion during exercise does not improve late-exercise time-trial performance, ameliorate markers of sarcolemmal disruption, or enhance the recovery of muscle function at 24 h postexercise over carbohydrates alone [10227].

One study examined the effect of amino acids in a carbohydrate beverage on cycling performance. Twelve male athletes cycled at 75 percent VO_{2peak} for 90 min followed by a ride to exhaustion at 85 percent VO_{2peak}, before (T1) and on 2 consecutive days (T2 and T3) after 2 weeks of supplementation with 3.6 percent carbohydrate plus 1 percent amino acids (AA) or 4.6 percent carbohydrate-only (CHO) isocaloric beverages. Muscle damage was assessed by plasma creatine kinase (CK), and muscle fatigue by changes in vertical jump pre- to postexercise. Muscle soreness, overall fatigue, and changes in mood state were assessed using questionnaires. Plasma CK was lower for amino acids in T3. Time to exhaustion decreased from T2 to T3 only in CHO. Vertical-jump change from pre- to postexercise was greater in T3 for the carbohydrate treatment. Total fatigue score and mood disturbance decreased significantly only with amino acids in T3. The addition of AA to a carbohydrate beverage after consecutive-day exercise bouts reduced muscle damage as indicated by CK levels, decreased fatigue, and maintained exercise performance compared with consuming carbohydrate alone [08390].

Endurance athletes commonly consume carbohydrate-electrolyte sports beverages during prolonged events. The benefits of this strategy are numerous--sports-beverage consumption during exercise can delay dehydration, maintain blood glucose levels, and potentially attenuate muscle glycogen depletion and central fatigue. Thus, it is generally agreed that carbohydrate-electrolyte beverages can improve endurance performance. A controversy has recently emerged regarding the potential role of protein in sports beverages. At least 3 recent studies have reported that carbohydrate-protein ingestion improves endurance performance to a greater extent than carbohydrate alone. In addition, carbohydrate-protein ingestion has been associated with reductions in markers of muscle damage and improved postexercise...
recovery. Although many of these muscle damage and recovery studies examined postexercise nutritional intake, recent evidence suggests that these benefits may be elicited with carbohydrate-protein consumption during exercise. These findings are intriguing and suggest that the importance of protein for endurance athletes has been underappreciated. However, 2 studies recently reported no differences in endurance performance between carbohydrate and carbohydrate-protein beverages. The varied outcomes may have been influenced by a number of methodological differences, including the amounts and types of carbohydrate or protein in the beverages, the exercise protocols, and the relative statistical power of the studies. In addition, although there are plausible mechanisms that could explain the ergogenic effects of carbohydrate-protein beverages, they remain relatively untested. One review examined the existing research regarding the efficacy of carbohydrate-protein consumption during endurance exercise [07291].

The majority of football players succumb to fatigue towards the end of the game. This study was designed to examine the influence of protein coingestion with carbohydrate (CHO) versus an isocaloric CHO supplement on subsequent running capacity towards the end of a simulated football match. Six male amateur football players participated in 3 trials applied in a randomized cross-over experimental design. A laboratory-based, football-specific intermittent exercise was allocated for 75 min interspersed with a 15-min recovery, immediately followed by run time to fatigue (RTF) at 80 percent peak oxygen consumption. In each trial, prior to exercise and during half-time, participants randomly ingested a placebo (PLC), 6.9 percent CHO, or 4.8 percent CHO plus 2.1 percent protein (CHO-P) supplements matched for color and taste. CHO-P resulted in longer RTF (23 ± 5 min) than did CHO (16 ± 3 min) and PLC (11 ± 2 min). Blood glucose was higher in CHO-P at the point of fatigue compared with CHO and PLC. Ratings of perceived exertion were lower in the CHO-P subjects at the onset of exercise and towards the end of intermittent exercise when compared with the PLC and CHO subjects. When protein was added to a CHO supplement, subsequent running capacity following limited recovery from intermittent exercise was enhanced. This improvement suggests that protein coingestion may exert an ergogenic benefit upon endurance capacity during intermittent activity [11522].

Influence on post-exercise glycogen levels of carbohydrates and protein
One study assessed whether liquid carbohydrate-protein (C+P) supplements, ingested early during recovery, enhance muscle glycogen resynthesis versus isoenergetic liquid carbohydrate (CHO) supplements, given early or an isoenergetic solid meal given later during recovery (PLB). Two hours after breakfast (7.0 kcal/kg; 0.3 g/kg P, 1.2 g/kg C, 0.1 g/kg F), six male cyclists performed a 60-min time trial (AMex). Pre- and postexercise, vastus lateralis glycogen concentrations were determined using nMRS. Immediately, 1 h, and 2 h postexercise, participants ingested C+P (4.8 kcal/kg; 0.8 g/kg C, 0.4 g/kg P), CHO (4.8 kcal/kg; 1.2 g/kg C), or PLB (no energy). Four hours postexercise, a solid meal was ingested. At that time, C+P and CHO received a meal identical to breakfast, whereas PLB received 21 kcal/kg (1 g/kg P, 3.6 g/kg C, 0.3 g/kg F); energy intake during 6 h of recovery was identical among treatments. After 6 h of recovery, measurement and cycling protocols (PMex) were repeated. Absolute muscle glycogen utilization was 18 percent greater during AMex relative to PMex but there were no differences between groups. During 6 h of recovery, muscle glycogen resynthesis was greater in C+P versus CHO or PLB. Cycling performance was similar among treatments during both AMex and PMex. It was concluded that C+P supplements, given early after exercise, enhance glycogen resynthesis relative to CHO and PLB. However, this does not influence performance in this type of exercise bout [06256].

Acute carbohydrate-protein ingestion has been shown to improve steady-state endurance performance. This study compared the effects of carbohydrate and carbohydrate-protein ingestion on self-regulated simulated multiple-sprint sport performance. Nine participants
completed two trials of a modified Loughborough Intermittent Shuttle Test involving 4 x 15 min blocks of regulated exercise followed by 2 x 15 min blocks of self-regulated exercise. Participants consumed 2.5 ml/kg of an 8 percent carbohydrate (CHO trial) or 6 percent carbohydrate plus 2 percent whey protein beverage (CHO-P trial) every 15 minutes. Distance covered (4 %) and maximal speed (6 %) decreased in the final 15 min of exercise, and whilst not significant, carbohydrate-protein elicited a very likely moderate and possibly small improvement in each variable, respectively. Average running speed declined in the final 15 min of the CHO trial only with protein providing a likely small improvement (2.7 %: ± 2.5 %). No differences between beverages were observed in body mass or plasma volume change, urine volume, heart rate, gut fullness, rating of perceived exertion (RPE), blood glucose or serum insulin. Blood urea concentration increased in the CHO-P trial only. These findings show carbohydrate-protein ingestion is likely to enhance multiple-sprint sport exercise performance above carbohydrate, potentially through altered central fatigue or increased protein oxidation [12383].

Protein supplements are consumed frequently by athletes and recreationally active adults for various reasons, including improved exercise performance and recovery after exercise. Yet, far too often, the decision to purchase and consume protein supplements is based on marketing claims rather than available evidence-based research. The purpose of one review was to provide a systematic and comprehensive analysis of the literature that tested the hypothesis that protein supplements, when combined with carbohydrate, directly enhance endurance performance by sparing muscle glycogen during exercise and increasing the rate of glycogen restoration during recovery. The analysis was used to create evidence statements based on an accepted strength of recommendation taxonomy. English language articles were searched with PubMed and Google Scholar using protein and supplements together with performance, exercise, competition, and muscle, alone or in combination as keywords. Additional articles were retrieved from reference lists found in these papers. Inclusion criteria specified recruiting healthy active adults less than 50 years of age and evaluating the effects of protein supplements in combination with carbohydrate on endurance performance metrics such as time-to-exhaustion, time-trial, or total power output during sprint intervals. The literature search identified 28 articles, of which 26 incorporated test metrics that permitted exclusive categorization into one of the following sections: ingestion during an acute bout of exercise (n=11) and ingestion during and after exercise to affect subsequent endurance performance (n=15). The remaining two articles contained performance metrics that spanned both categories. All papers were read in detail and searched for experimental design confounders such as energy content of the supplements, dietary control, use of trained or untrained participants, number of subjects recruited, direct measures of muscle glycogen utilization and restoration, and the sensitivity of the test metrics to explain the discrepant findings. The evidence statements assert that when carbohydrate supplementation was delivered at optimal rates during or after exercise, protein supplements provided no further ergogenic effect, regardless of the performance metric used. In addition, the limited data available suggested recovery of muscle glycogen stores together with subsequent rate of utilization during exercise is not related to the potential ergogenic effect of protein supplements. Many studies lacked ability to measure direct effects of protein supplementation on muscle metabolism through determination of muscle glycogen, kinetic assessments of protein turnover, or changes in key signaling proteins, and therefore could not substantiate changes in rates of synthesis or degradation of protein. As a result, the interpretation of their data was often biased and inconclusive since they lacked ability to test the proposed underlying mechanism of action. It was concluded that when carbohydrate is delivered at optimal rates during or after endurance exercise, protein supplements appear to have no direct endurance performance enhancing effect [13638].

Acute carbohydrate-protein ingestion has been shown to improve steady-state endurance
performance. This study compared the effects of carbohydrate and carbohydrate-protein ingestion on self-regulated simulated multiple-sprint sport performance. Nine participants completed two trials of a modified Loughborough Intermittent Shuttle Test involving 4 x 15 min blocks of regulated exercise followed by 2 x 15 min blocks of self-regulated exercise. Participants consumed 2.5 mL/kg of an 8 percent carbohydrate (CHO trial) or 6 percent carbohydrate plus 2 percent whey protein beverage (CHO-P trial) every 15 minutes. Distance covered (4.2 %) and maximal speed (6.1 %) decreased in the final 15 min of exercise, and whilst not significant, carbohydrate-protein elicited a very likely moderate and possibly small improvement in each variable, respectively. Average running speed declined in the final 15 min of the CHO trial only with protein providing a likely small improvement. No differences between beverages were observed in body mass or plasma volume change, urine volume, heart rate, gut fullness, rating of perceived exertion (RPE), blood glucose or serum insulin. Blood urea concentration increased in the CHO-P trial only. These findings show carbohydrate-protein ingestion is likely to enhance multiple-sprint sport exercise performance above carbohydrate, potentially through altered central fatigue or increased protein oxidation.

It is recommended that endurance athletes consume carbohydrate (CHO) supplements, providing 6-8 percent CHO concentration, during exercise >60 minutes to improve athletic performance. Recently research has compared carbohydrate-protein (CHO-P) supplementation to the traditionally used CHO supplementation during endurance exercise, following these supplementation recommendations, in controlled settings, but not under simulated applied conditions such as a field trial. Therefore, the purpose of one investigation was to test CHO and CHO-P supplementation under applied conditions such that commercially-available isocaloric (CHO-P & double-carbohydrate [CHO-CHO]) and isocarbohydrate (CHO-P & CHO) supplements were compared to a placebo (PLA), within an outdoor running field trial >60 minutes in order to assess their influence on endurance performance. Twelve male recreational runners completed four, 19.2 km runs, where they were instructed to run at a pace similar to race pace including a final sprint to the finish, which in this case was the final two laps of the course (1.92 km). Supplementation was provided before the start and in 4 km increments. Performance was measured by time to complete the 19.2 km run and last 1.92 km sprint. Analyses found no difference between supplements in time to complete the 19.2 km run or last 1.92 km sprint to the finish. Thus, when following recommendation for supplementation within a field trial, commercially available CHO and CHO-P supplements do not appear to enhance performance in male recreational runners.

In football
One study investigated the influence of carbohydrate supplementation on skill performance throughout exercise that replicates soccer match-play. Experimentation was conducted in a randomised, double-blind and cross-over study design. After familiarization, 15 professional academy soccer players completed a soccer match simulation incorporating passing, dribbling and shooting on two separate occasions. Participants received a 6 percent carbohydrate-electrolyte solution (CHO) or electrolyte solution (PL). Precision, success rate, ball speed and an overall index (speed-precision-success; SPS) were determined for all skills. Blood samples were taken at rest, immediately before exercise, every 15 min during exercise (first half: 15, 30 and 45 min; second half: 60, 75 and 90 min), and 10 min into the half time (half-time). Carbohydrate supplementation influenced shooting (time×treatment interaction), where CHO attenuated the decline in shot speed and SPS index. Supplementation did not affect passing or dribbling. Blood glucose responses to exercise were influenced by supplementation (time×treatment interaction), where concentrations were higher at 45 min and during half-time in CHO compared with PL. Blood glucose concentrations reduced by 30 ± 1 percent between half-time and 60 min in CHO. It was
concluded that carbohydrate supplementation attenuated decrements in shooting performance during simulated soccer match-play; however, further research is warranted to optimise carbohydrate supplementation regimes for high-intensity intermittent sports [12384].

In tennis
Twenty-two tennis players were individually studied on 2 occasions. They performed a prematch skill test, a 2-hr tennis match against an equally ranked opponent, and a postmatch skill test. A carbohydrate-electrolyte (CHO-E; Lucozade Sport) or flavor-matched placebo-electrolyte (PL) beverage was administered in a double-blind fashion. During the trials, heart-rate and movement intensity were monitored, and the match was recorded for performance analysis. There were no differences in skill-test scores pre- to postmatch or between trials (154 ± 38 pre- and 160 ± 35 postmatch on PL, 155 ± 36 pre- and 165 ± 33 postmatch on CHO-E). CHO-E ingestion elevated blood glucose concentration throughout the match, and participants reported feeling more energetic (general activation) and more tense (high activation) 1 hr into the match than at baseline. Participants in the CHO-E trial spent more time in moderate-intensity activity and less time in low-intensity activity than on PL. Performance analysis revealed that CHO-E ingestion increased overall serve success, success of first serves, and serves to the advantage side. Return success was greater during the second set of the match in the CHO-E trial. Differences in serve and return success were not associated with blood glucose response to CHO or player ability [12385].

Influence on DNA injuries
The aim of one study was to evaluate the effect of carbohydrate supplementation on free plasma DNA and conventional markers of training and tissue damage in long-distance runners undergoing an overload training program. Twenty-four male runners were randomly assigned to two groups (CHO group and control group). The participants were submitted to an overload training program (days 1-8), followed by a high-intensity intermittent running protocol (10 × 800 m) on day 9. The runners received maltodextrin solution (CHO group) or zero energy placebo solution as the control equivalent before, during, and after this protocol. After 8 days of intensive training, baseline LDH levels remained constant in the CHO group and increased in the control group. On day 9, LDH concentrations were lower in the CHO group than in the control group post-intermittent running. Carbohydrate ingestion attenuated the increase of free plasma DNA post-intermittent running when compared to the control group. Leukocyte counts were lower in the CHO group than in the control group post-intermittent running and at 80 min of recovery. Cortisol levels were positively correlated with free plasma DNA, leukocytes, and LDH. The results showed that ingestion of a carbohydrate beverage resulted in less DNA damage and attenuated the acute post-exercise inflammation response, providing better recovery during intense training [12386].

Influence on fat oxidation
The enhancement of fat oxidation during exercise is an aim for both recreational exercising individuals and endurance athletes. Nutritional status may explain a large part of the variation in maximal rates of fat oxidation during exercise. This review reveals novel insights into nutritional manipulation of substrate selection during exercise, explaining putative mechanisms of action and evaluating the current evidence. Lowering the glycaemic index of the pre-exercise meal can enhance lipid utilisation by up to 100 percent through reduced insulin concentrations, although its application may be restricted to specific training sessions rather than competition. Chronic effects of dietary glycaemic index are less clear and warrant future study before firm recommendations can be made. A flurry of recent advances has overturned the conventional view of l-carnitine supplementation, with skeletal muscle uptake possible under certain dietary conditions and providing a strategy to influence energy metabolism in an exercise intensity-dependent manner. Use of non-carbohydrate nutrients to stimulate muscle l-carnitine uptake may prove more beneficial for optimising lipid utilisation,
but this requires more research. Studies investigating fish oil supplementation on fat oxidation during exercise are conflicting. In spite of some strong putative mechanisms, the only crossover trial showed no significant effect on lipid use during exercise. Carbohydrates may increase NEFA availability although it is not clear whether these effects occur. Carbohydrates and caffeine can increase NEFA availability under certain circumstances which could theoretically enhance fat oxidation, yet strong experimental evidence for this effect during exercise is lacking. Co-administration of nutrients to maximise their effectiveness needs further investigation [12387].

Heavy aerobic exercise, particularly with short time periods between sessions, can result in incomplete muscle glycogen replenishment, increased indices of muscle disruption and soreness, and impaired performance in subsequent exercise. Recent studies have suggested that these aspects of muscle recovery may be influenced by the consumption of carbohydrate-protein (CHO + Pro) recovery beverages. For example, CHO + Pro intake following exercise may accelerate muscle glycogen replenishment rates compared to isocaloric CHO beverages consumed at sub-optimal intake rates (<1 g/kg BW/h); and glycogen repletion with CHO + Pro appears similar to optimal carbohydrate doses. Numerous studies have reported that post-exercise CHO + Pro ingestion attenuates changes in markers of post-exercise muscle disruption following exercise, such as creatine kinase (CK), myoglobin and lactate dehydrogenase. Others have reported that CHO + Pro intake is associated with reduced muscle soreness and enhanced post-exercise muscle function compared to when carbohydrate alone is consumed. However, the effects of CHO + Pro on these markers of recovery remain controversial, as other studies have reported no differences between CHO and CHO + Pro treatments on markers of muscle disruption, muscle soreness, or muscle function. Perhaps due to the varying effects of CHO + Pro on these factors, consumption of CHO + Pro supplements during recovery has been reported to augment performance during subsequent whole-body exercise in some but not all studies. The effects of different carbohydrate-protein (CHO + Pro) beverages were compared during recovery from cycling exercise. Twelve male cyclists (VO\textsubscript{2peak}: 65 ± 7 mL/kg/min) completed 1 h of high-intensity intervals (EX1). Immediately and 120 min following EX1, subjects consumed one of three calorically-similar beverages (285-300 kcal) in a cross-over design: carbohydrate-only (CHO; 75 g per beverage), high-carbohydrate/low-protein (HCLP; 45 g CHO, 25 g Pro, 0.5 g fat), or low-carbohydrate/high-protein (LCHP; 8 g CHO, 55 g Pro, 4 g fat). After 4 h of recovery, subjects performed subsequent exercise (EX2; 20 min at 70 % VO\textsubscript{2peak} + 20 km time-trial). Beverages were also consumed following EX2. Blood glucose levels (30 min after beverage ingestion) differed across all treatments (CHO > HCLP > LCHP), and serum insulin was higher following CHO and HCLP ingestion versus LCHP. Peak quadriceps force, serum creatine kinase, muscle soreness, and fatigue/energy ratings measured pre- and post-exercise were not different between treatments. EX2 performance was not significantly different between CHO (48.5 ± 1.5 min), HCLP (48.8 ± 2.1 min) and LCHP (50.3 ± 2.7 min). Beverages containing similar caloric content but different proportions of carbohydrate/protein provided similar effects on muscle recovery and subsequent exercise performance in well-trained cyclists [12395].

Previous studies have indicated that exercise-induced muscle damage might be attenuated by coingestion of protein and carbohydrate supplement. The purpose of one study was to compare the effect of three various ratios of carbohydrate-protein (CHO+PRO) supplements on resistance exercise-induced muscle damage indices. Twenty-eight untrained male students voluntarily participated in this study and were randomly assigned to one of the four groups: 1) CHO+PRO 2:1 ratio, n=7; 2) CHO+PRO 3:1 ratio, n=8; 3) CHO+PRO 4:1 ratio, n=7; 4) placebo group, n=6. They performed a single bout of resistance exercise (whole body: 3 set×8-10 reps with 70-75 % 1RM), with eccentric concentration. Every group consumed prepared CHO/PRO beverages (9 % concentration, 10 mL/kg/bw at different
ratios) or the same amount of placebo beverage before and in 15 min intervals during exercise. Blood samples were taken before the exercise bout and also at 1 and 24 h post-exercise. In addition, muscle soreness scores were recorded before and 1, 24, and 48 h postexercise. Serum creatine kinase (CK) and myoglobin (Mb) increased in all groups compared with pre-exercise but the significant difference among groups was observed in 24 h postexercise, in a way that both CK and Mb levels were higher in placebo group. Muscle soreness increased for all groups from pre to postexercise, but there was not any significant difference among groups at any time point. Findings of this study showed that CHO+PRO decreased serum CK and Mb at 24 h post exercise, but did not affect muscle soreness at any time points after exercise. Moreover, there were no significant differences between various ratios of CHO-PRO supplementation.

Carbohydrates and amino acids

This investigation examined chronic alteration of the acute hormonal response associated with liquid carbohydrate (CHO) and/or essential amino acid (EAA) ingestion on hormonal and muscular adaptations following resistance training. Thirty-two untrained young men performed 12 weeks of resistance training twice a week, consuming 675 ml of either, a 6 percent CHO solution, 6 g EAA mixture, combined CHO + EAA supplement or placebo (PLA). Blood samples were obtained pre- and post-exercise (week 0, 4, 8, and 12), for determination of glucose, insulin, and cortisol. 3-Methylhistidine excretion and muscle fibre cross-sectional area (fCSA) were determined pre- and post-training. Post-exercise cortisol increased during each training phase for PLA. No change was displayed by EAA; CHO and CHO + EAA demonstrated post-exercise decreases. All groups displayed reduced pre-exercise cortisol at week 12 compared to week 0. Post-exercise insulin concentrations showed no change for PLA; increases were observed for the treatment groups, which remained greater for CHO and CHO + EAA than PLA. EAA and CHO ingestion attenuated 3-methylhistidine excretion 48 h following the exercise bout. CHO + EAA resulted in a 26% decrease, while PLA displayed a 52 percent increase. fCSA increased across groups for type I, IIA, and IIB fibres, with CHO + EAA displaying the greatest gains in fCSA relative to PLA. These data indicate that CHO + EAA ingestion enhances muscle anabolism following resistance training to a greater extent than either CHO or EAA consumed independently. The synergistic effect of CHO + EAA ingestion maximises the anabolic response presumably by attenuating the post-exercise rise in protein degradation.

Carbohydrate versus carbohydrate plus protein

The purpose of this study was to investigate the effects of isocaloric carbohydrate (CHO) and carbohydrate-protein (CHO-Pro) supplements on time to exhaustion. Eleven moderately aerobically fit adults performed a maximal cycle ergometer test for the determination of VO\textsubscript{2max}. At least 72 hours later, the participants performed a time-to-exhaustion test at a power output equivalent to the power output when subjects were at 75 percent of their VO\textsubscript{2max}. Either the CHO or the CHO-Pro supplement was administered at 0, 30, 60, 90, and 120 minutes after this test. After 3 hours of recovery and supplement ingestion, a second time-to-exhaustion test was performed. This testing protocol was repeated for the third visit, but the supplement not given during the second visit was administered. The results indicated that there was no significant difference in time to exhaustion after isocaloric CHO (pretest 22.4 ± 2.84 minutes, posttest 25.4 ± 4.45 minutes) and CHO-Pro (pretest 22.3 ± 3.46 minutes, posttest 24.0 ± 5.08 minutes) supplementation. Carbohydrate and CHO-Pro ingestion after exercise appear to have similar effects on short-term recovery.

Carbohydrates plus whey
Whey protein is a supplemental protein source often used by athletes, particularly those aiming to gain muscle mass; however, direct evidence for its efficacy in stimulating muscle protein synthesis (MPS) is lacking. It was aimed to determine the impact of consuming whey protein on skeletal muscle protein turnover in the post-exercise period. Eight healthy resistance-trained young men (age=21 years; BMI=27) participated in a double-blind randomized crossover trial in which they performed a unilateral leg resistance exercise workout (4 sets of knee extensions and 4 sets of leg press; 8-10 repetitions/set; 80% of maximal), such that one leg was not exercised and acted as a rested (RE) comparator. After exercise, subjects consumed either an isoenergetic whey protein plus carbohydrate beverage (WHEY: 10 g protein and 21 g fructose) or a carbohydrate-only beverage (CHO: 21 g fructose and 10 g maltodextran). Subjects received pulse-tracer injections of L-[ring-2H5]phenylalanine and L-[15N]phenylalanine to measure MPS. Exercise stimulated a rise in MPS in the WHEY-EX and CHO-EX legs, which were greater than MPS in the WHEY-RE leg and the CHO-RE leg, respectively. The rate of MPS in the WHEY-EX leg was greater than in the CHO-EX leg. It was concluded that a small dose (10 g) of whey protein with carbohydrate (21 g) can stimulate a rise in MPS after resistance exercise in trained young men that would be supportive of a positive net protein balance, which, over time, would lead to hypertrophy [07292].

Ingesting carbohydrate plus protein following prolonged exercise may restore exercise capacity more effectively than ingestion of carbohydrate alone. The objective of the present study was to determine whether this potential benefit is a consequence of the protein fraction per se or simply due to the additional energy it provides. Six active males participated in three trials, each involving a 90-min treadmill run at 70 percent maximal oxygen uptake (run 1) followed by a 4-h recovery. At 30-min intervals during recovery, participants ingested solutions containing: 0.8 g carbohydrate/kg body mass/h plus 0.3 g/kg/h of whey protein isolate (CHO-PRO); 0.8 g carbohydrate/kg BM/h (CHO); or 1.1 g carbohydrate/kg BM/h (CHO-CHO). The latter two solutions matched the CHO-PRO solution for carbohydrate and for energy, respectively. Following recovery, participants ran to exhaustion at 70 percent maximal oxygen uptake (run 2). Exercise capacity during run 2 was greater following ingestion of CHO-PRO and CHO-CHO than following ingestion of CHO with no significant difference between the CHO-PRO and CHO-CHO treatments. In conclusion, increasing the energy content of these recovery solutions extended run time to exhaustion, irrespective of whether the additional energy originated from sucrose or whey protein isolate [07293].

**Carbohydrates with fat**

Pre-exercise meals containing carbohydrates (CHO) are recommended to athletes, although there is evidence to suggest that a high fat meal prior to exercise increases utilisation of fats yet may not adversely affect performance. This study investigated the effect of a high fat and high CHO pre-exercise meal prior to high intensity intermittent exercise. Ten male recreational soccer players performed a soccer specific protocol followed by a 1 km time trial 3½ h after ingesting one of 2 test meals, high fat meal (HFM) or a high CHO meal (HCM). Blood glucose, fatty acids (FA), glycerol, beta-hydroxybutyrate, lactate and insulin were assessed prior to the meal, pre-exercise, half-time, and post-exercise, whilst rates of CHO and fat oxidation were determined at 4 time points during the exercise as well as heart rate (HR) and rating of perceived exertion (RPE). Significant increases in FA, glycerol, β-hydroxybutyrate and fat oxidation after the HFM were observed, while CHO oxidation was significantly higher following the HCM. No performance effect was found for the 1 km time trial. These findings suggest that the type of meal ingested prior to soccer simulated exercise has an impact on metabolism, but not on the subsequent performance as determined in the present study [13641].
Milk carbohydrate and protein

Exercise-induced muscle damage leads to the degradation of protein structures within the muscle. This may subsequently lead to decrements in muscle performance and increases in intramuscular enzymes and delayed-onset muscle soreness. Milk, which provides protein and carbohydrate (CHO), may lead to the attenuation of protein degradation and an increase in protein synthesis that would limit the consequential effects of exercise-induced muscle damage. One study examined the effects of acute milk and milk-based protein-CHO supplementation on attenuating exercise-induced muscle damage. Delayed-onset muscle soreness was not significantly different between groups at any time point [08394].

Carbohydrates and caffeine

A round of golf lasts approximately 4 hours, during which time homeostasis could be challenged through either hypoglycemia or hypohydration. This might result in impaired motor skill or cognitive performance. Given the high cognitive demand of putting and the potential fatiguing effects from prolonged walking, the combination of a caffeine and carbohydrate drink could be beneficial in offsetting hypoglycemia and hypohydration. One study used a laboratory-simulated round of golf to examine the effect of an isotonic carbohydrate and caffeine sports drink on putting performance during a round of golf. After institutional ethics approval, 20 male golfers consumed either an isotonic sports drink containing caffeine (6.4 g carbohydrate and 16 mg caffeine per 100 mL) or a no-energy, flavour-matched placebo drink in a double-blind, randomized, counter-balanced crossover design. Drinks were consumed preround (5 mL/kg body mass) and at holes 6 and 12. Participants therefore consumed 1.6 mg/kg body mass of caffeine and 0.64 g/kg body mass of carbohydrate throughout the trial. Five and 2 m putting performance were assessed at each hole. Self-rated mood assessments were carried out every third hole. Putting performance over 5 m and 2 m and self-rated scores for alertness and relaxation showed a significant main effect for drink. Ratings of mental fatigue and tiredness significantly increased during the round. In experienced golfers, the consumption of an isotonic carbohydrate sports drink containing caffeine prior to and during a round of golf improved putting performance and increased feelings of alertness [09334].

Not all athletic competitions lend themselves to supplementation during the actual event, underscoring the importance of preexercise supplementation to extend endurance and improve exercise performance. Energy drinks are composed of ingredients that have been found to increase endurance and improve physical performance. The purpose of one study was to investigate the effects of a commercially available energy drink, ingested before exercise, on endurance performance. The study was a double-blind, randomized, crossover design. After a 12-hr fast, 6 male and 6 female trained cyclists consumed 500 ml of either flavored placebo or Red Bull Energy Drink (2.0 g taurine, 1.2 g glucuronolactone, 160 mg caffeine, 54 g carbohydrate, 40 mg niacin, 10 mg pantothenic acid, 10 mg vitamin B6, and 10 microg vitamin B12) 40 min before a simulated cycling time trial. Performance was measured as time to complete a standardized amount of work equal to 1 hr of cycling at 70 percent Wmax. Performance improved with energy drink compared with placebo, but there was no difference in rating of perceived exertion between treatments. Endorphin levels increased during exercise, with the increase for energy drink approaching significance over placebo. Substrate utilization, as measured by open-circuit spirometry, did not differ between treatments. These results demonstrate that consuming a commercially available energy drink before exercise can improve endurance performance and that this improvement might be in part the result of increased effort without a concomitant increase in perceived exertion.
Carbohydrate and caffeine are known to independently improve certain aspects of athletic performance. However, less is understood about physiological and performance outcomes when these compounds are coingested in a rehydration and carbohydrate-replacement strategy. The aim of one study was to examine the influence of adding a moderate dose of caffeine to a carbohydrate solution during prolonged soccer activity. Fifteen male soccer players performed two 90-min intermittent shuttle-running trials. They ingested a carbohydrate-electrolyte solution (CON) providing a total of 1.8 g/kg body mass (BM) of carbohydrate or a similar solution with added caffeine (CAF; 3.7 mg/kg BM). Solutions were ingested 1 hr before exercise and every 15 min during the protocol. Soccer passing skill and countermovement-jump height (CMJ) were quantified before exercise and regularly during exercise. Sprinting performance, heart rate, blood lactate concentration (La) and the subjective experiences of participants were measured routinely. Mean 15-m sprint time was significantly faster during CAF; over the final 15 min of exercise mean sprint times were CAF 2.48 ± 0.15 s versus CON 2.59 ± 0.2 s. Explosive leg power (CMJ) was improved during CAF. Heart rate was elevated throughout CAF, and ratings of pleasure were significantly enhanced. There were no significant differences in passing skill, rating of perceived exertion, La, or body-mass losses between trials. The addition of caffeine to the carbohydrate-electrolyte solution improved sprinting performance, countermovement jumping, and the subjective experiences of players. Caffeine appeared to offset the fatigue-induced decline in self-selected components of performance [10228].

Carbohydrates and electrolytes

To investigate the effect of ingesting a carbohydrate-electrolyte solution (CHO-E), in subjects with reduced carbohydrate stores, during an intermittent shuttle running test (LIST) on soccer passing (LSPT) and shooting (LSST) performance. Sixteen healthy male university soccer players ingested either a 6.4 percent CHO-E or placebo (PLA) solution during 90 min of the LIST (5 mL/kg BM before and 2 mL/kg BM every 15 min of exercise), in a double-blind, randomized, crossover design, with each trial separated by at least 7 d. On the evening before the main trial (17:00 h), subjects performed the glycogen-reducing cycling exercise (approximately 80 min at 70 % VO2max). They were then fed a low-carbohydrate evening meal and reported to the laboratory the following morning after a 10-h fast. Blood was collected at rest and after every 30 min of exercise; skill tests were performed before and after the LIST. The change in mean shooting performance from pre- to post-LIST was better in the CHO-E trial but not significantly different for the passing performance. Sprint performance during the LIST was quicker in the CHO-E trial. Plasma glucose was higher in the CHO-E trial after 90 min of exercise. It was concluded that ingestion of a carbohydrate-electrolyte solution improved sprinting performance, countermovement jumping, and the subjective experiences of players. Caffeine appeared to offset the fatigue-induced decline in self-selected components of performance [10228].

To examine the effect of the glycemic index (GI) of a pre-exercise (PRE-ex) meal on plasma cytokine responses and endurance performance when carbohydrate-electrolyte (CHO-E) drink was consumed during exercise. Eight endurance-trained male runners completed three trials in a randomized order. The pre-exercise meal consisted of either high-GI (HGI) (GI=83), low-GI (LGI) foods (GI=36) or control (CON) (low energy sugar-free jelly) was given to the participant 2h before a 21-km performance run on a level treadmill. During each trial, 2 ml/kg BM of 6.6 percent CHO-E solution was consumed immediately before exercise and every 2.5-km afterward. Blood samples were collected before (pre-meal), and 120 min after ingestion the meal (120 min), immediately (POST), and 60 min (POST-60 min) after exercise. No difference was found in time to complete the 21-km run between LGI and HGI. The interleukin-6 (IL-6) level increased by more than 100 times immediately after exercise in
the three trials and returned to the basal level only on LGI at POST-60 min. In contrast, interleukin-2 (IL-2) level showed a transitory but significant decrease at POST on CON. Glucose concentrations did not recover to the pre-meal level by POST-60 min on HGI only. Cortisol concentrations increased throughout the exercise and were significantly lower on LGI when compared with CON at POST-60 min. HGI and LGI demonstrated similar performance when CHO-E solution was consumed during a 21-km run. However, pre-exercise LGI meal attenuated the increases in cortisol and quickened the recovery of the increased IL-6 value [09336].

One study investigated the influence of consuming a 2, 6, and 10 percent carbohydrate-electrolyte (CHO-E) solution on the intermittent endurance capacity and sprint performance of adolescent team games players. Seven participants (five males and two females; mean age 13 ± 1 years, height 171 ± 5 cm, body mass 62.0 ± 6.3 kg) performed three trials separated by 3-7 days. In each trial, they completed four 15-min periods of part A of the Loughborough Intermittent Shuttle Test followed by an intermittent run to exhaustion (part B). Participants consumed 5 ml kg(-1) BM of the solution during the 5-min pre-exercise period, and a further 2 ml/kg BM every 15 min during part A. Intermittent endurance capacity increased by 34 percent with ingestion of the 6 percent CHO-E solution compared with the 10 percent solution (6 ± 1 vs 4 ± 2 min), equating to a distance of 931 ± 172 versus 706 ± 272 m). There was no significant difference between the 2 percent and 6 percent or the 2 and 10 percent solutions. Carbohydrate concentration did not significantly influence mean 15-m sprint time. These results suggest that the carbohydrate concentration of an ingested solution influences the intermittent endurance capacity of adolescent team games players with a 6 percent solution significantly more effective than a 10 percent solution [11382].

One study investigated the effects of drink composition on voluntary intake, hydration status, selected physiological responses and affective states during simulated gymnasium-based exercise. In a randomised counterbalanced design, 12 physically active adults performed three 20-min intervals of cardiovascular exercise at 75 percent heart rate maximum, one 20-min period of resistance exercise and 20min of recovery with ad libitum access to water (W), a carbohydrate-electrolyte solution (CES) or with no access to fluids (NF). Fluid intake was greater with CES than W and more adequate hydration was achieved in CES trials. Plasma glucose concentrations were highest with CES. Pleasure ratings were better maintained with ad libitum intake of CES. Under conditions of voluntary drinking, CES resulted in more adequate hydration and a better maintenance of affective states than W or NF during gymnasium-based exercise [11383].

**Influence of age and pubertal status on substrate utilization**

Substrate utilization during exercise is known to differ between children and adults, but whether these differences are related to pubertal status is unclear. The objective of this study was to investigate the effects of pubertal status on endogenous (CHOendo) and orally ingested exogenous (CHOexo) carbohydrate and fat oxidation rates during exercise. Twenty boys at the same chronological age (12 years) were divided into three pubertal groups (pre-pubertal, PP: n=7; early-pubertal, EP: n=7; mid- to late-pubertal, M-LP: n=6) and consumed either a placebo or 13C-enriched 6 percent CHO drink while cycling for 60 min at approximately 70 percent of their maximal aerobic power (VO2max). Another group of 14-year-old boys (pubertal, n=9) completed all procedures. Substrate utilization was calculated for the final 15 min of exercise using indirect calorimetry and stable isotope methodology. CHOexo significantly decreased fat and increased total CHO oxidation, irrespective of group. Fat oxidation was significantly higher in younger boys than in older boys, but similar among PP,
EP, and M-LP boys. CHOexo contributed to approximately 30 percent of energy expenditure (EE) in PP and EP, but to only 24 percent in M-LP, which was identical to the older boys (24%). CHOexo oxidation rate as a percentage of EE was inversely related to testosterone levels. It was concluded that reliance on CHOexo during exercise is particularly sensitive to pubertal status, with the highest oxidation rates observed in pre- and early-pubertal boys, independent of chronological age [07273].

**Carbohydrate gel**

The aim of one study was to investigate the effects of a carbohydrate (CHO) gel on performance after prolonged intermittent high-intensity shuttle running. Seven male soccer players performed 2 exercise trials, 7 d apart. On each occasion, participants completed five 15-min periods of intermittent variable-speed running, interspersed with periods of walking (Part A), followed by an intermittent run to exhaustion (Part B). Participants consumed either a CHO gel or placebo (PLA) immediately before exercise (0.89 mL/kg body mass, BM) and every 15 min thereafter (0.35 mL/kg BM). In addition, water was consumed at a rate of 5 mL/kg BM before and 2 mL/kg BM every 15 min during exercise. Blood glucose levels were significantly higher at 15, 30, and 60 min of exercise and at exhaustion in CHO than in PLA. During Part B, run time to exhaustion was significantly longer in the CHO trial. These results indicate that ingesting a CHO gel, along with water, improves performance after prolonged intermittent running in healthy male subjects, possibly by maintaining blood glucose levels during exercise [07285].

The aim of one study was to investigate the influence of ingesting a carbohydrate (CHO) gel on the intermittent endurance capacity and sprint performance of adolescent team games players. Eleven participants (mean age 13.5 ± 0.7 years, height 1.72 ± 0.08 m, body mass 62.1 ± 9.4 kg) performed two trials separated by 3-7 days. In each trial, they completed four 15 min periods of part A of the Loughborough Intermittent Shuttle Test, followed by an intermittent run to exhaustion (part B). In the 5 min pre-exercise, participants consumed 0.818 mL/kg BM of a CHO or a non-CHO placebo gel, and a further 0.327 mL/kg BM every 15 min during part A (38.0 ± 5.5 g CHO per h in the CHO trial). Intermittent endurance capacity was increased by 21 percent during part B when the CHO gel was ingested (4.6 ± 2.0 vs 3.8 ± 2.4 min), with distance covered in part B significantly greater in the CHO trial (787 ± 319 vs 669 ± 424 m). Gel ingestion did not significantly influence mean 15 m sprint time, peak sprint time, or heart rate. Ingestion of a CHO gel significantly increases the intermittent endurance capacity of adolescent team games players during a simulated team games protocol [11387].

The aim of one study was to investigate the effects of a carbohydrate (CHO) gel on performance after prolonged intermittent high-intensity shuttle running. Seven male soccer players performed 2 exercise trials, 7 days apart. On each occasion, participants completed five 15-min periods of intermittent variable-speed running, interspersed with periods of walking (Part A), followed by an intermittent run to exhaustion (Part B). Participants consumed either a CHO gel or placebo (PLA) immediately before exercise (0.89 mL/kg body mass, BM) and every 15 min thereafter (0.35 mL/kg BM). In addition, water was consumed at a rate of 5 mL/kg BM before and 2 mL/kg BM every 15 min during exercise. Blood glucose levels were higher at 15, 30, and 60 min of exercise and at exhaustion in CHO than in PLA. During Part B, run time to exhaustion was longer in the CHO trial. These results indicate that ingesting a CHO gel, along with water, improves performance after prolonged intermittent running in healthy male subjects, possibly by maintaining blood glucose levels during exercise [07286].

**Oral carbohydrate-protein gel**
Investigators have reported improved endurance performance and attenuated post-exercise muscle damage with carbohydrate-protein beverages (CHO+P) versus carbohydrate-only beverages (CHO). However, these benefits have been demonstrated only when CHO+P was administered in beverage-form, and exclusively in male subjects. Thus, the purposes of one study were to determine if an oral CHO+P gel improved endurance performance and post-exercise muscle damage compared to a CHO gel, and determine if responses were similar between genders. Thirteen cyclists (8 men, 5 women) completed two timed cycle-trials to volitional exhaustion at 75 percent of VO2peak. At 15-minute intervals throughout these rides, subjects received CHO or CHO+P gels, which were matched for carbohydrate content (CHO = 0.15 g CHO/kg bodyweight); CHO+P = 0.15 g CHO + 0.038 g protein/kg bodyweight). Trials were performed using a randomly counterbalanced, double-blind design. Subjects rode 13 percent longer when utilizing the CHO+P gel versus the CHO gel. In addition, men and women responded similarly to the CHO and CHO+P trials, with no significant treatment-by-gender effect. Postexercise creatine kinase (CK) was not significantly different between treatments. However, CK increased significantly following exercise in the CHO trial but not the CHO+P trial. Therefore, to prolong endurance performance and prevent increases in muscle damage, it is recommended that male and female cyclists consume CHO+P gels rather than CHO gels during and immediately following exercise [07287].

*Milk*

Resistance exercise (RE) preceding the provision of high-quality dairy protein supports muscle anabolism. Milk contains bioactive components, including two high-quality protein fractions, calcium and vitamin D, each of which has been shown modulate body composition (increasing lean mass and decreasing fat mass) under energy balance and hypoenergetic conditions. These dairy nutrients are also essential for skeletal health. Acutely, no study of RE and milk/whey consumption has been undertaken exclusively in female athletes, let alone women, nevertheless, studies with both men and women show increased lean mass accretion following milk/whey compared to soy/placebo. Currently, no longer-term RE studies with milk supplementation have been done in female athletes. However, trials in young recreationally active women demonstrated augmented increases in lean mass and decreases in fat mass with RE and milk or whey protein consumption. The amount of protein consumed post-exercise is also important; two trials using yogurt (5 g protein/6 oz) failed to demonstrate a positive change in body composition compared to placebo. For bone health, RE plus dairy improved bone mineral density at clinically important sites and reduced bone resorption. With energy restriction, in one study, higher dairy plus higher protein resulted in greater fat loss, lean mass gain and improved bone health in overweight women. In another study, milk and calcium supplementation showed no greater benefit. Neither trial exclusively utilized RE. Overall, RE and milk/dairy consumption positively impact body composition in women by promoting losses in fat, gains or maintenance of lean mass and preservation of bone [12388].

Sweat is produced during exercise to help dissipate some of the extra heat produced due to an increase in metabolic rate. Inadequate drink ingestion during exercise means athletes finish exercise hypohydrated and when the time between exercise bouts is short, effective rehydration strategies will be necessary to prevent subsequent performance impairment. For complete rehydration, drink volume must be sufficient to replace sweat losses as well as the additional water losses during recovery. Once a sufficient volume of drink is ingested it is the drink composition that dictates the rehydration success of the drink. It is well known that addition of sodium and some other nutrients to rehydration drinks enhances fluid balance restoration after exercise, but the effects of milk proteins have been less well documented. Skimmed milk is an effective post-exercise rehydration solution and enhances the restoration of fluid balance after exercise-induced dehydration to a greater extent than a carbohydrate-
electrolyte sports drink. Whilst there are a number of factors in skimmed milk that might be responsible for this enhancement of rehydration, it appears that some of the effect is due to the milk protein, as milk protein has been shown to be more effective for post-exercise rehydration than an isoenergetic amount of carbohydrate. Whilst the effects of whey protein on post-exercise rehydration are equivocal, whey protein addition to a carbohydrate-electrolyte rehydration solution certainly does not impair rehydration. Therefore, in situations where protein ingestion after exercise might be advantageous for the athlete, this protein might also enhance restoration of fluid balance [12389].

It has been found that ingestion of intrinsically labeled soy and milk proteins resulted in greater incorporation of nitrogen into serum proteins and urea when soy was ingested. The suggestion from these results, and from a modeling approach, was that proteins from soy are directed toward splanchnic metabolism, whereas milk proteins are directed to peripheral sites. It has also been shown that when milk and soy proteins are ingested after resistance exercise, milk protein resulted in a more positive net amino acid balance and a greater postexercise stimulation of protein synthesis. The acute findings observed should result, over the longer term, in a greater increase in muscle protein accrual with regular milk than with soy protein consumption. It was thus aimed to determine the long-term consequences of milk or soy protein or equivalent energy consumption on training-induced lean mass accretion. It was recruited 56 healthy young men who trained 5 d/week for 12 weeks on a rotating split-body resistance exercise program in a parallel 3-group longitudinal design. Subjects were randomly assigned to consume drinks immediately and again 1 h after exercise: fat-free milk (Milk; n=18); fat-free soy protein (Soy; n=19) that was isoenergetic, isonitrogenous, and macronutrient ratio matched to Milk; or maltodextrin that was isoenergetic with Milk and Soy (control group; n=19). Muscle fiber size, maximal strength, and body composition by dual-energy X-ray absorptiometry (DXA) were measured before and after training. No between-group differences were seen in strength. Type II muscle fiber area increased in all groups with training, but with greater increases in the Milk group than in both the Soy and control groups. Type I muscle fiber area increased after training only in the Milk and Soy groups, with the increase in the Milk group being greater than that in the control group. DXA-measured fat- and bone-free mass increased in all groups, with a greater increase in the Milk group than in both the Soy and control groups. The data show that the chronic consumption of fluid skim milk (500 mL) immediately and 1 h after resistance exercise promoted greater gains in FBFM (i.e. lean mass) than consumption of either an isonitrogenous, isoenergetic, and macronutrient ratio-matched soy protein-containing beverage or an isoenergetic carbohydrate drink. It was also observed a greater reduction in body fat mass associated with chronic postexercise milk consumption. On the basis of these results, extrapolations would predict that someone would gain twice as much lean mass with milk consumption as opposed to soy consumption, if only leg exercises were performed during a training program. Thus, it would appear that the acute findings may overestimate the magnitude of the effect in terms of differences in muscle protein accretion seen with soy and milk ingestion after exercise. Work comparing milk proteins with isolated whey and casein proteins indicates that postprandial nitrogen utilization with milk proteins may support greater anabolism than either isolated protein alone. The reason for this difference was not readily apparent, but in light of other data showing the superiority of milk proteins, including isolated casein. However, supplementation of soy protein with BCAAs can alter interorgan amino acid fluxes to favor muscle protein anabolism in aged and patient populations, whether this would be true in young persons under conditions of exercise-induced anabolism is not known. Hence, the data presented here, combined with previous data from chronic studies manipulating postexercise protein consumption, support the general thesis that immediate consumption of protein, particularly milk protein, after resistance exercise serves to maximize exercise-induced increases in muscle mass. In conclusion, immediate and 1-h postexercise milk consumption, as opposed to soy or isoenergetic carbohydrate, resulted in greater gains
in FBFM and type II muscle fiber area. Increases in type I muscle fiber area were greater in the Milk and the Soy groups than in the control group. All groups showed increased strength as a result of the training program; however, there were no between-group effects. A greater fat mass loss was seen in subjects who consumed the postexercise milk supplement than in both the Soy and control groups, which may be related to dietary calcium intake or an endogenous property of the milk proteins themselves [07309].

The effectiveness of low-fat milk, alone and with an additional 20 mmol/l NaCl, at restoring fluid balance after exercise-induced hypohydration was compared to a sports drink and water. After losing 1.8 percent of their body mass during intermittent exercise in a warm environment, eleven subjects consumed a drink volume equivalent to 150 percent of their sweat loss. Urine samples were collected before and for 5 h after exercise to assess fluid balance. Urine excretion over the recovery period did not change during the milk trials whereas there was a marked increase in output between 1 and 2 h after drinking water and the sports drink. Cumulative urine output was less after the milk drinks were consumed (611 and 550 mL for milk and milk with added sodium, respectively, compared to 1184 and 1205 mL for the water and sports drink). Subjects remained in net positive fluid balance or euhydrated throughout the recovery period after drinking the milk drinks but returned to net negative fluid balance 1 h after drinking the other drinks. The results of the present study suggest that milk can be an effective post-exercise rehydration drink and can be considered for use after exercise by everyone except those individuals who have lactose intolerance [07310].

Exercise-induced muscle damage (EIMD) leads to increases in intramuscular proteins observed in the blood stream and delayed onset of muscle soreness, but crucial for athletes are the decrements in muscle performance observed. Previous research has demonstrated that carbohydrate-protein supplements limit these decrements; however, they have primarily used isokinetic dynamometry, which has limited applicability to dynamic sport settings. Therefore, the aim of this study was to investigate the effects of a carbohydrate-protein milk supplement consumed after muscle-damaging exercise on performance tests specific to field-based team sports. Two independent groups of seven males consumed either 500 mL of milk or a control immediately after muscle-damaging exercise. Passive and active delayed onset of muscle soreness, creatine kinase, myoglobin, countermovement jump height, reactive strength index, 15 m sprint, and agility time were assessed before and 24, 48, and 72 h after EIMD. The Loughborough Intermittent Shuttle Test was also performed before and 48 h after EIMD. At 48 h, milk had a possible benefit for limiting increases in 10m sprint time and a likely benefit of attenuating increases in mean 15-m sprint time during the Loughborough Intermittent Shuttle Test. At 72 h, milk had a possible benefit for limiting increases in 15-m sprint time and a likely benefit for the attenuation of increases in agility time. All other effects for measured variables were unclear. It was concluded that the consumption of milk limits decrements in one-off sprinting and agility performance and the ability to perform repeated sprints during the physiological simulation of field-based team sports [13626].

One study investigated the relationship between the milk protein content of a rehydration solution and fluid balance after exercise-induced dehydration. On three occasions, eight healthy males were dehydrated to an identical degree of body mass loss (BML, approximately 1.8 %) by intermittent cycling in the heat, rehydrating with 150 percent of their BML over 1 h with either a 60 g/L carbohydrate solution (C), a 40 g/L carbohydrate, 20 g/L milk protein solution (CP20) or a 20 g/L carbohydrate, 40 g/L milk protein solution (CP40). Urine samples were collected pre-exercise, post-exercise, post-rehydration and for a further 4 h. Subjects produced less urine after ingesting the CP20 or CP40 drink compared with the C drink, and at the end of the study, more of the CP20 (59 %) and CP40 (64 %) drinks had been retained compared with the C drink (46 %). At the end of the study, whole-body net
fluid balance was more negative for trial C (-470 mL) compared with both trials CP20 (-181 mL) and CP40 (2107 mL). At 2 and 3 h after drink ingestion, urine osmolality was greater for trials CP20 and CP40 compared with trial C. The present study further demonstrates that after exercise-induced dehydration, a carbohydrate--milk protein solution is better retained than a carbohydrate solution. The results also suggest that high concentrations of milk protein are not more beneficial in terms of fluid retention than low concentrations of milk protein following exercise-induced dehydration [13627].

**Milk minerals**

Despite a high content of saturated fat, evidence from observational studies indicates that the consumption of dairy products may have a neutral effect or may be inversely associated with the risk of CVD. We aimed to examine whether milk minerals modify the effect of saturated fat on serum lipid profile. It was presented data from two studies. Study I had a randomised, blinded, parallel design (n 24 pigs) with a 10 d adaptation period during which a high-fat diet was fed to the pigs and a 14 d intervention period during which the same diet either enriched with milk minerals (MM group) or placebo (control group) was fed to the pigs. Study II had a randomised cross-over design (n 9 men) where the subjects were fed either a high-fat diet enriched with milk minerals (MM period) or a regular diet (control period). In both the studies, blood variables were measured before and after the intervention and faecal and urine samples were collected at the end of the dietary periods. The increase in plasma total cholesterol and LDL-cholesterol concentrations but not in HDL-cholesterol concentration was markedly lowered by milk minerals in both the studies. In the animal study, baseline adjusted total cholesterol and LDL-cholesterol concentrations in the MM group were 11 percent and 13 percent) lower compared with those in the control group after the intervention. Similarly in the human study, baseline adjusted total cholesterol and LDL-cholesterol concentrations were 6 percent and 9 percent lower after the MM period compared with those in the control period. HDL-cholesterol concentration was not lowered by milk minerals. These short-term studies indicate that the addition of milk minerals to a high-fat diet to some extent attenuates the increase in total cholesterol and LDL-cholesterol concentrations, without affecting HDL-cholesterol concentration [13630].

**Fermented milk**

One study investigated the effect of fermented milk supplementation on glucose metabolism associated with muscle damage after acute exercise in humans. Eighteen healthy young men participated in each of the three trials of the study: rest, exercise with placebo, and exercise with fermented milk. In the exercise trials, subjects carried out resistance exercise consisting of five sets of leg and bench presses at 70-100 percent 12 repetition maximum. Examination beverage (fermented milk or placebo) was taken before and after exercise in double-blind method. On the following day, we conducted an analysis of respiratory metabolic performance, blood collection, and evaluation of muscle soreness. Muscle soreness was significantly suppressed by the consumption of fermented milk compared with placebo. Serum creatine phosphokinase was significantly increased by exercise, but this increase showed a tendency of suppression after the consumption of fermented milk. Exercise significantly decreased the respiratory quotient, although this decrease was negated by the consumption of fermented milk. Furthermore, exercise significantly reduced the absorption capacity of serum oxygen radical although this reduction was not observed with the consumption of fermented milk. The results suggest that fermented milk supplementation improves glucose metabolism and alleviates the effects of muscle soreness after high-intensity exercise, possibly associated with the regulation of antioxidant capacity [13631].

**Effects depending on exercise status**

It has been suggested that milk protein intake for the improvement of metabolic health. 1697
However, the authors missed important insights into branched-chain amino acid (BCAA) metabolism under conditions of obesity and insulin resistance. They emphasized beneficial effects of milk protein ingestion for skeletal muscle but ignored adverse effects of BCAAs on adipose tissue and long-term beta-cell homeostasis. Obviously, milk’s physiological function promoting neonatal growth is not restricted to the musculoskeletal system. It is the intention of this perspective article to demonstrate that the evaluation of metabolic effects of milk protein consumption has to consider the nutritional and endocrine status and the level of physical activity of the milk protein consumer. Plasma BCAAs (leucine, isoleucine, valine) and glutamine/glutamate are increased in obesity, insulin resistance and type 2-diabetes (T2D). An extra daily intake of 53 g milk protein but not 53 g meat increased serum insulin and insulin resistance in 8-year-old boys. Impaired BCAA catabolism of adipocytes is a crucial metabolic deviation of obesity. As BCAA plasma levels in obesity are already elevated an additional BCAA influx may further deteriorate the pre-existing metabolic imbalance. In fact, the marked decrease in BCAA plasma levels resulting from gastric bypass surgery is associated with weight loss and improved insulin sensitivity. Palaeolithic, physically active hunter-gatherers consumed structural proteins like fish and meat. In contrast, modern Neolithic humans have “mutated” into physically inactive individuals, who particularly consume signalling proteins from milk providing abundant “fast dietary proteins” leading to high plasma BCAA and glutamine levels. Palaeolithic dairy-free diets exhibit lower insulin levels with improved insulin sensitivity protecting against the development of diseases of civilization. Milk protein consumption results in postprandial hyperinsulinemia in obese subjects, increases body weight of overweight adolescents and may thus deteriorate pre-existing metabolic disturbances of obese, insulin resistant individuals [13628].

Chocolate milk

An optimal post-exercise nutrition regimen is fundamental for ensuring recovery. Therefore, research has aimed to examine post-exercise nutritional strategies for enhanced training stimuli. Chocolate milk has become an affordable recovery beverage for many athletes, taking the place of more expensive commercially available recovery beverages. Low-fat chocolate milk consists of a 4:1 carbohydrate:protein ratio (similar to many commercial recovery beverages) and provides fluids and sodium to aid in post-workout recovery. Consuming chocolate milk (1.0-1.5 g/kg/h) immediately after exercise and again at 2 h post-exercise appears to be optimal for exercise recovery and may attenuate indices of muscle damage. Future research should examine the optimal amount, timing, and frequency of ingestion of chocolate milk on post-exercise recovery measures including performance, indices of muscle damage, and muscle glycogen resynthesis [12390].

Exercise-induced muscle damage (EIMD) leads to decrements in muscle performance, increases in intramuscular proteins and delayed-onset of muscle soreness (DOMS). Previous research demonstrated that one litre of milk-based protein-carbohydrate (CHO) consumed immediately following muscle damaging exercise can limit changes in markers of EIMD possibly due to attenuating protein degradation and/or increasing protein synthesis. If the attenuation of EIMD is derived from changes in protein metabolism then it can be hypothesised that consuming a smaller volume of CHO and protein will elicit similar effects. Three independent matched groups of 8 males consumed 500 mL of milk, 1,000 mL of milk or a placebo immediately following muscle damaging exercise. Passive and active DOMS, isokinetic muscle performance, creatine kinase (CK), myoglobin and interleukin-6 were assessed immediately before and 24, 48 and 72 h after EIMD. After 72 h 1,000 mL of milk had a likely benefit for limiting decrements in peak torque compared to the placebo. After 48 h, 1,000 mL of milk had a very likely benefit of limiting increases in CK in comparison to the placebo. There were no differences between consuming 500 or 1,000 mL of milk for changes in peak torque and CK. In conclusion, decrements in isokinetic muscle performance and
increases in CK can be limited with the consumption of 500 mL of milk [12086].

To maximize training quality, athletes have sought nutritional supplements that optimize recovery. This study compared chocolate milk (CHOC) with a carbohydrate replacement beverage (CRB) as a recovery aid after intense exercise, regarding performance and muscle damage markers in trained cyclists. Ten regional-level cyclists and triathletes completed a high-intensity intermittent exercise protocol, then 15-18 h later performed a performance trial at 85 percent of maximal oxygen uptake to exhaustion. Participants consumed 1.0 g carbohydrate/kg/h of a randomly assigned isocaloric beverage (CHOC or CRB) after the first high-intensity intermittent exercise session. The same protocol was repeated 1 week later with the other beverage. A 1-way repeated measures analysis of variance revealed no significant difference between trials for time to exhaustion at 85 percent of maximal oxygen uptake. The change in creatine kinase (CK) was significantly greater in the CRB trial than in the CHOC trial with differences not significant for CK levels before the second exercise session between the two trials. These findings indicate no difference between CHOC and this commercial beverage as potential recovery aids for cyclists between intense workouts [09337].

One study examined the effects of 3 recovery drinks on endurance performance following glycogen-depleting exercise. Nine trained male cyclists performed 3 experimental trials, in a randomized counter-balanced order, consisting of a glycogen-depleting trial, a 4-h recovery period, and a cycle to exhaustion at 70 percent power at maximal oxygen uptake. At 0 and 2 h into the recovery period, participants consumed chocolate milk, a carbohydrate replacement drink, or a fluid replacement drink. Participants cycled 51 percent and 43 percent longer after ingesting chocolate milk (32 ± 11 min) than after ingesting carbohydrate replacement drink (21 ± 8 min) or fluid replacement drink (23 ± 8 min). Chocolate milk is an effective recovery aid after prolonged endurance exercise for subsequent exercise at low-moderate intensities [09338].

Flavanol content
Dietary flavanols have been associated with reduced oxidative stress, however their efficacy in promoting recovery after exercise induced muscle damage is unclear. This study examined the effectiveness of acute consumption of cocoa-flavanols on indices of muscle recovery including: subsequent exercise performance, creatine kinase, muscle tenderness, force, and self-perceived muscle soreness. Eight endurance-trained athletes (VO2max 64 ± 8 mL/kg/min) completed a downhill running protocol to induce muscle soreness, and 48 h later completed a 5-K (kilometer) time trial. Muscle recovery measurements were taken at PRE, 24 h-POST, 48 h-POST, and POST-5K. Participants consumed 1.0 g of carbohydrate per kilogram of body weight of a randomly assigned beverage (CHOC: 0 mg flavanols vs CocoaCHOC: 350 mg flavanols per serving) immediately after the downhill run and again 2 h later. The same protocol was repeated three weeks later with the other beverage. An ANOVA revealed no significant difference between trials for 5 K completion time. No significant difference was found for creatine kinase (CK) levels, or muscle soreness between groups over time. These findings suggest that the acute addition of cocoa flavanols to low-fat chocolate milk offer no additional recovery benefits [13629].

Raisens
It was examined the metabolic, performance and gastrointestinal (GI) effects of supplementation with a natural food product (raisins) compared to a commercial product (sport chews). Eleven male (29 years) runners completed three randomized trials (raisins, chews and water only) separated by seven days. Each trial consisted of 80-min (75 %
VO$_2_{\text{max}}$ treadmill running followed by a 5-km time trial (TT). Heart rate (HR), respiratory exchange ratio (RER), blood lactate, serum free fatty acids (FFA), glycerol and insulin, plasma glucose and creatine kinase, GI symptoms and rating of perceived exertion (RPE) were recorded every 20-min. VO$_2$, HR, lactate, glycerol and RPE did not differ due to treatment. Average plasma glucose was maintained at resting levels during the sub-maximal exercise bout, and was significantly higher with chews than water only. RER and percent of non-protein macronutrient oxidation derived from carbohydrate was highest with chews, followed by raisins and water was the lowest during the sub-maximal exercise period. Serum FFA was higher in the water treatment versus both raisins and chews at 80 min of sub-maximal exercise. Serum insulin was higher with the chews than both raisins and water. Plasma creatine kinase, corrected for baseline values, for the last 40 min of the sub-maximal exercise bout, was higher with raisins compared to other treatments. The TT was faster for both carbohydrate supplements. GI disturbance was mild for all treatments. It was concluded that raisins and chews promoted higher carbohydrate oxidation and improved running performance compared to water only. Running performance was similar between the raisins and chews, with no significant GI differences [12397].

The purpose of one study was to examine the effects of a natural carbohydrate (CHO) source in the form of sun-dried raisins versus Sports Jelly Beans™ on endurance performance in trained cyclists and triathletes. Ten healthy men (18-33 years) completed 1 water-only acclimatization exercise trial and 2 randomized exercise trials administered in a crossover fashion. Each trial consisted of a 120-minute constant-intensity glycogen depletion period followed by a 10-km time trial (TT). During each experimental trial, participants consumed isocaloric amounts of sun-dried raisins or Sports Jelly Beans in 20-minute intervals. Measurements included time to complete 10-km TT, power output during 10-km TT, blood glucose levels and respiratory exchange ratio during glycogen depletion period, rate of perceived exertion (RPE), flow questionnaire responses, and a hedonic (i.e. pleasantness) sensory acceptance test. There were no significant differences in endurance performance for TT time or power, resting blood glucose levels, RPE, or flow experiences between sun-dried raisins and Sports Jelly Beans trials. However, the mean sensory acceptance scores were significantly higher for the sun-dried raisins compared to the beans. Consuming sun-dried raisins or Sports Jelly Beans during 120 minutes of intense cycling results in similar subsequent TT performances and are equally effective in maintaining blood glucose levels during exercise. Therefore, raisins are a natural, pleasant, cost-effective CHO alternative to commercial SJBs that can be used during moderate- to high-intensity endurance exercise [11527].

Research suggests that pre-exercise sources of dietary carbohydrate with varying glycemic indexes may differentially affect metabolism and endurance. One study was designed to examine potential differences in metabolism and cycling performance after consumption of moderate glycemic raisins vs. a high glycemic commercial sports gel. Eight endurance-trained male (n=4) and female (n=4) cyclists 30 ± 5 years of age completed two trials in random order. Subjects were fed 1 g carbohydrate per kilogram body weight from either raisins or sports gel 45 minutes prior to exercise on a cycle ergometer at 70 percent VO$_2_{\text{max}}$. After 45 minutes of submaximal exercise, subjects completed a 15-minute performance trial. Blood was collected prior to the exercise bout, as well as after the 45th minute of exercise, to determine serum concentrations of glucose, insulin, lactate, free fatty acids (FFAs), triglycerides, and beta-hydroxybutyrate. Performance was not different between the raisin and gel trials. Prior to exercise, serum concentrations of glucose and other fuel substrates did not differ between trials; however, insulin was higher for the gel versus raisin trial. After 45 minutes of exercise, insulin decreased to 14.2 ± 6.2 microU/mL and 13.3 ± 18.9 microU/mL for gel and raisin trials, respectively. The FFA concentration increased significantly during the raisin trial. Overall, minor differences in metabolism and no difference
in performance were detected between the trials. Raisins appear to be a cost-effective source of carbohydrate for pre-exercise feeding in comparison to sports gel for short-term exercise bouts [07288].

Research suggests that pre-exercise sources of dietary carbohydrate with varying glycemic indexes may differentially affect metabolism and endurance. One study was designed to examine potential differences in metabolism and cycling performance after consumption of moderate glycemic raisins vs. a high glycemic commercial sports gel. Eight endurance-trained male (n=4) and female (n=4) cyclists 30 years of age completed 2 trials in random order. Subjects were fed 1 g carbohydrate per kilogram body weight from either raisins or sports gel 45 minutes prior to exercise on a cycle ergometer at 70 percent VO2max. After 45 minutes of submaximal exercise, subjects completed a 15-minute performance trial. Blood was collected prior to the exercise bout, as well as after the 45th minute of exercise, to determine serum concentrations of glucose, insulin, lactate, free fatty acids (FFAs), triglycerides, and beta-hydroxybutyrate. Performance was not different between the raisin and gel trials. Prior to exercise, serum concentrations of glucose and other fuel substrates did not differ between trials; however, insulin was higher for the gel. After 45 minutes of exercise, insulin decreased for gel and raisin trials, respectively. The FFA concentration increased significantly during the raisin trial. Overall, minor differences in metabolism and no difference in performance were detected between the trials. Raisins appear to be a cost-effective source of carbohydrate for pre-exercise feeding in comparison to sports gel for short-term exercise bouts [07289].

Fruits and vegetables

Regular consumption of fruits and vegetables (FV) is widely regarded as an important contributor to a healthy diet. Inadequate consumption of plant foods is associated with an inadequate supply of important micronutrients like vitamins, phytochemicals and minerals. In athletes a deficit of these micronutrients can lead to excessive production of reactive oxygen and nitrogen species that induce tissue damage, a higher frequency of inflammatory processes, decreased immunity, increased susceptibility to injury, and prolonged recovery. But many athletes rarely achieve the recommended intake of FV due to difficult coordination of training activities and food intake, or to due to problems with digestion of FV. Therefore, in recent years more and more sports people have adopted supplemental FV concentrates to work around timing problems with uptake and the detrimental digestive effects during training of high FV intake. It is thought that supplementation of an athlete's basic diet with mixed FV concentrates can promote stable health and immunity, in order to provide a basis for optimal adaptation and performance. The intention of one article was to build a bridge between the science behind FV supplementation in exercise on the one hand and the practical relevance of its application on the other. For that purpose this paper addresses three questions: Is supplementation with a mixed FV concentrate to the athlete's diet appropriate to ensure stable health and immunity? Can supplementation with a mixed FV concentrate improve performance? Counseling guidance: how can sport nutrition advisors decide whether or not to supplement with mixed FV concentrates? [12393].

Cornstarch

The purpose of one study was to investigate differences in substrate oxidation between dextrose (DEX) and unmodified (UAMS) and acid/alcohol-modified (MAMS) cornstarches. Seven endurance-trained men participated in 2 h of exercise (66 % VO2peak) 30 min after ingesting 1 g/kg body weight of the experimental carbohydrate or placebo (PLA). Plasma glucose and insulin were elevated after DEX compared with UAMS, MAMS, and PLA.
Although MAMS and DEX significantly raised carbohydrate oxidation rate through 90 min of exercise, only MAMS persisted throughout 120 min. Exogenous-carbohydrate oxidation rate was higher in DEX than in MAMS and UAMS until 90 min of exercise. Acid/alcohol modification resulted in augmented carbohydrate oxidation with a small, sustained increase in exogenous-carbohydrate oxidation rate. MAMS appears to be metabolizable and available for oxidation during exercise [07290].

**Hydroxypropyl-distarch**

The aim of one study was to investigate the effects of hydroxypropyl-distarch phosphate (HDP) supplementation on postprandial energy metabolism and glucose-dependent insulinoetric polyepetide (GIP) in human subjects. A total of ten healthy male subjects, with a mean BMI of 24 kg/m², age 35 years and body weight 71 kg, participated in a randomised, cross-over, intervention study with two different test meals (1674 kJ) containing either waxy maize starch or HDP from waxy maize starch (degree of substitution 0.15, P content 0.004 %). Resting energy expenditure (REE) and blood concentrations of various biomarkers were measured at fasting and up to 180 min postprandially. Indirect calorimetry showed that the HDP meal caused higher REE and fat utilisation than the waxy maize starch meal. The HDP meal led to significantly lower postprandial glucose, insulin and GIP responses than the waxy maize starch meal. Both postprandial REE and fat utilisation were negatively correlated with the postprandial GIP response, but not with the glucose and insulin responses. In conclusion, dietary supplementation with HDP lowers postprandial GIP and increases postprandial REE and fat utilisation in healthy humans. An HDP-rich diet may therefore have beneficial implications in weight management [11399].

**Honey-sweetened beverage**

One study compared the effect of a honey-sweetened beverage with those of a commercial sports drink and a placebo on performance and inflammatory response to a 90-min soccer simulation. Ten experienced male soccer players randomly performed 3 trials (honey [H], sports drink [S], and placebo [P]), consuming the beverage before and during halftime for a total of 1.0 g/kg carbohydrate for H and S. Performance measures included 5 sets (T1-T5) of a high-intensity run and agility and ball-shooting tests followed by a final progressive shuttle-run test to exhaustion. Blood samples were drawn pretest, posttest (B2), and 1 hr posttest (B3) for markers of inflammation, oxygen radical absorbance capacity, and hormone response. T2-T5 were significantly slower than T1, and a decrease in progressive shuttle-run time was observed from baseline (-23 %) for all treatments. No significant effect of the interventions was observed for any performance measures. Plasma IL-1ra levels increased posttest for all treatments, but H was significantly less than S at posttest and P at B3. Other cytokines and ORAC increased at B2 with no difference by treatment. Acute ingestion of honey and a carbohydrate sports drink before and during a soccer-simulation test did not improve performance, although honey attenuated a rise in IL-1ra. Ingestion of carbohydrate and/or antioxidant-containing beverages at frequencies typical of a regulation match may not be beneficial for trained soccer players [09339].

**Low-carbohydrate diets and performance**

Athletes are continually searching for means to optimize their performance. Within the past 20 years, athletes and scientists have reported or observed that consuming a carbohydrate-restricted diet may improve performance. The original theories explaining the purported benefits centered on the fact that fat oxidation increases, thereby "sparing" muscle glycogen. More recent concepts that explain the plausibility of the ergogenicity of low-carbohydrate, or
high-fat, diets on exercise performance pertain to an effect similar to altitude training. We and others have observed that although fat oxidation may be increased, the ability to maintain high-intensity exercise (above the lactate threshold) seems to be compromised or at least indifferent when compared with consumption of more carbohydrate. That said, clinical studies clearly demonstrate that ad libitum low-carbohydrate diets elicit greater decreases in body weight and fat than energy-equivalent low-fat diets, especially over a short duration. Thus, although low-carbohydrate and high-fat diets appear detrimental or indifferent relative to performance, they may be a faster means to achieve a more competitive body composition [07299].

It has been speculated that dietary carbohydrate restriction is solely responsibly for mobilization of endogenous lipid stores, elevation of plasma free fatty acid (FFA) concentration, and an associated reduction in insulin sensitivity seen in starvation and low-carbohydrate diets. In 6 healthy men, dietary carbohydrate was eliminated but gluconeogenic substrate supply was maintained by 3 days of very low-carbohydrate/high-protein (HPLC) diet. Results were compared with 3-day starvation and 3-day mixed-carbohydrate diet. Intramyocellular lipid (IMCL) concentration was measured by \(^1\text{H}\) magnetic resonance spectroscopy, and insulin sensitivity was determined by intravenous glucose tolerance test. Fasting plasma glucose was significantly reduced, whereas IMCL to water ratio and fasting were significantly elevated after starvation but were unchanged after HPLC. Minimal model insulin sensitivity was significantly reduced after starvation. Plasma glucose, plasma FFAs, IMCLs, and insulin sensitivity are maintained when an HPLC diet is consumed, despite other forms of carbohydrate deprivation producing marked changes in these measures. It was conclude that dietary carbohydrate restriction does not cause circulating FFA to become elevated. However, it remains possible that circulating carbohydrate status has an important influence on plasma FFA and therefore insulin sensitivity in healthy people [10233].

Grain-based
To illustrate the effects of low-carbohydrate (LC) and grain-based (GB) diets on body composition, biomarkers, athletic training, and performance in an elite triathlete athlete followed 2 dietary interventions for 14 days while maintaining a prescheduled training program. Pre- and postintervention measurements for each diet included plasma and serum samples, resting energy expenditure, body composition, and a performance bike ride. Compared with the GB diet, the LC diet elicited more disruptions to training and unfavorable subjective experiences. Total cholesterol, HDL cholesterol, LDL cholesterol, ratings of perceived exertion, and heart rate were elevated on the LC diet. Blood insulin, resting lactate, postexercise lactate, and C-reactive protein were lowest on the LC diet. It was concluded that the LC diet resulted in both favorable and unfavorable outcomes. The primary observation was a disruption to scheduled training on the LC diet. Researchers should consider how the potential mediating effect of disruptions to training could influence pretest-posttest designs [07300].

Low energy
Energy availability is the amount of dietary energy remaining after exercise training for all other metabolic processes. Excessively low energy availability impairs reproductive and skeletal health, although genetics and age may alter an individual's initial conditions and sensitivity when low energy availability is imposed. Many marathon runners and other endurance athletes reduce energy availability either intentionally to modify body size and composition for improving performance; compulsively in a psychopathological pattern of disordered eating; or inadvertently because there is no strong biological drive to match energy intake to activity-induced energy expenditure. Inadvertent low energy availability is more extreme when consuming a low fat, high carbohydrate diet. Low energy availability, reproductive disorders, low bone mineral density and stress fractures are more common in
female than male athletes. Functional menstrual disorders caused by low energy availability should be diagnosed by excluding diseases that also disrupt menstrual cycles. To determine energy availability (in units of kilocalories or kilojoules per kilogram of fat-free mass), athletes can record their diets and use diet analysis software to calculate energy intake, measure energy expenditure during exercise using a heart monitor and measure fat-free mass using a bioelectrical impedance body composition scale. All are commercially available at consumer prices [07301].

**High and low glycaemic index recovery diets**

Intramyocellular lipid (IMCL) and plasma NEFA are important skeletal muscle fuel sources. By raising blood insulin concentrations, carbohydrate ingestion inhibits lipolysis and reduces circulating NEFA. We hypothesised that differences in the postprandial glycaemic and insulin response to carbohydrates (i.e. glycaemic index; GI) could alter NEFA availability and IMCL use during subsequent exercise. Endurance-trained individuals (n 7) cycled for 90 min at 70 % VO2peak and then consumed either high GI (HGI) or low GI (LGI) meals over the following 12 h. The following day after an overnight fast, the 90 min cycle was repeated. IMCL content of the vastus lateralis was quantified using magnetic resonance spectroscopy before and after exercise. Blood samples were collected at 15 min intervals throughout exercise and analysed for NEFA, glycerol, glucose, insulin, and lactate. Substrate oxidation was calculated from expired air samples. The 90 min cycle resulted in >2-fold greater reduction in IMCL in the HGI trial (3.5 (sem 1.0) mm/kg wet weight) than the LGI trial (1.6 mm/kg wet weight). During exercise, NEFA availability was reduced in the HGI trial compared to the LGI trial (area under curve 2.36 mEq/l per h vs 3.14 mEq/l per h, respectively). No other differences were significant. The findings suggest that HGI carbohydrates reduce NEFA availability during exercise and increase reliance on IMCL as a substrate source during moderate intensity exercise [07302].

**Carbohydrate loading effect of menstrual-cycle phase**

One study compared 3 d of carbohydrate loading (CHOL; 8.4 g carbohydrate per kg and day) in female eumenorrheic athletes with 3 d of an isoenergetic normal diet (NORM; 5.2 g carbohydrate per kg and day) and examined the effect of menstrual-cycle phase on performance, muscle-glycogen concentration [glyc], and substrate utilization. Nine moderately trained eumenorrheic women cycled in an intermittent protocol varying in intensity from 45 to 75 percent VO2max for 75 min, followed by a 16-km time trial at the midfollicular (MF) and midluteal (ML) phases of the menstrual cycle on NORM and CHOL. Time-trial performance was not affected by diet or menstrual-cycle phase. Resting [glyc] was lowest in the MF phase after NORM compared with the MF phase after CHOL and the ML phase after CHOL and NORM. No effect of phase on substrate utilization during exercise was observed. These data support previous observations of greater resting [glyc] in the ML than the MF phase of the menstrual cycle and suggest that lower glycogen storage in the MF phase can be overcome by carbohydrate loading [07303].

**Effects of carbohydrate beverage ingestion on the salivary IgA**

The purpose of one study was to establish if provision of carbohydrates altered the mucosal immune and salivary cortisol responses to intermittent exercise in the heat. In a double-blind design, 10 males undertook soccer-specific intermittent exercise on a motorized treadmill on 2 occasions, each over 90 min and separated by 1 week. During CHO and placebo trials, subjects were given either a carbohydrate solution (3 ml/kg body weight) or placebo drink, 5 min before the commencement of exercise, at 15, 30 min, at half time, 60 and 75 min into exercise. Salivary flow rate increased throughout the placebo trial and decreased throughout
the CHO treatment; the difference between conditions neared statistical significance. Neither s-IgA concentration nor s-IgA to osmolality ratio was affected by 2 conditions or differed at any time-point post-exercise. The s-IgA secretion rate increased, s-IgA to protein ratio decreased post-exercise and salivary cortisol decreased 24 h post-exercise compared to pre-exercise. Carbohydrate supplementation whilst exercising in the heat, does not influence rating of perceived exertion, thermal sensation, salivary flow rate, s-IgA concentration, s-IgA secretion rate, s-IgA to osmolality ratio or s-IgA to protein ratio and salivary cortisol but heart rate was increased [11385].

**Carbohydrate in young adolescents**

One study examined the effect of preexercise carbohydrate (CHO) feeding on performance on a Wingate anaerobic test (WAnT) in 11 boys (10 ± 1 years old). Four WAnTs with 2 min recovery were performed 30 min after consuming a CHO (1 g CHO/kg) or placebo drink. Peak power (PP) and mean power (MP) were similar between trials. The study found that the ingestion of a CHO solution before exercise did not influence power output during repeated performances of the WAnT [07304].

**Glucose polymers**

It was previously reported no difference in the oxidation rate of a high molecular weight glucose polymer (GP) versus maltodextrin (8 kDa) during exercise; however, the ingestion rate (1.8 g/min) was above the glucose absorption-oxidation maxima (about 1.0 g/min), possibly masking either faster gastric emptying of the GP and delivery to the circulation observed at rest or physical properties of the GP that might slow intestinal absorption. Therefore, we asked whether GP oxidation could be differentially affected when ingested at a lower rate (0.8 g/min). Eight cyclists performed three 150-min rides at 50 percent peak power while ingesting solutions containing 8 percent GP (500-750 kDa, 21 mosm/kg), 8 percent glucose (469 mosm/kg), or water. The exogenous carbohydrate oxidation rate was determined using stable isotope methodology and indirect calorimetry. Glucose and GP were oxidized on average at 0.54 g/min and 0.41 g/min, respectively, which equated to a moderate (effect size) reduction of 24 percent with GP. The endogenous carbohydrate oxidation rate with glucose (1.04 g/min) was not clearly different from GP (15 %) and total carbohydrate oxidation rate was not affected. Plasma glucose concentration was 8 percent lower and nausea 0.4 units higher with GP versus glucose. To conclude, the oxidation rate of GP when ingested below the glucose absorption-oxidation maxima is slower than glucose. Further work could determine the physical properties of the carbohydrate and (or) physiological mechanism determining this response. Meanwhile, utility of the glucose polymer over glucose or maltodextrin in energy beverages appears limited [11255].

**Carbohydrate effect on oxidative changes**

Carbohydrate administration during exercise diminishes stress hormone release, but the relationship of these hormones with oxidative stress has not been examined. Fifteen subjects functioned as their own controls and ingested carbohydrate (6 %) or placebo in a randomized design while cycling for 2.5-h approximately 75 % VO2peak). Blood and skeletal muscle samples were collected 30 min pre-exercise, immediately post-exercise, and 12-h post-exercise and analyzed for F (2)-isoprostanes, ferric reducing ability of plasma, glucose, insulin, cortisol, epinephrine, and muscle glycogen, respectively. Statistical design was a 2 (treatment) x 3 (time) repeated measures analysis of variance. Glucose, insulin, and ferric reducing ability of plasma were significantly higher and F (2)-isoprostanes, cortisol, and epinephrine significantly lower in carbohydrate versus placebo. The decrease in muscle
glycogen was not different. During cycling exercise, oxidative stress appears to be heavily influenced by carbohydrate ingestion and increased stress hormones [07294].

Increased lactate (decreased lipolysis) due to carbohydrates

The present study evaluated the acute effects of carbohydrate supplementation on heart rate (HR), rate of perceived exertion (RPE), metabolic and hormonal responses during and after sessions of high-intensity intermittent running exercise. Fifteen endurance runners (26 years) performed two sessions of intermittent exercise under carbohydrate (CHO) and placebo (PLA) ingestion. The sessions consisted of 12 x 800 m separated by intervals of 1 min 30 s at a mean velocity corresponding to the previously performed 3-km time trial. Both the CHO and PLA sessions were concluded within approximately 28 min. Blood glucose was significantly elevated in both sessions and mean blood lactate was significantly higher in the CHO than in the PLA condition. The metabolic stress induced by the exercise model used was confirmed by the elevated HR (approximately 182 bpm) and RPE (approximately 18 on the 15-point Borg scale) for both conditions. No significant differences in plasma insulin, cortisol or free fatty acids were observed during exercise between the two trials. During the recovery period, free fatty acid and insulin concentrations were significantly lower in the CHO trial. Supplementation with CHO resulted in higher lactate associated with lipolytic suppression, but did not attenuate the cortisol, RPE or HR responses [07295].

Lactate

For many years, the production and metabolism of lactate have been scrutinized by exercise physiologists. In the early days of study, lactate was considered to be a waste product formed when glucose-6-phosphate was catabolized by glycolysis under hypoxic conditions. Lactate production was also thought to release hydrogen ions, which promoted skeletal muscle fatigue by contributing to acidosis. Others suggested that high levels of lactate in the muscle cell could promote reductions in work capacity. Viewpoints on lactate started to change in the 1980s, when researchers began providing evidence that it was not a harmful waste product but an energy intermediate that could be further metabolized to provide substrate for the tricarboxylic acid cycle or gluconeogenesis. In either case, lactate could enhance energy substrate status during exercise by sparing muscle glycogen or by fortifying blood glucose stores. Close examination of glycolysis reveals that complete metabolism of glucose to lactate results in no net release of protons and, thus, does not contribute to acidosis. In fact, during the production of lactate from pyruvate, protons are consumed and acidosis is inhibited. Furthermore, lactate oxidation and lactate consumption via gluconeogenesis consume hydrogen ions and are alkalinizing processes. Lactate’s role as an energy substrate and mediator of pH balance has sparked interest into the metabolic and exercise performance effects of orally consumed lactate. Evidence has revealed no effects of lactate consumption on time to exhaustion during low- to moderate-intensity exercise, suggesting that it is ineffective as an energy supplement. Lactate ingestion has been shown to increase blood pH and bicarbonate levels and increase time to exhaustion in short, high-intensity work bouts. Future work should focus on determining optimal doses of lactate, temporal relationships between doses and exercise, and the efficacy of lactate as an ergogenic in different types of high-intensity exercise [12513].

Oral lactate as an energy substrate

Investigations have shown that orally consumed lactate is oxidized readily by working muscle and can maintain blood glucose levels during extended exercise bouts. Two studies have investigated the effects of lactate, consumed alone or with carbohydrate, on time to exhaustion during low- to moderate-intensity exercise and neither demonstrated ergogenic
The initial investigations of lactate consumption as an energy supplement evolved from previous works that studied the metabolic fates of intravenously infused lactate in exercising subjects. These studies of lactate metabolism demonstrated that substantial amounts of infused lactate were oxidized in exercising skeletal muscle and led some investigators to ponder the effects of oral lactate consumption on endurance exercise performance. Early attempts of lactate ingestion were unsuccessful because oral consumption of large boluses was found to result in extreme gastric distress. As lactate is not well tolerated by the gastrointestinal track it can be consumed only in relatively dilute solutions. Thus, the total caloric load that can be provided by oral lactate consumption is limited and relatively low. However, it was eventually identified tolerable oral doses of lactate and compared the effects of consuming beverages containing 7 percent lactate, 7 percent maltodextrin, or aspartame on various metabolic responses during 3 h of cycle ergometry at 50 percent of VO$_{2\text{max}}$. The beverages were provided in 250-mL doses 5 min before and every 20 min during exercise. Treatments were applied in a randomized, double-blind, crossover design. In each of the three treatments, blood glucose remained at basal levels through 100 min of exercise. During the final 60 min of exercise, blood glucose dropped significantly from preexercise levels, when subjects consumed the placebo, but was maintained at basal levels in the lactate and maltodextrin trials. No difference in blood glucose was observed between the lactate and maltodextrin trials. Blood pH and bicarbonate increased significantly over basal levels during the final 60 min of the lactate trial, while no differences in these variables were observed in the placebo and maltodextrin trials. While these results demonstrated positive metabolic responses to lactate ingestion, the investigation lacked key evidence to support the use of oral lactate consumption as an ergogenic aid. If acidosis is a major contributing factor to fatigue in their protocol, the consumption of lactate could provide an ergogenic effect by acting as a buffering agent [12392].

**Oral lactate as a buffering agent**

Numerous investigations have monitored the metabolic fates of infused or ingested lactate. During rest, approximately half of exogenous lactate has is oxidized while the remainder is used as substrate for numerous metabolic processes, most notably gluconeogenesis. Disposal of lactate by oxidation or gluconeogenesis consumes protons and thus has the potential to affect blood bicarbonate and pH levels [12392].

**Sucrose**

Sucrose is a disaccharide (two linked sugar molecules), which is broken down during digestion by the enzyme sucrase located in the intestinal microvilli, into the monosaccharides glucose and fructose; it has a glycaemic index of 64. Sucrose is odourless and has good palatability, it is not as sweet as fructose but is sweeter than glucose, and in solution it is colourless and very stable with a long shelf-life. Sucrose (table sugar) normally comes from sugar beet and cane, but is also found naturally in all fruits and vegetables, and even most herbs and spices. As a sweetener it has acquired a bad reputation for being associated with obesity, insulin resistance and dental caries. However, when consumed in moderation as a sport supplement it can have a positive effect on peak performance. There is much evidence for the use of carbohydrate ingestion before, during and after prolonged strenuous exercise to increase fuel availability for muscle and central nervous system. Carbohydrates, both sugars and starches, with moderate-to-high glycaemic index, such as glucose (high) and sucrose (moderate), are absorbed rapidly, providing a readily available source of carbohydrate and so are viewed as effective sources, particularly for intake during exercise. The two monosaccharide components of sucrose are absorbed by differing mechanisms: glucose is absorbed by a sodium co-transporter SGLUT-1 and rapidly enters the blood stream, while fructose is absorbed by glucose transporter (GLUT5) and has to be converted
to glucose by the liver before it is available for muscle metabolism. Therefore, the bioavailability of sucrose as an energy source is greater than by ingesting fructose or glucose alone. Because lower concentrations are required, there is less risk of gastro-intestinal slowing and stomach upset. While sucrose ingestion at rest can lead to rebound hypoglycaemia from a surge in insulin release, evidence suggests that serum insulin levels actually fall within minutes of commencing exercise and remain low for the duration of activity. Hypoglycaemia during prolonged exercise is more likely to occur as a consequence of glycogen depletion and is a cause of fatigue which can be prevented by sucrose ingestion before and during exercise. In summary, at a time when community health issues raise some concern about our daily consumption of sucrose, there may be value in, or at least room for, its inclusion in sports products targeting the provision of carbohydrate fuel during exercise [12382].

The consumption of carbohydrate before, during and after exercise is a central feature of the athlete's diet, particularly those competing in endurance sports. Sucrose is a carbohydrate present within the diets of athletes. Whether sucrose, by virtue of its component monosaccharide's glucose and fructose, exerts a meaningful advantage for athletes over other carbohydrate types or blends is unclear. This narrative reviews the literature on the influence of sucrose, relative to other carbohydrate types, on exercise performance or the metabolic factors that may underpin exercise performance. Inference from the research to date suggests that sucrose appears to be as effective as other highly metabolizable carbohydrates (e.g., glucose, glucose polymers) in providing an exogenous fuel source during endurance exercise, stimulating the synthesis of liver and muscle glycogen during exercise recovery and improving endurance exercise performance. Nonetheless, gaps exist in our understanding of the metabolic and performance consequences of sucrose ingestion before, during and after exercise relative to other carbohydrate types or blends, particularly when more aggressive carbohydrate intake strategies are adopted. While further research is recommended and discussed in this review, based on the currently available scientific literature it would seem that sucrose should continue to be regarded as one of a variety of options available to help athletes achieve their specific carbohydrate intake goals [13622].

**Ribose**

The amount of adenosine triphosphate (ATP) stored in the muscle available for immediate use is limited, and once used, must be resynthesized in the muscle. Ribose, a naturally occurring pentose sugar, helps resynthesize ATP for use in muscles. There have been claims that ribose supplements increase ATP levels and improve performance. Other studies have provided mixed results on the effectiveness of ribose as an ergogenic aid at high doses. None of these studies have compared the impact of the recommended dose of ribose on athletes and nonathletes under exercise conditions that are most conducive for effectiveness. The purpose of one study was to evaluate the effectiveness of ribose as an ergogenic aid at the dose recommended for supplements currently on the market during an exercise trial to maximize its efficacy. Male subjects (n=11) performed 2 trials 1 week apart. Each trial consisted of three 30-second Wingate tests with a 2-minute recovery between each test. Trials were counterbalanced, with 1 trial being performed with 625 mg of ribose and the other with a placebo. Peak power, mean power, and percent decrease in power were recorded during each Wingate test. Repeated-measures analysis of variance found no significant differences between ribose and placebo. These results suggest that ribose had no effect on performance when taken orally, at the dose suggested by the distributor [06255].

One article reviewed the current literature regarding the use of ribose as an ergogenic aid. Ribose manufacturers claim that it provides ergogenic benefit, but this has not been
substantiated through scientific investigations. Data have shown promise that ribose supplementation leads to enhanced restoration of ATP levels following exercise, but this has seldom translated into increased athletic performance. However, as with many ergogenic aids, additional research is needed to clarify its value as a supplement [07306].

ATP is the only directly usable source of energy for muscle contraction. At high-exercise intensities, the rate of ATP utilisation can exceed that of its regeneration from other energy sources and ATP levels in the muscle cells decrease. Most degraded ATP remains within the muscle as inosine monophosphate (IMP) which, after exercise, is used for resynthesis of ATP. However, a fraction of the IMP is degraded and lost from the muscle as purines. If intense exercise sessions are repeated, there may be an accumulated loss of ATP through the release of purines, whereby ATP stores in the muscle cells are reduced. The ATP lost from muscle may be replenished by de novo synthesis and D-ribose availability may be limiting for ATP de novo synthesis. Experimental studies have shown that ribose supplementation does not lower the loss in nucleotides with repeated intense exercise bouts but allows for a faster recovery of ATP levels within 72 h after termination of exercise training, most likely due to an improved rate of de novo ATP synthesis. However, despite a higher level of ATP after ribose supplementation, the study showed no effect on intense intermittent exercise performance. Accordingly, other studies examining the effect of ribose on performance during intense intermittent exercise and rowing8 have not been able to demonstrate improved performance in humans. Ribose dosages up to about 40 g/day, at times divided in 2–3 supplementations per day have been examined. There are no known adverse effects of ribose but reports on long-time use are lacking. It is concluded that, although ribose supplementation appears to improve the rate of de novo synthesis of ATP in muscle, existing scientific evidence do not support the use of ribose as an ergogenic aid in young, healthy individuals [12459].

**Galactose**

One study tested the hypothesis that supplementation with galactose before and during endurance exercise would spare carbohydrate (CHO), optimize fat utilization and improve performance compared with a typical sports drink formulation. Nine well-trained cyclists undertook three trials, each consisting of 120 min at 65 percent of VO$_{2\text{max}}$ followed immediately by a set work, self-paced time trial (TT). Three treatments, allocated as a randomized balanced design, consisted of the following: 8 percent (w/w) solution of galactose (Gal); 8 percent solution of 50 percent galactose/50 percent glucose (Gluc/Gal); and 8 percent solution of 80 percent glucose/20 percent fructose (Gluc/Fru). These were consumed as 0.67 g CHO per kg body wt 45-min pre-exercise; 1.0 g CHO per kg body wt per h for the first 120 min of exercise; 0.33 g CHO per kg body wt during the TT. Blood samples were collected before and during exercise; respiratory gas samples were collected only during fixed workload exercise. Mean TT power output was significantly less in Gal compared with Gluc/Gal (P=0.030). Blood glucose and insulin concentrations were lower, and free fatty acids higher in Gal compared with Gluc/Gal and Gluc/Fru. Respiratory exchange ratio was not significantly different between trials. It was concluded that ingestion of an 8 percent galactose-only solution (12.5 ml per kg body wt per h) is detrimental to endurance performance compared with equivalent volumes of iso-osmotic solutions containing 50 percent galactose/50 percent glucose or 80 percent glucose/20 percent fructose. This may reflect the inability of the liver to convert galactose into glucose at a rate required to support strenuous exercise intensity [07307].

A study was performed to determine beneficial effects of short-term galactose (GAL) supplementation over a 50:50 glucose-maltodextrin (GLUC) equivalent on self-paced
endurance cycling performance. On 2 separate occasions, subjects performed a 100-km self-paced time trial (randomized and balanced order). This was interspersed with four 1-km and four 4-km maximal efforts reflecting the physical requirements of racing. Before each trial 38 ± 3 g of GAL or GLUC was ingested in a 6 percent concentrate fluid form 1 hr preexercise and then during exercise at a rate of 37 ± 3 g/hr. Performance variables were recorded for all 1- and 4-km efforts, all interspersed intervals, and the total 100-km distance. Noninvasive indicators of work intensity (heart rate, HR, and rating of perceived exertion) were also recorded. Times taken to complete the 100-km performance trial were 8,298 ± 502 and 8,509 ± 578 s, with mean power outputs of 271 ± 37 and 256 ± 45 W, for GAL and GLUC, respectively. Mean HR did not differ. A main effect of carbohydrate (CHO) type on time to complete 4-km efforts occurred, with no CHO Type×Effort Order interaction observed. No main effect of CHO type or interaction of CHO Type×Sequential Order occurred for 1-km efforts. It was concluded that a 6 percent GAL drink does not enhance performance time during a self-paced cycling performance trial in highly trained endurance cyclists compared with a formula typically used by endurance athletes but may improve the ability to produce intermediate self-paced efforts [12460].

**Galactose and fructose**

Both liver and muscle glycogen stores play a fundamental role in exercise and fatigue, but the effect of different CHO sources on liver glycogen synthesis in humans is unclear. The aim was to compare the effect of maltodextrin (MD) drinks containing galactose, fructose, or glucose on postexercise liver glycogen synthesis. In a double-blind, triple crossover, randomized clinical trial, 10 well-trained male cyclists performed three experimental exercise sessions separated by at least 1 wk. After performing a standard exercise protocol to exhaustion, subjects ingested one of three 15 percent CHO solutions, namely, FRU (MD + fructose, 2:1), GAL (MD + galactose, 2:1), or GLU (MD + glucose, 2:1), each providing 69 g CHO per hour during 6.5 h of recovery. Liver glycogen changes were followed using $^{13}$C magnetic resonance spectroscopy. Liver glycogen concentration increased at faster rates with FRU and with GAL than with GLU. Liver volumes increased with FRU (9 % ± 2 %) and with GAL (10 % ± 2 %) but not with GLU (2 % ± 1%). Net glycogen synthesis appeared linear and was faster with FRU and with GAL than with GLU. When ingested at a rate designed to saturate intestinal CHO transport systems, MD drinks with added fructose or galactose were twice as effective as MD + glucose in restoring liver glycogen during short-term postexercise recovery [11587].

**Multiple transportable carbohydrates**

Since the 1980s, it has been known that carbohydrate intake during exercise can improve exercise performance lasting 2 h or longer. Soon after this discovery, it was established that not all carbohydrates are equal and carbohydrates ingested during exercise may be utilised at different rates. Until a landmark publication in 2004, it was believed that carbohydrate ingested during exercise could only be oxidised at a rate not higher than 1 g/min (60 g/h) independent of the type of carbohydrate. This is reflected in the guidelines published by the American College of Sports Medicine, which recommend that athletes should take between 30 and 60 g of carbohydrates during endurance exercise (>1 h) or 0.7 g/kg/h. Exogenous carbohydrate oxidation appears limited by the intestinal absorption of carbohydrates. It is believed that glucose uses a sodium dependent transporter (SGLT1) for absorption, which becomes saturated at a carbohydrate intake around 60 g/h (or 1 g/min). When glucose was ingested at this rate and another carbohydrate (fructose) that uses a different transporter was ingested simultaneously, oxidation rates well above 1 g/min (1.26 g/min) were observed. At present only two different intestinal carbohydrate transporters have been identified (SGLT1...
for glucose or glucose polymers and galactose, and glucose transporter type 5 for fructose). Interestingly, sucrose (a disaccharide of glucose and fructose), which is said to have its own disaccharide transporter, appears to behave more like glucose than glucose:fructose. Studies suggest that exogenous carbohydrate oxidation from sucrose is similar to glucose and does not reach the high oxidation rates observed with glucose and fructose (or other MTC). With the knowledge that a single carbohydrate could only be oxidised at a rate of 1 g/min, a series of studies was initiated in an attempt to find the combination that would result in the highest oxidation rates. In these studies, the rate of carbohydrate ingestion as well as the combinations of carbohydrates varied. All studies confirmed that MTC resulted in higher (up to 75 %) oxidation rates than carbohydrates that use the SGLT1 transporter only. Combinations of maltodextrin and fructose, and glucose and fructose or glucose, plus sucrose and fructose, seemed to produce the most favourable effects. From a practical perspective, it is important to note that such high oxidation rates can not only be achieved with carbohydrate ingested in a beverage but also as a gel or a low fat, low protein, low fibre energy bar. Strong evidence is now emerging of a dose–response relationship between carbohydrate intake and endurance performance. Studies have demonstrated that MTC can result in improved performance over and above the performance enhancing effect of a carbohydrate drink with one single carbohydrate. It has also been demonstrated that MTC may have advantages in fluid delivery and studies suggest less gastrointestinal discomfort. Recently published recommendations take these findings into account, acknowledging that there may be different carbohydrate needs for different durations of exercise as well as for different levels of athletes. MTC can be recommended at all durations but are most effective when the exercise is 2.5 h or longer. In those conditions, carbohydrate intakes of up to 90 g/h are recommended and these would only be oxidised to any significant degree if they are MTC in which glucose makes up no more than about 60 g [11523].

**Carbohydrates in tennis**

Carbohydrate supplementation in prolonged aerobic exercise has been shown to be effective in improving performance and deferring fatigue. However, there is confounding evidence with regard to carbohydrate supplementation and tennis performance, which may be due to the limited number of studies on this topic. One evidence based review, using database searches of Medline and SPORTDiscus, summarises the limited relevant literature to determine if carbohydrate supplementation benefits tennis performance, and, if so, the appropriate amounts and timing. Although more research is required, it appears that it may be beneficial in tennis sessions lasting more than 90 minutes [06257].

**Energy beverages/Sport drinks**

Energy drinks have become more and more popular since the late nineties. The manufactures claim that these drinks improve physical endurance, reaction speed and concentration. The main ingredients of energy drinks are caffeine, sugar, taurine and glucuronolactone. According to the manufacturers, the stimulating effects of these drinks are due to interaction between the various ingredients. To investigate whether energy drinks do indeed improve cognitive performance and to find out which ingredients are responsible for this effect and other benefits it was made a search of the literature for the period from 1997 to 2006 on the basis of Medline, by using the search term "energy drink or energy drinks" and restricting the search to "humans". results Not only did focused and sustained attention improve significantly but so did reaction speed in all sorts of reaction-time tasks. Memory improved too, but not to the same degree. The findings suggest that most of the effects of energy drinks on cognitive performance are related mainly to the presence of caffeine
The author examined gendered links among sport-related identity, endorsement of conventional masculine norms, risk taking, and energy-drink consumption by surveying 795 undergraduate students enrolled in introductory-level courses at a public university. Of participants, 39 percent consumed an energy drink in the past month, with more frequent use by men (2.5 d/month) than by women (1.2 d/month). Strength of jock identity was positively associated with frequency of energy-drink consumption; this relationship was mediated by both masculine norms and risk-taking behavior. The author concluded that sport-related identity, masculinity, and risk taking are components of the emerging portrait of a toxic jock identity, which may signal an elevated risk for health-compromising behaviors. College undergraduates’ frequent consumption of Red Bull and comparable energy drinks should be recognized as a potential predictor of toxic jock identity [08392].

Numerous studies have shown that ingesting carbohydrate in the form of a drink can improve exercise performance by maintaining blood glucose levels and sparing endogenous glycogen stores. The effectiveness of carbohydrate gels or jellybeans in improving endurance performance has not been examined. On 4 separate days and 1-2 hr after a standardized meal, 16 male and female athletes cycled at 75 percent VO$_{2\text{peak}}$ for 80 min followed by a 10-km time trial. Participants consumed isocaloric (0.6 g of carbohydrate per kg per hour) amounts of randomly assigned sports beans, sports drink, gel, or water only, before, during, and after exercise. Blood glucose concentrations were similar at rest between treatments and decreased significantly during exercise with the water trial only. Blood glucose concentrations for all carbohydrate supplements were significantly higher than water during the 80-min exercise bout and during the time trial. There were no significant differences in blood glucose between carbohydrate treatments. The 10-km time trials using all 3 carbohydrate treatments were significantly faster for sports beans, for sports drink, and for gel than water. All carbohydrate-supplement types were equally effective in maintaining blood glucose levels during exercise and improving exercise performance compared with water only [08393].

To investigate the frequency of energy-drink consumption and associated factors in a group of college students a cross-sectional study was conducted and included 439 students pursuing a career in medicine, sports, and arts. Only fourth-year students were approached. Data were collected using a self-administered standard questionnaire. In bivariate analyses, frequency of energy-drink consumption was higher in students of arts and sports and in those who did not have breakfast on a regular basis, ever smoked cigarettes, drank alcoholic beverages, and regularly engaged in sports compared with their counterparts. Many students who had “ever” tried an energy drink did so the first time because they wondered about its taste. Of regular users of energy drinks, reasons for using such drinks varied across the three selected groups of students and included obtaining getting energy, staying awake, boosting performance while doing sports, or mixing with alcoholic beverages. About 40 percent of all current users of energy drinks reported that they mixed those with alcoholic beverages. In multivariate analyses, statistically significant predictors of energy-drink consumption were faculty type, presence of any health insurance, use of alcoholic beverages, and monthly income, controlling for gender. Most students could not correctly define the ingredients of energy drinks or their potential hazardous health effects, and they could not distinguish energy and sports drinks when they were requested to select them from a list of commercial names of various drinks. It was concluded that consumption of energy drinks, despite the variation in the reason for choosing such drinks, is quite common in college students [10229].

Energy drinks are frequently marketed to individuals interested in athletics and an active
lifestyle. From 2001 to 2008, estimates of energy drink use in adolescent to middle-aged populations ranged from 24 to 56 percent. Most energy drinks feature caffeine and a combination of other components, including taurine, sucrose, guarana, ginseng, niacin, pyridoxine, and cyanocobalamin. This article examines the evidence for 2 commonly purported uses of energy drinks: athletic performance enhancement and weight loss. Observed ergogenic benefits of energy drinks are likely attributable to caffeine and glucose content. There is conflicting evidence regarding the impact of energy drinks on weight loss, although some data suggest that combining energy drink use with exercise may enhance body fat reduction. As with any pharmacologically active substance, energy drinks are associated with adverse effects. Combining energy drinks with alcohol exacerbates safety concerns and is an increasingly common practice contributing to toxic jock identity among college-aged male athletes. Practitioners should monitor identified populations likely to consume these loosely regulated beverages [10230].

The purpose of one study was to compare the effects of a carbohydrate-electrolyte plus caffeine, carnitine, taurine, and B vitamins solution (CE+) and a carbohydrate-electrolyte-only solution (CE) versus a placebo solution (PLA) on cycling performance and maximal voluntary contraction (MVC). In a randomized, double-blind, crossover, repeated-measures design, 14 male cyclists cycled for 120 min submaximally and then completed a 15-min performance trial (PT). Participants ingested CE+, CE, or PLA before (6 ml/kg) and every 15 min during exercise (3 ml/kg). MVC was measured as a single-leg isometric extension (70 degree knee flexion) before (pre) and after (post) exercise. Rating of perceived exertion (RPE) was measured throughout. Total work accumulated during PT was significantly greater in CE+ than PLA but not in CE versus PLA. MVC declined significantly from pre to post in PLA and CE but not in CE+. At Minutes 60, 90, 105, and 120 RPE was lower in CE+ than in PLA. CE+ resulted in greater total work than PLA. CE+, but not PLA or CE, attenuated pre-to-post MVC declines. Performance increases during CE+ may have been influenced by lower RPE and greater preservation of leg strength during exercise in part as a result of the hypothesized effects of CE+ on the central nervous system and skeletal muscle [10231].

Pre-exercise sports drinks (PRX) are commonly used as ergogenic aids in athletic competitions requiring aerobic power. However, in most cases, claims regarding their effectiveness have not been substantiated. In addition, the ingredients in PRX products must be deemed acceptable by the athletic governing bodies that regulate their use in training and competition. The purpose of one study was to examine the effects of a modified PRX formulation (known as EM.PACT) from earlier investigations on factors related to maximal aerobic performance during a graded exercise test. The modification consisted of removing creatine to meet the compliance standards set forth by various athletic organizations that regulate the use of nutritional supplements. Twenty-nine male and female college students varying in levels of aerobic fitness participated in a randomized crossover administration of PRX (containing 14 g/serving of fructose, medium-chain triglycerides, and amino acids mixed with 8 oz. of water) and placebo (PL) 30 minutes prior to performing a treadmill test with approximately one week separation between the trials. \( \text{VO}_{2\text{max}} \), maximal heart rate (HR), time to exhaustion (Time), and percentage estimated non-protein fat substrate utilization (FA) during two a priori submaximal stages of a graded exercise testing were evaluated. The \( \text{VO}_{2\text{max}} \) mean value of the PRX trial was significantly greater than the PL trial. The mean value for Time was also observed to be significantly greater for the PRX trial compared to PL. Additionally, percentage of FA during submaximal stages of the exercise test was significantly greater for PRX trial in comparison to PL. It was concluded that the modified PRX formulation utilized in this investigation supports the findings of the previous investigation and its efficacy for enhancing indices of aerobic performance during graded exercise testing [10232].
Exercise is making a resurgence in many countries, given its benefits for fitness as well as prevention of obesity. This trend has spawned many supplements that purport to aid performance, muscle growth, and recovery. Initially, sports drinks were developed to provide electrolyte and carbohydrate replacement. Subsequently, energy beverages (EBs) containing stimulants and additives have appeared in most gyms and grocery stores and are being used increasingly by “weekend warriors” and those seeking an edge in an endurance event. Long-term exposure to the various components of EBs may result in significant alterations in the cardiovascular system, and the safety of EBs has not been fully established. For one review, it was searched the MEDLINE and EMBASE databases from 1976 through May 2010, using the following keywords: energy beverage, energy drink, power drink, exercise, caffeine, red bull, bitter orange, glucose, ginseng, guarana, and taurine. Evidence regarding the effects of EBs is summarized, and practical recommendations are made to help in answering the patient who asks, “Is it safe for me to drink an energy beverage when I exercise?”

It has been reported that the frequency of cola intake (COLA) is positively associated with serum triglycerides and negatively associated with high-density-lipoprotein (HDL) cholesterol, both components of the metabolic syndrome (MetS). The question now is whether noncola soft drink intake (NCOLA) is associated with MetS. Among the 18770 participants in the Oslo Health Study, 5373 men and 6181 women had data on COLA and NCOLA and risk factors for MetS (except fasting glucose). Main MetS requirements are central obesity and 2 of the following: increased triglycerides, low HDL cholesterol, increased systolic or diastolic blood pressure, and elevated fasting blood glucose. The MetSRisk index was calculated to estimate many MetS components. Using regression analyses, the association between COLA (NCOLA) and MetS (MetSRisk) was studied. In young (aged 30 years), middle-aged (aged 40 and 45 years), and senior (aged 59 and 60 years) men and women, there was, in general, a positive correlation between COLA and MetSRisk, and between COLA and single MetS risk factors, except HDL cholesterol, which was negatively correlated. A less consistent picture was found for NCOLA. By regression analyses, after adjustment for sex, age, time since last meal, and use of sugar-sweetened soft drinks, a positive association between COLA (NCOLA) and MetSRisk (MetS) was still found. However, when also controlling for cheese, fatty fish, coffee, alcohol, smoking, physical activity, education, and birthplace, only the association with COLA remained significant, irrespective of the presence or absence of sugar. In conclusion, the self-reported intake frequency of soft drinks can be positively associated with MetS.

To review the effects, adverse consequences, and extent of energy drink consumption among children, adolescents, and young adults it was searched PubMed and Google using “energy drink,” “sports drink,” “guarana,” “caffeine,” “taurine,” “ADHD,” “diabetes,” “children,” “adolescents,” “insulin,” “eating disorders,” and “poison control center” to identify articles related to energy drinks. According to self-report surveys, energy drinks are consumed by 30 to 50 percent of adolescents and young adults. Frequently containing high and unregulated amounts of caffeine, these drinks have been reported in association with serious adverse effects, especially in children, adolescents, and young adults with seizures, diabetes, cardiac abnormalities, or mood and behavioral disorders or those who take certain medications. Of the 5448 US caffeine overdoses reported in 2007, 46 percent occurred in those younger than 19 years. Several countries and states have debated or restricted energy drink sales and advertising. It was concluded that energy drinks have no therapeutic benefit, and many ingredients are understudied and not regulated. The known and unknown pharmacology of agents included in such drinks, combined with reports of toxicity, raises concern for potentially serious adverse effects in association with energy drink use. In the short-term, pediatricians need to be aware of the possible effects of energy drinks in vulnerable populations and screen for consumption to educate families. Long-term research should aim to understand the effects in at-risk populations. Toxicity surveillance should be improved, and
regulations of energy drink sales and consumption should be based on appropriate research [11259].

The aim of one study was to examine sensory perceptions towards different formulations of sports drinks when consumed before, at various points during, and following exercise. Following familiarization 14 recreational runners underwent four trials in a single blind counterbalanced design. Each trial utilised one of four different solutions: 7.5 percent carbohydrate, 421 mg/L electrolyte (HiC-HiE); 7.5 percent carbohydrate, 140 mg/L electrolyte (HiC-LoE); 1.3 percent carbohydrate, 421 mg/L electrolyte (LoC-HiE) and water. Subjects were provided with 50 mL samples to ingest and then rate (using a 100 mm line scale) the intensity of sweetness, saltiness, thirst-quenching ability and overall liking before (-30 min), during (0, 30 and 60 min) and following (90 and 120 min) treadmill running exercise. Ratings of sweetness for all energy-containing drinks were significantly higher during exercise relative to pre- and post-exercise conditions (P<0.05); ratings also increased with duration of exercise. Sweetness ratings for LoC-HiE increased during exercise but remained the same for other beverages. Ratings of saltiness decreased for all energy-containing drinks during exercise relative to pre-exercise; ratings decreased with duration of exercise in these drinks. Ratings of thirst-quenching ability and overall liking increased with duration of exercise with all beverages. Significant changes in sensory perception occur when consuming sports drinks during exercise relative to non-exercise conditions. Temporal changes also occur during exercise itself which leads to enhanced liking of all beverages [11260].

Sports and energy drinks are being marketed to children and adolescents for a wide variety of inappropriate uses. Sports drinks and energy drinks are significantly different products, and the terms should not be used interchangeably. The primary objectives of this clinical report are to define the ingredients of sports and energy drinks, categorize the similarities and differences between the products, and discuss misuses and abuses. Secondary objectives are to encourage screening during annual physical examinations for sports and energy drink use, to understand the reasons why youth consumption is widespread, and to improve education aimed at decreasing or eliminating the inappropriate use of these beverages by children and adolescents. Rigorous review and analysis of the literature reveal that caffeine and other stimulant substances contained in energy drinks have no place in the diet of children and adolescents. Furthermore, frequent or excessive intake of caloric sports drinks can substantially increase the risk for overweight or obesity in children and adolescents. Discussion regarding the appropriate use of sports drinks in the youth athlete who participates regularly in endurance or high-intensity sports and vigorous physical activity was beyond the scope of this report [11261].

One study explored relationships regarding perceived stress, energy drink consumption, and academic performance among college students. Participants included 136 undergraduates attending a large southern plains university. Participants completed surveys including items from the Perceived Stress Scale and items to describe energy drink consumption, academic performance, and demographics. Positive correlations existed between participants' perceived stress and energy drink consumption. Participants' energy drink consumption and academic performance were negatively correlated. Freshmen and sophomores consumed a lower number of energy drinks yesterday than juniors. Males reported higher means than females for selected energy drink consumption items. Statistically significant interactions existed between gender and year in school for selected energy drink consumption items. Results confirm gender differences in energy drink consumption and illuminate a need for education regarding use of energy drinks in response to perceived stress [11262].

Energy drinks are attractive and readily available in every grocery store and gas station. While most youth verbalize an understanding that too much caffeine is bad for one's health,
at an age of multiple demands, an over-the-counter offer of increased energy and alertness is hard to ignore. What makes energy drinks different from regular coffee? Although the heavily caffeinated drinks promise increased energy and stamina and are loaded with healthy natural ingredients, excessive consumption is of concern on many levels. One article discussed some of the effects of excessive caffeine, as well as risks associated with energy drinks mixed with alcohol [11524].

The aim of one study was to investigate the effects of a naturally composed sports drink containing proteins and carbohydrates used during recovery in competitive badminton players. The hypothesis was that the use of a recovery drink would lead to positive subjective effects, enhanced physical performance and less signs of overtraining. During an indoor season 18 badminton players were instructed to drink at least 250 mL of a given sports drink immediately after each training or playing session. The study design was prospective double blind crossover with one active drink and one placebo. The active drink was based on natural products containing whey and orange juice, and the placebo was made of diluted apple juice. Evaluation of effects was done with laboratory tests, self-registered values and field tests. The players perceived statistically significant short-term subjective positive effects after using the active drink, compared with after using placebo. The blood hemoglobin concentration was also higher after the period with active drink. There were no other differences concerning other laboratory tests (leg strength, endurance, body fat percent, lean arm and leg masses), self-registered values (body weight, pulse, training amount and intensity) or field tests (speed, explosive effort, grip strength, endurance and POMS) between the periods with the different sports drinks. It was concluded that supplementation with a sports drink during recovery showed a significant short-term subjective positive effect compared with placebo. However, no effects were seen on physical performance or signs of overtraining [06258].

The term "energy drink" designates "any product in the form of a drink or concentrated liquid, which claims to contain a mixture of ingredients having the property to raise the level of energy and vivacity". The main brands, Red Bull, Dark Dog, Rockstar, Burn, and Monster, are present in food stores, sports venues, and bars among other soft drinks and fruit juices. Their introduction into the French market raised many reluctances, because of the presence of taurine, caffeine and glucuronolactone. These components present in high concentrations, could be responsible for adverse effects on health. The association of energy drinks and spirits is widely found among adolescents and adults who justify drinking these mixed drinks by their desire to drink more alcohol while delaying drunkenness. Given the importance of the number of incidents reported among the energy drinks consumers, it seemed appropriate to make a synthesis of available data and to establish causal links between the use of these products and the development of health complications. For a literature review, it was selected scientific articles both in English and French published between 2001 and 2011 by consulting the databases Medline, Embase, PsycINFO and Google Scholar. The words used alone or in combination are "energy drinks", "caffeine", "taurine", "toxicity", "dependence". An occasional to a moderate consumption of these drinks seems to present little risk for healthy adults. However, excessive consumption associated with the use of alcohol or drugs in amounts that far exceed the manufacturers recommended amount, could be responsible for negative consequences on health, particularly among subjects with cardiovascular disease [12398].

Sports drinks are increasingly regarded as an essential adjunct for anyone doing exercise, but the evidence for this view is lacking. It was investigated the links between the sports drinks industry and academia that have helped market the science of hydration: prehydrate; drink ahead of thirst; train your gut to tolerate more fluid; your brain doesn’t know you’re thirsty – the public and athletes alike are bombarded with messages about what they should
drink, and when, during exercise. But these drinking dogmas are relatively new. In the 1970s, marathon runners were discouraged from drinking fluids for fear that it would slow them down. At the first New York marathon in 1970, there was little discussion about the role of hydration – it was thought to have little scientific value. An investigation by the BMJ has found that companies have sponsored scientists, who have gone on to develop a whole area of science dedicated to hydration. These same scientists advise influential sports medicine organisations, which have developed guidelines that have filtered down to everyday health advice. These guidelines have influenced the European Food Safety Authority, the EU agency that provides independent advice on the evidence underpinning health claims relating to food and drink. And they have spread fear about the dangers of dehydration. Much of the focus on hydration can be traced back to the boom in road running, which began with the New York marathon. Manufacturers of sports shoes and the drink and nutritional supplement industries spotted a growing market. One drink in particular was quick to capitalise on the burgeoning market. Robert Cade, a renal physician from the University of Florida, had produced a sports drink in the 1960s that contained water, sodium, sugar, and monopotassium phosphate with a dash of lemon flavouring. Gatorade – named after the American Football team, the Gators, that it was developed to help – could prevent and cure dehydration, heat stroke, and muscle cramps, and improve performance, it was claimed. The first experimental batch of the sports drink cost GBP 28 to produce but has spawned an industry with sales of around GBP 260m a year in the UK alone – and consumption is increasing steadily. In the US the market is even bigger. In 2009, forecasters, Mintel, valued it at USD 1.6bn, and the market is projected to reach USD 2bn by 2016. PepsiCo bought Gatorade in 2001 and both Coca-Cola and GlaxoSmithKline (GSK) have their own sports drinks – Powerade and Lucozade respectively. The companies are a partner and service provider, respectively, to the London 2012 Olympics. The key behind the meteoric rise in consumption of sports drinks lies in the coupling of science with creative marketing. What started life as a mixture of simple kitchen food stuffs has become an “essential piece of sporting equipment.” The US National Athletic Trainers’ Association (NATA), a representative body of sports health professionals with over 35 000 members, works closely with Gatorade. The company has taken out advertisements in NATA’s newsheet that look like academic papers. These “research adverts” are just one example of how companies promote the idea that the benefits of their drinks are based on decades of thorough scientific research. Selling science. Indeed, just as drug companies have appointed key opinion leaders to influence doctors’ prescribing patterns, sports drink and supplement companies seek to work with gyms and instructors. Virgin Active has a partnership with Powerade, for example, and the GSK owned supplement brand, Maximuscle, has a partnership with LA Fitness. Perhaps one of Gatorade Sports Science Institute’s greatest successes was to undermine the idea that the body has a perfectly good homeostatic mechanism for detecting and responding to dehydration – thirst. “The human thirst mechanism is an inaccurate short-term indicator of fluid needs … Unfortunately, there is no clear physiological signal that dehydration is occurring.” The science of dehydration has led to another widely held belief that is not based on robust evidence – that the colour of urine is a good guide to hydration levels. Like athletes, British soldiers are told to check their urine. The Ministry of Defence signed a GBP 1.5m three year deal with GSK in 2005 to supply soldiers with Lucozade. The Mayo Clinic’s online guidance to patients also suggests urine is a good guide of hydration. “Unfortunately, thirst isn’t always a reliable gauge of the body’s need for water, especially in children and older adults. A better indicator is the color of your urine: Clear or light-colored urine means you’re well hydrated, whereas a dark yellow or amber color usually signals dehydration,” it says. However, a review of the evidence Oxford University’s Centre of Evidence Based Medicine linked to this investigation has assessed the predictive value of urine colour as a diagnostic test. “There is a lack evidence for the widely recommended practice of assessing hydration status by looking at the colour of urine,” it suggests. “The limited evidence shows that only first morning urine colour can be reliably used to assess dehydration and
rehydration," it adds. Studies suggest that thirst is a more reliable trigger. A meta-analysis of data from cyclists in time trials concluded that relying on thirst to gauge the need for fluid replacement was the best strategy. In 1993, a group of experts led by Ron Maughan, professor of sport and exercise nutrition at Loughborough University and a member of GSSI’s sports medicine review board since 1990, produced a consensus statement at a meeting funded by Isostar, a sports drink then owned by drug company, Novartis. “There is a need to make athletes more aware of the dangers of dehydration and of the importance of adequate fluid intake. Water is not the best fluid for rehydration, either during or after exercise,” they wrote in an article published in the British Journal of Sports Medicine. In America, the sports drinks industry also made a push into the area of clinical science. In 1992, the American College of Sports Medicine – the "premier organization in sports medicine and exercise science" with over 45 000 members – accepted a USD 250,000 donation from Gatorade. Four years later, in 1996, the American College of Sports Medicine produced guidelines that adopted a “zero percent dehydration” doctrine, advising athletes to “drink as much as tolerable.” Half the guideline’s authors either worked with the US military – the world’s biggest customer of Gatorade – or had a financial relationship with the Gatorade institute. The 1996 guidance stood until 2007, when in updated guidance the college acknowledged that people should drink according to the dictates of thirst. However, it still promoted the idea that people should lose no more than 2 percent of body weight during exercise, and this remains the position in the published literature. As sports drinks rise in popularity among children, there is concern their consumption is contributing to obesity levels. A 500 mL bottle of Powerade Ion4 contains 19.6 g of sugar, and the same sized bottles of Lucozade Sport and Gatorade Perform contain 17.5 g (3 g carbohydrate) and 30 g respectively (a teaspoon of sugar weighs about 4 g) [12399].

Energy drinks (EDs) contain caffeine and are a new, popular category of beverage. It has been suggested that EDs enhance physical and cognitive performance; however, it is unclear whether the claimed benefits are attributable to components other than caffeine. A typical 235 mL ED provides between 40 and 250 mg of caffeine, equating to doses that improve cognitive and, at the higher levels, physical performance. EDs often contain taurine, guaranã, ginseng, glucuronolactone, B-vitamins, and other compounds. A literature search using PubMed, Psych Info, and Google Scholar identified 32 articles that examined the effects of ED ingredients alone and/or in combination with caffeine on physical or cognitive performance. A systematic evaluation of the evidence-based findings in these articles was then conducted. With the exception of some weak evidence for glucose and guaranã extract, there is an overwhelming lack of evidence to substantiate claims that components of EDs, other than caffeine, contribute to the enhancement of physical or cognitive performance. Additional well-designed, randomized, placebo-controlled studies replicated across laboratories are needed in order to assess claims made for these products [12400].

Energy drink usage is common and contains caffeine or other stimulants. It was evaluated demographics, prevalence, reasons and adverse effects with consuming energy beverages. Cross-sectional study of a convenience sample of patients recruited from two US Emergency Departments from January to December 2009. 1298 subjects participated of which 53 percent were male. Ethnicity: Caucasian 48 percent, African American 17 percent, Hispanic 18 percent, and other 17 percent. Age ranges: 18-29 years (38 %), 30-54 years (50 %) and greater than 55 years (12 %). Reasons for use: 57 percent to "increase energy", 10 percent for studying/work projects, 2 percent while prolonged driving, improve sports performance 2 percent, with ethanol 6 percent, and "other" reasons 22 percent. Adverse reactions reported by 34 percent (429) patients. 280 report feeling "shaky/jittery", insomnia 136, palpitations 150, gastrointestinal upset 82, headache 68, chest pain 39, and seizures in 6. Eighty-five patients reported co-ingestion with illicit "stimulants" including cocaine and methamphetamine. It was identified one-third of patients reported at least one adverse effect.
Whilst most were not severe, a small number were serious e.g. seizures. In addition, some report purposely ingesting with illicit drugs [12401].

Consumption of energy drinks by both recreational and competitive athletes has increased dramatically in recent years. The primary ingredients in many energy drinks include caffeine (CAF) in various forms, as well as taurine. The purpose of this randomized, double-blind, crossover study was to examine the effect of sugar-free (SF) Red Bull (RB) containing CAF and taurine to a CAF only drink and a SF, CAF-free placebo (PL) on one repetition maximum (1RM) bench press (BP) and the volume load (VL; repetitions x kg at 70 % 1RM) during one BP set to failure in experienced weight lifters. Seventeen college-age men randomly received: (A) 500 ml of SF-RB containing CAF (160 mg) and taurine (2000 mg); (B) 500 ml of a SF drink containing CAF only (160 mg); or (C) a SF, CAF-free 500 ml PL drink 60 min prior to testing on three separate occasions. Following a standard warm-up, the 1RM was determined for each subject and, after 5 min rest, they completed repetitions to failure at 70% of their 1RM to assess VL. The results indicated that neither SF-RB nor the CAF drink had any effect on 1RM BP or VL compared to PL. Although the CAF content in the energy drinks used in the present study was low (2.0 mg/kg), the finding of no effect of the CAF containing energy drinks for 1RM BP are in agreement with previous studies using intakes up to 6.0 mg/kg. These findings suggest that SF-RB has no effect on upper body 1RM strength or VL in resistance trained men [12402].

The descriptive analytical study was conducted at a University Medical School from 2011 and 2012. A semi-structured questionnaire was filled by students who were asked about their socio-demographic status and their energy drink consumption. The mean age of the 390 students in the study was 21 years (range:16-27). Of them, 204 (52 %) were females. Overall 52 (13 %) were smoking regularly at least one cigarette per day; 122 (31 %) were consuming alcohol; 127 (33 %) had consumed energy drinks at least once and 73 (19 %) more than once. In terms of perception, 110 (28 %) students said energy drinks were similar to sports drinks, while only 121 (41 %) named the brands correctly; 96 (25 %) students did not answer this particular question. Although consumption of energy drinks was common among medical students, the knowledge of ingredients and knowledge of health risks of energy drinks among them was unsatisfactory [13632].

According to published research, energy drinks (ED) are the most popular dietary supplement besides multivitamins in the American adolescent and young adult population. ED are also reported to be the most popular supplement among British athletes. More recently, energy shots (ES) have also been purported to possess ergogenic value on mental focus and/or performance. It is important to make a distinction between ED, ES, and sports drinks. Sports drinks are a unique category within the beverage industry and are marketed to consumers with the primary function of promoting hydration, replacing electrolytes and sustaining endurance performance capacity. They typically provide a small amount of carbohydrate (e.g. 6-8 grams/100 mL) and electrolytes (sodium, potassium, calcium, magnesium). ED, on the other hand, typically contain higher amounts of carbohydrate along with nutrients purported to improve perceptions of attention and/or mental alertness. Low calorie ED are also marketed to increase mental alertness, energy metabolism, and performance. Energy shots are typically 2-4 oz. servings of concentrated fluid containing various purported ergogens. Since ED and ES contain carbohydrate, caffeine, and/or nutrients that may affect mental focus and concentration, they have the potential to affect exercise capacity and perceptions of energy and/or fatigue. One analysis represents a systematic review of the literature on the effects of “energy drinks” on exercise and cognitive performance as well as primary ingredients contained in popular energy drinks. A comprehensive literature search was performed by searching the Medline database of the US National Library of Medicine of the National Institutes of Health. The search strategy
involved entering "energy drinks" and commercial names of energy drinks and/or caffeinated beverages as well as a search of primary nutrients contained in popular energy drinks (e.g., caffeine, carbohydrate, taurine, glucuronolactone, Guarana, Yerba Mate, etc.). It is important to note, from a United States regulatory perspective, several of these ED are marketed as dietary supplements and not beverages, and the label on the product will indicate which category of Food and Drug Administration (FDA) authority the product falls under. Each category has its own set of governing laws and regulations. For example, depending on the category, the labels will include Supplement Facts (dietary supplements) or Nutrition Facts (beverages). Thus, the International Society of Sports Nutrition (ISSN) bases the following position stand on a critical analysis of the literature on the safety and efficacy of the use of energy drinks (ED) or energy shots (ES). The ISSN has concluded the following [13633]:

- Although ED and ES contain a number of nutrients that are purported to affect mental and/or physical performance, the primary ergogenic nutrients in most ED and ES appear to be carbohydrate and/or caffeine
- The ergogenic value of caffeine on mental and physical performance has been well-established but the potential additive benefits of other nutrients contained in ED and ES remains to be determined
- Consuming ED 10-60 minutes before exercise can improve mental focus, alertness, anaerobic performance, and/or endurance performance
- Many ED and ES contain numerous ingredients; these products in particular merit further study to demonstrate their safety and potential effects on physical and mental performance
- There is some limited evidence that consumption of low-calorie ED during training and/or weight loss trials may provide ergogenic benefit and/or promote a small amount of additional fat loss. However, ingestion of higher calorie ED may promote weight gain if the energy intake from consumption of ED is not carefully considered as part of the total daily energy intake
- Athletes should consider the impact of ingesting high glycemic load carbohydrates on metabolic health, blood glucose and insulin levels, as well as the effects of caffeine and other stimulants on motor skill performance
- Children and adolescents should only consider use of ED or ES with parental approval after consideration of the amount of carbohydrate, caffeine, and other nutrients contained in the ED or ES and a thorough understanding of the potential side effects
- Indiscriminant use of ED or ES, especially if more than one serving per day is consumed, may lead to adverse events and harmful side effects
- Diabetics and individuals with pre-existing cardiovascular, metabolic, hepatorenal, and neurologic disease who are taking medications that may be affected by high glycemic load foods, caffeine, and/or other stimulants should avoid use of ED and/or ES unless approved by their physician

The ingestion of nutrients prior to, during, and/or following exercise can affect exercise performance and/or training adaptations. ED typically contain water, carbohydrates (e.g. glucose, maltodextrin), vitamins, minerals, and "proprietary blends" of various nutrients purported to increase energy, alertness, metabolism, and/or performance (e.g., caffeine, taurine, amino acids, glucuronolactone, Guarana, Ginkgo biloba, Carnitine, Panax ginseng, Green Tea, Yerba Mate, etc.). Therefore, ingestion of ED or ES prior to, during, and/or following exercise could have some ergogenic value [13633].

The purpose of one study was to investigate the influence of an energy drink on cycling performance and immune-related variables. Eleven trained male cyclists consumed 500 mL of 1) energy drink (2.0g taurine, 1.2 g glucuronolactone, 160 mg caffeine, 56 g carbohydrate
(CHO), and B vitamins), 2) cola matched for caffeine and CHO (CC), or 3) flavored placebo (PL- sparkling water and flavoring) 50 min prior to racing in a randomized, cross-over design. Performance was measured as time to complete (TTC) a 25-mile simulated road race. Blood was collected at baseline (BASE), 30 minutes after drink consumption (PODR), during exercise at miles 5 (M5), 15 (M15), and immediately (POEX) and 30 min post-exercise (30 minPO). TTC was not different among trials. CC and ED elicited a mile hypoglycemia during cycling. POEX IL-6 was greatest after ED while CC IL-6 was greater than PL. Cycling increased leukocyte number in all conditions with energy drink leukocyte number greater than that of PL at M15. The drink induced an earlier recruitment of monocytes to the blood stream than CC. Mean fat oxidation was greater in PL compared to CC, but did not differ between energy drink and PL. Lactate was higher in energy drinkers compared to CC and PL at M5 and M15, but there was no significant influence of either energy drinkers or CC on performance. CHO and caffeine consumption prior to endurance cycling significantly increased the IL-6 release and leukocytosis, and the additional ingredients in energy drinkers appear to have further augmented these responses [13634].

Science on “sports drinks”

Exogenous carbohydrate oxidation was assessed in 6 male Category 1 and 2 cyclists who consumed CytoMax (C) or a leading sports drink (G) before and during continuous exercise (CE). C contained lactate-polymer, fructose, glucose and glucose polymer, while G contained fructose and glucose. Peak power output and VO\textsubscript{2} on a cycle ergometer were 408 ± 13 W and 67 mL O\textsubscript{2} per kg and minute. Subjects performed 3 bouts of CE with C, and 2 with G at 62 percent VO\textsubscript{2peak} for 90 min, followed by high intensity (HI) exercise (86 % VO\textsubscript{2peak}) to volitional fatigue. Subjects consumed 250 ml fluid immediately before (-2 min) and every 15 min of cycling. Drinks at -2 and 45 min contained 100 mg of [U-\textsuperscript{13}C]-lactate, -glucose or -fructose. Blood, pulmonary gas samples and \textsuperscript{13}CO\textsubscript{2} excretion were taken prior to fluid ingestion and at 5, 10, 15, 30, 45, 60, 75, and 90 min of CE, at the end of HI, and 15 min of recovery. HI after CE was 25 percent longer with C than G. \textsuperscript{13}CO\textsubscript{2} from the -2 min lactate tracer was significantly elevated above rest at 5 min of exercise, and peaked at 15 min. \textsuperscript{13}CO\textsubscript{2} from the -2 min glucose tracer peaked at 45 min for C and G. \textsuperscript{13}CO\textsubscript{2} increased rapidly from the 45 min lactate dose, and by 60 min of exercise was 33 percent greater than glucose in C or G, and 36 percent greater than fructose in G. \textsuperscript{13}CO\textsubscript{2} production following tracer fructose ingestion was greater than glucose in the first 45 minutes in C and G. Cumulative recoveries of tracer during exercise were: 92 percent for lactate in C and 25 percent for glucose in C or G. Recoveries for fructose in C and G were 75 percent and 26 percent respectively. Lactate was used more rapidly and to a greater extent than fructose or glucose. CytoMax significantly enhanced HI. In summary, this is the first report of greater fractional oxidation of lactate in comparison to other carbohydrate energy substrates during exercise. As well, the presence of fructose as an ingredient in an energy-electrolyte hydration beverage provides and advantage over glucose alone in terms of providing energy to an exercising athlete. By providing PolyLactate™ as well as fructose, glucose and glucose polymers as CHO-energy forms, CytoMax possesses clear advantages in terms of providing rapid and sustained energy allowing superior sprint finishing performance in comparison to a popular HFCS-based sports drink. It was concluded that intense endurance exercise promotes dehydration and depletion of blood glucose, muscle and liver glycogen, and electrolytes. Endurance athletes must satisfy the needs for fluids, energy, and electrolytes for optimal performance. Fluid-energy-electrolyte replacement beverages (i.e. sports drinks) improve endurance because they satisfy these needs, particularly in hot and humid environments [07308].

Substrates
Traditional sports drinks supply energy in the form of sugars (glucose, fructose, sucrose) and 1721
glucose polymers. Carbohydrate is the main energy source for prolonged physical activity, and of the dietary energy substrates, carbohydrates are most readily digested and absorbed. The drinks also contain electrolytes to replace those lost in sweat. Electrolytes also stimulate thirst, promote solute absorption in the gastrointestinal (GI) tract, and buffer endogenous acids. A sports drink containing a 6 percent (w/v) glucose solution is efficacious for promoting GI emptying and exercise performance. Consumption of 1 liter per hour in 250 ml aliquots delivers 1 g/min of glucose, which enhances fuel availability and provides other benefits. More, investigators have experimented with combinations of hexoses (e.g. 2 glucose/fructose) to raise drink solute content above 6 percent by taking advantage of specific intestinal transporters that promote solute absorption. The same investigators have used isotopically labeled solutes to track the oxidation of specific energy substrates in sports drinks. The results support the concept of increasing energy delivery by expanding the metabolite delivery profile of the beverages. Lactate is a dynamic substrate with great potential as an energy source in sports drinks. To date, however, the efficacy of adding lactate to these drinks has been sparsely assessed. Lactate was once considered a metabolic waste but is now recognized as an important energy substrate in the body. Lactate is the main product of carbohydrate metabolism and can be used as a fuel in working muscle cells shuttled to other tissues such as the heart where lactate is fuel, or to the liver were lactate serves as a gluconeogenic precursor. Lactate is transported across cell plasma and mitochondrial membranes by a family of proton-lactate anion-coupled symporter proteins, of which MCT1 is the predominant isof orm in muscle. Related, but from a different gene family is the sodium-coupled intestinal lactate transporter, sMCT, also known as the slc5a8. The presence of monocarboxylate (i.e. lactate) transport proteins in the GI tract, erythrocytes, myocytes, cardiocytes, hepatocytes, astrocytes and neurons provide a metabolic rationale for including lactate-containing food additives in sports drinks. PolyLactate™ in CytoMax™ (C) might hasten the delivery of substrate during prolonged intense exercise, which may improve sprint performance and delay prevent fatigue after prolonged, hard exercise. In one study it was evaluated rapidity and extent of use of substrates present in C and a popular brand (G). The main finding was that lactate was oxidized faster and to a greater extent than fructose or glucose, which are the principle nutrients contained in most sports drinks. Including lactate as a component of sports drinks is logical based on the research showing its role in carbohydrate utilization during exercise (i.e. the lactate shuttle) and the present results show that exogenous lactate is a readily available substrate in that it is rapidly transported and oxidized. On the bases of fractional oxidation rate and cumulative recovery of tracer in expired CO2 collected over more than 90 min of continuous followed by high intensity exercise, results showed that lactate was used as a fuel much faster and more completely than glucose, particularly in the drink formulations tested which are typical of sports drink platforms that are commonly used. Given the plethora of scientific evidence regarding endogenous lactate oxidation in humans in vivo, the results showing rapid and extensive oxidation of orally supplied lactate are not surprising. The rapid rate of lactate assimilation, distribution and oxidation could be predicted given its central role in linking glycolytic and oxidative metabolism, as well as the wide-spread expression of lactate-hydrogen ion symporters (referred as monocarboxylate transporters, or MCTs) in muscle and other tissues, and the presence of a sodium ion-mediated intestinal MCT. The initial oxidation rate of lactate was clearly superior to glucose and fructose at the outset of exercise, but equally or more impressive was the rapid assimilation and use of lactate during exercise. The oxidation rate of fructose was intermediate between lactate and glucose, actually tracking the pattern of lactate-derived tracer excretion in breath at the beginning of exercise. The results may indicate muscle fructose uptake and oxidation. However, a more likely route of entry for fructose is that it may undergo glycolysis in the intestinal mucosa or elsewhere in the splanchnic bed, causing a rapid entry of lactate into the systemic circulation [07308]
**Lactate oxidation**

Results obtained in one investigation indicate that various fuel energy substrates in sports drinks use different transport systems to gain access to the systemic circulation and cellular pathways of oxidative metabolism at different rates. Results can be interpreted to mean that the ideal sports drink should contain several different energy substrates because the absorption of any single substrate is limited by competition for its unique transporter sites. Including several substrates in a sports drink might accelerate the rate of energy absorption due to the utilization of various independent transport systems, and therefore the best way to provide energy substrate during prolonged exercise. In terms of the fractional oxidation rates of exogenously supplied fuel energy substrates, the results obtained in the present investigation are likely also attributable to the presence of muscle cell (sarcolemmal) transport systems as well as the intracellular pathways of energy substrate utilization. The preference of working muscle for lactate over glucose has been established in combined lactate clamp and tracer studies. The apparent preference for fructose over glucose is likely attributable to the conversion of fructose to lactate and subsequent use of lactate derived from exogenously supplied fructose. Lactate can be taken up by more than one type of tissue during exercise, so it is not known which tissue oxidized lactate in each study. However because working muscle accounts for most of the whole-body pulmonary oxygen consumption during exercise, it can reasonably assumed that working muscle accounted for most of the observed \([U^{13}C]lactate oxidation. Although it is well established that lactate is also the major gluconeogenic precursor that is taken up by the liver and converted to glucose which can be released to maintain blood glucose, if ingested lactate first went to the liver and was converted to glucose, an entirely different kinetic response from that observed would be expected. The appearance of \(^{13}CO_2\) from lactate in the breath would have been far slower than the rapid lactate fractional oxidation rates observed in the present study if gluconeogenesis was a major route of disposal of exogenously supplied lactate. Therefore, it is appropriate to conclude that the rapid oxidation of lactate in comparison to glucose is consistent with results of vascular lactate tracer and clamp procedures showing preferential and direct oxidation of lactate over glucose, and not lactate carbon converted to glucose and then oxidized. The results of the present investigation are important from another aspect because they indicate that at the exercise power output studied, splanchnic blood flow is sufficient for assimilation of the exogenous carbohydrate supply [07308].

**Buffering capacity**

Besides the well-established role of lactate as an essential intermediate between glycolytic and oxidative metabolism, the increased performance occurred could be partially explained by the enhanced buffering capacity of PolyLactate. It has been demonstrated that there is an increased bicarbonate and blood pH during exercise in subjects consuming a drink with PolyLactate as opposed to glucose polymer alone. The lactate in CytoMax is able to stoichiometrically scavenge protons because the lactate anion is the salt of the acid. By scavenging protons, the lactate in C acts to spare bicarbonate during periods of high proton efflux from skeletal muscle or intense exercise (which may explain why five of six subjects sprinted longer after prolonged, hard continuous exercise when consuming C than they did when consuming G). As well, the disposal of exogenous lactate as lactic acid via oxidation or gluconeogenesis results in stoichiometric removal of protons (H\(^+\)). That such a buffering, or other, effect of PolyLactate may have been in operation is suggested because the effect on sprint finishing performance can not be explained on the bases of respiratory gas exchange or blood metabolite levels [07308].

**With caffeine**

Caffeine is the most common ingredient utilized in energy drinks. Caffeine is extracted from the raw fruit of over sixty species of coffee plants (*coffea Arabica*), all part of the
methylxanthine family. Caffeine is also extracted from tea, kola nuts, and cocoa. After ingestion, caffeine is quickly absorbed and increases in plasma concentrations are generally observed between 30-60 minutes following ingestion. The difference in absorption time is dependent on the physicochemical formulation properties of the product dose. Caffeine is a strong cardiovascular stimulant that increases epinephrine output to a greater extent when ingested via its anhydrous formulation when compared to an equal amount of brewed or instant caffeinated coffee. In addition, caffeine’s half-life ranges from approximately 2 to 10 hours with 0.5-3.5 percent of its content excreted unchanged in urine and select amounts eliminated via perspiration. A recent position stand from the Journal of the International Society of Sports Nutrition summarized the effects of caffeine on exercise performance as follows [13633]:

- Caffeine is effective for enhancing sport performance in trained athletes when consumed in low-to-moderate dosages (3-6 mg/kg BM) and overall does not result in further enhancement in performance when consumed in higher dosages (≥ 9 mg/kg BM).
- Caffeine exerts a greater ergogenic effect when consumed in an anhydrous state as compared to coffee.
- It has been shown that caffeine can enhance vigilance during bouts of extended exhaustive exercise, as well as periods of sustained sleep deprivation.
- Caffeine is ergogenic for sustained maximal endurance exercise, and has been shown to be highly effective for time-trial performance.
- Caffeine supplementation is beneficial for high-intensity exercise, including team sports such as soccer and rugby, both of which are categorized by intermittent activity within a period of prolonged duration.
- The literature is equivocal when considering the effects of caffeine supplementation on strength-power performance, and additional research in this area is warranted.
- The scientific literature does not support caffeine-induced diuresis during exercise, or any harmful change in fluid balance that would negatively affect performance.

Several studies have reported significant improvements in both aerobic and resistance exercise with a relative dosage of approximately 2 mg/kg BM of caffeine. This is less than the amount recommended (3-6 mg/kg BM) to enhance performance, and may contribute to the hypothesis that the synergistic effects of the various ingredients contained in ED/ES are responsible for the reported improvements in exercise performance [13633].

With carbohydrate, protein and antioxidants

Another common ingredient in most ED is some type of carbohydrate source (e.g. glucose, sucrose, maltodextrin, etc.). Energy drinks also typically contain glucuronolactone, an ingredient which is involved in ascorbic acid synthesis and is metabolized into xylulose. Evidence from numerous studies indicates that carbohydrate feeding during exercise of about 45 minutes or longer can improve endurance capacity and performance. Mechanisms by which carbohydrate feeding prior to and during exercise improves endurance performance include maintaining blood glucose levels, maintaining high levels of carbohydrate oxidation, and the sparing of liver and possibly skeletal muscle glycogen. Peak rates of carbohydrate oxidation are commonly around 1 g of carbohydrate per minute or 60 g/h. Glucose, sucrose, maltodextrins and amyllopectin are oxidized at high rates, while fructose, galactose and amylose are oxidized at lower rates (approximately 25-50 % lower). Consequently, sports drinks typically contain a mixture of various types of carbohydrates designed to optimize exogenous carbohydrate oxidation. ED’s contain approximately 25-30 grams of carbohydrate per 240 mL (8 fluid ounces) serving. This amount nearly meets the lower value of 30 grams/hour recommended during endurance exercise, but falls short of the upper range of
60 g/hr. In order to meet this upper level of 60 grams of carbohydrate per hour during endurance exercise, approximately 530 mL (18 fluid ounces) of a typical ED per hour would need to be consumed. While the total carbohydrate content of typical ED is quite high, a shortcoming exists in regards to the concentration of commercially available energy drinks. The American College of Sports Medicine and the ISSN recommend ingesting carbohydrate in a 6-8 percent solution (6-8 grams per 100 ml of fluid) during endurance exercise. A typical ED provides carbohydrates at a greater concentration, typically around an 11-12 percent solution. Ingesting higher percentages (>10 %) of carbohydrate in fluids has been reported to delay gastric emptying and increase gastrointestinal distress. Consequently, athletes who want to use ED as sports drinks may need to dilute the beverage and/or alternate consumption of ED and water during exercise [13633].

Fourteen male cyclists were studied to compare the effect of carbohydrate-protein-antioxidant beverage (CHOPA) to an isocaloric carbohydrate-only (CHO) beverage on time to fatigue and muscle damage. Subjects performed two sets of rides to exhaustion on a cycle ergometer. In each set, the first ride was performed at 70 percent VO$_{2peak}$, and the second was performed 24 h later at 80 percent. CHO or CHOPA was consumed every 15 min during exercise and immediately afterward. Plasma CK and LDH and muscle soreness were measured pre- and postexercise. Time to fatigue was not different between CHO and CHOPA at 70 percent VO$_{2peak}$, 80 percent VO$_{2peak}$, or total performance time. Postexercise CK was increased from baseline in CHO but not with CHOPA. Similarly, LDH values increased over baseline in CHO, but not with CHOPA. Postexercise CPK and LDH were higher after the CHO trial than after the CHOPA trial. Median postexercise muscle soreness was higher in CHO than with CHOPA. Thus, no differences in time to fatigue were observed between the beverages, despite lower total carbohydrate content in the CHOPA beverage. The CHOPA beverage attenuated postexercise muscle damage, as evidenced by CK and LDH values, compared with an isocaloric CHO beverage [06259].

With other nutrients

Most ED and ES also contain a small amount of vitamins (e.g. thiamin, riboflavin, niacin, Vitamin B6, Vitamin B12, pantothenic acid, Vitamin C) and electrolytes (e.g. sodium, potassium, phosphorus, etc). While the addition of these nutrients may add to the nutrient density of these products, there is little evidence that ingestion of these vitamins and minerals in the amounts found in ED and ES would provide any ergogenic benefit during exercise performance in well-nourished individuals. Additionally, ED and ES typically contain nutrients purported to promote cognition and mental focus (e.g. Taurine, Ginkgo biloba, L-Tyrosine, Citocoline, 5-Hydroxy-L-Tryptophan [5-HTP], St. John’s Wort, etc), stimulants (e.g. caffeine, Guarana, Green Tea, Synephrine, Yerba mate, Yohimbine, Tyramine, Vinpocetine, etc.), and/or various purported ergogenic nutrients (e.g. panax ginseng, l-carnitine, d-ribose, beta-alanine, inositol, citrulline, quercetin, etc). While there are data to support the potential ergogenic value of some of these nutrients on cognitive function and/or exercise capacity; the amounts found in ED and ES are generally much lower than the typical concentrations associated with an ergogenic effect. Consequently, it is unclear whether adding these nutrients to ED and/or ES provides a synergistic or additive effect to the carbohydrate and caffeine found in these products. In addition, adding these nutrients to the caffeine found in ED and/or ES may change the adverse effect profile of these finished products, and warrant further study [13633].

Effect on exercise performance
Several studies have investigated the effects of ED consumption prior to exercise. The types of exercise that were evaluated include resistance exercise, anaerobic exercise, and aerobic/endurance exercise. Many of the studies investigating the effects of ED ingestion on anaerobic performance measures have been conducted within the past several years. ED (containing approximately 2 mg/kg BM caffeine) consumed 45 to 60 minutes prior to anaerobic/resistance exercise may improve upper- and lower- body total lifting volume, but has no effect on repeated high intensity sprint exercise, or on agility performance. ED containing approximately 2 mg/kg BM caffeine consumed 10 to 40 minutes prior to aerobic exercise improve cycling and running performance in both trained cyclists and recreationally active participants. In the one investigation in which no aerobic performance improvement was reported, the ED (containing 2 mg/kg BM caffeine) was ingested 60-minutes prior to the performance assessment. In light of the other findings, ingestion of the caffeine-containing ED 60-minutes prior to the exercise bout may be too long of a period to realize improvements in aerobic exercise performance. To date, most studies on ED have reported improvements in mood, reaction time, and/or markers of alertness, even though the relative importance of the various ingredients is not fully understood. The primary ergogenic value appears to be due to the caffeine and/or carbohydrate contained in these drinks. Individuals looking to enhance reaction time, mental alertness, and/or focus may benefit from consuming an ED prior to exercise [13633].

Energy drinks and their role in energy expenditure and weight loss

ED and some commercial beverages designed to increase metabolism typically contain a number of stimulants (e.g. caffeine, Guarana, Green Tea, synephrine, Yerba mate, Yohimbine, Tyramine, Vinocetine, etc). Several low-calorie ED and beverages have been marketed as “thermogenic blends” with a focus on increasing metabolism. Theoretically, ingestion of ED prior to exercise may increase energy expenditure which over time could help manage and/or promote weight loss. In support of this theory, studies have shown that ingestion of caffeine (e.g. 200-500 mg) can increase acute (1-24 hours) energy expenditure, chronic (28 days) energy expenditure, and elevate plasma free-fatty acid and glycerol levels. Collectively, these findings suggest that the stimulant properties of caffeine contained in ED can elevate an individual's metabolic rate as well as elevate the rate of lipolysis in the body. However, these studies used various types of caffeine/stimulant/vitamin-enriched coffee, a caffeine/stimulant blend supplement, and various calorie-free thermogenic ED. Consumption of low calorie ED and thermogenic beverages have been reported to increase resting energy expenditure and fat metabolism on an acute basis. Preliminary studies suggest that ingesting some types of ED and thermogenic beverages prior to exercise during training could promote positive adaptations in body composition. However, more research is needed to determine whether daily use of ED would affect long-term energy balance and body composition [13633].

Gastric emptying

The purpose of one study was to examine the gastric emptying and rehydration effects of hypotonic and hypertonic glucose-electrolyte drinks after exercise-induced dehydration. Eight healthy males lost about 1.8 percent body mass by intermittent cycling and rehydrated (150 % of body mass loss) with a hypotonic 2 percent (2 % trial) or a hypertonic 10 percent (10 % trial) glucose-electrolyte drink over 60 min. Blood and urine samples were taken at pre-exercise, post-exercise, and 60, 120, 180 and 240 min post-exercise. Gastric and test drink volume were determined 15, 30, 45, 60, 90 and 120 min post-exercise. At the end of the gastric sampling period 0.3 percent (2 % trial) and 42 percent (10 % trial) of the drinks remained in the stomach. Plasma volume was lower and serum osmolality was greater at 60
and 120 min during the 10 percent trial. At 240 min, 52 percent (2% trial) and 64 percent (10% trial), a statistically significant difference, of the drinks were retained. Net fluid balance was greater from 120 min during the 10 percent trial. When net fluid balance was corrected for the volume of fluid in the stomach, it was greater at 60 and 120 min during the 2 percent trial. These results suggest that the reduced urine output following ingestion of a hypertonic rehydration drink might be mediated by a slower rate of gastric emptying, but the slow gastric emptying of such solutions makes rehydration efficiency difficult to determine in the hours immediately after drinking, compromising the calculation of net fluid balance [13637].

Safety considerations

ED have had a negative connotation in the media and more recently medical community, mostly related to potential concerns about excessive caffeine intake and/or potential deleterious effects of mixing ED with alcohol. While safety concerns and use of alcohol go beyond the scope of this paper, the reader is referred to a recent viewpoint published in the Journal of the American Medical Association related to safety concerns of mixing ED with alcohol. In terms of use of ED in the traditional sense, most concerns have been based on case studies or adverse event reports that have serve only to document a potential association, but does not establish causality. In reality, there are currently only a few studies (acute or long term) that have investigated the side effects of ED. There appear to be two primary active nutrients in most ED and ES (i.e. carbohydrate and caffeine) that may possess safety concerns in some populations. Many ED contain 25-50 g of simple sugars, therefore, ingestion of ED prior to exercise are likely to rapidly increase insulin in order to maintain normal blood glucose levels. For this reason, diabetics and pre-diabetics should avoid high glycemic load ED or consider consuming low carbohydrate versions of ED. Very often, ED also contain various stimulants with the most common being caffeine. Some concern has been raised about excessive caffeine intake that could be obtained from consuming too many ED and/or from a lack of knowledge that that some ingredients contained in ED may contain caffeine. However, if caffeine is added to a food, it must then be listed; therefore many individuals may consume more caffeine than they realize. In Canada, caffeine levels are limited to 180 mg per drink. The caffeine content of common ED and ES has been reported to range from about 100 to 286 mg. As a comparison, the average cup of coffee or contains between 40 and 150 mg caffeine, while a 20 oz. cup of Starbucks regular drip coffee has been found to contain as much as 480 mg of caffeine. The potential side effects of caffeine include: insomnia, nervousness, restlessness, gastric irritation, nausea, vomiting, tachycardia, tremors, and anxiety; which have been reported at doses as low as 250 to 300 mg. Caffeine availability is ubiquitous and it is one of the most extensively studied substances in the food supply with a long history as generally regarded as safe when consumed in moderation. However, all substances may be toxic under the right conditions, with toxicity being a function of the interaction of many physiologic variables that include the following: acute and chronic dosing, route of administration, genetics, age, sex, environment, and intrinsic health of the individual being exposed. Young adults have been found to have subclinical coronary atherosclerosis. In addition, post-mortem assessment of sudden cardiac death in young persons (<35 years) reveals a variety of anatomic abnormalities of the coronary arteries, myocardium, valves and the conduction system. A lethal dose of caffeine has been typically in excess of 5 g, which equates to about 42 cups of coffee at 120 mg of caffeine per cup. Individuals with certain medical conditions (e.g. metabolic syndrome or diabetes mellitus) should avoid consumption of high glycemic drinks and/or foods and therefore should not consume the high caloric versions of ED. It would be prudent for individuals with known cardiovascular disease to avoid altogether their use of ED and/or ES, or other products with known cardio-stimulant effects. While ED containing caffeine and other stimulants may have negative effects upon health and cardiac parameters in individuals with such pre-existing health conditions, the current evidence (although small) suggests that
consumption of ED and ES are safe in healthy populations and similar to ingesting other foods and beverages containing caffeine [13633].

**Consumption pattern**

Sales of sports and energy drinks have increased dramatically, but there is limited information on regular consumers of sports and energy drinks. Characteristics associated with sports and energy drink intake were examined among a sample representing the civilian noninstitutionalized US adult population. The 2010 National Health Interview Survey data for 25,492 adults (18 years of age or older; 48 % males) were used. Nationwide, 31 percent of adults were sports and energy drink consumers during the past 7 days, with 22 percent consuming sports and energy drinks one or more times per week and 11.5% consuming sports and energy drinks three or more times per week. Based on multivariable logistic regression, younger adults, males, non-Hispanic blacks and Hispanics, not-married individuals, adults with higher family income, those who lived in the South or West, adults who engaged in leisure-time physical activity, current smokers, and individuals whose satisfaction with their social activities/relationships was excellent had significantly higher odds for drinking sports and energy drinks one or more times per week. In this model, the factor most strongly associated with weekly sports and energy drink consumption was age. Lower odds for consuming sports and energy drinks one or more times per week were associated with other/multiracial (OR=0.80 vs non-Hispanic white) and obesity (OR=0.87 vs underweight/normal weight). Separate modeling of the association between other beverage intake and sports and energy drink intake showed that higher intake of regular soda, sweetened coffee/tea drinks, fruit drinks, milk, 100 percent fruit juice, and alcohol were significantly associated with greater odds for drinking sports and energy drinks one or more times per week. These findings can help medical care providers and public health officials identify adults most in need of encouragement to reduce sports and energy drink intake and increase healthier beverage intake [13635].

**Beverage after aerobic activity**

Recovery beverages are commonly used by endurance and team-sport athletes during the time between exercise sessions. Practical recommendations on the optimal nutrient composition of these drinks and timing of their consumption are therefore needed. One article summarized research to date on the use of recovery beverages after aerobic activities and provides the following recommendations for practitioners on the optimal formula and timing of use for endurance and team-sport athletes. Current evidence suggests that, to maximize glycogen resynthesis, athletes should consume about 1.2 g carbohydrate per kilogram body weight as glucose and sucrose immediately after exercise and each hour thereafter for 4-6 hours postexercise. Alternatively, they may consume 0.8 g/kg/h in combination with 0.4 g/kg/h amino acids or protein. Liquids provide valuable fluids for rehydration, and an ideal recovery beverage should not only contain carbohydrate and protein but also contain electrolytes, including about 0.3-0.7 g sodium-per liter fluid to help restore sodium lost through sweat. Commercial beverages with this type of nutrient composition are effective, and recent work indicates that chocolate milk may be as effective as or superior to these in promoting recovery. Research regarding the effects of specific types of amino acids and antioxidants on recovery is mixed; thus, further investigation is needed before specific recommendations about these nutrients can be made. Future studies that include women and athletes representing a variety of sports, ages, and training levels and that use consistent methodology will lead to a better understanding of the effects of postexercise intake on recovery [11525].
In school children

High intake of sugar-sweetened beverages in childhood is linked to increased risk of obesity and type II diabetes later in life. Using three nationally representative surveys of dietary intake, we investigated beverage patterns and trends among US school-aged children from 1989/91 to 2007/08. 3, 583 participants ages 6-11 years old were included. It was reported per capita trends in beverage consumption, percent consuming, and amount per consumer for the following categories of beverages: sugar-sweetened beverages (SSB), caloric nutritional beverages (CNB) and low calorie beverages (LCB). While per capita kcal contribution from total beverages remained constant over the study period, per capita consumption of SSBs increased and CNBs decreased in similar magnitude. The substantial increase in consumption of certain SSBs, such as fruit drinks and soda, high fat high sugar milk, and sports drinks, coupled with the decrease in consumption of high fat low sugar milk was responsible for this shift. The percent consuming SSBs as well as the amount per consumer increased significantly over time. Per capita intake of total milk declined, but the caloric contribution from high fat high sugar milk increased substantially. Among ethnicities, important differences in consumption trends of certain SSBs and 100 percent juice indicate the complexity in determining strategies for children's beverage calorie reduction. It was concluded that as upward trends of SSB consumption parallel increases in childhood obesity, educational and policy interventions should be considered [11526].

Organized sport provides one option for children to be physically active. However, there is a paucity of information about the relationship between children's participation in organized sport and their diet, and specifically their sports drink consumption. Therefore, the relationship between sports participation in children and the consumption of sports drinks, sugar-sweetened beverages (SSBs) and other components of diet was examined. A cross-sectional descriptive study was conducted using baseline data from the Action Schools! BC Dissemination study cohort (n=1421; 10 years; 736 girls, 685 boys). The differences between the dietary behaviours of children participating in organized sport (sport) versus those that did not participate (non-sport) was examined. A modified Physical Activity Questionnaire for Older Children (PAQ-C) was used to measure physical activity levels and participation in organized sport. A Food Frequency Questionnaire (FFQ) and 24-hour dietary recall were used to assess eating behaviour and macronutrient intake (including protein, fat, and carbohydrate as well as sugar, fibre and total calories). Fruit, vegetable and beverage quantities were hand-tallied from the dietary recall. Fruit, vegetable and beverage frequency was assessed using the FFQ. Analysis of covariance (ANCOVA) was used to analyse differences between groups and a chi-square test of association was use to determine if participation in sport was significantly associated with the proportion of children consuming sports drinks and SSBs, and with gender. Children involved in sport had a lower body mass index (BMI) and were more physically active than children in the non-sport group. Only a small number (n = 20/1421) of children consumed sports drinks and no difference in consumption of sports drink between sport and non-sport participants was observed. However, children involved in organized sport consumed more total calories, fat, fibre, fruit, vegetables and non-flavoured milk than non-sport children. It was concluded that children involved in organized sport were more physically active, consumed a healthier diet than non-participants and on average had lower BMI's despite consuming more calories. As consumption of sports drinks among this age group was low, this may be an ideal time to begin educating children and their parents about the appropriate consumption of sports drinks and the perils of consuming too many SSBs, specifically [13636].

Adverse effects
It was reported a case of a 17-year-old boy who suffered acute renal failure after consuming 3 L of energy drink in combination with 1 L of vodka amounting to 4600 mg of taurine and 780 mg of caffeine mixed with 380 g of alcohol. The consumption of this mixture is extremely popular in adolescents, because the joint effects of caffeine and taurine reduce the effect of alcohol. Although there have been case reports of deaths linked to the consumption of energy drinks with and without alcohol, awareness of the possible dangers is still low. The fact that athletes and major sports events are sponsored by energy drink manufacturers imply that they may even be healthy and performance-enhancing [11395].

**Sweet, non-alcoholic beverages**

One study aimed to analyse the contribution of Australian print news coverage to the public profile of sweet, non-alcoholic beverages. News media portrayal of health contributes to individuals' decision-making. The focus on sugar-sweetened beverages reflects their contribution to excessive energy intake. One year's coverage of sweet, non-alcoholic beverages by major Australian newspapers was analysed using content and frame analysis. Research questions addressed which sweet drinks are most prominently covered, what makes sweet drinks newsworthy and how are the health aspects of sweet drinks framed? Fruit juice was the most widely covered sweet drink, closely followed by carbonated, sugar-sweetened soft drinks. Overall coverage was positively oriented towards sweet drinks, with fruit juice primarily portrayed as having health benefits. Some coverage mentioned risks of sweet drinks, such as obesity, tooth decay, metabolic syndrome and heart attack. Sweet drinks often enjoy positive coverage, with their health benefits and harms central to their ability to attract journalists' attention. However, the mix of coverage may be contributing to consumer confusion about whether it is safe and/or healthy to consume sweet non-alcoholic drinks. Framing of sweet drinks as healthy may undermine efforts to encourage individuals to avoid excess consumption of energy-dense drinks which offer few or minimal health benefits [11396].

**Red bull**

Energy drinks are frequently consumed by athletes prior to competition to improve performance. This study examined the effect of Red Bull® on repeated sprint performance in women athletes. Fifteen collegiate soccer players participated. After performing a familiarization trial, subjects performed three sets of eight bouts of the modified t test after ingestion of 255 mL of placebo or Red Bull 1 h pre-exercise in a randomized, placebo-controlled crossover design. Throughout testing, sprint time, heart rate (HR), and rating of perceived exertion (RPE) were continuously obtained. Repeated measures analysis of variance was used to examine differences in variables between drink conditions. Across athletes, t test time ranged from 10.4 to 12.7 s. Mean sprint time was similar between Red Bull and placebo. HR and RPE increased during the bouts, but there was no effect of Red Bull on either variable versus placebo. Findings indicate that 255 mL of Red Bull containing 1.3 mg/kg of caffeine and 1 g of taurine does not alter repeated sprint performance, RPE, or HR in women athletes versus placebo. One serving of this energy drink provides no ergogenic benefit for women athletes engaging in sprint-based exercise [11263].

The purpose of one study was to determine the effects of Red Bull energy drink on Wingate cycle performance and muscle endurance. Healthy young adults (n=15, 11 men, 4 women, 21 years old) participated in a crossover study in which they were randomized to supplement with Red Bull (2 mg/kg body mass of caffeine) or isoenergetic, isovolumetric, noncaffeinated placebo, separated by 7 days. Muscle endurance (bench press) was assessed by the maximum number of repetitions over 3 sets (separated by 1-min rest intervals) at an intensity
corresponding to 70 percent of baseline 1-repetition maximum. Three 30-s Wingate cycling tests (load = 0.075 kp/kg body mass), with 2 min recovery between tests, were used to assess peak and average power output. Red Bull energy drink significantly increased total bench-press repetitions over 3 sets, but had no effect on Wingate peak or average power. It was concluded that Red Bull energy drink significantly increased upper body muscle endurance but had no effect on anaerobic peak or average power during repeated Wingate cycling tests in young healthy adults [07311].

Energy drinks (ED) such as Red Bull (RB) are marketed to enhance metabolism. Secondary ingredients of EDs (e.g., taurine) have been purported to improve time-trial performance; however, little research exists on how such secondary ingredients affect aerobic metabolism during heavy exercise. The purpose of one study was to investigate the effect of the secondary ingredients of RB on aerobic metabolism during and subsequent to heavy exercise. In double-blind, counterbalanced, and crossover fashion, 8 recreationally trained individuals completed a graded exercise test to determine the gas exchange threshold (GET). Subjects returned on two separate occasions and ingested either an 245 ml serving of RB or a control (CTRL) drink with the equivalent caffeine prior to engaging in two, 10-min constant-load cycling bouts, at an intensity equivalent to GET, with 3 min of rest between bouts. Accumulated liters of O\textsubscript{2} (10 min) was higher for the first (17.1 ± 3.5 L) versus the second (16.7 ± 3.5 L) bout but did not differ between drinks. Similarly, excess post-exercise oxygen consumption was higher following the initial versus second bout but did not differ between drinks. No differences occurred between drinks for measures of heart rate or rating of perceived exertion. These results indicate that the secondary ingredients contained in a single serving of RB do not augment aerobic metabolism during or subsequent to heavy exercise [12403].

Energy drinks are frequently consumed by athletes prior to competition to improve performance. One study examined the effect of Red Bull™ on repeated sprint performance in women athletes. Fifteen collegiate soccer players participated, with mean age, height, and body mass equal to 20 year, 168 cm, and 63 kg, respectively. After performing a familiarization trial, subjects performed three sets of eight bouts of the modified t test after ingestion of 255 mL of placebo or Red Bull 1 h pre-exercise in a randomized, placebo-controlled crossover design. Throughout testing, sprint time, heart rate (HR), and rating of perceived exertion (RPE) were continuously obtained. Repeated measures analysis of variance was used to examine differences in variables between drink conditions. Across athletes, t test time ranged from 10.4 to 12.7 s. Mean sprint time was similar between Red Bull and placebo. HR and RPE increased during the bouts, but there was no effect of Red Bull on either variable versus placebo. Findings indicate that 255 mL of Red Bull containing 1.3 mg/kg of caffeine and 1 g of taurine does not alter repeated sprint performance, RPE, or HR in women athletes versus placebo. One serving of this energy drink provides no ergogenic benefit for women athletes engaging in sprint-based exercise [12404].

To investigate the effects of a caffeine-containing energy drink on soccer performance during a simulated game 19 semiprofessional soccer players ingested 630 ± 52 mL of a commercially available energy drink (sugar-free Red Bull®) to provide 3 mg of caffeine per kg of body mass, or a decaffeinated control drink (0 mg/kg). After sixty minutes they performed a 15-s maximal jump test, a repeated sprint test (7 × 30 m; 30 s of active recovery) and played a simulated soccer game. Individual running distance and speed during the game were measured using global positioning satellite devices. In comparison to the control drink, the ingestion of the energy drink increased mean jump height in the jump test, mean running speed during the sprint test and total distance covered at a speed higher than 13 km/h during the game. In addition, the energy drink increased the number of sprints during the whole game. Post-exercise urine caffeine concentration was higher after the
energy drink than after the control drink. A caffeine-containing energy drink in a dose equivalent to 3 mg/kg increased the ability to repeatedly sprint and the distance covered at high intensity during a simulated soccer game. In addition, the caffeinated energy drink increased jump height which may represent a meaningful improvement for headers or when players are competing for a ball [12274].

Preworkout products - unregulated dietary supplements - typically contain "proprietary blends" of multiple ingredients, including caffeine, dimethylamylamine, creatine, arginine, beta-alanine, taurine, and phosphates. While some dietary supplement labels instruct consumers to seek the advice of a health care professional before using the products, the labels usually do not disclose all ingredients or their precise amounts, and evidence to support the purported performance-enhancing benefits is generally lacking. There is limited evidence to support the use of some preworkout supplement ingredients. For example, in one small placebo-controlled study (n=12), the use of the energy drink Red Bull (containing caffeine and taurine) 40 minutes before a simulated cycling time trial appeared to provide a meaningful ergogenic benefit; in another small study (n=12), the use of a similar caffeine-containing product (Redline) by strength-trained athletes was found to improve reaction time, energy, and mental focus relative to placebo use. However, published evidence on the use of the other ingredients listed above is scant, inconclusive, or conflicting. Adverse effects reported in association with preworkout supplements include gastrointestinal symptoms, cardiac arrhythmia, blood pressure increases, and potential effects on lipids and blood glucose. Thus, although evidence exists to support the performance-enhancement efficacy of some preworkout ingredients as standalone agents, published data on combination products are scant, inconclusive, or conflicting. The safety of these products may be compromised if users consume larger-than-recommended amounts or use more than one product [13623].

Consumption of energy drinks by both recreational and competitive athletes has increased dramatically in recent years. The primary ingredients in many energy drinks include caffeine (CAF) in various forms and taurine. The purpose of this randomized, double-blind, crossover study was to examine the effect of sugar-free (SF) Red Bull (RB) containing CAF and taurine to a CAF only drink and a SF CAF-free placebo (PL) on 1 repetition maximum (1RM) bench press (BP) and the volume load (VL; repetitions x kg at 70 % 1RM) during one BP set to failure in experienced lifters. Seventeen college-age men randomly received the following: (A) 500 mL of SF-RB containing CAF (160 mg) and taurine (2000 mg); (B) 500 mL of a SF drink containing CAF only (160 mg); or (C) a SF CAF-free 500 mL PL drink 60 minutes before testing on 3 separate occasions. After a standard warm-up, the 1RM was determined for each subject and, after 5 minutes rest, they completed repetitions to failure at 70 percent of their 1RM to assess VL. Differences between trials for 1RM BP and the VL were identified using repeated measures analysis of variance. The results indicated that neither SF-RB nor the CAF drink had any effect on 1RM BP or VL compared with PL. Although the CAF content in the energy drinks used in the present study was low (2.0 mg/kg), the finding of no effect of the CAF containing energy drinks for 1RM BP are in agreement with previous studies using intakes up to 6.0 mg/kg. These findings suggest that SF-RB has no effect on upper body 1RM strength or VL in resistance trained men [13624].

Energy drinks (EDs) such as Red Bull (RB) are marketed to enhance metabolism. Secondary ingredients of EDs (e.g. taurine) have been purported to improve time trial performance; however, little research exists on how such secondary ingredients affect aerobic metabolism during heavy exercise. The purpose of one study was to investigate the effect of the secondary ingredients of RB on aerobic metabolism during and subsequent to heavy exercise. In double-blind, counterbalanced, and crossover fashion, 8 recreationally trained individuals completed a graded exercise test to determine the gas exchange threshold (GET). Subjects returned on 2 separate occasions and ingested either a 245 ml serving of
RB or a control (CTRL) drink with the equivalent caffeine before engaging in two 10-minute constant-load cycling bouts, at an intensity equivalent to GET, with 3 minutes of rest between bouts. Accumulated liters of O₂ (10 minutes) were higher for the first bout (17.1 ± 3.5 L) versus the second bout (16.7 ± 3.5 L) but did not differ between drinks. Similarly, excess postexercise oxygen consumption was higher after the initial bout (RB mean, 2.6 ± 0.85 L; CTRL mean, 2.9 ± 0.90 L) versus the second bout (RB mean, 1.5 ± 0.85 L; CTRL mean, 1.9 ± 0.87 L) but did not differ between drinks. No differences occurred between drinks for measures of heart rate or rating of perceived exertion. These results indicate that the secondary ingredients contained in a single serving of RB do not augment aerobic metabolism during or subsequent to heavy exercise [13625].

Canada

Although many of us regularly enjoy tea, coffee and other caffeinated beverages, most of us have enough common sense not to willingly allow children to consume 10 cans of cola in one sitting — the amount of caffeine in 500 mL of some energy drinks. Owing to inadequate labelling requirements, a lack of awareness of caffeine’s harmful effects and marketing campaigns that appeal to children and youth, this is precisely what we are unwittingly allowing in Canada and elsewhere. Energy drinks are very effective high-concentration caffeine delivery systems. These sugar-loaded syrups typically contain 80 to 140 mg of caffeine per 250 mL — the equivalent caffeine in one cup of coffee or two cans of cola. However, beverage companies are offering formulations with caffeine concentrations as high as 500 mg per can in US products such as Wired X505™ and Fixx™. Caffeine can also be purchased in 100- and 200-mg tablets in Canada and the United States. However, even tablets with two and one-half to five times less caffeine have mandatory health warnings guarding against use in children and cautions to limit use because too much caffeine may cause nervousness, irritability, sleeplessness and, occasionally, rapid heart rate. Caffeine-loaded energy drinks have now crossed the line from beverages to drugs delivered as tasty syrups. Health Canada has taken steps to regulate many energy drinks as natural health products with warnings on labels. However, many energy drinks are still considered foods that only list ingredients. Neither natural health products nor foods list total caffeine content or easily understood equivalents in terms of cups of coffee because caffeine-containing herbal extracts are listed separately. People who are inclined to downplay such concerns might argue that caffeine has been safely consumed in foods for centuries. Consumers of more traditional caffeinated beverages indicate that acute intoxication lasts only a few hours, with seemingly few serious short- or long-term health consequences. Moreover, popular coffee retailers sell products with large amounts of caffeine. For instance, a 16-oz “grande” coffee at Starbucks contains 330 mg of caffeine. However, marketing of energy drinks is distinctly different from that of other highly caffeinated beverages. Energy drinks are often targeted toward children and youth through carefully designed advertising campaigns as well as sponsorship of events such as snowboarding and skateboarding competitions. Children and youth are notorious for making poor health choices. They can hardly be expected to make appropriate decisions about consuming energy drinks when information on caffeine concentration and appropriate safe amounts is not visible on these products. In children, effects of high concentrations of caffeine should concern us. A study of 100 US adolescents aged 12 to 18 found that 73 percent consumed 100 mg or more of caffeine per day, with most consumption in the evening, the time of day most likely to negatively affect sleep. Poor sleep quality and quantity in adolescents has been associated with mood disorders, exacerbation of asthma, obesity, lower sense of well-being and poor school performance. Given the potential for harm, regulatory authorities such as Health Canada should step in. Regulations could include government-mandated restrictions on labelling, sales and marketing, or self-imposed industry-wide standards with clear labelling accompanied by public education. Many countries have either imposed or tried to impose strict regulations
because of potential health risks of caffeine. Until 2008, France did not even allow the sale of Red Bull™, and in Denmark, sale was prohibited as of 2009 [10523].

In Canada, energy drinks are formulated, labelled and marketed in accordance with Health Canada’s Natural Health Product Regulation and policies. They are not regulated or labelled as foods. Energy drinks must be marketed in compliance with the Consumer Advertising Guidelines for Marketed Health Products. Energy drinks are intended for adults; the labels clearly indicate that this category of beverage is not recommended for children and people who are sensitive to caffeine, and they include warnings not to mix the beverage with alcohol. Unlike coffee and iced coffee beverages, which have no warnings or quantitative labelling, all energy drinks declare levels of caffeine from all sources (natural and synthetic).

In Canada, mainstream energy drinks contain less caffeine by volume than a cup of filter drip coffee (80–140 mg per energy drink v. 179 mg per 237 mL cup of coffee). Labels on energy drinks advise consumers to have only one drink per day. Nowhere in this country are there energy drinks with caffeine levels approaching those suggested in the editorial. Energy drinks have been the subject of extensive review and analysis by regulatory authorities worldwide. Without exception, these reviews have confirmed the safety of these products in markets around the world [10524].

USA

To examine the dietary and activity correlates of sugar-sweetened beverage consumption by children in middle and high school data were obtained from a cross-sectional survey of 15,283 children in middle and high schools in Texas. Consumption of sodas and noncarbonated flavored and sports beverages (FSBs) were examined separately for their associations with the level of (1) unhealthy food (fried meats, French fries, desserts) consumption, (2) healthy food (vegetables, fruit, and milk) consumption, (3) physical activity including usual vigorous physical activity and participation in organized physical activity, and (4) sedentary activity, including hours spent watching television, using the computer, and playing video games. For both genders, consumption of soda and FSBs was systematically associated with a number of unhealthy dietary practices and with sedentary behaviors. However, consumption of FSBs showed significant positive graded associations with several healthy dietary practices and level of physical activity, whereas soda consumption showed no such associations with healthy behaviors. It was concluded that consumption of FSBs coexists with healthy dietary and physical activity behaviors, which suggests popular misperception of these beverages as being consistent with a healthy lifestyle. Assessment and obesity-prevention efforts that target sugar-sweetened beverages need to distinguish between FSBs and sodas [10525].

Effects of cold drinks

The aims of one study were to determine the effect of cold (4 °C) and thermoneutral (37 °C) beverages on thermoregulation and performance in the heat and to explore sensory factors associated with ingesting a cold stimulus. Seven males completed cold, thermoneutral, and thermoneutral + ice trials in randomized order. Participants cycled for 90 min at 65 percent of $\text{VO}_{2\text{peak}}$, followed by a 15-min performance test at 28 °C and 70 percent relative humidity. They ingested 2.3 ml per kg of a 7.4 percent carbohydrate-electrolyte solution every 10 min during the 90-min steady-state exercise including 30 ml ice puree every 5 min in the ice trial. Absolute changes in skin temperature, mean body temperature, and heat storage were lower across the 90-min exercise bout for the cold compared with the thermoneutral trial. Significant improvements in performance were observed with cold but no significant differences were detected with ice. Consumption of cold beverages during prolonged exercise in the heat improves body temperature measures and performance. Consumption of
ice did not reveal a sensory response, but requires further study. Beverages consumed by athletes exercising in the heat should perhaps be cold for performance and safety reasons [10404].

Proteins

Skeletal muscle protein turnover rates are 1-2 percent/d and exist in dynamic, usually balanced, equilibrium between muscle protein breakdown (MPB) and muscle protein synthesis (MPS). For example, in the fasted state, MPB>MPS, whereas in response to ingestion of protein-containing meals, MPS>MPB. Thus, in healthy adults, muscle mass remains relatively stable due to “fed-gain” being balanced by fasted-loss, so daily protein flux, while it may be 3-4 times greater than net intake and loss, is in tight balance. Fasted-state protein losses are typically about 40-60 g/d for a sedentary person weighing 70-90 kg and it is debatable what the losses would be in athletes, be they aerobically or resistance trained. Dietary protein for athletic populations can serve as signal and substrate for MPS, resulting in protein accretion for hypertrophy, repair of damaged proteins or assisting the maintenance of lean mass. There are important messages for athletes, who differ from sedentary individuals, in terms of quantity, timing and quality of protein intake in relation to an athlete's training stimulus. The molecular changes underpinning these adaptations are gene transcription and mRNA translational signalling and are highlighted in a review. The general consensus is that adults need no more than 0.8-0.9 g/kg/d of protein to meet their needs. However, the notion of consumption of “extra” protein above these levels to cover the needs of increased physical activity is not considered. Dietary guidelines for athletes typically recommend protein intakes of 1.2–1.7 g/kg/d, based on maintaining nitrogen (i.e. protein) balance. By all accounts, nitrogen balance is a flawed method, measuring the minimum amount of protein required to balance losses. Given the functional demands of training and performance, an optimal protein intake for athletes might exist beyond merely satisfying a minimal requirement and thus being in nitrogen balance. Indeed, protein intakes of 0.86 g/kg/d have been shown to reduce whole-body protein synthesis rates in strength-trained athletes, suggesting that current recommendations for athletes may be insufficient if synthetic rates of proteins are adversely affected. Recently, it was demonstrated a protein dose response following resistance exercise. Specifically, resistance exercise-induced MPS increased in a curvilinear fashion with ingestion of graded amounts of isolated egg protein, reaching a plateau at 20 g, with no further increase at 40 g of protein. The amino acids supplied beyond 20 g of postexercise protein were not assimilated into new muscle protein but instead were directed toward oxidation. Interestingly, 10 g of essential amino acids (EAA), equivalent to 25 g of most high-quality intact protein, has been shown to maximally stimulate MPS at rest also [12405].

There is no clear consensus as to whether protein ingestion before, during or after exercise promotes the greatest adaptive response. With respect to pre-exercise feeding, acute and long-term studies, comparing pre- and post-training protein feeding have yielded equivocal results. Consumption of protein during exercise may serve to provide amino acids required to improve protein balance during and after exercise. However, in these studies, carbohydrate and amino acids were provided: given the profound impact of insulin for the suppression of MPB, it may be that the greater net balance is simply an artefact of energy intake suppressing MPB and not a protein-mediated rise in MPS. In addition to adaptation, ingestion of additional protein during endurance exercise does not improve performance, reduce proxy markers of muscle damage or hasten the recovery of muscle function. The potency of postexercise protein ingestion for potentiating MPS is unequivocal. After exercise, the energy status of the cell is returning to resting levels, signalling that pathways are still active, the muscle is prone to greater rates of MPS, and all of these effects are enhanced.
with feeding. Resistance exercise specifically targets a synthetic response of myofibrillar proteins, it is therefore not surprising that protein ingestion augments this response. Interestingly, protein ingestion also potentiates the acute muscle protein synthetic response to endurance exercise. Surprisingly, despite acute increases in mitochondrial protein synthesis with endurance exercise, protein ingestion following a prolonged cycle did not potentiate this response, but instead increased the synthesis of myofibrillar proteins. Thus, protein ingestion may assist in maintaining muscle structural integrity and power-generating capacity, rather than influencing muscle aerobic capacity [12405].

High volume resistance exercise appears to sensitise the muscle to amino acid provision beyond the so called ‘window of opportunity’; a period thought to induce the greatest muscle anabolic effect. Thus, while there is some debate about the critical nature of the timing of postexercise protein consumption, it was recommend that the sooner athletes consume protein after exercise the better. In addition, relatively frequent protein ingestion (i.e. every 3-4 h) over 24 h after exercise to sustain the elevation in MPS is also recommended. A protein digestibility corrected amino acid score close to 1.0 is defined as “high quality”. This includes animal protein sources such as milk (composed of whey and casein protein), eggs, isolated soya protein and most meats. Habitual consumption of high-quality protein sources has a pronounced effect on muscle recovery and adaptation. For example, milk proteins result in a pronounced increase in MPS after resistance exercise, compared with equivalent amounts of isolated soya protein which, over time, promotes greater hypertrophy and is likely to be due to the whey protein constituent in milk. Whey proteins stimulate greater rates of MPS over isonitrogenous amounts of casein and soy protein at rest and after exercise. The mechanisms underpinning the anabolic advantage of whey protein are not entirely clear, but maybe due to the relative amount of the branched-chain amino acids, in particular, leucine. Leucine occupies a position of prominence in that it alone can act as a stimulatory signal for MPS. Milk proteins and whey, in particular, are highly enriched with leucine. More importantly perhaps, the rapid absorption kinetics of whey proteins (or hydrolysed slow digested proteins) induces a greater rate of leucine appearance in the circulation than soy and casein proteins and may be important for stimulating MPS. Thus, although rapid leucinemia may be important in activating MPS, provision of other EAAs may be required to sustain the anabolic response [12405].

Based on the current evidence, the following strategies are proposed which should be very effective at allowing repair, remodelling and adaptation, and gains in lean mass in athletes [12405]:

- daily intakes higher than the RDA (1.2–1.6 g/kg/d)
- emphasise dairy source proteins enriched in leucine
- consume protein in doses of 20-25 g/serving to maximise adaptive responses
- equally spaced protein meals throughout the day
- consumption of protein immediately after exercise.

Carbohydrate ingestion after prolonged strenuous exercise enhances recovery, but protein might also be important. In a crossover with 2-week washout, 10 cyclists completed 2.5 h of intervals followed by 4-h recovery feeding, provided 218 g protein, 435 g carbohydrate, and 79 g fat (protein enriched) or 34 g protein, 640 g carbohydrate, and 79 g fat (isocaloric control). The next morning, cyclists performed 10 maximal constant-work sprints on a Velotron cycle ergometer, each lasting approximately 2.5 min, at approximately 5-min intervals. Test validity was established and test reliability and the individual response to the protein-enriched condition estimated by 6 cyclists' repeating the intervals, recovery feeding, and performance test 2 week later in the protein-enriched condition. During the 4-h recovery, the protein-enriched feeding had unclear effects on mean concentrations of plasma insulin,
cortisol, and growth hormone, but testosterone was 25 percent higher (90 % confidence limits ± 14 %). Protein enrichment also reduced plasma creatine kinase by 33 percent (90 % confidence limits ± 38 %) the next morning and reduced tiredness and leg-soreness sensations during the sprints, but effects on mean sprint power were unclear. To conclude, protein-enriched recovery feeding had no clear effect on next-day performance [08385].

Muscle protein turnover following resistance exercise and amino acid availability are relatively well described. By contrast, the beneficial effects of different sources of intact proteins in relation to exercise need further investigation. The objective of one report was to compare muscle anabolic responses to a single bolus intake of whey or casein after performance of heavy resistance exercise. Young male individuals were randomly assigned to participate in two protein trials (n = 9) or one control trial (n = 8). Infusion of L-[1-13C]leucine was carried out, and either whey, casein (0.3 g/kg lean body mass), or a noncaloric control drink was ingested immediately after exercise. L-[1-13C]leucine-labeled whey and casein were used while muscle protein synthesis (MPS) was assessed. Blood and muscle tissue samples were collected to measure systemic hormone and amino acid concentrations, tracer enrichments, and myofibrillar protein synthesis. Western blots were used to investigate the Akt signaling pathway. Plasma insulin and branched-chain amino acid concentrations increased to a greater extent after ingestion of whey compared with casein. Myofibrillar protein synthesis was equally significantly increased 1-6 h postexercise after whey and casein intake, both of which were higher compared with control. Phosphorylation of Akt and p70(S6K) was increased after exercise and protein intake, but no differences were observed between the types of protein except for total 4E-BP1, which was higher after whey intake than after casein intake. In conclusion, whey and casein intake immediately after resistance exercise results in an overall equal MPS response despite temporal differences in insulin and amino acid concentrations and 4E-BP1 [10515].

Amino acids are commonly described as the building blocks of protein. In chemistry, an amino acid is a molecule containing both amine and carboxyl functional groups. The majority of amino acids ingested by humans are in a combined form as dietary proteins from both animal and vegetable sources. Not all proteins in the diet have the same nutritional value, because they contain different proportions of essential amino acids. Essential and non-essential amino acids refers to whether or not the amino acid in question can be synthesised by the body at a rate sufficient to meet normal requirements for protein synthesis. On this basis, sufficient essential amino acids are contained in “first-class proteins” or “complete proteins”, for example dairy products, eggs, fish and meat. However, proteins from plant sources, known as “second-class proteins” can be combined with each other to make complete proteins. For example, grains plus legumes, grains plus nuts or seeds, and legumes plus nuts or seeds, with legumes including both pulses (peas and beans) and peanuts, can be consumed during the day to ensure adequate amounts of essential amino acids are obtained. Strict vegetarian athletes and, in particular, vegans, need to plan their diet to ensure that their daily combination of plant foods provides them with all the essential amino acids. During intensive training they may need to consider supplementing the diet with essential amino acids. Recent research suggests that the timing of the intake of protein related to exercise may be more important than the total amount of protein consumed in a day. In the case of resistance training, an intake of approximately 20-25 g of a high quality protein source in the hour after exercise appears to produce the maximum rate of protein synthesis. More work is needed to examine the case for other types of exercise. However, it is only the essential amino acids that are needed to achieve this effect, so athletes who need to be energy conscious may opt to consume simply 6-8 g of essential amino acids rather than a whole protein source. Several exercise studies have looked at changes in total plasma amino acids; this seems unhelpful, because some do not change, some go up and some go down. Rather than simply considering amino acids as a precursor for protein
synthesis, it is likely to be of more benefit to look at individual amino acids and specific roles they may play in metabolism and cell signalling pathways. Those that have so far been researched either individually or in combination within supplements will each be the focus of a short, separate section in this review series. Concerns arise over the consumption of single amino acids, due to the impact it may have on an imbalance of other amino acids. In general, therefore, it is better to opt for an even mix of all or just essential amino acids. Nevertheless, there may sometimes be a sound biochemical argument in favour of the repletion of specific nutrients, certainly during long-term depletion, and sometimes during transient depletion, in a variety of situations.

Ingesting protein (PRO) with CHO during prolonged exercise is purported to improve performance compared with CHO alone by altering the regulation of skeletal muscle energy provision. However, no study has directly investigated this issue. It was therefore tested the hypothesis that compared with CHO alone, coingestion of PRO would alter markers of metabolic control, including the magnitude of glycogen use and the net expansion of the tricarboxylic acid cycle intermediate pool, which has been linked to the capacity for oxidative energy delivery. Eight trained men cycled at 69 % VO2peak for 90 min on two occasions, and biopsy samples (vastus lateralis) were obtained before and after exercise. In a randomized, double-blind manner, subjects ingested one of two drinks during exercise that contained either 6 percent CHO or 6 percent CHO + 2 percent PRO (CHO + PRO) at a rate of 1 L per hour. CHO + PRO ingestion significantly increased the plasma concentration of branched chain and essential amino acids after exercise versus CHO. However, net muscle glycogen use and tricarboxylic acid cycle intermediate expansion were similar between trials. Blood creatine kinase activity and 20-km time trial performance measured approximately 24 h after the first exercise bout were not different between treatments. It was concluded that coingestion of protein does not alter specific markers proposed to reflect an enhanced capacity for skeletal muscle energy delivery.

One study was designed to compare the acute response of mixed muscle protein synthesis (MPS) to rapidly (i.e. whey hydrolysate and soy) and slowly (i.e. micellar casein) digested proteins both at rest and after resistance exercise. Three groups of healthy young men (n=6 per group) performed a bout of unilateral leg resistance exercise followed by the consumption of a drink containing an equivalent content of essential amino acids (10 g) as either whey hydrolysate, micellar casein, or soy protein isolate. Mixed MPS was determined by a primed constant infusion of l-[ring-13C(6)]phenylalanine. Ingestion of whey protein resulted in a significant larger increase in blood essential amino acid, branched-chain amino acid, and leucine concentrations than either casein or soy. Mixed MPS at rest (determined in the nonexercised leg) was higher with ingestion of faster proteins. MPS after consumption of whey was approximately 93 percent greater than casein and approximately 18 percent greater than soy, which was a significant difference. A similar result was observed after exercise (whey > soy > casein); MPS following whey consumption was approximately 122 percent greater than casein and 31 percent greater than soy, which also was significant differences. MPS was also greater with soy consumption at rest (64 %) and following resistance exercise (69 %) compared with casein. It was conclude that the feeding-induced simulation of muscle protein synthesis in young men is greater after whey hydrolysate or soy protein consumption than casein both at rest and after resistance exercise; moreover, despite both being fast proteins, whey hydrolysate stimulated muscle protein synthesis to a greater degree than soy after resistance exercise. These differences may be related to how quickly the proteins are digested (i.e. fast vs slow) or possibly to small differences in leucine content of each protein.

Protein supplements commonly are ingested by athletes to improve strength, agility, and speed. While athletes require a higher amount of protein (g/kg body weight) than nonathletes
do to support protein synthesis, they do not necessarily need to consume protein from supplemental sources. To date, no studies have shown an advantage of ingesting protein supplements over natural, protein-containing foods; therefore, dietary sources of protein may be just as effective as protein supplemental sources in the regulation of muscle protein synthesis. Misconceptions regarding protein supplement effectiveness may originate from athletes' nutrition information sources. A survey questionnaire queried high school football players about sources of information and measured protein supplement misconceptions by using scores on a Protein Supplement Misconceptions Index. Sixty-one high school football players participated in the study; 39 were protein supplementers, and 22 were non-protein supplementers. There was a significant difference between index scores of protein supplementers and non-protein supplementers, indicating that protein supplementers had a greater level of misconceptions than non-protein supplementers did. Bonferroni post hoc procedures used with individual index items revealed that protein supplementers were significantly more likely than non-protein supplementers to agree that "athletes should take protein supplements" and needed them "to gain as much muscle as possible". Greater misconceptions for protein supplementers may have resulted from the sources chosen for information and advice. Since coaches, parents, and friends were the primary sources of advice about protein supplements for protein supplementers, it would be valuable to provide nutrition education to these groups concurrently with educating young athletes to dispel ongoing misconceptions regarding the need for and effectiveness of protein supplements [08386].

The purpose of one study was to examine the impact of increased protein intake on short-term decrements in endurance performance during a block of high intensity training. Trained male cyclists completed two, three-week trials, both divided equally into normal (NOR), intensified (INT) and recovery (REC) training. In a counter-balanced, crossover experimental design, cyclists received either a high protein (PRO) (3 g protein per kg body mass (BM) per day) or a normal diet (CON) (1.5 g protein per kg BM per day) during INT and REC. Dietary carbohydrate content remained constant at 6 g per kg BM per day. Energy balance was maintained during each training week. Endurance performance was assessed with a VO$_{2\text{max}}$ test and a pre-loaded time trial. Alterations in blood metabolite responses to exercise were measured at rest, during and following exercise. Cyclists completed the Daily Analysis of Life Demands for Athletes (DALDA) questionnaire each day. Increased dietary protein intake led to a possible attenuation (4.3) in the decrement in time trial performance following a block of high-intensity training compared with normal diet. Restoration of endurance performance during recovery training possibly benefited (2.0 %) from additional protein intake. Frequency of symptoms of stress described as "worse than normal" reported following a block of high-intensity training was very likely (97 %) attenuated by increasing the protein content of the diet. No discernable changes in blood metabolite concentrations were observed in PRO. It was concluded that additional protein intake reduced symptoms of psychological stress, and may result in a worthwhile amelioration of the performance decline experienced during a block of high-intensity training [10405].

Fashion for a healthy lifestyle, muscular and athletic silhouette change our approach to diet. Sports sculpture highlighting the body forces the consumption of larger quantities of proteins than the commonly recommended optimum protein, which is 1 g/kg b.w./24 hours. Raises the question whether or not damages the kidneys? A protein-rich diet has the same haemodynamic effects on the kidneys as well as starvation. In diabetic nephropathy consumed a moderate reduction of protein slows the progression of renal failure, but such actions are not significant restrictions protein. It seems that the protein intake has adverse effects contained in them, salt (up to 3 % by weight). Persons undergoing dialysis should consume at least 1.5 g protein/kg b.w./24 hours. Even more is recommended for sport's people. Both resistance exercise and aerobic are necessary to maintain proper physical
fitnness and muscle mass, which provides better and longer survival. Everything is banned in competitive sports is recommended in dialysis: EPO, anabolic steroids, growth hormone [10219].

One study investigated effects of a high protein (PROT) versus a high carbohydrate (CHO) diet on performance and physiological responses during an ultraendurance climbing race at moderate altitude. On two different periods, in a randomised crossover design, ten climbers (30 years of age) participated in the race (duration 29 h approximately, energy expenditure 44 MJ/day) and were fed either with the PROT (30 % protein content) or the CHO diet (68 % carbohydrate) each providing 17 MJ. Mental performance was assessed by the Stroop test and we estimated maximal voluntary strength of quadriceps muscle. It was quantified metabolic and hormonal circulating concentrations. Mental performance was unaffected after the two races, while muscular performance and body weight were decreased with no diet effects. Significant decreases were measured for IGF-I concentration and its binding protein IGFBP-3, and increases for cortisol and norepinephrine with no diet effects. Glucose concentration decreased without diet effects, while amino acids (leucine, isoleucine, valine, and tyrosine) decreased in CHO group. Leptin concentration decreased without diet effects, whereas total ghrelin increased in CHO group. The results showed that a high PROT or high CHO intake during physical exertion at moderate altitude maintained mental performance, but did not limit muscle force reduction and body weight loss. There was decreased glucose availability, and hormonal responses indicated both catabolism and extreme energy deficiency induced by exercise with opposite responses of ghrelin and leptin. The ghrelin response was additionally indicative of macronutrient intake during the race [10220].

The effect of 42 g of protein ingested pre- and post-exercise on recovery from an acute resistance exercise session was examined in 15 male strength/power athletes who were randomly divided into a supplement (SUP) or placebo (PL) group. Subjects reported to the Human Performance Laboratory (HPL) on four separate occasions (T1-T4). Maximal strength (one repetition-maximum, 1-RM) testing was performed during T1. During T2 subjects performed four sets of ten repetitions at 80 percent of their 1-RM in the squat, dead lift and barbell lunge exercises with 90 s of rest between each set. Blood draws occurred at baseline (BL), immediate and 15 min post-exercise to determine testosterone, cortisol and creatine kinase (CK) concentrations. Subjects reported back to the HPL 24 (T3) and 48 h (T4) post-exercise for a BL blood draw and to perform four sets of ten repetitions with 80 percent of 1-RM for the squat exercise only. No differences in the number of repetitions performed in the squat exercise were seen between the groups at T2. Relative to T2, PL performed significantly fewer repetitions than SUP at T3 and T4. No differences in hormonal measures were seen between the groups. CK concentrations were significantly elevated at T3 for both groups, but continued to elevate at T4 for PL only. No significant group differences were noted for CK at any time point. Results indicate that a proprietary protein supplement consumed before and after a resistance training session significantly contributes to improvements in exercise recovery 24 and 48 h post-exercise [10221].

The purpose of the one study was to examine the effect of increased protein intake on short-term decrements in endurance performance during a block of high-intensity training. Trained male cyclists completed two 3-wk trials both divided equally into normal (NOR), intensified (INT), and recovery (REC) training. In a counterbalanced crossover experimental design, cyclists received either a high-protein (PRO; 3 g protein/kg body mass (BM)/d) or a normal diet (CON; 1.5 g protein/kg BM/d) during INT and REC. Dietary carbohydrate content remained constant at 6 g/kg BM/d. Energy balance was maintained during each training week. Endurance performance was assessed with a VO2max test and a preloaded time trial. Alterations in blood metabolite responses to exercise were measured at rest, during, and after exercise. Cyclists completed the Daily Analysis of Life Demands for Athletes (DALDA)
questionnaire each day. Increased dietary protein intake led to a possible attenuation (4.3%) in the decrement in time trial performance after a block of high-intensity training compared with NOR. Restoration of endurance performance during recovery training possibly benefited from additional protein intake. Frequency of symptoms of stress described as "worse than normal" reported after a block of high-intensity training was very likely (97%) attenuated by increasing the protein content of the diet. No discernable changes in blood metabolite concentrations were observed in PRO. It was concluded that additional protein intake reduced symptoms of psychological stress and may result in a worthwhile amelioration of the performance decline experienced during a block of high-intensity training [11264].

The effect of dietary protein ingested after exercise on recovery in women athletes is unknown. Therefore, it was asked whether there is a meaningful difference between high- and low-protein recovery diets on the subsequent performance of well-trained female cyclists. In a crossover, 12 female cyclists completed three high-intensity rides composed of 2.5-h intervals on day 1, followed by repeat-sprint performance tests on days 2 and 4, interspersed with a rest day. During the 4-h recovery on days 1 and 2, cyclists ingested 1.4/0.7/0.26 or 2.1/0.1/0.26 g/kg/h of CHO/protein/fat in high-protein or isocaloric control conditions, respectively. At other times, cyclists ingested an isoenergetic high-CHO diet. No effect of protein dose on the mean power during repeat sprint was evident on day 2 or on day. Furthermore, fatigue effects (slope) were unclear. Perceptions of leg tiredness and soreness were increased, and leg strength was reduced in the high-protein condition relative to control. In the high-protein condition, plasma glucose concentrations were lower during recovery, and plasma lactate concentrations were lower during the sprints. Effects on circulating creatine kinase activity were trivial. Net nitrogen balance during the experiment was positive in the high-protein condition but negative in the control condition; the estimated protein requirement was 1.28 g/kg/d. In contrast with the previous findings in males, it was observed no clear influence of dietary protein quantity on the subsequent performance in females. The findings on nitrogen balance suggest that female cyclists training intensely have daily protein requirements approximately 1.6 times the recommended daily allowance but 0.65 times that of males [11265].

The purpose of one review was to determine whether past research provides conclusive evidence about the effects of type and timing of ingestion of specific sources of protein by those engaged in resistance weight training. Two essential, nutrition-related, tenets need to be followed by weightlifters to maximize muscle hypertrophy: the consumption of 1.2-2.0 g protein/kg of body weight, and ≥44-50 kcal/kg of body weight. Researchers have tested the effects of timing of protein supplement ingestion on various physical changes in weightlifters. In general, protein supplementation pre- and post-workout increases physical performance, training session recovery, lean body mass, muscle hypertrophy, and strength. Specific gains, differ however based on protein type and amounts. Studies on timing of consumption of milk have indicated that fat-free milk post-workout was effective in promoting increases in lean body mass, strength, muscle hypertrophy and decreases in body fat. The leucine content of a protein source has an impact on protein synthesis, and affects muscle hypertrophy. Consumption of 3-4 g of leucine is needed to promote maximum protein synthesis. An ideal supplement following resistance exercise should contain whey protein that provides at least 3 g of leucine per serving. A combination of a fast-acting carbohydrate source such as maltodextrin or glucose should be consumed with the protein source, as leucine cannot modulate protein synthesis as effectively without the presence of insulin. Such a supplement post-workout would be most effective in increasing muscle protein synthesis, resulting in greater muscle hypertrophy and strength. In contrast, the consumption of essential amino acids and dextrose appears to be most effective at evoking protein synthesis prior to rather than following resistance exercise. To further enhance muscle hypertrophy and strength, a
resistance weight-training program of at least 10-12 weeks with compound movements for both upper and lower body exercises should be followed [12407].

The pattern of protein intake following exercise may impact whole-body protein turnover and net protein retention. It was determined the effects of different protein feeding strategies on protein metabolism in resistance-trained young men. Participants were randomly assigned to ingest either 80 g of whey protein as 8x10 g every 1.5h (PULSE; n=8), 4x20 g every 3 h (intermediate, INT; n=7), or 2x40g every 6h (BOLUS; n=8) after an acute bout of bilateral knee extension exercise (4x10 repetitions at 80 % maximal strength). Whole-body protein turnover (Q), synthesis (S), breakdown (B), and net balance (NB) were measured throughout 12h of recovery by a bolus ingestion of [15N]glycine with urinary [15N]ammonia enrichment as the collected end-product. PULSE Q rates were greater than BOLUS (19 %) with a trend towards being greater than INT (9 %). Rates of S were 32 and 19 percent greater and rates of B were 51 percent and 57 percent greater for PULSE as compared to INT and BOLUS, respectively, with no difference between INT and BOLUS. There were no statistical differences in NB between groups; however, magnitude-based inferential statistics revealed likely small and moderate increases in NB for PULSE and INT compared to BOLUS and possible small increase for INT versus PULSE. It was concluded that the pattern of ingested protein, and not only the total daily amount, can impact whole-body protein metabolism. Individuals aiming to maximize NB would likely benefit from repeated ingestion of moderate amounts of protein (20g) at regular intervals (3h) throughout the day [12408].

To prospectively evaluate the effects of resistance training combined with increased energy intake or protein-supplementation on lean body-mass, resting metabolic-rate (RMR) and cardiovascular risk factors 24 healthy males (aged 19-32 years) performed resistance exercise for 12 weeks aiming for at least 1 hour training-sessions 3 times a week. The participants were randomized to consume extra protein (33 g whey protein/day) or a meal of fast-food/day (1350 kcal, 41 g protein). Body-composition was measured with Dual-Energy X-ray Absorptiometry (DEXA) and RMR by indirect calorimetry. Fasting blood samples were drawn before and after the 3-month training period and after 12 months. The body weight increased from 75.1 ± 6.9 kg to 78.7 ± 7.2 kg, without differences between the groups. RMR increased from 1787 ± 143 kcal/24 h to 1954 ± 187 kcal/24 h (n=24), which was more than expected from the increase in lean body-mass (increase from 59.7 ± 4.3 kg to 61.8 ± 4.1 kg). Fasting serum-insulin levels increased in the fast-food group compared with the extra-protein group. ApoB increased from 0.691 ± 0.14 g/L to 0.768 ± 0.17 g/L. in the fast-food group only. Long-term follow up after 12 months showed that RMR, body weight, total fat and lean body-masses did not differ from baseline (n=19). It was concluded that resistance training for 12 weeks increased RMR and lean body-mass similarly when based on either an increased energy-intake or protein supplement. However, the increase in RMR was higher than expected from the increase in lean body-mass. Thus resistance training could potentially decrease the risk of obesity by induction of increased RMR [12409].

One study investigated the impact of protein coingestion with carbohydrate on muscle protein synthesis during endurance type exercise. Twelve healthy male cyclists were studied during 2 h of fasted rest followed by 2 h of continuous cycling at 55 percent W_max. During exercise, subjects received either 1.0 g/kg/h carbohydrate (CHO) or 0.8 g/kg/h carbohydrate with 0.2 g/kg/h protein hydrolysate (CHO+PRO). Continuous intravenous infusions with l-(ring-13C3)phenylalanine and l-(ring-3H2)tyrosine were applied, and blood and muscle biopsies were collected to assess whole body protein turnover and muscle protein synthesis rates at rest and during exercise conditions. Protein coingestion significantly stimulated whole body protein synthesis and oxidation rates during exercise. Whole body protein breakdown rates did not differ between experiments. As a consequence, whole body net protein balance was slightly negative in CHO and positive in the CHO+PRO treatment, respectively. Mixed
muscle protein fractional synthetic rates were higher during exercise compared with resting conditions. Fractional synthetic rates during exercise did not differ between experiments. It was concluded that muscle protein synthesis is stimulated during continuous endurance type exercise activities when carbohydrate with or without protein is ingested. Protein coingestion does not further increase muscle protein synthesis rates during continuous endurance type exercise [11266].

Protein nutrition for athletes has long been a topic of interest. From the legendary Greek wrestler Milo – purported to eat copious amounts of beef during his five successive Olympic titles – to modern athletes consuming huge amounts of supplements, protein intake has been considered paramount. Recommendations for protein intake for athletes has not been without controversy, however. In general, scientific opinion on this controversy seems to divide itself into two camps—those who believe participation in exercise and sport increases the nutritional requirement for protein and those who believe protein requirements for athletes and exercising individuals are no different from the requirements for sedentary individuals. There seems to be evidence for both arguments. Although this issue may be scientifically relevant, from a practical perspective, the requirement for protein—as most often defined—may not be applicable to most athletes [07312].

The accretion of muscle protein as a result of resistance exercise occurs because of successive periods of positive muscle protein balance. Periods of positive protein balance are due to a synergistic interaction of an exercise and feeding-induced stimulation of muscle protein synthesis (MPS). Protein ingestion provides essential amino acids for protein synthesis, which also act, in the case of leucine, to stimulate the translational machinery. Protein ingestion also increases systemic insulin, which has a mild stimulatory effect on MPS. Rather than a dose-dependent stimulation, a minimal threshold of insulin is required to allow MPS to proceed unabated; however, further stimulation of MPS is not seen at higher doses [07309].

Consuming protein following exercise has been shown to stimulate protein synthesis acutely in skeletal muscle and has been recommended to prevent sarcopenia. It is not known, however, whether acute stimulation persists long term or includes muscle cell division. It was asked whether consuming protein following exercise during aerobic training increases long-term protein and DNA synthesis rates in skeletal muscle of adult humans. Sixteen previously untrained participants (50 ± 8 years) consumed either a carbohydrate or carbohydrate and protein drink following each session during 6 week of treadmill training. A younger untrained group provided a nonexercising comparison. Participants were administered heavy water (²H₂O; deuterium oxide) continuously for 6 weeks to isotopically label newly synthesized skeletal muscle proteins and DNA. Muscle biopsies were performed after 6 wk of training. Contrary to acute studies, consuming protein after exercise did not increase skeletal muscle protein synthesis rates. In contrast, muscle protein synthesis, DNA, and phospholipid synthesis were significantly higher in the older exercise groups than the younger sedentary group. The higher DNA replication rate could not be attributed to mitochondrial DNA and may be due to satellite cell activation. It was concluded that postexercise protein supplementation does not increase rates of mixed protein synthesis over 6 week and that aerobic exercise may stimulate long-term cell division (DNA synthesis) in skeletal muscle of humans. Measurements of long-term synthesis rates provide important insights into aging and exercise adaptations [11388].

Variability in protein consumption may influence muscle mass changes induced by resistance exercise training (RET). It was sought to administer a post-exercise protein supplement and determine if daily protein intake variability affected variability in muscle mass
gains. Men (n=22) and women (n=30) ranging in age from 60 to 69 y participated in a 12-week RET program. At each RET session, participants consumed a post-exercise drink (0.4 g/kg lean mass protein). RET resulted in significant increases in lean mass (1.1 ± 1.5 kg), similar between sexes. Variability in mean daily protein intake was not associated with change in lean mass. The group with the highest protein intake (1.35 g/kg/day, n=8) had similar changes in lean mass as the group with the lowest daily protein intake (0.72 g/kg/day, n=9). These data suggest that variability in total daily protein intake does not affect variability in lean mass gains with RET in the context of post-exercise protein supplementation [06260].

Protein supplement use is common among athletes, active adults, and military personnel. This review provides a summary of the evidence base that either supports or refutes the ergogenic effects associated with different mechanisms that have been proposed to support protein supplementation. It was clear that if carbohydrate delivery was optimal either during or after an acute bout of exercise that additional protein will not increase exercise capacity. Evidence was also weak to substantiate use of protein supplements to slow the increase in brain serotonin and onset of central fatigue. It was also evident that additional research is warranted to test whether the benefits of protein supplements for enhancing recovery of fluid balance after exercise will affect subsequent work in the heat. In contrast, with repeated exercise, use of protein supplementation was associated with reductions in muscle soreness and often a faster recovery of muscle function due to reductions in protein degradation. There was also good supportive evidence for long-term benefits of protein supplementation for gains in muscle mass and strength through accelerated rates of protein synthesis, as long as the training stimulus was of sufficient intensity, frequency, and duration. However, studies have not examined the impact of protein supplements under the combined stress of a military environment that includes repeated bouts of exercise with little opportunity for feeding and recovery, lack of sleep, and exposure to extreme environments. Both additional laboratory and field research is warranted to help provide evidence-based guidance for the choice of protein supplements to enhance soldier performance [13643].

**Peroxiredoxins (PRDXs)**

Peroxiredoxins (PRDXs) are multifunctional proteins that have recently received much attention. They are part of the endogenous antioxidative capacity and function as efficient scavengers, especially for hydrogen peroxides. Studies show that physical training can induce an upregulation of PRDX isoform contents in the long term. This might help counteract chronic diseases that are causally linked to a high amount of free radicals, e.g., diabetes mellitus. Furthermore, it has been demonstrated that PRDX can overoxidize under pathological conditions during acute exercise. Overoxidized PRDXs could be useful because they act as protective chaperones. Taken together, it can be speculated that physical activity has a positive effect on the PRDX system and thereby prevents cells from free radical-induced damage [13642].

**Protein turnover**

Skeletal muscle is the major deposit of protein molecules. As for any cell or tissue, total muscle protein reflects a dynamic turnover between net protein synthesis and degradation. Noninvasive and invasive techniques have been applied to determine amino acid catabolism and muscle protein building at rest, during exercise and during the recovery period after a single experiment or training sessions. Stable isotopic tracers (13C-lysine, 15N-glycine, ²H5-phenylalanine) and arteriovenous differences have been used in studies of skeletal muscle and collagen tissues under resting and exercise conditions. There are different fractional synthesis rates in skeletal muscle and tendon tissues, but there is no major difference between collagen and myofibrillar protein synthesis. Strenuous exercise provokes increased proteolysis and decreased protein synthesis, the opposite occurring during the recovery period. Individuals who exercise respond differently when resistance and endurance types of
contractions are compared. Endurance exercise induces a greater oxidative capacity (enzymes) compared to resistance exercise, which induces fiber hypertrophy (myofibrils). Nitrogen balance (difference between protein intake and protein degradation) for athletes is usually balanced when the intake of protein reaches 1.2 g/kg/day compared to 0.8 g/kg/day in resting individuals. Muscular activities promote a cascade of signals leading to the stimulation of eukaryotic initiation of myofibrillar protein synthesis. As suggested in several publications, a bolus of 15-20 g protein (from skimmed milk or whey proteins) and carbohydrate (± 30 g maltodextrine) drinks is needed immediately after stopping exercise to stimulate muscle protein and tendon collagen turnover within 1 h [12411].

**Recommended daily allowance in athletes**

There is likely no other dietary component that inspires as much debate, insofar as athletes are concerned, as protein. How much dietary protein is required, optimal, or excessive? Dietary guidelines from a variety of sources have settled on an adequate dietary protein intake for those over the age of 19 of about 0.8-0.9 g protein/kg body weight and day. According to US and Canadian dietary reference intakes, the recommended allowance for protein of 0.8 g protein/kg and day is "the average daily intake level that is sufficient to meet the nutrient requirement of nearly all [i.e. 98 %] . . . healthy individuals". The panel also stated, "in view of the lack of compelling evidence to the contrary, no additional dietary protein is suggested for healthy adults undertaking resistance or endurance exercise". Currently, no group or groups of scientists involved in establishing dietary guidelines see a need for any statement that athletes or people engaging in regular physical activity require more protein than their sedentary counterparts. Popular magazines, numerous Web sites, trainers, and many athletes decry protein intakes even close to those recommended. Even joint position stands from policy-setting groups state that "protein recommendations for endurance athletes are 1.2 to 1.4 g/kg body weight per day, whereas those for resistance and strength-trained athletes may be as high as 1.6 to 1.7 g/kg body weight per day". The divide between those setting dietary protein requirements and those who might be making practical recommendations for athletes appears substantial, but ultimately, most athletes indicate that they consume protein at levels beyond even the highest recommendations. Thus, one might conclude that any debate on protein "requirements" for athletes is inconsequential; however, a critical analysis of existing and new data reveals novel ideas and concepts that may represent some common ground between these apparently conflicted groups. The goal of one review was to provide a critical and thorough analysis of current data on protein requirements in an attempt to provide some guidance to athletes, trainers, coaches, and sport dietitians on athletes' protein intake. In addition, an effort was made to clearly distinguish between "required" dietary protein, "optimal" intakes, and intakes that are likely "excessive," perhaps not from the standpoint of health, but certainly from the standpoint of potentially compromised performance [07313].

**High protein feeding**

The effect of dietary protein ingested following exercise on recovery in woman athletes is unknown. Therefore, it was asked whether there is a meaningful difference between high-versus low-protein recovery diets on subsequent performance in well-trained female cyclists. In a cross-over, 12 female cyclists completed 3 high-intensity rides comprising 2.5 h of intervals on day 1, followed by repeat-sprint performance tests on days 2 and 4, interspersed with a rest day. During the 4-h recovery on days 1 and 2, cyclists ingested 1.4/0.7/0.26 or 2.1/0.1/0.26 g.kg.h carbohydrate/protein/fat in high-protein or isocaloric control conditions, respectively. At other times, cyclists ingested an isoenergetic high-carbohydrate diet. No effect of protein dose on repeat-sprint mean power was evident on day 2 or day 4;
furthermore, fatigue effects (slope) were unclear. Perception of leg tiredness and soreness were increased, and leg strength reduced in the high-protein condition relative to control. In the high-protein condition, plasma-glucose concentrations were lower during recovery, and plasma-lactate concentrations were lower during the sprints. Effects on circulating creatine-kinase activity were trivial. Net nitrogen balance over the experiment was positive in the high-protein condition but negative in control, estimated protein requirement was 1.28 ± 0.57 g/kg/d. It was concluded that in contrast with previous findings in males, it was observed no clear influence of dietary protein quantity on subsequent performance in females. The nitrogen balance findings suggest that female cyclists training intensely have daily protein requirements approximately 1.6 times the recommended daily allowance, but 0.65 times that of males [10222].

**Egg white protein**

The aim of one study was to evaluate the effects of egg white protein compared to carbohydrate intake prior to exercise on fat free mass (FFM), one repetition maximum (1RM) muscle strength and blood biochemistry in female athletes. Thirty healthy female collegiate athletes were recruited for this study and matched by sport type, body fat percentage and 1RM leg curl muscle strength. Participants were randomly divided into two groups: protein group (15.0 g egg white protein; 75 kcal) and carbohydrate group (17.5 g maltodextrin, 78 kcal). Supplements were administered daily at the same time in a double-blind manner prior to training during an 8-week period. Measurements were performed before and after the 8-week regimen. The mean dietary energy intake did not change throughout the study period. FFM and 1RM assessments (i.e. leg curl, leg extension, squat, and bench press) increased in both groups. Furthermore, serum urea and serum citrulline levels after the 8-week regimen increased significantly only in the protein group. Our findings indicated that compared to the carbohydrate supplement, the protein supplement was associated with some changes in protein metabolites but not with changes in body composition or muscle strength. Fifteen grams of egg white protein contain 1341 mg of leucine (Leu), 837 mg of isoleucine (Ile), and 1096 mg of valine (Val), and there is also an abundant source of branched amino acids (BCAA) and aromatic amino acids (AAA) [12410].

**Whey**

Previously, we have shown that consuming carbohydrate plus whey protein hydrolysates (WPHs) replenished muscle glycogen after exercise more effectively than consuming intact whey protein or branched-chain amino acids (BCAAs). The mechanism leading to superior glycogen replenishment after consuming WPH is unclear. In this 5 week intervention, ddY mice were fed experimental diets containing WPH, a mixture of whey amino acids (WAAs), or casein (control). After the intervention, gastrocnemius muscle glycogen levels were significantly higher in the WPH group (4.35 mg/g) than in the WAA (3.15 mg/g) or control (2.51 mg/g) groups. In addition, total glycogen synthase (GS) protein levels were significantly higher in the WPH group (153 %) than in the WAA (89 %) or control groups, and phosphorylated GS levels were significantly decreased in the WPH group (51 %). These results indicate that dietary WPH may increase the muscle glycogen content through increased GS activity [12413].

To determine the effects of whey protein before and during resistance exercise (RE) on body composition and strength in young adults participants were randomized to ingest whey protein (PRO; 0.3 g/kg protein; n=9, 25 years, 88 kg) or placebo (PLA; 0.2 g/kg cornstarch maltodextrin + 0.1 g/kg sucrose; n=8) during RE (3 sets of 6-10 repetitions for 9 whole-body exercises), which was performed 4 d/week for 8 weeks. PRO and PLA were mixed with
water (600 ml); 50 percent of the solution containing 0.15 g/kg of PRO or PLA was consumed immediately before the start of exercise, and about 2 percent of the remaining solution containing 0.006 g/kg of PRO or PLA was consumed immediately after each training set. Before and after the study, measures were taken for lean-tissue mass (dual-energy X-ray absorptiometry), muscle size of the elbow and knee flexors and extensors and ankle dorsiflexors and plantar flexors (ultrasound), and muscle strength (1-repetition-maximum chest press). There was a significant increase in muscle size of the knee extensors, knee flexors, and ankle plantar flexors and chest-press strength over time, with no differences between groups. It was concluded that the ingestion of whey protein immediately before the start of exercise and again after each training set has no effect on muscle mass and strength in untrained young adults [12412].

Different dietary proteins affect whole body protein anabolism and accretion and therefore, have the potential to influence results obtained from resistance training. This study examined the effects of supplementation with two proteins, hydrolyzed whey isolate and casein (C), on strength, body composition, and plasma glutamine levels during a 10 wk, supervised resistance training program. In a double-blind protocol, 13 male, recreational bodybuilders supplemented their normal diet with either whey or C (1.5 gm/kg body wt/d) for the duration of the program. Strength was assessed by 1-RM in three exercises (barbell bench press, squat, and cable pull-down). Body composition was assessed by dual energy X-ray absorptiometry. Plasma glutamine levels were determined by the enzymatic method with spectrophotometric detection. All assessments occurred in the week before and the week following 10 wk of training. Plasma glutamine levels did not change in either supplement group following the intervention. The whey group achieved a significantly greater gain in lean mass than the C group and a significant change in fat mass compared to the C group. The whey group also achieved significantly greater improvements in strength compared to the C group in each assessment of strength. When the strength changes were expressed relative to body weight, the whey group still achieved significantly greater improvements in strength compared to the C group [06263].

The purpose of one study was to examine the effects of whey protein supplementation on body composition, muscular strength, muscular endurance, and anaerobic capacity during 10 weeks of resistance training. Thirty-six resistance-trained males (31 years) followed a 4 days-per-week split body part resistance training program for 10 weeks. Three groups of supplements were randomly assigned, prior to the beginning of the exercise program, in a double-blind manner to all subjects: 48 g per day (g/day carbohydrate placebo (P), 40 g/day of whey protein + 8 g/day of casein (WC), or 40 g/day of whey protein + 3 g/day branched-chain amino acids + 5 g/day L-glutamine (WBG)). At 0, 5, and 10 weeks, subjects were tested for fasting blood samples, body mass, body composition using dual-energy x-ray absorptiometry (DEXA), 1 repetition maximum (1RM) bench and leg press, 80 percent 1RM maximal repetitions to fatigue for bench press and leg press, and 30-second Wingate anaerobic capacity tests. No changes were noted in all groups for energy intake, training volume, blood parameters, and anaerobic capacity. WC experienced the greatest increases in DEXA lean mass and DEXA fat-free mass. Significant increases in 1RM bench press and leg press were observed in all groups after 10 weeks. In the study, the combination of whey and casein protein promoted the greatest increases in fat-free mass after 10 weeks of heavy resistance training. Athletes, coaches, and nutritionists can use these findings to increase fat-free mass and to improve body composition during resistance training [06264].

Whey protein is a widely consumed dietary supplement purported to enhance weight loss or support gains in skeletal muscle mass after a programme of resistance exercise training. Whey is the liquid portion of coagulated milk and represents about 20 percent of the total protein content of milk. It is a high-quality protein source that contains all the building blocks...
(amino acids) for the synthesis of new skeletal muscle proteins. An innovative study, using intrinsically labelled protein sources, demonstrated that whey is rapidly digested and absorbed, and resulted in a greater postprandial muscle protein accretion as compared to other dietary protein sources (casein or hydrolysed casein). The greater anabolic potential of whey is probably attributable to its faster protein digestion and amino acid absorption rates and a higher leucine content; this ultimately results in a large and transient spike in plasma leucine concentrations. The latter appears to be fundamental in maximising the feeding-mediated stimulation of muscle protein synthesis rates during resistance exercise recovery. However, further work is required to establish firmly whether the leucine content of a meal is of equal value in the postexercise phase, as it appears to be in the postprandial phase in absence of exercise. Some evidence suggests that ingestion of whey promotes greater satiety when compared against casein. It was speculated that ingestion of whey protein prior to meals may be a helpful in weight management strategy. In recent work, however, demonstrated that whey protein supplementation during a 9-month exercise training programme does not further enhance strength or changes in body composition in the middle-aged overweight and obese adults. Overall, these data showed that increasing habitual physical activity is a simple and effective lifestyle strategy to promote healthy aging. Whey protein supplements (or proteins in food) appear to be safe to consume with no direct evidence to suggest that excessive protein intake, as commonly seen in athletes, is harmful to healthy kidneys. Moreover, whey protein ingestion appears to be a highly effective protein source for the stimulation of postprandial muscle protein synthesis rates [13694].

It is well known that ingestion of a protein source is effective in stimulating muscle protein synthesis after exercise. In addition, there are numerous reports on the impact of leucine and leucine-rich whey protein on muscle protein synthesis and mammalian target of rapamycin (mTOR) signalling. However, there is only limited information on the effects of whey protein hydrolysates (WPH) on muscle protein synthesis and mTOR signalling. The aim of one study was to compare the effects of WPH and amino acids on muscle protein synthesis and the initiation of translation in skeletal muscle during the post-exercise phase. Male Sprague-Dawley rats swam for 2 h to depress muscle protein synthesis. Immediately after exercise, the animals were administered either carbohydrate (CHO), CHO plus an amino acid mixture (AA) or CHO plus WPH. At 1 h after exercise, the supplements containing whey-based protein (AA and WPH) caused a significant increase in the fractional rate of protein synthesis (FSR) compared with CHO. WPH also caused a significant increase in FSR compared with AA. Post-exercise ingestion of WPH caused a significant increase in the phosphorylation of mTOR levels compared with AA or CHO. In addition, WPH caused greater phosphorylation of ribosomal protein S6 kinase and eukaryotic initiation factor 4E-binding protein 1 than AA and CHO. In contrast, there was no difference in plasma amino acid levels following supplementation with either AA or WPH. These results indicate that WPH may include active components that are superior to amino acids for stimulating muscle protein synthesis and initiating translation [13695].

The purpose of one study was to investigate the effects of a controlled typical one day diet supplemented with two different doses of whey protein isolate on blood amino acid profiles and hormonal concentrations following the final meal. Nine males (age: 30 ± 6 years) completed four conditions in random order: a control (C) condition of a typical mixed diet containing about 10 percent protein (0.8 g/kg), 65 percent carbohydrate and 25 percent fat; a placebo (P) condition calorically matched with carbohydrate to the whey protein conditions; a low dose condition of 0.8 grams of whey protein isolate per kilogram body mass per day (g/kg/d; W1) in addition to the typical mixed diet; or a high dose condition of 1.6 g/kg/d (W2) of supplemental whey protein in addition to the typical mixed diet. Following the final meal, significant increases in total amino acids, essential amino acids (EAA), branch-chained amino acids (BCAA), and leucine were observed in plasma with whey protein
supplementation while no changes were observed in the control and placebo conditions. There was no significant group difference for glucose, insulin, testosterone, cortisol, or growth hormone. In conclusion, supplementing a typical daily food intake consisting of 0.8 g of protein/kg/d with a whey protein isolate (an additional 0.8 or 1.6 g/kg/d) significantly elevated total amino acids, EAA, BCAA, and leucine but had no effect on glucose, insulin, testosterone, cortisol, or growth hormone following the final meal. Future acute and chronic supplementation research examining the physiological and health outcomes associated with elevated amino acid profiles is warranted [13696].

The purpose of this study was to examine the effects of 2 different types of protein supplementation on thigh muscle cross-sectional area (CSA), blood markers, muscular strength, endurance, and body composition after 8 weeks of low- or moderate-volume resistance training in healthy, recreationally trained, college-aged men. One hundred and six men were randomized into 5 groups: low-volume resistance training with bioenhanced whey protein (BWPLV; n=22), moderate-volume resistance training with BWP (BWPMV; n=20), moderate-volume resistance training with standard whey protein (SWPMV; n=22), moderate-volume resistance training with a placebo (PLA; n=21), or moderate-volume resistance training with no supplementation (CON; n=21). Except for CON, all groups consumed 1 shake before and after each exercise session and one each on the nontraining day. The BWPLV, BWPMV, and SWPMV groups received approximately 20 g of whey protein per shake, whereas the BWP groups received 5 g of additional polyethylene glycosylated (PEG) leucine. Resistance training sessions were performed 3 times per week for 8 weeks. There were no interactions for muscle strength and endurance variables, body composition, muscle CSA, and safety blood markers, but the main effects for training were observed. However, the Albumin:Globulin ratio for SWPMV was lower than BWPLV and BWPMV. Relative protein intake (PROREL) indicated a significant interaction with no differences across groups at pre; however, BWPLV, BWPMV, and SWPMV had a greater intake than did PLA or CON at post. This study indicated that 8 weeks of resistance training improved muscle performance and size similarly among groups regardless of supplementation [13697].

Wheat germ

The wheat germ (Triticum vulgare, Gramineae), a by-product of the flour-milling industry, represents about 2.5-3.8 percent of the total seed weight. Wheat germ and the oil extracted from wheat germ contain significant quantities of bioactive compounds and, in particular, are known to be the richest plant origin source of tocopherols (vitamin E), with the antioxidant activity of tocopherols being well-documented. Wheat germ contains mainly alpha-tocopherols and beta-tocopherols, alongside other bioactive compounds such as phytosterols, polycosanols (POC), carotenoids, particularly lutein and zeaxanthin, thiamine (vitamin B₁) and riboflavin (vitamin B₂). Wheat germ is also a source of α-linolenic-rich polyunsaturated fatty acids, and contains several minerals, principally potassium, magnesium, calcium, zinc and manganese. Wheat germ contains about 10-15 percent lipids (oil), with oil extraction being primarily achieved by mechanical pressing or solvent extraction, which retrieves about 50 percent or >90 percent of the total lipids, respectively. Crude wheat germ oil (WGO) is usually dark coloured and may have a strong odour and flavour depending on the oxidative conditions of the oil. To produce high-quality, stable oils, undesirable compounds must be eliminated while retaining as much of tocopherols and other key nutritional compounds as possible. WGO is widely utilised for vitamin production (e.g. alpha-tocopherol) in medication and in the cosmetic industry, as well as in food, animal feed and as a biological insect control agent. WGO has been purported to improve human physical endurance/fitness, an effect attributed to its high POC, specifically its high octacosanol content, alongside other marketed health benefits such as reducing plasma and liver
cholesterol levels and possibly helping to delay the effects of aging. Despite these claims, studies investigating WGO supplementation effects in humans, on exercise performance and health, are sparse. A study investigating the effects of phytosterols from wheat germ on cholesterol absorption in humans found that consuming a meal containing 80 g of original wheat germ containing 328 mg phytosterols resulted in less cholesterol absorption when compared to ingestion of phytosterol-free wheat germ. This suggests that phytosterols found in wheat germ may have an important role in cholesterol metabolism. Another study recruited 32 patients with hypercholesterolaemia to examine the effects of 2 months of daily WGO supplementation or a placebo (maize oil) on oxidative stress. Although no differences in serum lipid profile was observed in both the groups, oxidative stress and platelet CD40L, a protein with inflammatory and prothrombotic properties, were reduced. This suggests that WGO supplementation had positive anti-inflammatory effects in patients with hypercholesterolaemia. Despite the lack of supporting evidence regarding a role for WGO in sports performance, it does provide an excellent source of vitamin E, with the high fat content of the wheat germ enabling its transport. The recommended dietary intake for vitamin E of 15 mg/day could be reached through consumption of 100 g of wheat germ – that's a pretty large handful! A more practical alternative source would therefore be WGO, being more concentrated in vitamin E than raw wheat germ [13694].

Soy-protein

The aim of one study was to determine in what areas the therapeutic application of soy predominates in clinical trials and to assess the emerging fields of its use by means of an analysis of bibliographic resources. A search was performed in the MEDLINE database up to 31 december 2004, limited to the Title/Abstract field, and Clinical Trials as the type of publication. The abstracts from the publications selected (n=86) were reviewed and different variables were assessed. A total of 3280 subjects were included: 15 percent men and 59 percent women (71 % postmenopausal). The studies were performed basically in healthy individuals (71 %). Twenty five percent of the studies investigated plasma levels of different metabolites and 21% determined hormone or lipid profiles. After the year 2000 a new population focus was detected, with the publication of two studies in elite gymnasts and judoists, with positive results. The present observations indicate that soy supplementation in the competitive sports elite may be an emerging application [06262].

To determine the changes in endurance capacity as well as in metabolic, hormonal and inflammatory markers induced by endurance training combined with a soy-been protein based supplement a randomized controlled study consisting of moderate endurance training without (GO) or with (G1) a soy protein based supplement. Two groups of 15 subjects (10 males and 5 females in each group): healthy sports students aged 24 years. Body composition (body mass (BM), body density (BD) by air displacement) and physical fitness (determined by treadmill ergometry) were measured at baseline and after 6 weeks of the intervention; changes in circulating metabolic and hormonal parameters (glucose, lactate, urea, uric acid, ammonia, cortisol, insulin, IGF-1), and exercise-induced stress and inflammatory markers (CK, LDH, myoglobin, hs-CRP, IL-6, IL-10, blood cell counts) were determined after the intervention period in afield test (12 km running on hilly ground). Thirty participants completed the 6-week study; 28 students were able to perform the field test. No significant changes in BM and BD were noted after intervention with only slight increases in running performance and maximum aerobic capacity in the total group (2 %). Subjects in the G1 group showed significant improvements in running velocity and lower lactate values following the intervention (-12 %). In addition, the G1 group showed significantly lower differences in the exercise-induced increase of metabolic parameters (triglycerides, uric acid) and insulin in the post-exercise recovery period. The data suggest that moderate endurance
training in combination with a soy-based protein supplement improves aerobic energy supply and metabolic function in healthy sports students, even without changes in body composition and without changes in the exercise-induced stress and inflammatory reaction [12406].

**Combination of sago and soy-protein**

The purpose of one study was to investigate whether a combination of sago and soy protein ingested during moderate-intensity cycling exercise can improve subsequent high-intensity endurance capacity compared with a carbohydrate in the form of sago and with a placebo. The participants were 8 male recreational cyclists. The design of the study was a randomized, double-blind placebo-controlled crossover comprising 60 min of exercise on a cycle ergometer at 60 percent VO$_{2\text{max}}$ followed by a time-to-exhaustion ride at 90 percent VO$_{2\text{max}}$. The sago feeding provided 60 g of carbohydrate, and the sago-soy combination provided 53 g of carbohydrate and 15 g of protein, both at 20-min intervals during exercise. Times to exhaustion for the placebo, sago, and sago-soy supplementations were 4.1 ± 1.3, 5.5 ± 1.2, and 7.5 ± 2.0 min, respectively. Sago-soy supplementation increased endurance by 84 percent and by 37 percent relative to placebo and sago, respectively. The plasma insulin response was elevated above that with placebo during sago and sago-soy supplementations. The authors conclude that a combination of sago and soy protein can delay fatigue during high-intensity cycling [10249].

**Wheat gluten hydrolysate**

Wheat gluten hydrolysate (WGH) is reported to suppress the muscle injuries associated with exercise in long distance running and weight training. In one study, it was investigated the effects of WGH consumption on suppression of muscle injury after soccer training in a double-blind crossover study. Immediately after a mini soccer game, six soccer players consumed 18.0 g of WGH, and muscle injury was investigated using serum creatine kinase (CK) as an indicator. The results showed a significant increase in serum CK from immediately after exercise to 12 h after exercise stress in the placebo group, while serum CK decreased during this same time period in the WGH group, and the difference between the two groups was significant. This suggests that WGH consumption suppresses delayed-onset muscle injury after exercise in soccer [12433].

**Building muscles in fed and fasted state**

The purpose of one investigation was to assess mixed-muscle fractional synthesis rate (FSR) and the expression of genes involved in skeletal muscle remodeling after aerobic exercise in the fasted and fed states. Eight recreationally active males (25 ± 1 yr; VO$_{2\text{max}}$: 52 ± 2 ml/kg and min) performed 60-min of cycle ergometry at 72 ± 1 percent VO$_{2\text{max}}$ on two occasions in a counter-balanced design. Subjects ingested a noncaloric placebo (EX-FAST) or a beverage containing (per kg body wt): 5 kcal, 0.83 g carbohydrate, 0.37 g protein, and 0.03 g fat (EX-FED) immediately and 1 h after exercise. FSR was assessed at rest and following exercise with the use of a l-[ring (2)H(5)]-phenylalanine infusion combined with muscle biopsies at 2 and 6 h postexercise. mRNA expression was assessed at 2 and 6 h postexercise via real-time RT-PCR. FSR was significantly higher after exercise in both EX-FAST (0.112 ± 0.010 % per hour) and EX-FED (0.129 ± 0.014 % per hour) compared with rest (0.071 ± 0.005 % per hour). Feeding attenuated the mRNA expression of proteolytic factors MuRF-1 (6 h) and calpain-2 (2 and 6 h) postexercise but did not alter FOXO3A, calpain-1, caspase3, or myostatin mRNA expression compared with EX-FAST. Myogenic regulatory factor (MRF4) mRNA was also significantly attenuated at 2 and 6 h postexercise in EX-FED compared with EX-FAST. These data demonstrate that a nonexhaustive bout of
aerobic exercise stimulates skeletal muscle FSR in the fasted state and that feeding does not measurably enhance FSR between 2 and 6 h after aerobic exercise. Additionally, postexercise nutrient intake attenuates the expression of factors involved in the ubiquitin-proteosome and Ca^{2+}-dependent protein degradation pathways. These data provide insight into the role of feeding on muscle protein metabolism during recovery from aerobic exercise [10516].

Research measuring whole-body protein turnover (WBPT) after both exercise and nutrition has generally focused on resistance exercise; however, there is a paucity of data regarding the effect of postaerobic exercise nutrition, especially in older adults. It is not known if postexercise protein feeding has a beneficial effect on protein turnover after low- to moderate-intensity exercise. We investigated whether consuming protein plus carbohydrate (PRO) immediately after an acute bout of aerobic exercise has an additive effect over carbohydrate alone (CHO) on WBPT in older individuals. Twelve healthy older adults (age, 59 ± 4 years) were studied on 2 separate occasions after 1 h of exercise at approximately 50% of maximal rate of oxygen uptake, followed by 4 h of recovery. Immediately following exercise, subjects ingested a CHO (60 g) or an isocaloric PRO beverage (40 g carbohydrate, 20 g whey protein). Whole-body protein metabolism was determined using [1-^{13}C]leucine infusion (60 mg prime; 75 mg/h continuous), and sampling blood and expired breath. Rates of whole-body leucine appearance and oxidation, and nonoxidative leucine disposal during the third and fourth hours of postexercise recovery were higher in the PRO group, than in the CHO group. The results indicate that consumption of a PRO beverage after aerobic exercise increased WBPT to a greater extent than a CHO beverage [10517].

Protein drinks

Post-workout nutrient timing and macronutrient selection are essential for recovery, glycogen replenishment and muscle protein synthesis (MPS). Performance repeatability, particularly after strenuous activity, can be influenced by substrate availability, recovery markers and perceived rate of exertion. One study compared the differential effects of a complex protein ready-to-drink drink (VPX) and isocaloric carbohydrate drink (iCHO) on performance – agility T-test, push-up test, 40-yard sprint, and rate of perceived exertion (RPE), following high-intensity resistance training (HIRT). In a randomized, double blind two-arm crossover controlled trial, 15 subjects performed a 15-18 minute (2:1 work to rest) HIRT and then immediately drank one of the two treatments. After a 2-hour fast, subjects returned to execute the field tests and report RPE. The protocol was repeated one week later with the other treatment. There were no significant main effect differences in the agility T-test, push-up, sprint, average agility RPE, average push-up RPE or average sprint RPE between the two trials and the two treatments. The multivariate analysis yielded a cumulative significant interaction effect amongst the three performance variables after consuming VPX. These results suggest a complex protein drink is a better post-workout choice compared to an isocaloric carbohydrate drink for repeated performance for activities that require multiple energy demands and athletic skills; however, this outcome was not observed for each single performance event or RPE. Thus, when considering the collective physical effects of the agility T-test, push-up and sprint tests, a complex protein drink may provide a recovery advantage as it relates to repeated-bout performance compared to an iCHO-only drink. Additional research examining the chronic effects of post-exercise protein versus iCHO drinks on performance repeatability, particularly in special populations (e.g. tactical and elite athletes), is warranted to further develop these findings [13648].
Effect on endurance and muscles

Dietary CHO intake is fundamental to an athlete’s nutritional program to provide fuel to the working muscle and to facilitate muscle glycogen synthesis between exercise sessions. As a consequence of this, a wide range of CHO-based sports supplements are commercially available. During the last 20 years, evidence has been emerging that the addition of protein to CHO-based supplements may be beneficial; however, this remains a controversial topic. This challenging view will present the evidence that demonstrates the favorable metabolic consequences of consuming protein along with CHO. The majority of studies in this area have focused on CHO-protein intake either during exercise or in recovery from exercise, but of course, nutritional strategies during recovery also become pre-exercise nutritional strategies in many instances. Before any such strategy can be truly advocated, published evidence should first reveal consistently positive effects on practically meaningful outcomes (i.e. performance) across multiple independent laboratories, ideally also isolating plausible mechanisms of action. With due consideration of the precise context and nature of these effects, it is proposed that a “worthwhile” nutritional supplement must fulfill at least one of the following interrelated criteria:

- true “supplementation” of the diet (i.e. either compensating for deficiencies or meeting increased requirements)
- supplement formulation facilitates digestion, absorption, and/or metabolism to more effectively deliver active ingredients than possible via whole foods
- optimal timing for supplement ingestion renders it impractical to acquire active ingredients via whole foods as a meal (e.g. effects are either short-lived or situation dependent).

A relevant example to illustrate these contextual issues is CHO-based sports supplements per se (i.e. without added protein), the use of which is supported in a recent joint position statement both because of the increased CHO requirements of many athletes beyond the typical diet and the efficacy of specially formulated CHO supplements, which are easily incorporated into athletes' preexercise, midexercise, or postexercise regimen. In contrast, that same position statement attests that even the slightly elevated protein requirements of athletes are almost always met by diet alone and that “protein or amino acid supplementation has not been shown to positively impact athletic performance”. The perspective set out below will therefore defend the prevailing view that CHO without protein should be included in sports supplements; initially by presenting the balance of published data that have yet to reveal any ergogenic or mechanistic benefit of added protein or amino acids during exercise, before questioning whether the positive effects evident in recovery can legitimately be interpreted as supporting any practical value of these supplements when considered in a real-world context (e.g. in the fed state and/or when following existing guidelines for CHO intake) [11389].

One study examined 10 weeks of resistance training and the ingestion of supplemental protein and amino acids on muscle performance and markers of muscle anabolism. Nineteen untrained males were randomly assigned to supplement groups containing either 20 g protein (14 g whey and casein protein, 6 g free amino acids) or 20 g dextrose placebo ingested 1 h before and after exercise for a total of 40 g/d. Participants exercised 4 times/wk using 3 sets of 6-8 repetitions at 85-90 percent of the one repetition maximum. The protein supplement resulted in greater increases in total body mass, fat-free mass, thigh mass, muscle strength, serum IGF-1, IGF-1 mRNA, MHC I and IIa expression, and myofibrillar protein. Ten weeks of resistance training with 20 g protein and amino acids ingested 1 h before and after exercise is more effective than carbohydrate placebo in up-regulating markers of muscle protein synthesis and anabolism along with subsequent improvements in
muscle performance [07314].

One investigation examined the effect of variations in protein intake on whole-body protein turnover (WBPTO) after exercise in endurance-trained males. Five male runners (21 years) participated in a randomized, crossover-design diet intervention, where they consumed either a low- (0.8 g/kg; LP), moderate- (1.8 g/kg; MP), or high-protein (3.6 g/kg; HP) diet for 4 weeks. WBPTO (Ra, leucine rate of appearance; NOLD, nonoxidative leucine disposal; and Ox, leucine oxidation) were assessed after a 75-min run at 70 percent VO\textsubscript{2peak} after each diet-intervention period. Leucine Ra (indicator of protein breakdown) and leucine Ox were greater on the HP diet than on the LP diet. No differences were noted in NOLD (an indicator of protein synthesis) across diets. Plasma branched chain amino acids (BCAA) at rest were greater for MP and HP than for LP, and nonessential amino acids (NEA) were greater for LP than MP at rest and greater than MP and HP after exercise. Findings from this study show that variations in protein intake can alter plasma amino acid levels and modulate rates of WBPTO after exercise. Additionally, a lower protein intake was associated with decreased rates of WBPTO after exercise [07315].

One study compared a training diet recommended for endurance athletes (H-CHO) with an isoenergetic high protein (whey supplemented), moderate carbohydrate (H-Pro) diet on endurance cycling performance. Over two separate 7-d periods subjects (n=7) ingested either H-CHO (8 g/kg/day carbohydrate; 1.2 g/kg/day fat; 1.3 g/kg/day protein) or H-Pro (5 g/kg/day, 1.3 g/kg/day, or 3.3 g/kg/day, respectively) diet in a randomized, balanced order. On day 8 subjects cycled (self-paced) for a body weight dependent (60 kJ/bm) amount of work. No differences occurred between energy intake or fat intake during the two dietary conditions. Performance was significantly impaired following H-Pro compared with H-CHO. No differences between treatments were observed for physiological measures taken during the performance trials. These results indicate an ergolytic effect of a 7-d high protein diet on self-paced endurance cycling performance [06261].

The effects of protein intake timing in relation to strength training

Protein timing is a popular dietary strategy designed to optimize the adaptive response to exercise. The strategy involves consuming protein in and around a training session in an effort to facilitate muscular repair and remodeling, and thereby enhance post-exercise strength- and hypertrophy-related adaptations. It is generally accepted that protein should be consumed just before and/or immediately following a training session to take maximum advantage of a limited anabolic window. Proponents of the strategy claim that, when properly executed, precise intake of protein in the peri-workout period can augment increases in fat-free mass. Some researchers have even put forth the notion that the timing of food intake may have a greater positive effect on body composition than absolute daily nutrient consumption. A number of studies support the superiority of protein timing for stimulating increases in acute protein synthesis pursuant to resistance training when compared to placebo. Protein is deemed to be the critical nutrient required for optimizing post-exercise protein synthesis. The essential amino acids, in particular, are believed primarily responsible for enhancing this response, with little to no contribution seen from provision of non-essential amino acids. It was found that a 6 g dose of essential amino acids (EAAs) consumed immediately post-exercise produced an approximate twofold increase in net protein balance compared to a comparable dose containing an approximately equal mixture of essential and non-essential amino acids, indicating a dose–response relationship up to 6 g EAAs. However, increasing EAA intake beyond this amount has not been shown to significantly heighten post-exercise protein synthesis. There is limited evidence that carbohydrate has an additive effect on enhancing post-exercise muscle protein synthesis when combined with amino acid ingestion with a majority of studies failing to demonstrate any such benefit. The
The purpose of one paper therefore was to conduct a multi-level meta-regression of randomized controlled trials to determine whether protein timing is a viable strategy for enhancing post-exercise muscular adaptations. The strength analysis comprised 478 subjects and 96 ESs, nested within 41 treatment or control groups and 20 studies. The hypertrophy analysis comprised 525 subjects and 132 ESs, nested with 47 treatment or control groups and 23 studies. A simple pooled analysis of protein timing without controlling for covariates showed a small to moderate effect on muscle hypertrophy with no significant effect found on muscle strength. In the full meta-regression model controlling for all covariates, however, no significant differences were found between treatment and control for strength or hypertrophy. The reduced model was not significantly different from the full model for either strength or hypertrophy. With respect to hypertrophy, total protein intake was the strongest predictor of ES magnitude. These results refute the commonly held belief that the timing of protein intake in and around a training session is critical to muscular adaptations and indicate that consuming adequate protein in combination with resistance exercise is the key factor for maximizing muscle protein accretion. The Recommended Dietary Allowance (RDA) for protein is 0.8 g/kg/day. However, these values are based on the needs of sedentary individuals and are intended to represent a level of intake necessary to replace losses and hence avert deficiency; they do not reflect the requirements of hard training individuals seeking to increase lean mass. Studies do in fact show that those participating in intensive resistance training programs need significantly more protein to remain in a non-negative nitrogen balance. Position stands from multiple scientific bodies estimate these requirements to be approximately double that of the RDA. Higher levels of protein consumption appear to be particularly important during the early stages of intense resistance training. The average protein intake for controls in the unmatched studies was 1.33 g/kg/day while average intake for treatment was 1.66 g/kg/day. Since a preponderance of these studies involved untrained subjects, it seems probable that a majority of any gains in muscle mass would have been due to higher protein consumption by the treatment group. The findings also support previous recommendations that a protein consumption of at least 1.6 g/kg/day is necessary to maximize muscle protein accretion in individuals involved in resistance training programs. In conclusion, current evidence does not appear to support the claim that immediate (≤ 1 hour) consumption of protein pre- and/or post-workout significantly enhances strength- or hypertrophic-related adaptations to resistance exercise. The results of this meta-analysis indicate that if a peri-workout anabolic window of opportunity does in fact exist, the window for protein consumption would appear to be greater than one-hour before and after a resistance training session. Any positive effects noted in timing studies were found to be due to an increased protein intake rather than the temporal aspects of consumption, but a lack of matched studies makes it difficult to draw firm conclusions in this regard. The fact that protein consumption in non-supplemented subjects was below generally recommended intake for those involved in resistance training lends credence to this finding. Since causality cannot be directly drawn from our analysis, however, we must acknowledge the possibility that protein timing was in fact responsible for producing a positive effect and that the associated increase in protein intake is merely coincidental. Future research should seek to control for protein intake so that the true value regarding nutrient timing can be properly evaluated. Particular focus should be placed on carrying out these studies with well-trained subjects to better determine whether resistance training experience plays a role in the response [13644].

Plus maltodextrine
One study investigated the ingestion of maltodextrin, fructose, and protein on exogenous carbohydrate oxidation (CHOEXO) and exercise performance. Seven trained cyclists and (or) triathletes (maximal oxygen consumption, 59 ± 9 mL/kg/min) performed 3 exercise trials that consisted of 150 min of cycling at 50 percent maximal power output (160 ± 11 W), followed by a 60 km time trial. One of 3 beverages were randomly assigned during each trial and consumed at 15-min intervals: 0.84 g/min maltodextrin + 0.52 g/min fructose + 0.34
g/min protein (MD+F+P); 1.10 g/min maltodextrin + 0.60 g/min fructose (MD+F); or 1.70 g/min maltodextrin (MD). CHOEXO and fuel utilisation were assessed via measurement of expired air $^{13}$C content and indirect calorimetry, respectively. Mean total CHO oxidation (CHOTOT) rates were 2.35 ± 0.18, 2.76 ± 0.08, and 2.61 ± 0.17 g/min with MD, MD+F, and MD+F+P, respectively, although not significantly different. Peak CHOEXO rates with MD+F were significantly greater by 41 percent and 45 percent compared with MD+F+P and MD, respectively. Performance times were 2.2 percent and 5.0 percent faster with MD+F compared with MD+F+P and MD, respectively; however, they were not statistically significant. Ingestion of an MD-fructose-protein commercial sports beverage significantly reduced peak and mean CHOEXO rates compared with MD+F, but did not significantly influence CHOTOT. The addition of protein to an MD+F beverage did not enhance performance times [13645].

**Influence on muscle synthesis**

Hyperaminoacidemia stimulates myofibrillar fractional synthesis rate (myoFSR) transiently in resting skeletal muscle. It was investigated whether light-load resistance exercise can extent this responsiveness. Ten healthy males exercised one leg with a light-load resistance-like exercise at 16 percent of 1 repetition maximum and received oral protein boluses every hour for a 10-h period. Their myoFSR was determined by $[1^{-13}$C$]$-leucine incorporation. Muscle biopsies were obtained from the resting (REST) and exercised (EXC) muscles every 2.5-h in the protein-fed period. Protein feeding significantly elevated plasma leucine and essential amino acids by an average of 39 ± 9 percent (mean ± SEM) and 20 ± 4 percent, respectively, compared to the basal concentrations: 197 ± 12 micromol/L and 854 ± 35 micromol/L, respectively. The myoFSR was similar in EXC and REST muscles in the first 8 h. After 8 h the myoFSR dropped in the REST muscle to 0.041 ± 0.005 percent/h, which was 65 ± 5 percent of the rate in EXC leg at the same time point (0.062 ± 0.004 %/h) and 80 ± 14 percent of the level in REST leg from 0.5 to 8 h. Thus, compared to rest, light-load exercise prolonged the stimulatory effect of dietary protein on muscle biosynthesis providing perspectives for a muscle restorative effect in clinical settings where strenuous activity is intolerable [13646].

High-quality proteins such as soy, whey, and casein are all capable of promoting muscle protein synthesis postexercise by activating the mammalian target of rapamycin (mTORC1) signaling pathway. It was hypothesized that a protein blend of soy and dairy proteins would capitalize on the unique properties of each individual protein and allow for optimal delivery of amino acids to prolong the fractional synthetic rate (FSR) following resistance exercise (RE). In this double-blind, randomized, clinical trial, 19 young adults were studied before and after ingestion of about 19 g of protein blend (PB) or about 18 g whey protein (WP) consumed 1 h after high-intensity leg RE. It was examined mixed-muscle protein FSR by stable isotopic methods and mTORC1 signaling with western blotting. Muscle biopsies from the vastus lateralis were collected at rest (before RE) and at 3 postexercise time points during an early (0-2 h) and late (2-4 h) postingestion period. WP ingestion resulted in higher and earlier amplitude of blood branched-chain amino acid (BCAA) concentrations. PB ingestion created a lower initial rise in blood BCAA but sustained elevated levels of blood amino acids later into recovery. Postexercise FSR increased equivalently in both groups during the early period, however, FSR remained elevated only in the PB group during the late period. mTORC1 signaling similarly increased between groups, except for no increase in S6K1 phosphorylation in the WP group at 5 h postexercise. It was concluded that a soy-dairy PB ingested following exercise is capable of prolonging blood aminoacidemia, mTORC1 signaling, and protein synthesis in human skeletal muscle and is an effective postexercise nutritional supplement [13647].

**Proteins before exercise**
Adaptations to exercise training are determined by the response of metabolic and molecular mechanisms that determine changes in proteins. The type, intensity, and duration of exercise, as well as nutrition, determine these responses. The importance of protein, in the form of intact proteins, hydrolysates, or free amino acids, for exercise adaptations is widely recognized. Exercise along with protein intake results in accumulation of proteins that influence training adaptations. The total amount of protein necessary to optimize adaptations is less important than the type of protein, timing of protein intake, and the other nutrients ingested concurrently with the protein. Acute metabolic studies offer an important tool to study the responses of protein balance to various exercise and nutritional interventions. Recent studies suggest that ingestion of free amino acids plus carbohydrates before exercise results in a superior anabolic response to exercise than if ingested after exercise. However, the difference between pre- and postexercise ingestion of intact proteins is not apparent. Thus, the anabolic response to exercise plus protein ingestion seems to be determined by the interaction of timing of nutrient intake in relation to exercise and the nutrients ingested. More research is necessary to delineate the optimal combination of nutrients and timing for various types of training adaptations. Protein and amino acid intake have long been deemed important for athletes and exercising individuals. Olympic athletes, from the legendary Milo to many in the 1936 Berlin games, reportedly consumed large amounts of protein. Modern athletes may consume slightly less than these historical figures, yet protein is deemed extremely important by most. Protein is important as a source of amino acids for recovery from exercise and repair of damaged tissues, as well as for adaptations to exercise training, such as muscle hypertrophy and mitochondrial biogenesis [07316].

**Protein-rich intake for recovery after exercise**

Protein, protein hydrolysates, and amino acids have become popular ingredients in sports nutrition. The use of protein, protein hydrolysates, and amino acid mixtures has multiple applications when aiming to improve postexercise recovery. After exhaustive endurance-type exercise, muscle glycogen repletion is the most important factor determining the time needed to recover. Coingestion of relatively small amounts of protein and/or amino acids with carbohydrate can be used to augment postprandial insulin secretion and accelerate muscle glycogen synthesis rates. Furthermore, it has been well established that ingesting protein, protein hydrolysates, and amino acid can stimulate protein synthesis and inhibit protein breakdown and, as such, improve net muscle protein balance after resistance- or endurance-type exercise. The latter has been suggested to lead to a more effective adaptive response to each successive exercise bout. To augment net muscle protein accretion, athletes involved in resistance-type exercise generally ingest both protein and carbohydrate during postexercise recovery. However, carbohydrate ingestion after resistance-type exercise does not seem to be warranted to further stimulate muscle protein synthesis or improve whole-body protein balance when ample protein has already been ingested. Because resistance-type exercise is also associated with a substantial reduction in muscle glycogen content, it would be preferred to coingest some carbohydrate when aiming to accelerate glycogen repletion. More research is warranted to assess the impact of ingesting different proteins, protein hydrolysates, and/or amino acids on muscle protein accretion after exercise [07317].

The purpose of one study was to determine whether resistance exercise performance and postexercise muscle damage were altered when consuming a carbohydrate and protein beverage (CHO-PRO; 6.2 % and 1.5 % concentrations). Thirty-four male subjects (age: 22) completed 3 sets of 8 repetitions at their 8 repetition maximum to volitional fatigue. The exercise order consisted of the high pull, leg curl, standing overhead press, leg extension, lat pull-down, leg press, and bench press. In a double-blind, posttest-only control group design,
subjects consumed 355 ml of either CHO-PRO or placebo (electrolyte and artificial sweetener beverage) 30 minutes prior to exercise, 177 ml immediately prior to exercise, 177 ml halfway through the exercise bout, and 355 ml immediately following the exercise bout. There were no significant differences between groups relative to exercise performance. Cortisol was significantly elevated in the placebo group compared to the CHO-PRO group at 24 hours postexercise. Insulin was significantly elevated immediately pre-exercise, after the fourth lift, immediately postexercise, 1 hour, and 6 hours postexercise in CHO-PRO compared to the placebo group. Myoglobin levels in the placebo group approached significance halfway through the exercise bout and at 1 hour postexercise (p = 0.06 and 0.07, respectively) and were significantly elevated at 6 hours postexercise compared to the CHO-PRO group. Creatine kinase levels were significantly elevated in the placebo group compared to the CHO-PRO group. The CHO-PRO supplement did not improve performance during a resistance exercise bout, but appeared to reduce muscle damage, as evidenced by the responses of both myoglobin and creatine kinase. These results suggest the use of a CHO-PRO supplement during resistance training to reduce muscle damage and soreness [07318].

Carbohydrate ingestion after prolonged strenuous exercise enhances recovery, but protein might also be important. In a crossover with 2-week washout, 10 cyclists completed 2.5 h of intervals followed by 4-h recovery feeding, provided 218 g protein, 435 g carbohydrate, and 79 g fat (protein enriched) or 34 g protein, 640 g carbohydrate, and 79 g fat (isocaloric control). The next morning, cyclists performed 10 maximal constant-work sprints on a Velotron cycle ergometer, each lasting approximately 2.5 min, at approximately 5-min intervals. Test validity was established and test reliability and the individual response to the protein-enriched condition estimated by 6 cyclists repeating the intervals, recovery feeding, and performance test 2 wk later in the protein-enriched condition. During the 4-h recovery, the protein-enriched feeding had unclear effects on mean concentrations of plasma insulin, cortisol, and growth hormone, but testosterone was 25 percent higher (90 % confidence limit ± 14 %). Protein enrichment also reduced plasma creatine kinase by 33 percent (± 38 %) the next morning and reduced tiredness and leg-soreness sensations during the sprints, but effects on mean sprint power were unclear (-1.4 %). The between-subjects trial-to-trial coefficient of variation in overall mean sprint power was 3.1 percent, whereas the variation in the protein-enriched condition was 5.9 percent, suggesting that individual responses to the protein-enriched treatment contributed to the unclear performance outcome. To conclude, protein-enriched recovery feeding had no clear effect on next-day performance [07319].

Carbohydrate ingestion after prolonged strenuous exercise enhances recovery, but protein might also be important. In a crossover with 2-weeks washout, 10 cyclists completed 2.5 h of intervals followed by 4-h recovery feeding, provided 218 g protein, 435 g carbohydrate, and 79 g fat (protein enriched) or 34 g protein, 640 g carbohydrate, and 79 g fat (isocaloric control). Ingestion of carbohydrate (CHO) and protein (PRO) following intense exercise has been reported to increase insulin levels, optimize glycogen resynthesis, enhance PRO synthesis, and lessen the immuno-suppressive effects of intense exercise. Since different forms of CHO have varying glycemic effects, the purpose of this study was to determine whether the type of CHO ingested with PRO following resistance-exercise affects blood glucose availability and insulin levels, markers of anabolism and catabolism, and/or general immune markers. Forty resistance-trained subjects performed a standardized resistance training workout and then ingested in a double blind and randomized manner 40 g of whey PRO with 120 g of sucrose (S), honey powder (H), or maltodextrin (M). A non-supplemented control group (C) was also evaluated. Blood samples were collected prior to and following exercise as well as 30, 60, 90, and 120 min after ingestion of the supplements. Glucose concentration 30 min following ingestion showed the H group to be greater than S; M and C groups. No significant differences were observed among groups in glucose area under the curve (AUC) values, although the H group showed a trend versus control. Insulin response for each treatment was significant by time, treatment and AUC. 30-min peak post-feeding insulin for S, H, and M were greater than C as was AUC with no significant differences observed among types of CHO. No significant group x time effects were observed among groups in testosterone, cortisol, the ratio of testosterone to cortisol, muscle and liver enzymes, or general markers of immunity. It was concluded that CHO and PRO ingestion following exercise significantly influences glucose and insulin concentrations. Although some trends were observed suggesting that H maintained blood glucose levels to a better degree, no significant differences were observed among types of CHO ingested on insulin levels. These findings suggest that each of these forms of CHO can serve as effective sources of CHO to ingest with PRO in and attempt to promote post-exercise anabolic responses [07321].

**Protein-carbohydrate-antioxidant**

The authors investigated the effects of postexercise carbohydrate-protein-antioxidant (CHO+P+A) ingestion on plasma creatine kinase (CK), muscle soreness, and subsequent cross-country race performance. Twenty-three runners consumed 10 mL/kg body weight of CHO or CHO+P+A beverage immediately after each training session for 6 d before a cross-country race. After a 21-d washout period, subjects repeated the protocol with the alternate beverage. Postintervention CK and soreness were significantly lower after CHO+P+A intervention than after CHO, despite no differences in baseline measures. There were no overall differences in running performance after CHO and CHO+P+A interventions. There were, however, significant correlations between treatment differences and running mileage, with higher mileage runners having trends toward improved attenuations in CK and race performance after CHO+P+A intervention than lower mileage runners. We conclude that muscle damage incurred during training was attenuated with postexercise CHO+P+A ingestion, which could lead to performance improvements in high-mileage runners [07322].

**Combined CHO-protein ingestion during exercise**

Although some studies have shown ergogenic benefits when combined CHO–protein supplements are ingested during exercise, one of these actually reflects an alternative but ultimately no more effective choice of pacing strategy, and the majority of evidence on this topic conforms to the prevailing view that there is no benefit. Could it then be argued that positive findings emerging from even only a minority of studies nonetheless demonstrate that added protein can enhance performance, albeit if that effect may be specific to the experimental setup in certain laboratories? On the contrary, even those researchers observing performance benefits have also reported negative outcomes when conducting similar studies. In fact, the only discernible methodological factor to explain why certain
studies have observed a benefit of added protein is that all these studies have compared CHO–protein supplements relative to control supplements providing CHO alone at a lower energy content and/or below the recommended intake for the exercise tests used. Whereas these findings are undoubtedly of mechanistic interest, the only logical interpretation from a practical viewpoint is that protein is an unnecessary addition to an otherwise adequate CHO supplementation regimen. In summary, the case against including protein in CHO supplements to be ingested during exercise is fundamentally grounded in the numerical balance of just four published studies demonstrating any benefit of added protein opposed to nine showing no effects on physical performance with the few extant reports of benefit explained by the insufficient quantities of CHO ingested in these studies. Lastly, another major problem facing the challenging view is the absence of any empirically supported mechanism to explain why ingesting protein during exercise would be expected to impart performance gains, with the most plausible proposed mechanisms (e.g. altered skeletal muscle metabolism) having recently been comprehensively examined and largely discounted. Several studies have investigated the effect of consuming protein with CHO compared with CHO only during prolonged exercise. One reported a 36 percent improvement in time to fatigue after 3 h of variable intensity cycling when cyclists ingested a mixture of CHO and protein compared with a matched quantity of CHO. Subsequently, several others have reported improvements in time to fatigue when including protein in a CHO supplement during exercise. The studies that have shown no performance improvement after a mixture of CHO and protein over CHO only are those that have provided sufficient CHO to satisfy oxidative requirements during exercise or when the addition of protein does not increase the energy content of the supplement. Although the evidence for an improvement in performance from adding protein to a CHO supplement during exercise seems to be equivocal, it is unlikely that consuming protein with CHO during prolonged endurance exercise will have a detrimental effect on performance. Indeed, there are other physiological effects that may be of benefit to the exercising individual. Coingestion of protein with CHO during prolonged endurance exercise has been shown to improve protein balance by increasing synthesis and decreasing breakdown, resulting in a positive net protein balance during exercise and during recovery. The inclusion of protein in a CHO supplement consumed during exercise has also been shown to reduce indices of postexercise muscle disruption compared with CHO supplements matched for CHO content or total calories. It is therefore clear that, although the benefits of consuming a CHO-protein mixture during exercise on immediate performance are still uncertain, this nutritional strategy can have a positive effect on the recovery process and therefore may improve exercise performance on subsequent days [11389].

In the fasted state, resistance exercise does not result in net protein accretion because muscle protein breakdown exceeds muscle protein synthesis; however, consumption of protein and/or essential amino acid provision shifts net protein balance to positive and promotes muscle protein accretion during the acute recovery period after resistance exercise. Recent reports suggest that hyperinsulinemia stimulated by the co-ingestion of CHO with protein does not seem to provide an even greater stimulus for muscle protein accretion. However, hyperinsulinemia is reported to stimulate rates of muscle protein breakdown and/or inhibit leg protein breakdown, both of which could augment protein accretion. These effects are equivocal, however, in terms of their beneficence for postexercise protein accretion; in particular, they are not seen when protein or amino acid consumption is sufficient to maximally stimulate rates of muscle protein synthesis. To date, no workers have examined rates of MPS or MPB after the consumption of a bolus of protein with and/or without CHO. Studies have examined the effects of a mixed amino acid infusion and repeated feedings of small doses of protein on MPS, neither of which would yield practical information for athletes or those concerned with gaining muscle mass. In previous works, the methods used resulted in a sustained hyperaminoacidemia and hyperinsulinemia,
which is not typical of what happens when food and/or drinks are consumed in a normal feeding pattern. Thus, the primary purpose of the present study was to use direct measures of muscle protein turnover and examine whether a bolus dose of high-quality whey protein, which contains sufficient essential amino acids to maximally stimulate rates of MPS, coingested with CHO (50 g) would augment rates of MPS and/or inhibit rates of MPB compared with protein alone. Further, it was examined intramuscular signaling events shown to be involved in the regulation of mRNA translation and elongation. This approach would provide practical insight on the relevance of CHO to a single-dose protein beverage on postexercise muscle protein turnover and intramuscular signaling events. It was hypothesized that insulin, if it were to be stimulatory for rates of MPS, might stimulate limb blood flow and enhance amino acid delivery to the limb at rest; however, insulin would not further stimulate limb blood flow or rates of MPS after resistance exercise followed by adequate protein consumption. The areas under the glucose and insulin curves were 17.5-fold and 5-fold greater, respectively, for PRO + CARB than for PRO. Exercise increased MPS and MPB, but there were no differences between PRO and PRO + CARB in the rested or exercised legs. Phosphorylation of Akt was greater in the PRO + CARB than in the PRO trial; phosphorylations of Akt and acetyl coA carboxylase-beta were greater after exercise than at rest. The concurrent ingestion of 50 g of CHO with 25 g of protein did not stimulate mixed MPS or inhibit MPB more than 25 g of protein alone either at rest or after resistance exercise. The data suggest that insulin is not additive or synergistic to rates of MPS or MPB when CHO is co-ingested with a dose of protein that maximally stimulates rates of MPS.

It was examined the hypothesis that protein co-ingestion with glucose during endurance exercise increases exogenous glucose-oxidation rate, gut comfort, and lowers perceived exertion. In a randomized crossover design, eight male cyclists rode 150-min at 50 percent of peak power on three occasions while ingesting solutions containing either: 8 percent C-enriched glucose and 2 percent milk protein concentrate (protein-glucose); glucose only (glucose), or non-caloric placebo (water). All solutions contained sodium citrate and flavor and were ingested at 150 ml per 15 min. The exogenous-carbohydrate oxidation rate was determined using stable isotope methodology and indirect calorimetry. Protein co-ingestion had no impact on the exogenous-glucose oxidation rate, but increased endogenous-carbohydrate oxidation rate (16 %) relative to glucose. Total carbohydrate and fat oxidation rates were increased (25 %) and decreased (17 %), respectively, by protein co-ingestion relative to water, but the effect relative to glucose was trivial. The plasma glucose concentration relative to glucose was 5.8 percent lower with protein co-ingestion; there were no clear differences in glucose concentration for the remaining comparisons, nor for lactate concentration. Perceived exertion was not altered by protein co-ingestion, however, there was a small decrease in nausea with the protein-glucose solution relative to water, other protein-affected comparisons were without note. Adding protein to a glucose-sodium solution ingested during exercise had neutral impact on exogenous carbohydrate oxidation and perception, and little impact on metabolic measures associated with endurance performance. It was concluded that previously reported effects of protein co-ingestion on endurance capacity were unlikely due to increased exogenous carbohydrate provision.

**Combined CHO-protein ingestion in recovery**

Whereas combined CHO and protein simply lacks efficacy when ingested during exercise, this does not negate any possibility that added protein may be of practical value in other situations (e.g. between exercise bouts). The question under debate, however, is not whether ingesting protein can be efficacious under certain circumstances but whether protein should be included in CHO-based sports supplements. These are conceptually very different questions, with valid justification for the inclusion of protein dependent not only on demonstrable efficacy but also on whether benefits persist even when evaluated within the
context of the habitual diet. This point has greater relevance to recovery than during exercise, as meals are usually a more viable option in recovery. For this reason, consideration of the criteria identified earlier leads inexorably to the conclusion that protein is an unnecessary addition to supplements in a real-world setting. The first of these criteria is easiest to address. Athletes may have a slightly increased daily protein requirement, so dietary protein supplementation might at first seem appropriate for this population. However, the vast majority of athletes in westernized societies exceed their recommended protein intake even without supplementation such that long-term protein requirements are almost always met by diet alone and even the potential short-term benefit of added protein for muscle glycogen synthesis after exercise does not apply to conditions where the existing diet is already adequate. Ingestion of added protein therefore does not supplement the habitual diet in the true sense because there is no chronic protein deficiency to be rectified and also no acute acceleration in the delivery of co-ingested CHO, provided that sufficient is ingested. The only remaining issues to consider are whether protein itself might be more effectively delivered to relevant tissues if ingested in the form of a supplement, particularly at time points so proximal to exercise that meals become an impractical option. Indeed, recent studies on this topic indicate that the temporal proximity and precise types of protein or amino acids ingested can mediate both acute protein synthetic rates and chronic accrual of lean tissue [11389].

Ultimately, rather than adding protein or anything else to sports supplements “just in case,” the approach informing a prevailing view was evidence based, with plausible explanations to reconcile any apparently conflicting findings. In this case, the few documented benefits of added protein for either performance during exercise or recovery thereafter are easily accounted for by the low amounts of CHO ingested in those studies. It therefore remains questionable why anyone would even consider including protein in a sports supplement when the likelihood of attaining a slight performance enhancement is entirely dependent on that supplement already being deficient in another nutrient with far better established ergogenic properties (i.e. CHO). Indeed, co-ingestion of CHO and protein in the immediate postexercise period clearly facilitates processes contributing to both short-term recovery and long-term adaptations (e.g. muscle glycogen and protein synthesis, respectively), with consequent translation into functional/whole-body end points (e.g. improved restoration of performance and training responses). There is no reason why these same outcomes cannot be achieved using nutritionally balanced whole foods as part of a more holistic approach. In fact, studies cited in the challenging view as evidence of improved rehydration with combined CHO-protein ingestion is a prime example of this reasoning. This is because the superior supplement in these studies was actually milk, with the greater fluid retention primarily attributed not to the presence of protein but to milk’s naturally elevated electrolyte content. Athletes, coaches, and supplement manufacturers understandably strive to gain competitive advantage by adopting nutritional strategies in anticipation of future empirical support. However, the scientific data currently available indicate that protein is not an effective addition to CHO-based sports supplements when ingested during exercise, whereas the potential advantages of added protein during recovery can be most comprehensively achieved via whole foods as part of a balanced diet [11389].

Nutritional interventions during recovery from exercise focus on CHO intake to maximize muscle glycogen resynthesis. Studies investigating the effects of adding protein to CHO have very much focused on enhancing muscle glycogen resynthesis during short-term recovery through maximizing the postexercise insulinenic response. Despite some contrasting evidence, the general consensus is similar to that for during exercise; if CHO is provided in adequate quantities then the addition of protein provides no extra benefit. However, reducing the CHO content of a supplement and adding an appropriate source of protein does not seem to have any detrimental effects on muscle glycogen resynthesis or subsequent
performance. Indeed, the addition of protein to a CHO supplement has many other potential benefits, and therefore, in many circumstances, reducing the CHO content and increasing the protein content of a supplement will result in a superior recovery strategy than consuming CHO alone. The majority of studies investigating the performance benefits of adding protein to a CHO recovery supplement have only considered the effect of supplementation on a subsequent exercise bout performed a few hours later. Although some athletes will train twice a day, many more will train hard or compete on consecutive days and therefore require a supplement that will enable them to maintain a high level of performance over multiple days. The addition of amino acids to a CHO drink consumed regularly during a 2-week period has been shown to reduce muscle damage (as evidenced by a decrease in plasma CK), decrease subjective fatigue, and maintain exercise performance after consecutive days of exercise compared with when CHO only was consumed in trained male athletes. Therefore, for those athletes who want to maintain performance over days of heavy training or competition, adding protein to a CHO supplement would be beneficial. Consuming CHO alone in the recovery period after a muscle-damaging exercise seems to have no beneficial effect on attenuating indirect measures of exercise induced muscle damage. The addition of protein to a CHO drink may confer advantages in terms of rehydration during recovery from exercise. There is evidence that consuming solutions containing protein after exercise-induced dehydration improves fluid retention over solutions with no added. Recent interesting data suggest that supplementation with a mixture of CHO and protein after exercise increases plasma albumin content and plasma volume in both older and younger subjects. Postexercise plasma volume increases result in cardiovascular and thermoregulatory adaptation and are therefore an important part of the training process. It has been reported that older individuals have an attenuated postexercise increase in plasma volume potentially due to an insufficient protein intake for albumin synthesis. Although further research is warranted in this area, this provides further evidence that consuming CHO alone during the postexercise period may not be the most appropriate nutritional practice to facilitate all aspects of recovery. In summary, the favorable consequences of consuming CHO–protein mixtures in many cases make them a more effective nutritional strategy than consuming CHO only, particularly over the longer term [11389].

Needs in older, training subjects

The regular performance of resistance exercises and the habitual ingestion of adequate amounts of dietary protein from high-quality sources are two important ways for older persons to slow the progression of and treat sarcopenia, the age-related loss of skeletal muscle mass and function. Resistance training can help older people gain muscle strength, hypertrophy muscle, and increase whole body fat-free mass. It can also help frail elderly people improve balance and physical functioning capabilities. Inadequate protein intake will cause adverse metabolic and physiological accommodation responses that include the loss of fat-free mass and muscle strength and size. Findings from controlled feeding studies show that older persons retain the capacity to metabolically adjust to lower protein intakes by increasing the efficiency of nitrogen retention and amino acid utilization. However, they also suggest that the recommended dietary allowance of 0.8 g protein/kg and day might not be sufficient to prevent subtle accommodations and blunt desired changes in body composition and muscle size with resistance training. Most of the limited research suggests that resistance training-induced improvements in body composition, muscle strength and size, and physical functioning are not enhanced when older people who habitually consume adequate protein (modestly above the recommended dietary allowance, RDA) increase their protein intake by either increasing the ingestion of higher-protein foods or consuming protein-enriched nutritional supplements. The habitual consumption of adequate amounts of high-quality dietary protein and the inclusion of resistance exercise training as part of a physically
active lifestyle are considered important contributors to an adult person's skeletal muscle size and strength, whole body fat-free mass, and health and well-being as they progress through the lifespan. Recent evidence suggests that protein intakes above the RDA might promote resistance-training-induced muscle hypertrophy. If true, this would provide older persons with an effective strategy to counter sarcopenia, the age-related loss of muscle mass, strength, and function that occurs in all persons and contributes to the need for about 15 percent of persons 65 to 75 years of age and 50 percent of persons over age 85 years to require assistance with activities of daily living [07323].

Acute dietary protein intake and resistance exercise
Research primarily done in younger adult men and women provides a strong foundation for how dietary protein and resistance exercise might synergistically work to ultimately promote muscle hypertrophy and increased whole body fat-free mass. Review articles describe these interactions in more detail. However, in general, proteins are constantly being formed (synthesized) and broken down and these processes are influenced by external cues including feeding and physical activity. On a daily to weekly basis the cumulative rates of protein synthesis and breakdown are in equilibrium; consequently, muscle and lean tissue mass are maintained. Measurements of the rates of protein synthesis and breakdown during short-term (acute) experiments have established the following knowledge:

- in a post-absorptive (fasting) state, the rate of protein synthesis is slower than the rate of protein breakdown, which results in a net catabolic state
- in a postprandial (fed) state that includes the ingestion of proteins or mixtures of amino acids, the rate of protein synthesis increases and is faster than the rate of protein breakdown (which is not appreciably changed); a net anabolic state results. As previously stated, these events typically balance each other over time and skeletal muscle and fat-free mass are unchanged
- in a post-absorptive state during the period soon after resistance exercise is performed, the rate of protein synthesis increases modestly more that the rate of protein breakdown increases. While this increases net protein balance, a catabolic state still remains
- the combination of feeding proteins or mixtures of amino acids and resistance exercise result in the greatest net anabolic state. This is achieved via amino acid and exercise-induced increases in protein synthesis and minimal or no change in protein breakdown

The effects of ingesting proteins and resistance exercise on muscle protein synthesis are considered to be independent and additive. Muscle hypertrophy theoretically is achieved from the cumulative periods of positive protein balance that occur after resistance exercise when protein is consumed. While this knowledge has resulted from studies in younger adults, several acute studies in older persons also document that amino acid feeding and resistance exercise increase muscle protein synthesis, findings that support the combined use of dietary protein and resistance training to hypertrophy muscle and offset sarcopenia [07323].

Dietary protein needs of older adults who perform resistance training
Adequate dietary protein is critical to promote the maintenance of skeletal muscle and treat sarcopenia. The RDA for protein is set at 0.8 g protein per day and kg bodyweight for all men and women age 19 years and above, independent of physical activity status. For younger adults, the American College of Sports Medicine, American Dietetic Association and Dietitians of Canada joint position statement on nutrition and athletic performance indicates that athletes might need to consume 50-100 percent more protein for exercise-related energy production, post-exercise muscle damage repair, and muscle hypertrophy. The protein needs of older persons who perform resistance training are not known with confidence. Sarcopenia
and reductions in the intensity and volume of training might modestly reduce the need for protein in older versus younger resistance-trained persons. The influence of resistance training on nitrogen balance and amino acid utilization has been evaluated in a strictly controlled diet study where the 54-78 year-old subjects either remained sedentary or performed lower-body or whole-body resistance exercise 3 days/week for 12 weeks. All of the subjects consumed diets that contained the RDA for protein and sufficient energy for weight maintenance throughout the study. During the first six weeks of intervention, urinary nitrogen excretion decreased and nitrogen balance increased comparably in all three groups, findings that support metabolic adaptation to the constant protein intake and the achievement of increased efficiency of nitrogen retention and amino acid utilization. Over the next six weeks of intervention, the two resistance training groups experienced a modest increase in urinary nitrogen excretion, compared to a continued progressive decline in the sedentary group. While being cautious not to over-interpret these findings, they are consistent with an increased protein requirement for the resistance-training older persons [07323].

Peptides

The production of sport nutrition foods (or parts of foods) and supplements to improve athletic performance, image or health for the consumer is a multibillion dollar industry. Within the broad supplement spectrum are the protein and/or free-form amino acid-based supplements. Research substantiating the efficacy of these supplements is wide-ranging from good evidence to support a reproducible anabolic effect of the ingestion of whey protein for the stimulation of muscle protein accretion, to no evidence for supplements, such as deer antler extracts, which are purported to boost concentrations of the peptide hormone IGF-1. Certainly, peptides have gained unfavourable attention in sports for their use in the (presumed) enhancement of performance, aiming to help athletes/teams to gain a competitive advantage [13357].

Peptides are short chains of amino acids that are produced synthetically, endogenously or derived from food. The longer chains of amino acids are known by most as protein. The peptides derived from dietary proteins by enzymatic hydrolysis are not the concern of the sport authorities involved in the maintenance of the integrity in professional sport. However, certain synthetic peptides can be administered, via a variety of methods (orally, intravenous, intranasal or transdermal cream, etc), that may exert anabolic effects and/or serve as masking agents for other drugs. In particular, the synthetic growth hormone releasing peptides (GHRP), for example, GHRP-6, Hexarelin or CJC-1295, have been demonstrated to stimulate the release of GH from the pituitary gland thereby enhancing its endogenous production. The synthetic GHRPs were specifically developed and intended for patients (not for athletes) with intact or impaired pituitary function to mimic the pulsatile nature of endogenous GH release. In the case of CJC-1295, a single injection of this peptide has been demonstrated to induce an increase in serum GH concentrations that seems to persist for about 2 weeks in healthy adults. GH therapy, however, is often administered in a single daily dose and results in a robust (supraphysiological) increase in systemic concentrations of GH that wanes over time [13357].

Amino acids

It has previously been shown that the aminoacidemia caused by the consumption of a rapidly digested protein after resistance exercise enhances muscle protein synthesis (MPS) more than the amino acid (AA) profile associated with a slowly digested protein. Here, we
investigated whether differential feeding patterns of a whey protein mixture commencing before exercise affect postexercise intracellular signaling and MPS. Twelve resistance-trained males performed leg resistance exercise 45 min after commencing each of three volume-matched nutrition protocols: placebo (PLAC, artificially sweetened water), BOLUS (25 g of whey protein + 5 g of leucine dissolved in artificially sweetened water; 1 × 500 mL), or PULSE (15 × 33 mL aliquots of BOLUS drink every 15 min). The preexercise rise in plasma AA concentration with PULSE was attenuated compared with BOLUS; this effect was reversed after exercise, with two-fold greater leucine concentrations in PULSE compared with BOLUS. One-hour postexercise, phosphorylation of p70 S6K(thr389) and rpS6(ser235/6) was increased above baseline with BOLUS and PULSE, but not PLAC; furthermore, PULSE > BOLUS. MPS throughout 5 h of recovery was higher with protein ingestion compared with PLAC (0.037 ± 0.007), with no differences between BOLUS or PULSE (0.085 ± 0.013 vs 0.095 ± 0.010 % per h, respectively). It was concluded that manipulation of aminoacidemia before resistance exercise via different patterns of intake of protein altered plasma AA profiles and postexercise intracellular signaling. However, there was no difference in the enhancement of the muscle protein synthetic response after exercise. Protein sources producing a slow AA release, when consumed before resistance exercise in sufficient amounts, are as effective as rapidly digested proteins in promoting postexercise MPS [12424].

The authors undertook 2 crossover-designed studies to characterize plasma amino acid (AA) responses to the intake of 20 g of protein. In Study 1, 15 untrained and overnight-fasted subjects consumed 20 g protein from skim milk, soy milk, beefsteak, boiled egg, and a liquid meal supplement. In Study 2, 10 fasted endurance-trained subjects consumed 20 g protein from a protein-rich sports bar at rest and after a 60-min submaximal ride. Plasma AA concentrations were measured immediately before and for 180 min after food ingestion using a gas-chromatography flame-ionization detection technique. A pharmacokinetic analysis was undertaken for profiles of total AAs (TAA), essential AAs, branched-chain AAs (BCAA), and leucine. Although area-under-the-curve values for plasma TAA were similar across protein sources, the pattern of aminoacidemia showed robust differences between foods, with liquid forms of protein achieving peak concentrations twice as quickly after ingestion as solid protein-rich foods (e.g. 50 min vs 100 min) and skim milk achieving a significantly faster peak leucine concentration than all other foods (25 min). Completing exercise before ingesting protein sources did not cause statistically significant changes in the pattern of delivery of key AAs, BCAAs, and leucine apart from a 20-40 percent increase in the rate of elimination. These results may be useful to plan the type and timing of intake of protein-rich foods to maximize the protein synthetic response to various stimuli such as exercise [12421].

Effects of amino acid derivatives on physical, mental and physiological activities
Nutritional ergogenic aids have been in use for a long time to enhance exercise and sports performance. Dietary components that exhibit ergogenic activity are numerous and their consumption is common and popular among athletes. They often come under scrutiny by legal authorities for their claimed benefits and safety concerns. Amino acid derivatives are propagated as being effective aids to enhance physical and mental performance in many ways, even though studies have pointed out that individuals who are deficient are more likely to benefit from dietary supplementation of amino acid derivatives than normal humans. In this review, some of the most common and widely used amino acids derivatives in sports and athletics namely creatine, tyrosine, carnitine, HMB and taurine have been discussed for their effects on exercise performance, mental activity as well as body strength and composition. Creatine, carnitine, HMB and taurine are reported to delay the onset of fatigue, improve exercise performance and body strength. HMB helps in increasing fat free mass and reduce exercise induced muscle injury. Taurine has been found to reduce oxidative stress during exercise and also act as an antihypertensive agent. Although, studies have not been able to
find any favourable effect of tyrosine administration on exercise performance, it has been proved to be very effective in fighting stress, improving mood and cognitive performance particularly in sleep deprived subjects. While available data from published studies and findings are equivocal about the efficacy of creatine, tyrosine and HMB; more comprehensive researches on carnitine and taurine are necessary to provide evidence for the theoretical basis of their ergogenic role in nutritional modification and supplementation [13649].

**Branched-chain amino acid (BCAA)**

The purpose of one study was to determine whether branched-chain amino acid (BCAA) supplementation attenuates indirect indicators of muscle damage during endurance exercise as compared with an isocaloric, carbohydrate (CHO) beverage or a noncaloric placebo (PLAC) beverage. Nine untrained men performed three 90 min cycling bouts at 55 percent VO\(_{2}\text{peak}\). Subjects, blinded to beverage selection, ingested a total of 200 kcal of energy via the CHO or BCAA beverage before and at 60 min of exercise, or they drank the PLAC beverage. Creatine kinase (CK), lactate dehydrogenase (LDH), isokinetic leg-extension and -flexion torque, and muscle soreness were assessed before and immediately, 4 h, 24 h, and 48 h postexercise. The trials were separated by 8 weeks. CK activities were significantly lower after the BCAA trial than in the PLAC trial at 4, 24, and 48 h postexercise, as well as lower than the CHO beverage at 24 h postexercise. CK was lower in the CHO trial at the 24- and 48-h time points than in the PLAC trial. LDH activities were lower in the BCAA trial at 4 h than in the PLAC trial. As compared with the CHO and PLAC trials, ratings of perceived soreness were lower at 24 h postexercise, and leg-flexion torque was higher at the 48-h time point after the BCAA trial. The present data suggest that BCAA supplementation attenuates muscle damage during prolonged endurance exercise in untrained college-age men. CHO ingestion attenuates CK activities at 24 and 48 h postexercise as compared with a placebo beverage [07324].

It was investigated the effect of branched-chain amino acids (BCAA) supplementation on tissue damage during distance running. Eight male distance runners (mean 20 years) participated in a double blinded cross over designed study conducted during training camp. During each intervention period, the subjects were asked to participate in a 25-km run, and the blood BCAA and lactate dehydrogenase (LDH) level, an index of tissue damage, were measured pre- and post-run. Either a drink containing BCAA (0.4 % BCAA in a 4 % carbohydrate solution) or an iso-calorie placebo drink was provided to the subjects 5 times during the run without any restriction in the volume. The total volume of the drink consumed by the subjects did not differ substantially between the trials: 591 ± 188 (2.36 g BCAA) versus 516 ± 169 mL in BCAA and placebo trial, respectively. During the run, the blood BCAA concentration was maintained in the BCAA trial. However, the blood BCAA concentration level tended to decrease in the placebo trial. The extent of the blood LDH increase in the BCAA trial was significantly less than that of the placebo trial (48 % vs 58 %). It was concluded that maintaining the blood BCAA level throughout a long distance run contributes to a reduction in the LDH release and, therefore, the effect of BCAA supplementation is suggested to reduce the degree of muscle damage [07325].

The mechanisms of maintenance of the protein mass of muscle and associated connective tissue and bone are becoming more accessible as a result of the use of a combination of well-established techniques for measurement of protein turnover and measurement of protein expression and phosphorylation state of signalling molecules involved in anabolic and catabolic responses. Amino acids, hormones and physical activity appear to be the major short-term physiological regulators of muscle mass, mainly through their actions on protein
synthesis and breakdown, on a time scale of minutes to hours, with duration of changes in
gene expression up to weeks. Amino acids are the main components in the diet regulating
protein turnover, having marked effects in stimulating muscle protein synthesis and with
almost no effect on muscle protein breakdown. Branched-chain amino acids, and in
particular leucine, simulate protein synthesis via signalling pathways involving mTOR
(mammalian target of rapamycin) in a dose-response manner. Insulin has little effect on
protein synthesis in human muscle, but it has a marked inhibitory effect on protein
breakdown. The amino acid simulation of anabolism is not dependent on the presence of
insulin, IGF-1 (insulin-like growth factor-1) or growth hormone. Exercise not only stimulates
protein synthesis in muscle, but also in tendon; and disuse atrophy is accompanied by
marked decreases of both muscle and tendon collagen protein synthesis. Bone collagen
synthesis appears to be nutritionally regulated by the availability of amino acids, but not lipid
or glucose [07326].

One study was designed to investigate whether a protein hydrolysate enriched in branched
chain amino acids and antioxidants, trace and mineral elements, and vitamins would affect
performance and fatigue. Eighteen sportsmen underwent testing before and after 28 days
supplementation with either treatment in protein hydrolysate or placebo. Testing included
exhaustive aerobic and anaerobic exercises with determination of blood lactate concentration
through exercise and recovery and antioxidant status, but also measurements of maximal
oxidative capacity (VO_{2\text{max}}) and citrate synthase activity from a resting muscle biopsy. Protein
hydrolysate resulted in a significant decrease in fatigue indices, without affecting
performances. A significant increase in enzymatic antioxidant and a decrease in oxidative
damage were observed at rest after treatment but not with a placebo. Decrease in maximal
blood lactate and improvement of blood lactate removal were only observed after protein
hydrolysate treatment. Furthermore, citrate synthase activity increased significantly, whereas
no change was observed in VO_{2\text{max}}. In conclusion, this protein hydrolysate treatment induced
adaptations that may promote a decrease in fatigue during exercises, potentially explained
by changes in parameters used to represent oxidative damage and antioxidant status at rest
and changes in lactate metabolism [07327].

Prolonged endurance exercise stimulates whole-body protein turnover (synthesis and
degradation) but it remains contentious whether this translates into an increased net protein
oxidation or dietary requirement for protein. Skeletal muscle is the major energy consumer
during exercise and the oxidation of branched-chain amino acids (BCAA) is increased
several-fold, suggesting an increased requirement for fuel. Increased BCAA oxidation has
been proposed to impair aerobic energy provision during prolonged exercise, but there is
little evidence to support this theory. Endurance training blunts the acute exercise-induced
increase in whole-body protein turnover and skeletal BCAA oxidation at a given work
intensity. However, training also increases the maximal capacity for skeletal muscle BCAA
oxidation, as evidenced by a higher maximal activity of the rate-determining enzyme
branched-chain oxo acid dehydrogenase. Exercise-induced changes in protein metabolism
are affected by nutritional status, with high carbohydrate availability (as typically practiced by
endurance athletes) generally associated with reduced net protein utilisation. Ingestion of
protein with carbohydrate improves net protein balance during exercise and recovery
compared with carbohydrate alone, but it remains to be determined whether this practice
facilitates the adaptive response to chronic training [07328].

The purpose of one study was to determine whether branched-chain amino acid (BCAA)
supplementation attenuates indirect indicators of muscle damage during endurance exercise
as compared with an isocaloric, carbohydrate (CHO) beverage or a noncaloric placebo
(PLAC) beverage. Nine untrained men performed three 90 min cycling bouts at 55 percent
VO_{2\text{peak}}. Subjects, blinded to beverage selection, ingested a total of 200 kcal of energy via
the CHO or BCAA beverage before and at 60 min of exercise, or they drank the PLAC beverage. Creatine kinase (CK), lactate dehydrogenase (LDH), isokinetic leg-extension and -flexion torque, and muscle soreness were assessed before and immediately, 4 h, 24 h, and 48 h postexercise. The trials were separated by 8 wk. CK activities were significantly lower after the BCAA trial than in the PLAC trial at 4, 24, and 48 h postexercise, as well as lower than the CHO beverage at 24 h postexercise. CK was lower in the CHO trial at the 24- and 48-h time points than in the PLAC trial. LDH activities were lower in the BCAA trial at 4 h than in the PLAC trial. As compared with the CHO and PLAC trials, ratings of perceived soreness were lower at 24 h postexercise, and leg-flexion torque was higher at the 48-h time point after the BCAA trial. The present data suggest that BCAA supplementation attenuates muscle damage during prolonged endurance exercise in untrained college-age men. CHO ingestion attenuates CK activities at 24 and 48 h postexercise as compared with a placebo beverage [07329].

Since the 1980's there has been high interest in branched-chain amino acids (BCAA) by sports nutrition scientists. The metabolism of BCAA is involved in some specific biochemical muscle processes and many studies have been carried out to understand whether sports performance can be enhanced by a BCAA supplementation. However, many of these researches have failed to confirm this hypothesis. Thus, in recent years investigators have changed their research target and focused on the effects of BCAA on the muscle protein matrix and the immune system. Data show that BCAA supplementation before and after exercise has beneficial effects for decreasing exercise-induced muscle damage and promoting muscle-protein synthesis. Muscle damage develops delayed onset muscle soreness: a syndrome that occurs 24-48 h after intensive physical activity that can inhibit athletic performance. Other recent works indicate that BCAA supplementation recovers peripheral blood mononuclear cell proliferation in response to mitogens after a long distance intense exercise, as well as plasma glutamine concentration. The BCAA also modifies the pattern of exercise-related cytokine production, leading to a diversion of the lymphocyte immune response towards a Th1 type. According to these findings, it is possible to consider the BCAA as a useful supplement for muscle recovery and immune regulation for sports events [08387].

The purpose of one study was to determine whether branched-chain amino acid (BCAA) supplementation attenuates indirect indicators of muscle damage during endurance exercise as compared with an isocaloric, carbohydrate (CHO) beverage or a noncaloric placebo beverage. Nine untrained men performed three 90 min cycling bouts at 55 percent of VO2 peak. Subjects, blinded to beverage selection, ingested a total of 200 kcal of energy via the CHO or BCAA beverage before and at 60 min of exercise, or they drank the placebo beverage. Creatine kinase (CK), lactate dehydrogenase (LDH), isokinetic leg-extension and -flexion torque, and muscle soreness were assessed before and immediately, 4 h, 24 h, and 48 h postexercise. The trials were separated by 8 week. Creatine kinase activities were significantly lower after the branched-chain amino acid trial than in the placebo trial at 4, 24, and 48 h postexercise, as well as lower than the carbohydrate beverage at 24 h postexercise. Creatine kinase was lower in the carbohydrate trial at the 24- and 48-h time points than in the placebo trial. LDH activities were lower in the branched-chain amino acid trial at 4 h than in the placebo trial. As compared with the carbohydrate and placebo trials, ratings of perceived soreness were lower at 24 h postexercise, and leg-flexion torque was higher at the 48-h time point after the branched-chain amino acid trial. The presented data suggest that branched-chain amino acid supplementation attenuates muscle damage during prolonged endurance exercise in untrained college-age men. Carbohydrate ingestion attenuates creatine kinase activities at 24 and 48 h postexercise as compared with a placebo beverage [08388].
The three branched chain amino acids (BCAA; leucine, isoleucine and valine) cannot be synthesised by the human body and must therefore be provided in the diet. Food sources containing BCAA are dietary proteins such as meat, poultry, fish, egg, milk and cheese, which contain 15-20 g of BCAA per 100 g of protein. The BCAA are metabolised mainly in skeletal muscle, which means they escape the liver, and ingestion of BCAA causes a rapid increase in the plasma level. The anabolic effect of BCAA on human skeletal muscle was first demonstrated under resting conditions, followed by studies showing similar effects in the recovery period after endurance and resistance exercise. More recent data indicate that the effect of BCAA, particularly leucine, is mediated through activation of regulatory enzymes in the protein synthesis machinery. Increasing the plasma level of BCAA during exercise may reduce the transport of tryptophan into the brain and the synthesis of 5-hydroxytryptamine (5-HT). 5-HT has been suggested to be involved in central fatigue, that is, fatigue emanating from the brain rather than muscle. BCAA supplementation during sustained physical activity has exerted positive effects on cognitive performance and perceived exertion. Under certain conditions, BCAA supplementation can also improve physical performance, although the majority of studies have found no effect of BCAA on performance when supplied together with carbohydrates. The amount of BCAA recommended is 0.03-0.05 g/kg body weight per hour or 2-4 g per hour ingested repeatedly during exercise and recovery, preferably taken as a drink. Large doses (about 30 g per day) are well tolerated; however, they may be detrimental to performance due to increased production of ammonia by the exercising muscle [09344].

The effects of branched-chain amino acid (BCAA) supplementation on the lactate threshold were investigated as an index of endurance exercise capacity. Eight trained male subjects (21 ± 2 y) participated in a double-blind crossover placebo-controlled study. The subjects were randomly assigned to two groups and were provided either a BCAA drink (0.4 % BCAA, 4 % carbohydrate; 1,500 mL/d) or an iso-caloric placebo drink for 6 d. On the 7th day, the subjects performed an incremental loading exercise test with a cycle ergometer until exhaustion in order to measure the lactate threshold. The test drink (500 mL) was ingested 15-min before the test. Oxygen consumption VO$_2$ and the respiratory exchange ratio (RER) during the exercise test were measured with the breath-by-breath method. Blood samples were taken before and during the exercise test to measure the blood lactate and plasma BCAA concentrations. The same exercise test was performed again 1 wk later. BCAA supplementation increased the plasma BCAA concentration during the exercise test, while plasma BCAA concentration decreased in the placebo trial. The RER during the exercise test in the BCAA trial was significantly lower than that in the placebo trial. The VO$_2$ and workload levels at lactate threshold point in the BCAA trial were higher than those in the placebo trial. The VO$_{2\max}$ in the BCAA trial was higher than that in the placebo trial. These results suggest that BCAA supplementation may be effective to increase the endurance exercise capacity [09345].

Skeletal muscle growth is thought to be regulated by the mammalian target of rapamycin (mTOR) pathway, which can be activated by resistance exercise and branched-chain amino acids (BCAA). The major aim of one study was to distinguish between the influence of resistance exercise and BCAA on key enzymes considered to be involved in the regulation of protein synthesis, including p70(S6) kinase (p70(S6k)). Nine healthy subjects (four men and five women) performed unilateral resistance exercise on two occasions separated by 1 month. Subjects were randomly supplied either a mixture of BCAA or flavoured water. Muscle biopsies were taken from both resting and exercising muscle before, after and 1 h after exercise. Phosphorylation of Akt was unaltered by either resistance exercise and/or BCAA supplementation whereas mTOR phosphorylation was significantly enhanced to a similar extent in both exercising and resting muscle following exercise in the absence (70-90 %) and presence of BCAA supplementation (80-130 %). Phosphorylation of p70(S6k) was
unaffected by resistance exercise alone; however, BCAA intake significantly increased this phosphorylation in both legs following exercise. In resting muscle, a 5- and 16-fold increase in p70(S6k) was observed immediately after and 1 h after exercise, respectively, as compared to 11- and 30-fold increases in the exercising muscle. Phosphorylation of eukaryotic elongation factor 2 was attenuated 1 h after exercise in both resting (10-40 %) and exercising muscle (30-50 %) under both conditions. The present findings indicate that resistance exercise and BCAA exert both separate and combined effects on the p70(S6k) phosphorylation in an Akt-independent manner [10496].

The purpose of one study was to investigate whether short-term amino acid supplementation could maintain a short-term net anabolic hormonal profile and decrease muscle cell damage during a period of high-intensity resistance training (overreaching), thereby enhancing recovery and decreasing the risk of injury and illness. Eight previously resistance trained males were randomly assigned to either a high branched chain amino acids (BCAA) or placebo group. Subjects consumed the supplement for 3 weeks before commencing a fourth week of supplementation with concomitant high-intensity total-body resistance training (overreaching) (3 x 6-8 repetitions maximum, 8 exercises). Blood was drawn prior to and after supplementation, then again after 2 and 4 days of training. Serum was analyzed for testosterone, cortisol, and creatine kinase. Serum testosterone levels were significantly higher, and cortisol and creatine kinase levels were significantly lower in the BCAA group during and following resistance training. These findings suggest that short-term amino acid supplementation, which is high in BCAA, may produce a net anabolic hormonal profile while attenuating training-induced increases in muscle tissue damage. Athletes’ nutrient intake, which periodically increases amino acid intake to reflect the increased need for recovery during periods of overreaching, may increase subsequent competitive performance while decreasing the risk of injury or illness [10236].

It has been demonstrated that branched-chain amino acids (BCAA) transaminase activation occurs simultaneously with exercise-induced muscle glycogen reduction, suggesting that BCAA supplementation might play an energetic role in this condition. One study aimed to test whether BCAA supplementation enhances exercise capacity and lipid oxidation in glycogen-depleted subjects. Using a double-blind cross-over design, volunteers (n=7) were randomly assigned to either the BCAA (300 mg/kg/day) or the placebo (maltodextrine) for 3 days. On the second day, subjects were submitted to an exercise-induced glycogen depletion protocol. They then performed an exhaustive exercise test on the third day, after which time to exhaustion, respiratory exchange ratio (RER), plasma glucose, free fatty acids (FFA), blood ketones and lactate were determined. BCAA supplementation promoted a greater resistance to fatigue when compared to the placebo (+17 %). Moreover, subjects supplemented with BCAA showed reduced RER and higher plasma glucose levels during the exhaustive exercise test. In conclusion, BCAA supplementation increases resistance to fatigue and enhances lipid oxidation during exercise in glycogen-depleted subjects [11274].

The purpose of one study was to determine whether branched-chain amino acid (BCAA) supplementation affects aerobic performance, ratings of perceived exertion (RPE), or substrate utilization as compared with an isocaloric, carbohydrate (CHO) beverage or a noncaloric placebo (PLAC) beverage. Nine untrained males performed three 90-minute cycling bouts at 55 percent VO₂ peak followed by 15-minute time trials. Subjects, who were blinded to beverage selection, ingested a total of 200 kcal via the CHO or BCAA beverage before and at 60 minutes of exercise or the PLAC beverage on the same time course. RPE and metabolic measurements were taken every 15 minutes during steady-state exercise, and each of the trials was separated by 8 weeks. Plasma glucose and BCAA concentrations were measured pre- and post-exercise. A significantly greater distance (4.6 ± 0.6 km) was traveled in the time-trial during the CHO trial than the PLAC trial (3.9 ± 0.4 km). There was no
difference between the BCAA (4.4 ± 0.5 km) and PLAC trials. RPE was reduced at the 75-minute and 90-minute mark during the BCAA trial as compared with the PLAC trial. There were no significant differences found for the trial vs. time interaction in regard to respiratory exchange ratio. Thus, CHO supplementation improves performance in a loaded time-trial as compared with a PLAC beverage. BCAA supplementation, although effective at increasing blood concentrations of BCAA, did not influence aerobic performance but did attenuate RPE as compared with a PLAC beverage [11275].

One study investigated the effects of BCAA, arginine and carbohydrate combined beverage (BCAA Drink) on biochemical responses and psychological conditions during recovery after a single bout of exhaustive exercise. Fourteen healthy males were assigned to drink either BCAA Drink (BA trial) or placebo (PL trial) on two sessions separated by 2 weeks. Blood samples of each subject were collected before exercise, 0, 10, 20, 40, 60, 120 min and 24 h after exercise. No significant differences in the levels of lactate, ammonia, creatine kinase and glycerol between the two groups were observed at any of the time points. However, the levels of glucose and insulin were significantly higher in the BA trial as compared to those in the PL trial at the 40 and 60 min recovery points. Furthermore, the testosterone-to-cortisol ratio at the 120 min recovery point was significantly higher in the BA trial as compared to that in the PL trial. The results indicate the occurrence of anabolic response during the recovery period. The benefit of BCAA Drink was also performed by Profile of Mood States to assess the psychological condition. Fatigue score increased immediately at exhaustion in both groups, but the decrease in the fatigue score at 120 min recovery point was significant only in BA trial. These data indicate that a single bout of exhaustive exercise enhanced the feeling of fatigue. The detrimental consequence was reduced by an ingestion of BCAA Drink [11276].

Branched-chain amino acids (BCAAs) especially leucine, were shown in the mid-1970s to be potent regulators of protein turnover. In the mid-1980s BCAAs were also shown to compete with other large neutral amino acids (LNAAs), suggesting that raising the blood concentration of BCAA would limit the formation of false neurotransmitters within the brain. Although these findings would seem to have provided an attractive basis for BCAA supplementation in various physiological or pathological situations, they were not sufficient at that time because the understanding of in vivo metabolism and cell signaling were limited and no clear biomarkers of BCAA status were available. The definition of BCAA requirements in healthy subjects remains a matter of debate, despite the use of accurate modern methods (i.e. 24-h direct amino acid oxidation and balance technique, providing a total of 84 mg/kg/day, which is lower than the 110 mg/kg/day obtained using the short-term indicator amino acid oxidation method). Another important question is how the requirements of a given BCAA influences the requirements of the other two. It has been provided convincing data that varying the intake of one BCAA in the range supplied by normal diets has no effect on the oxidation of the two others. However, these authors also show that this is not the case when a large nonphysiological BCAA intake is given. This is a key factor in the effects (including side effects) of pharmacological administration of a given BCAA or a mixture of BCAA in physiological (e.g. exercise) or pathological (e.g. injury) situations. The rationale behind consuming a BCAA in addition to diet before, during, and/or after exercise is that exercise leads to a considerable increase in BCAA oxidation, especially during endurance exercise, and most of the oxidized BCAA appears to be released into the system by depression of protein synthesis. Thus, the theoretical utility of providing a BCAA supplement is:

- to replace oxidized molecules
- to upregulate protein synthesis

However, this nice story is hampered by a series of facts. First, recent evidence shows that
endurance training does not really increase leucine oxidation and that protein metabolism becomes more efficient (i.e., increased nitrogen balance achieved at a lower rate of oxidation). Second, meeting energy requirements by eating a normal diet limits BCAA oxidation, making BCAA supplementation unwarranted. Nevertheless, a series of elegant studies suggest BCAA supplementation may increase protein synthesis during or after exercise. The molecular targets have been identified: mTOR, p70 S6 kinase, and S6 phosphorylation. Whether the mechanisms underlying the action of BCAAs in resistance and endurance exercise are similar or different remains unclear [06268].

Another action of BCAAs in an exercise context is their action on central fatigue syndrome. Central fatigue is defined as an inability to maintain power output due to events within the central nervous system. One of the various mechanisms that have been proposed to explain central fatigue is an increase in the amount of tryptophan taken up by the brain leading to excessive amounts of the neurotransmitter S-hydroxytryptamine in some neurons. The transport of tryptophan into the brain is regulated by blood concentrations of other LNAAs, in particular the BCAAs that compete with tryptophan for this transport. Hence, it makes sense to provide extra BCAAs to limit brain uptake of tryptophan and consequently central fatigue. The concept has been supported by data obtained during standardized cycle ergometer exercise and in a competitive 30-km cross-country race. Another situation where protein synthesis is depressed is with aging, which leads to sarcopenia, the progressive loss of muscle mass. Given demographic evolution in western countries, this is certainly a major public health concern. The decrease in protein synthesis in the elderly is multifactorial, but amino acids, and especially leucine, could play a major role in this process: first, splanchnic sequestration of leucine following a meal is almost doubled in the elderly compared with young adults; and second, the ability of leucine to stimulate muscle protein synthesis becomes blunted with aging. In other words, more leucine is needed to induce protein synthesis in the elderly to the same extent as in young adults. Resistance to the anabolic action of insulin, energy-dependent–related abnormalities (as gauged by the low stimulation of protein synthesis in the presence of carbohydrates in the meal), blunted leucine transduction signal (at S6K1), and low-grade chronic inflammation could be involved (21). However, to date, and to the best of our knowledge, there is no available clinical interventional study on the effects of BCAA supplementation in preventing or treating sarcopenia [06268].

Fatigue may be defined as the inability to maintain the expected muscle strength, leading to a reduced performance during prolonged exercise. The mechanisms that directly affect the muscles are peripheral and those residing in the brain are central. The following events are considered to be the five major metabolic causes of fatigue:

- muscle phosphocreatinine depletion
- proton accumulation in muscle (acidosis)
- muscle glycogen depletion
- reduced blood glucose concentration
- increased ratio of specific amino acids in plasma (free tryptophan/branched-chain amino acids (TRP/BCAA)).

The first three causes are directly related to peripheral fatigue and the last two are probably related to central fatigue. In addition to these causes, the increased plasma ammonia concentration that occurs during prolonged exercise can be highly toxic and is associated with both peripheral and central fatigue. In contrast to the liver, which can oxidize the twenty amino acids present in the tissue protein of the organism, skeletal muscle can oxidize only six: BCAA, aspartate, asparagine and glutamate. In muscle tissue, BCAA participates in protein synthesis and act as a precursor in the synthesis of other amino acids, in addition to
being used as energy substrates during physical exercise. Of the three BCAAs, leucine is the one primarily responsible for the stimulation of protein synthesis induced by intake of a mixed meal. The stimulatory effect of leucine on protein synthesis is mediated through upregulation of the initiation of mRNA translation. The hypothesis of central fatigue suggests that the increase in serotonin or 5-hydroxytryptamine (5-HT) concentration in the brain during prolonged exercise may be directly related to the development of fatigue and to the consequent reduction in performance. On the other hand, BCAA supplementation may act on the reduction of the plasma TRP/BCAA ratio since these amino acids have the same mechanism of transport through the blood-brain barrier, a fact that may reduce the influx of TRP (a serotonin precursor) in the central nervous system (CNS). This occurrence may cause a reduced 5-HT synthesis in the brain, consequently delaying the symptoms of fatigue. In addition, BCAA may act on glycogen metabolism during prolonged exercise, since supplementation with these amino acids can preserve hepatic and muscle glycogen possibly resulting in increased performance. One study aimed to determine the effects of diets chronically supplemented with branched-chain amino acids (BCAA) on the fatigue mechanisms of trained rats. Thirty-six adult Wistar rats were trained for six weeks. The training protocol consisted of bouts of swimming exercise (one hour a day, five times a week, for six weeks). The animals received a control diet (C) (n=12), a diet supplemented with 3.6 percent BCAA (S1) (n=12), or a diet supplemented with 4.8 percent BCAA (S2) (n=12). On the last day of the training protocol, half the animals in each group were sacrificed after one hour of swimming (1H), and the other half after a swimming exhaustion test (EX). Swimming time until exhaustion was increased by 37 percent in group S1 and reduced by 43 percent in group S2 compared to group C. Results indicate that the S1 diet had a beneficial effect on performance by sparing glycogen in the soleus muscle and by inducing a lower concentration of plasma ammonia, whereas the S2 diet had a negative effect on performance due to hyperammonemia. The hypothalamic concentration of serotonin was not significantly different between the 1H and EX conditions. In conclusion, chronic BCAA supplementation led to increased performance in rats subjected to a swimming test to exhaustion. However, this is a dose-dependent effect, since chronic ingestion of elevated quantities of BCAA led to a reduction in performance [12426].

Previous studies have evaluated the effectiveness of branched-chain amino acid (BCAA) supplementation for preventing delayed onset muscle soreness (DOMS) and muscle damage induced by eccentric exercise, their findings have been inconclusive. Since taurine has anti-inflammatory and anti-oxidative effects, the present study investigated the combined effect of BCAA and taurine on DOMS and muscle damage. Thirty-six untrained male subjects (23 ± 4 years) were assigned to four groups (placebo + placebo [placebo], BCAA + placebo, placebo + taurine, and BCAA + taurine [combined]) and given a combination of 3.2 g BCAA (or placebo) and 2.0 g taurine (or placebo), three times a day, for two weeks prior to and three days after eccentric elbow flexor exercises. DOMS and muscle damage in the biceps brachii were subjectively and objectively evaluated using the visual analogue scale (VAS), upper arm circumference (CIR), and blood parameters (creatine kinase, lactate dehydrogenase, LDH, aldolase, and 8-hydroxydeoxyguanosine, 8-OHdG). In the combined group, VAS and 8-OHdG two days after exercise, CIR two and three days after exercise and LDH from one to three days after exercise were significantly lower than the placebo group. The area under the curve from before exercise to four days later for CIR, LDH, and aldolase was also significantly lower in the combined group than in the placebo group. It was concluded that a combination of 3.2 g BCAA and 2.0 g taurine, three times a day, for two weeks prior to and three days after exercise may be a useful nutritional strategy for attenuating exercise-induced DOMS and muscle damage [13650].

**BCAA plus arginine**
One study aimed at evaluating the effect of a single oral intake of branched-chain amino acids (BCAA) with Arg on skeletal muscle protein metabolism during moderate exercise in young individuals. Eight healthy volunteers (4 males and 4 females) were studied in a randomized double-blind placebo-controlled cross-over trial. The subjects performed 3 bouts of 20-min cycling exercise (5-min break between each bout) at 126 ± 13 W corresponding to 50 percent of the maximal work intensity. A single oral supplement of either a BCAA drink containing 2 g of BCAA and 0.5 g of Arg or an isocaloric placebo drink was given at 10 min of the 1st exercise bout. Both arterial and venous blood samples were simultaneously taken from the radial artery and the femoral vein, respectively. Blood flow in the femoral artery was determined using the ultrasound Doppler technique. The blood sampling and blood flow measurements were performed at rest, every 10 min during each exercise bout. Net balance of BCAA and Phe across the leg muscles were measured by the arteriovenous difference method. The BCAA ingestion resulted in increases in both the plasma BCAA concentration and BCAA uptake into the working leg. The Phe release from the leg during exercise significantly increased as compared to the basal level in the placebo trial. In the BCAA trial, the cumulative Phe release from the leg during the 3rd exercise bout was significantly lower than that in the placebo trial. These results suggest that endurance exercise at moderate intensity enhances proteolysis in working muscles, and a single oral intake of 2 g of BCAA with Arg at onset of exercise effectively suppresses exercise-induced skeletal muscle proteolysis [07330].

Neutral amino acids

One study investigated the effects of high-dose large neutral amino acid (LNAA) supplementation on attenuating fatigue-induced decrements in exercise and motor skill performance in Australian Rules Football players. Fifteen subelite ARF players participated in 3 testing sessions separated by 7 days. Players completed an initial control trial involving a reactive motor skills test (RMST) and a reactive agility test (RAT) carried out before and after fatiguing exercise. In the subsequent experimental trials, players ingested a serotonin-depleting or protein control (PC) LNAA mixture 3 h before testing, allocated in a double-blind randomized cross-over design. Blood samples were taken at presupplementation and pre- and postexercise for analysis of plasma amino acid, insulin, and metabolite concentrations. The effect of the LNAA was established as the difference in the change in the mean RMST and RAT test scores among the depleting, PC, and baseline (BL) trials. Mean overall repetition time of the RAT was moderately improved after ingestion of the serotonin-depleting mixture compared with the BL trial. Serotonin-depleting and PC supplements had a divergent effect on mean repetition time after fatiguing exercise in RMST: depleting serotonin elicited a small improvement in motor skill performance in contrast to a small decrement after ingestion of the PC mixture, when compared to the BL. High-dose serotonin-“depleting” LNAA supplementation given 3 h prior to intermittent high-intensity exercise improved reactive motor skill and agility performance in football players [11528].

Effect on performance

The purpose of one investigation was to examine the effects of amino acid supplementation on muscular performance and resting hormone concentrations during resistance training overreaching. Seventeen resistance-trained men were randomly assigned to either an amino acid (AA) or a placebo (P) group and underwent 4 weeks of total-body resistance training designed to induce a state of overreaching. The protocol consisted of two 2-week phases (phase 1, 3 sets of 8 exercises performed for 8-12 repetitions; phase 2, 5 sets of 5 exercises
performed for 3-5 repetitions). Muscle strength and resting blood samples were determined before (T1) and at the end of each training week (T2-T5). One-repetition maximum squat and bench press decreased at T2 in the P group but not in the AA group; both groups showed similar increases in strength at T3 to T5. Significant elevations in serum creatine kinase and uric acid were observed at T2 in the P group; the elevation in creatine kinase correlated highly to reductions in 1-repetition maximum squat. Significant elevations in serum sex hormone-binding globulin were observed during overreaching in the P group from T2 to T5; this response was abolished in the AA group. Significant reductions in total testosterone were observed in the P group at T4 compared with T1, and total testosterone values were higher for the AA group than for the P group from T2 to T4. Serum 22-kd growth hormone concentrations were elevated at T2 to T5 in P group only. No differences were observed in resting cortisol and insulinlike growth factor 1. Hemoglobin concentrations were significantly reduced at T2 to T5 in the P group. These results indicate that the initial impact of high-volume resistance training is muscle strength reduction and hormonal/biochemical alterations. It appears that amino acid supplementation is effective for attenuating muscle strength loss during initial high-volume stress, possibly by reducing muscle damage by maintaining an anabolic environment [06265].

One study examined 10 weeks of resistance training and the ingestion of supplemental protein and amino acids on muscle performance and markers of muscle anabolism. Nineteen untrained males were randomly assigned to supplement groups containing either 20 g protein (14 g whey and casein protein, 6 g free amino acids) or 20 g dextrose placebo ingested 1 h before and after exercise for a total of 40 g/d. Participants exercised 4 times/week using 3 sets of 6-8 repetitions at 85-90 percent of the one repetition maximum. Data were analyzed with two-way ANOVA. The protein supplement resulted in greater increases in total body mass, fat-free mass, thigh mass, muscle strength, serum IGF-1, IGF-1 mRNA, MHC I and IIa expression, and myofibrillar protein. Ten weeks of resistance training with 20 g protein and amino acids ingested 1 h before and after exercise is more effective than carbohydrate placebo in up-regulating markers of muscle protein synthesis and anabolism along with subsequent improvements in muscle performance [06266].

Effects on muscle soreness

One study investigated the effect of a supplement containing 9 essential and 3 non-essential amino acids on muscle soreness and damage by comparing two endurance exercise bouts of the elbow flexors with amino acid or placebo supplementation in a double blind crossover design. The supplement was ingested 30 min before (10 h post-fasting) and immediately after exercise (Experiment 1), or 30 min before (2-3 h after breakfast), immediately post, and 8 more occasions over 4-day post-exercise (Experiment 2). Changes in muscle soreness and indicators of muscle damage for 4 days following exercise were compared between supplement conditions using two-way ANOVA. No significant differences between conditions were evident for Experiment 1; however, plasma creatine kinase, aldolase, myoglobin, and muscle soreness were significantly lower for the amino acid versus placebo condition in Experiment 2. These results suggest that amino acid supplementation attenuates DOMS and muscle damage when ingested in recovery days [06267].

Arginine

Arginine is a conditionally essential amino acid (C6H14N4O2). It is found in a wide variety of protein-rich foods, including both animal and plant sources. Arginine is an amino acid that serves functions of relevance to athletes. It is not only required for protein synthesis but also
plays a role in regulating protein synthesis. In addition, arginine is a precursor for the production of the messenger molecule nitric oxide, an important vasodilator and also for creatine. Arginine can remove ammonia from the blood, which may be important in recovery from hard training. Finally, the ingestion of arginine can stimulate the secretion of growth hormone and the recovery of muscles after exercise. Supplementation with arginine could be expected to enhance the response to training but may be particularly important to aid recovery from severe training sessions. Under normal conditions blood flow during aerobic exercise is sufficient and arginine supplementation has no beneficial effect. However, blood flow through tendon connective tissue is normally poor and may not provide nutrients sufficiently rapidly for cells to repair stressed or damaged tendons during training. Arginine supplementation increases blood flow due to the provision of nitric oxide. Recovery is dependent upon the activity of the tendon cells, which must be provided with oxygen and nutrients. The ability of arginine to stimulate creatine synthesis and growth hormone secretion could enhance muscle gain from resistance training. Studies have shown varying results, perhaps because the dose of ingested arginine is often insufficient. Effects of arginine supplementation on strength gains during training may be related to the naturally occurring level of arginine. Beneficial effects of arginine supplementation on muscle strength may be minimal in young, healthy men who are already eating plenty of protein. If further research is undertaken, it might be prudent to focus on groups who wish to improve muscle strength without increasing the amount of muscle and therefore body weight (e.g. lightweight rowers, boxers, endurance runners) [09135].

There has been substantial examination of the effect of infusion and ingestion of L-arginine at rest. It has been clearly demonstrated that L-arginine administration improves endothelial function in various disease states. In addition, L-arginine infusion at rest increases plasma insulin, growth hormone, glucagon, catecholamines and prolactin. Such hormonal changes affect metabolism. There has, however, been very little examination of the effect of increases in L-arginine availability during exercise. This is important to study as there is preliminary evidence that L-arginine infusion, probably via increases in nitric oxide (NO), alters skeletal-muscle metabolism during exercise. There is a need for further research, especially to understand the mechanisms of how L-arginine affects exercise metabolism and also to determine whether the hormonal responses that occur in response to L-arginine at rest are also present to some extent during exercise. This line of research may have important therapeutic implications as there are indications that L-arginine augments the effects of exercise training on insulin sensitivity and capillary growth in muscles [07335].

The purpose of one study was to examine the effects of daily oral administration of arginine-based supplements for 4 weeks on the physical working capacity at the fatigue threshold (PWCFT). The PWCFT test is an electromyographic (EMG) procedure for estimating the highest power output that can be maintained without neuromuscular evidence of fatigue. The study used a double-blind, placebo-controlled design. Fifty college-aged men were randomized into 1 of 3 groups: placebo (n=19); 1.5 g arginine (n=14); or 3.0 g arginine (n=17). The placebo was microcrystalline cellulose. The 1.5-g arginine group ingested 1.5 g of arginine and 300 mg of grape seed extract, whereas the 3.0 g arginine group ingested 3.0 g of arginine and 300 mg of grape seed extract. All subjects performed an incremental test to exhaustion on a cycle ergometer to determine their PWCFT before supplementation (PRE) and after 4 weeks of supplementation (POST). Surface EMG signals were recorded from the vastus lateralis using a bipolar electrode arrangement during the incremental tests for the determination of the PRE and POST supplementation PWCFT values. There were significant mean increases (PRE to POST) in PWCFT for the 1.5 g (22 %) and 3.0 g (19 %) supplement groups, but no change for the placebo group (-2 %). These findings supported the use of arginine-based supplements, at the dosages examined in the present investigation, as an ergogenic aid for untrained individuals [10237].
Increasing literature has studied the effects of dietary nitrates and moreover, L-arginine supplementation on tolerance to exercise and O₂ consumption during exercise. However, few studies have investigated the effects of L-arginine on performance measures such as a time trial. It was hypothesised that an acute 3-day L-arginine supplementation would elicit a significant improvement in performance and reduce oxygen consumption during a 20 km time trial. 6 healthy male competitive cyclists (23 ± 5 years) participated in a double-blind crossover study, and consumed either one 500 m placebo (PLA) or L-arginine (ARG) beverage, containing 6 g of L-arginine, over a 2 week testing period. Following a 3-day supplementation, participants completed a ramped incremental test to exhaustion, followed by an hours rest and subsequently a 20 km time trial. Time trial completion time was significantly reduced by 34 s, O₂ consumption during the time trial was also significantly reduced. Furthermore, both systolic and diastolic blood pressure were greatly reduced. However, no differences were seen in participants' VO₂max during the ramped incremental test to exhaustion although Wₚeak was higher during the same test. In conclusion, acute 3-day L-arginine supplementation at a dose of 6 g day⁻¹ increases 20 km time trial performance and reduces O₂ consumption during time trial performance, in addition to reducing systolic and diastolic blood pressure. However, L-arginine appears to have no effect upon VO₂max [11529].

L-arginine may enhance endurance performance mediated by two primary mechanisms including enhanced secretion of endogenous growth hormone (GH) and as a precursor of nitric oxide (NO); however, research in trained participants has been equivocal. The purpose of one study was to investigate the effect of acute L-arginine ingestion on the hormonal and metabolic response during submaximal exercise in trained cyclists. Fifteen aerobically trained men (age: 28 ± 5 years; body mass: 77.4 ± 9.5 kg; height: 180.9 ± 7.9 cm; VO₂max: 59.6 ± 5.9 ml/kg/min) participated in a randomized, double-blind, crossover study. Subjects consumed L-arginine (ARG; 0. 075 g/kg body mass) or a placebo (PLA) before performing an acute bout of submaximal exercise (60 min at 80 % of power output achieved at ventilatory threshold). The ARG condition significantly increased plasma L-arginine concentrations (about 146 %), while no change was detected in the PLA condition. There were no differences between conditions for GH, nonesterified fatty acids (NEFA), lactate, glucose, VO₂, VCO₂, RER, CHO oxidation, and NOx. There was reduced fat oxidation at the start of exercise (ARG 0.36 ± 0.25 vs PLA 0.42 ± 0.23 g/min) and an elevated plasma glycerol concentrations at the 45-min time point (ARG 340 vs PLA: 289 micromol/L) after L-arginine consumption. In conclusion, the acute ingestion of L-arginine did not alter any hormonal, metabolic, or cardio-respiratory responses during submaximal exercise except for a small but significant increase in glycerol at the 45-min time point and a reduction in fat oxidation at the start of exercise [13655].

Combined with ornithine

A placebo-controlled double-blind study was designed to investigate the effect of arginine and ornithine (Arg and Orn) supplementation during 3-week heavy-resistance training on serum growth hormone/insulin-like growth factor-1/insulin-like growth factor-binding protein 3 (GH/IGF-1/IGFBP-3), testosterone, cortisol, and insulin levels in experienced strength-trained athletes. The subjects were randomly divided between a placebo group (n=8) and the L-Arg/L-Orn-supplemented group (n=9), and performed pre and posttraining standard exercise tests with the same absolute load, which consisted of the same exercise schedule as that applied in the training process. Fasting blood samples were obtained at rest, 2 minutes after the cessation of the strength exercise protocol, and after 1 hour of recovery. The resting concentrations of the investigated hormones and IGFBP-3 did not differ significantly between the study groups. In response to exercise test, all the hormones were significantly elevated at

1778
both time points. Significant increases were observed in both GH and IGF-1 serum levels after arg and orn supplementation at both time points, whereas a significant decrease was seen in IGFBP-3 protein during the recovery period [10238].

**Combined with citrulline**

Dietary L-citrulline malate supplements may increase levels of nitric oxide (NO) metabolites, although this response has not been related to an improvement in athletic performance. NO plays an important role in many functions in the body regulating vasodilatation, blood flow, mitochondrial respiration and platelet function. L-Arginine is the main precursor of NO via nitric oxide synthase (NOS) activity. Additionally, L-citrulline has been indicated to be a second NO donor in the NOS-dependent pathway, since it can be converted to L-arginine. The importance of L-citrulline as an ergogenic support derives from the fact that L-citrulline is not subject to pre-systemic elimination and, consequently, could be a more efficient way to elevate extracellular levels of L-arginine by itself. L-Citrulline malate can develop beneficial effects on the elimination of NH₃ in the course of recovery from exhaustive muscular exercise and also as an effective precursor of L-arginine and creatine. Dietary supplementation with L-citrulline alone does not improve exercise performance. The ergogenic response of L-citrulline or L-arginine supplements depends on the training status of the subjects. Studies involving untrained or moderately healthy subjects showed that NO donors could improve tolerance to aerobic and anaerobic exercise. However, when highly-trained subjects were supplemented, no positive effect on performance was indicated [12429].

**Leucine**

Leucine is a key amino acid involved in the regulation of skeletal muscle protein synthesis. It was assessed the effect of the supplementation of a lower-protein mixed macronutrient beverage with varying doses of leucine or a mixture of branched chain amino acids (BCAAs) on myofibrillar protein synthesis (MPS) at rest and after exercise. In a parallel group design, 40 men (21 ± 1 years) completed unilateral knee-extensor resistance exercise before the ingestion of 25 g whey protein (W25) (3.0 g leucine), 6.25 g whey protein (W6) (0.75g leucine), 6.25 g whey protein supplemented with leucine to 3.0 g total leucine (W6+Low-Leu), 6.25 g whey protein supplemented with leucine to 5.0 g total leucine (W6+High-Leu), or 6.25 g whey protein supplemented with leucine, isoleucine, and valine to 5.0 g total leucine. A primed continuous infusion of L-13C6-phenylalanine with serial muscle biopsies was used to measure MPS under baseline fasted and postprandial conditions in both a rested (response to feeding) and exercised (response to combined feeding and resistance exercise) leg. The area under the blood leucine curve was greatest for the W6+High-Leu group compared with the W6 and W6+Low-Leu groups. In the postprandial period, rates of MPS were increased above baseline over 0-1.5 h in all treatments. Over 1.5-4.5 h, MPS remained increased above baseline after all treatments but was greatest after W25 (267 %) and W6+High-Leu (220 %) treatments. It was concluded that a low-protein (6.25 g) mixed macronutrient beverage can be as effective as a high-protein dose (25 g) at stimulating increased MPS rates when supplemented with a high (5.0 g total leucine) amount of leucine. These results have important implications for formulations of protein beverages designed to enhance muscle anabolism [13651].

The aim of one study was to evaluate the effects of the mixture of branched-chain amino acids (BCAAs) supplementation compared with leucine administered orally on muscle biochemical parameters of trained rats submitted to an exercise-induced protocol of glycogen depletion. After 6 weeks of swimming exercise, 8 week-old (250 g, adult) male Wistar rats
were randomly divided into three experimental groups (n=8 per group): the mixture of BCAAs (BCAAs), leucine (LEU), and placebo (PLA). All groups were submitted to swimming exercise for 6 wk and supplemented with either the mixture of BCAAs, leucine, or placebo during the last week of training. At week 7 of the protocol, the rats were submitted to an intermittent, progressive swimming test until exhaustion and sacrificed. Muscle gastrocnemius and liver were depicted to determine total glycogen, tricarboxylic acid cycle (TCA) intermediates, and enzymatic activities. Statistical evaluation was performed by one-way analysis of variance with Tukey post hoc test. Both muscle and liver glycogen degradation ratio were significantly higher in the mixture of BCAAs group compared to the PLA group and the LEU group presented decreased liver glycogen degradation ratio compared with the mixture of BCAAs group. Both muscle and liver glycogen content were significantly spared in the mixture of BCAAs and LEU groups compared to the PLA group. A performance test demonstrated that LEU supplementation enhanced resistance to exhaustion compared to the mixture of BCAAs, however, no difference was found when LEU supplementation was compared to PLA. Muscle citrate content was significantly higher in the mixture of BCAAs group compared with the PLA group. Muscle malate content was significantly elevated in the mixture of BCAAs group compared with both the PLA and LEU groups. BCAT activity was significantly reduced in the mixture of BCAAs supplementation group compared with the LEU group. It was concluded that leucine supplementation improved performance compared with the mixture of BCAAs supplementation, sparing muscle glycogen stores despite the augmentation of some TCA intermediate concentrations on the left side of the TCA cycle [13652].

Prolonged inactivity induces muscle loss due to an activation of proteolysis and decreased protein synthesis; the latter is also involved in the recovery of muscle mass. The aim of the present work was to explore the evolution of muscle mass and protein metabolism during immobilization and recovery and assess the effect of a nutritional strategy for counteracting muscle loss and facilitating recovery. Adult rats (6-8 months) were subjected to unilateral hindlimb casting for 8 days (I0-I8) and then permitted to recover for 10 to 40 days (R10-R40). They were fed a Control or Experimental diet supplemented with antioxidants/polyphenols (AOX) (I0 to I8), AOX and leucine (AOX + LEU) (I8 to R15) and LEU alone (R15 to R40). Muscle mass, absolute protein synthesis rate and proteasome activities were measured in gastrocnemius muscle in casted and non-casted legs in post prandial (PP) and post absorptive (PA) states at each time point. Immobilized gastrocnemius protein content was similarly reduced (-37 %) in both diets compared to the non-casted leg. Muscle mass recovery was accelerated by the AOX and LEU supplementation (+6 % AOX+LEU vs Control, at R40) due to a higher protein synthesis both in PA and PP states (+23 % and 31 % respectively, Experimental vs Control diets, at R40) without difference in trypsin- and chymotrypsin-like activities between diets. Thus, this nutritional supplementation accelerated the recovery of muscle mass via a stimulation of protein synthesis throughout the entire day (in the PP and PA states) and could be a promising strategy to be tested during recovery from bed rest in humans [13653].

Whey protein and leucine ingestion following exercise increases muscle protein synthesis and could influence neutrophil function during recovery from prolonged intense exercise. We examined the effects of whey protein and leucine ingestion post-exercise on neutrophil function and immunomodulators during a period of intense cycling. In a randomized double-blind crossover, 12 male cyclists ingested protein/leucine/carbohydrate/fat (LEUPRO 20/7.5/89/22 g/h, respectively) or isocaloric carbohydrate/fat control (CON 119/22 g/h) beverages for 1-3 h post-exercise during 6 days of high-intensity training. Blood was taken pre- and post-exercise on days 1, 2, 4 and 6 for phorbol myristate acetate (PMA)-stimulated neutrophil superoxide (O_2^-) production, immune cell counts, amino acid and lipid metabolism via metabolomics, hormones (cortisol, testosterone) and cytokines (interleukin-6, interleukin-
During recovery on day 1, LEUPRO ingestion increased mean concentrations of plasma amino acids (glycine, arginine, glutamine, leucine) and myristic acid metabolites (acylcarnitines C14, myristoylcarnitine; and C14:1-OH, hydroxymyristoylcarnitine) with neutrophil priming capacity, and reduced neutrophil O$_2^-$ production (15-17 mmol O$_2^-$/cell ± 90 % confidence limits 20 mmol O$_2^-$/cell). On day 2, LEUPRO increased pre-exercise plasma volume (6.6 ± 3.8 %) but haematological effects were trivial. LEUPRO supplementation did not substantially alter neutrophil elastase, testosterone, or cytokine concentrations. By day 6, however, LEUPRO reduced pre-exercise cortisol 21 percent (±15 %) and acylcarnitine C16 (palmitoylcarnitine) during exercise, and increased post-exercise neutrophil O$_2^-$ (33 ± 20 mmol O$_2^-$/cell) relative to control. Altered plasma amino acid and acylcarnitine concentrations with protein-leucine feeding might partly explain the acute post-exercise reduction in neutrophil function and increased exercise-stimulated neutrophil oxidative burst on day 6, which could impact neutrophil-dependent processes during recovery from intense training [13654].

One study aimed to determine the effect of postexercise protein-leucine coingestion with CHO-lipid on subsequent high-intensity endurance performance and to investigate candidate mechanisms using stable isotope methods and metabolomics. In the double-blind, randomized, crossover study, 12 male cyclists ingested a leucine/protein/CHO/fat supplement (LEUPRO 7.5/20/89/22 g/h), respectively) or isocaloric CHO/fat control (119/22 g/h) 1-3 h after exercise during a 6-d training block (intense intervals, recovery, repeated-sprint performance rides). Daily protein intake was clamped at 1.9 g/kg/d (LEUPRO) and 1.5 g/kg/d. Stable isotope infusions (1-$^{13}$C-leucine and 6,6-$^{2}$H$_2$-glucose), mass spectrometry-based metabolomics, and nitrogen balance methods were used to determine the effects of LEUPRO on whole-body branched-chain amino acid (BCAA) and glucose metabolism and protein turnover. After exercise, LEUPRO increased BCAA levels in plasma (2.6-fold) and urine (2.8-fold) and increased products of BCAA metabolism plasma acylcarnitine C5 (3.0-fold) and urinary leucine (3.6-fold) and beta-aminoisobutyrate (3.4-fold), indicating that ingesting about 10 g leucine per hour during recovery exceeds the capacity to metabolize BCAA. Furthermore, LEUPRO increased leucine oxidation (5.6-fold) and nonoxidative disposal (4.8-fold) and left leucine balance positive relative to control. With the exception of day 1 subsequent (days 2-5) nitrogen balance was positive for both conditions. Compared with control feeding, LEUPRO lowered the serum creatine kinase concentration by 21-25 percent but the effect on sprint power was trivial. Thus, postexercise protein-leucine supplementation saturates BCAA metabolism and attenuates tissue damage, but effects on subsequent intense endurance performance may be inconsequential under conditions of positive daily nitrogen balance [12428].

One study determined the effect of nutritional supplementation throughout endurance exercise on whole-body leucine kinetics (leucine rate of appearance [Ra], oxidation [Ox], and nonoxidative leucine disposal [NOLD]) during recovery. Five trained men underwent a 2-h run at 65% VO$_{2\text{max}}$, during which a carbohydrate (CHO), mixed protein-carbohydrate (milk), or placebo (PLA) drink was consumed. Leucine kinetics were assessed during recovery using a primed, continuous infusion of 1-$^{13}$C leucine. Leucine Ra and NOLD were lower for milk than for PLA, Ox was higher after milk-supplemented exercise than after CHO or PLA. Although consuming milk during the run affected whole-body leucine kinetics, the benefits of such a practice for athletes remain unclear. Additional studies are needed to determine whether protein supplementation during exercise can optimize protein utilization during recovery [07340].

Leucine has been suggested to have the potential to modulate muscle protein metabolism by increasing muscle protein synthesis. The objective of one study was to investigate the surplus value of the co-ingestion of free leucine with protein hydrolysate and carbohydrate
following physical activity in elderly men. Eight elderly men (mean age 73 ± 1 years) were randomly assigned to two cross-over treatments consuming either carbohydrate and protein hydrolysate (CHO+PRO) or carbohydrate, protein hydrolysate with additional leucine (CHO+PRO+leu) after performing 30 min of standardized physical activity. Primed, continuous infusions with L-(ring-\(^{13}\)C\(_6\))phenylalanine and L-(ring-\(^2\)H\(_2\))tyrosine were applied, and blood and muscle samples were collected to assess whole-body protein turnover as well as protein fractional synthetic rate in the vastus lateralis muscle over a 6 h period. Whole-body protein breakdown and synthesis rates were not different between treatments. Phenylalanine oxidation rates were significantly lower in the CHO+PRO+leu versus CHO+PRO treatment. As a result, whole-body protein balance was significantly greater in the CHO+PRO+leu compared to the CHO+PRO treatment. Mixed muscle fractional synthetic rate averaged 0.081 and 0.082 percent/h in the CHO+PRO+leu and CHO+PRO treatment, respectively. Thus, co-ingestion of leucine with carbohydrate and protein following physical activity does not further elevate muscle protein fractional synthetic rate in elderly men when ample protein is ingested [07341].

One study determined the effect of nutritional supplementation throughout endurance exercise on whole-body leucine kinetics (leucine rate of appearance [Ra], oxidation [Ox], and nonoxidative leucine disposal, NOLD, during recovery. Five trained men underwent a 2-h run at 65 percent VO\(_{2}\)max, during which a carbohydrate (CHO), mixed protein-carbohydrate (milk), or placebo (PLA) drink was consumed. Leucine kinetics were assessed during recovery using a primed, continuous infusion of 1-\(^{13}\)C leucine. Leucine Ra and NOLD were lower for milk than for PLA. Ox was higher after milk-supplemented exercise than after CHO or PLA. Although consuming milk during the run affected whole-body leucine kinetics, the benefits of such a practice for athletes remain unclear. Additional studies are needed to determine whether protein supplementation during exercise can optimize protein utilization during recovery [07342].

Essential amino acids (EAA) stimulate skeletal muscle protein synthesis (MPS) in humans. Leucine may have a greater stimulatory effect on MPS than other EAA and/or decrease muscle protein breakdown (MPB). To determine the effect of 2 different leucine concentrations on muscle protein turnover and associated signaling, young men (n=6) and women (n=8) ingested 10 g EAA in 1 of 2 groups: composition typical of high quality proteins (CTRL; 1.8 g leucine) or increased leucine concentration (LEU; 3.5 g leucine). Participants were studied for 180 min postingestion. Fractional synthetic rate and leg phenylalanine and leucine kinetics were assessed on muscle biopsies using stable isotopic techniques. Signaling was determined by immunoblotting. Arterial leucine concentration and delivery to the leg increased in both groups and was significantly higher in LEU than in CTRL; however, transport into the muscle and intracellular availability did not differ between groups. MPS increased similarly in both groups 60 min postingestion. MPB decreased at 60 min only in LEU, but net muscle protein balance improved similarly. Components of mammalian target of rapamycin (mTOR) signaling were improved in LEU, but no changes were observed in ubiquitin-proteasome system signaling. Changes in light chain 3 and mTOR association with Unc-51-like kinase 1 indicate autophagy decreased more in LEU. We conclude that in 10 g of EAA, the leucine content typical of high quality proteins (1.8 g) is sufficient to induce a maximal skeletal muscle protein anabolic response in young adults, but leucine may play a role in autophagy regulation [10497].

To investigate the effects of daily oral L-leucine ingestion on strength, bone mineral-free lean tissue mass (LTM) and fat mass (FM) of free living humans during a 12-wk resistance-training program 26 initially untrained men (n=13 per group) ingested either 4 g/d of L-leucine (leucine group: age 29 ± 8 years, body mass index 25 ± 4 kg/m\(^2\)) or a corresponding amount of lactose (placebo group: age 28 ± 7 years, body mass index 25 ± 4 kg/m\(^2\)). All participants
trained under supervision twice per week following a prescribed resistance training program using eight standard exercise machines. Testing took place at baseline and at the end of the supplementation period. Strength on each exercise was assessed by five repetition maximum (5-RM), and body composition was assessed by dual energy X-ray absorptiometry (DXA). The leucine group demonstrated significantly higher gains in total 5-RM strength (sum of 5-RM in eight exercises) and 5-RM strength in five out of the eight exercises. Significant differences did not exist between groups in either total percentage LTM gains or total percentage FM losses. These results suggest that 4 g/d of L-leucine supplementation may be used as a nutritional supplement to enhance strength performance during a 12-week resistance training program of initially untrained male participants [11277].

Growing evidence supports the conclusion that consumption of protein in close temporal proximity to the performance of resistance exercise promotes greater muscular hypertrophy. It can also be stated with good certainty that merely consuming energy, as carbohydrate for example, is also not sufficient to maximise muscle protein synthesis leading to anabolism and net new muscle protein accretion. Recent work also indicates that certain types of proteins, particular those that are rapidly digested and high in leucine content (i.e. whey protein), appear to be more efficient at stimulating muscle protein synthesis. Continued practice of consumption of these types or proteins after exercise should lead to greater hypertrophy. Reviews of numerous training studies indicate that studies in which milk proteins and principally whey protein show an advantage of these proteins over and above isoenergetic carbohydrate and soya protein in promoting hypertrophy. Thus, the combined evidence suggests a strategic advantage of practising early post-exercise consumption of whey protein or dairy-based protein to promote muscle protein synthesis, net muscle protein accretion and ultimately hypertrophy [11278].

Leucine is one of the three BCAAs and is an essential amino acid (EAA) that has to be provided in the diet. Besides serving as building blocks for protein synthesis, leucine can also regulate the rate of protein synthesis via a stimulatory effect on enzymes involved in the translation of specific mRNAs. Direct stimulation by leucine of the rate of protein synthesis in muscle tissue was first demonstrated in various preparations from experimental animals and, more recently, in the intact animal after oral administration. Infusion of leucine in human subjects was shown to improve the net protein balance and to increase phosphorylation/activation of the regulatory enzyme 70-kD ribosomal protein S6 kinase (p70S6K), indicating a stimulatory effect of leucine on protein synthesis also on human muscle after oral ingestion, although this remains to be confirmed. When leucine is ingested together with the other EAA as after resistance exercise, the rate of protein synthesis increases to a larger extent than without nutritional supply and a positive net protein balance is achieved during the period after exercise. However, adding extra leucine to a protein hydrolysate or an EAA mixture has no effect, or only minor additional effect, on the rate of protein synthesis in young subjects. On the other hand, recent data show that excluding leucine from the EAA mixture eliminates the stimulatory effect on protein synthesis and on phosphorylation of p70S6K. There is some evidence from animal studies that leucine can also inhibit muscle protein breakdown, however, this has not yet been confirmed in human muscle. Intake of leucine together with the other EAAs is recommended in connection with exercise. Available data indicate that the amount of leucine required to reach an optimal effect is 1.5-2.5 g in young individuals, which is the normal content in about 20 g of high-quality protein. In elderly individuals, the amount can be increased [11279].

The purpose of one study was to determine whether a practical leucine-protein, high-carbohydrate postexercise feeding regimen could improve recovery, as measured by subsequent cycling performance and mechanistic markers, relative to control feeding. In a crossover, 10 male cyclists performed 2- to 2.5-h interval training bouts on 3 consecutive
evenings, ingesting either leucine-protein, high-carbohydrate nutrition (0.1/0.4/1.2/0.2 g/kg/h; leucine, protein, carbohydrate, fat, respectively) or isocaloric control (0.06/1.6/0.2 g/kg/h; protein, carbohydrate, fat, respectively) nutrition for 1.5 h postexercise. Throughout the experimental period diet was controlled, energy and macronutrient intake balanced, and protein intake clamped at 1.6 g/kg/day. The alternate supplement was provided the next morning, thereby isolating the postexercise nutrition effect. Following 39 h of recovery, cyclists performed a repeat-sprint performance test. Postexercise leucine-protein ingestion significantly improved mean sprint power by 2.5 percent and reduced perceived overall tiredness during the sprints by 13 percent, but perceptions of leg tiredness and soreness were unaffected. Before exercise, creatine-kinase concentration was lowered by 19 percent, but lactate dehydrogenase and pressure-pain threshold were unaltered. There was a small reduction in anger, but other moods were unchanged. Plasma leucine (3-fold) and essential amino acid (47 %) concentrations were elevated postexercise. Net nitrogen balance trended mildly negative in both conditions. The ingestion of a leucine-protein supplement along with other high-carbohydrate food following intense training on consecutive days enhances subsequent high-intensity endurance performance and may attenuate muscle membrane disruption in well-trained male cyclists [11280].

To determine the effect of post-exercise protein-leucine co-ingestion with carbohydrate-lipid on subsequent high-intensity endurance performance, and to investigate candidate mechanisms using stable isotope methods and metabolomics in a double-blind randomized crossover, 12 male cyclists ingested a leucine/protein/carbohydrate/fat supplement (LEUPRO, respectively 7.5/20/89/22 g/h) or isocaloric carbohydrate/fat control (119/22 g/h) 1-3 h post-exercise during a 6-day training block (intense intervals, recovery, repeated-sprint performance rides). Daily protein intake was clamped at 1.9 (LEUPRO) and 1.5 g/kg/d (control). Stable isotope infusions (1-C-leucine and 6,6-H2-glucose), mass-spectrometry based metabolomics, and nitrogen balance methodology were used to determine effects of LEUPRO on whole-body branch-chain amino acid (BCAA) and glucose metabolism, and protein turnover. Following exercise, LEUPRO increased BCAAs in plasma (2.6-fold) and urine (2.8-fold), and products of BCAA metabolism plasma acylcarnitine C5 (3.0-fold) and urinary leucine (3.6-fold) and beta-aminoisobutyrate (3.4-fold), indicating ingesting about 10 g leucine/h during recovery exceeds the capacity to metabolise BCAA. Furthermore, LEUPRO increased leucine oxidation (5.6-fold), non-oxidative disposal (4.8-fold), and left leucine balance positive, relative to control. With the exception of day-1 (LEUPRO 17 ± 20 mg N/kg; control 90 ± 44 mg N/kg), subsequent (day 2-5) nitrogen balance was positive for both conditions (LEUPRO 130 ± 110 mg N/kg; control 111 ± 86 mg N/kg). Compared to control feeding, LEUPRO lowered the serum creatine kinase concentration by 21-25 percent, but the impact on sprint power was trivial. It was concluded that post-exercise leucine-protein supplementation saturates BCAA metabolism and attenuates tissue damage, but effects on subsequent intense endurance performance may be inconsequential under conditions of positive daily nitrogen balance [11281].

Leucine is one of the three BCAAs and is an essential amino acid (EAA) that has to be provided in the diet. Besides serving as building blocks for protein synthesis, leucine can also regulate the rate of protein synthesis via a stimulatory effect on enzymes involved in the translation of specific mRNAs. Direct stimulation by leucine of the rate of protein synthesis in muscle tissue was first demonstrated in various preparations from experimental animals and, more recently, in the intact animal after oral administration. Infusion of leucine in human subjects was shown to improve the net protein balance and to increase phosphorylation/activation of the regulatory enzyme 70-kD ribosomal protein S6 kinase (p7OS6k), indicating a stimulatory effect of leucine on protein synthesis also on human muscle after oral ingestion, although this remains to be confirmed. When leucine is ingested together with the other EAAs after resistance exercise, the rate of protein synthesis increases to a larger extent than
without nutritional supply and a positive net protein balance is achieved during the period after exercise. However, adding extra leucine to a protein hydrolysate or an EAA mixture has no effect, or only minor additional effect, on the rate of protein synthesis in young subjects. On the other hand, recent data show that excluding leucine from the EAA mixture eliminates the stimulatory effect on protein synthesis and on phosphorylation of p70S6k. In elderly subjects, in whom the required amount of leucine to reach optimal stimulation on protein synthesis may be enhanced, leucine-enriched diet improves muscle protein synthesis acutely, whereas no effect on muscle mass is observed during long-term supplementation. There is some evidence from animal studies that leucine can also inhibit muscle protein breakdown, however, this has not yet been confirmed in human muscle. Intake of leucine together with the other EAA's is recommended in connection with exercise. Available data indicate that the amount of leucine required to reach an optimal effect is 1.5-2.5 g in young individuals, which is the normal content in about 20 g of high-quality protein. In elderly individuals, the amount can be increased [11414].

The effects of essential amino acid (EAA) supplementation during moderate steady state (ie, endurance) exercise on postexercise skeletal muscle metabolism are not well described, and the potential role of supplemental leucine on muscle protein synthesis (MPS) and associated molecular responses remains to be elucidated. One randomized crossover study examined whether EAA supplementation with 2 different concentrations of leucine affected post-steady state exercise MPS, whole-body protein turnover, and mammalian target of rapamycin 1 (mTORC1) intracellular signaling. Eight adults completed 2 separate bouts of cycle ergometry (60 min, 60 % VO_2 peak, peak oxygen uptake). Isonitrogenous (10 g EAA) drinks with different leucine contents (leucine-enriched (L)-EAA, 3.5 g leucine; EAA, 1.87 g leucine) were consumed during exercise. MPS and whole-body protein turnover were determined by using primed continuous infusions of (2H_5)phenylalanine and 1_13C-leucine. Multiplex and immunoblot analyses were used to quantify mTORC1 signaling. MPS was 33 percent greater after consumption of L-EAA than after consumption of EAA. Whole-body protein breakdown and synthesis were lower and oxidation was greater after consumption of L-EAA than after consumption of EAA. Regardless of dietary treatment, multiplex analysis indicated that Akt and mammalian target of rapamycin phosphorylation were increased 30 min after exercise. Immunoblot analysis indicated that phosphorylation of ribosomal protein S6 and extracellular-signal regulated protein kinase increased and phosphorylation of eukaryotic elongation factor 2 decreased after exercise but was not affected by dietary treatment. These findings suggest that increasing the concentration of leucine in an EAA supplement consumed during steady state exercise elicits a greater MPS response during recovery [11389].

Branched chain amino acids (BCAA), particularly leucine, have been suggested to be ergogenic for both endurance and strength/power performance. One study investigated the effects of dietary leucine supplementation on the exercise performance of outrigger canoeists. Thirteen (ten female, three male) competitive outrigger canoeists underwent testing before and after 6-week supplementation with either capsulated L-leucine (45 mg/kg/day; n=6) or placebo (cornflour; n=7). Testing included anthropometry, 10 s upper body power and work and a row to exhaustion at 70-75 percent maximal aerobic power where perceived exertion (RPE), heart rate (HR) and plasma BCAA and tryptophan concentrations were assessed. Leucine supplementation resulted in significant increases in plasma leucine and total BCAA concentrations. Upper body power and work significantly increased in both groups after supplementation but power was significantly greater after leucine supplementation compared to the placebo. Rowing time significantly increased and average RPE significantly decreased with leucine supplementation while these variables were unchanged with the placebo. Leucine supplementation had no effect on the plasma tryptophan to BCAA ratio, HR or anthropometric variables. Six weeks' dietary leucine supplementation significantly improved endurance performance and upper body power in
outrigger canoeists without significant change in the plasma ratio of tryptophan to BCAA [06276].

4-hydroxyisoleucine

The purpose of this study was to determine the effect of adding fenugreek extract (FG) to post-exercise carbohydrate feeding on glycogen resynthesis and subsequent exercise performance in normoglycemic male endurance athletes. A muscle biopsy sample was obtained from the vastus lateralis from subjects prior to exercise for 5 h at 50 percent of peak cycling power (VO$_{2peak}$). A second muscle biopsy sample was obtained immediately after exercise. Immediately after and 2 h after the second biopsy subjects ingested either an oral dose of dextrose (GLU) or GLU with FG containing 1.99 ± 0.20 mg/kg 4-hydroxyisoleucine (GLU + FG) in a randomized, cross-over, double blind design. At 4 h post-exercise a third biopsy was taken and subjects received a standardised meal along with FG or a placebo capsule. At 15 h post-exercise subjects underwent their final muscle biopsy before completing a simulated 40 km cycling time trial. There was no difference in muscle glycogen at any time between GLU and GLU + FG. Additionally, 40 km time trial performance was similar for average power output and for time to completion for the GLU and GLU + FG, respectively. Despite earlier data to the contrary, the present results do not support an effect of fenugreek supplementation on glycogen resynthesis, even though this may have been the result of differences in experimental protocol [07343].

L-tryptophan

Physical exercise is often terminated not due to muscle fatigue but because of inadequate neural drive in the serotonergic system. Modifications in activity levels of the serotonergic system, induced by variations in the availability of L-tryptophan (a serotonin precursor) may alter neural drive. It was examined the effect of L-tryptophan supplementation on physical performance by combining aerobic work with brief periods of supramaximal intensity that closely mimics the activity typical of team sports. Twenty healthy young sportsmen performed a submaximal exercise on a cycle ergometer, with a workload corresponding to 50 percent of their respective VO$_{2max}$ for 10 min, followed by a maximal intensity exercise for 30 s. This sequence was repeated three times and, after the fourth series, each participant continued to exercise at the highest speed that he could sustain for 20 min. This protocol was performed twice: once with and finally without supplementation of L-tryptophan, in random order and double-blind. Peak power output, average anaerobic power output, and power output during the last 20 min of the trial were higher on the trials performed with L-tryptophan supplementation than on those performed with placebo. The distance covered during the last 20 min of the trial was 11,959 ± 1,753 m on placebo and 12,526 ± 1,617 m on L-tryptophan, which was a significant difference. In conclusion, in some types of exercises, modification of the serotonergic system may improve the physical performance [10239].

Taurine

Taurine is a sulphur-containing beta-amino acid (2-aminoethanesulphonic acid) that is conditionally classified as an indispensable amino acid. It is the most abundant free amino acid in the heart, brain, leukocytes and skeletal muscle but is not incorporated into protein within skeletal muscle. It has been suggested to be involved in a wide range of cellular processes including regulation of cell volume, Ca$^{2+}$-dependent excitation-contraction processes, antioxidant defence from stress responses, modulation of nerve excitement.
potential, and several metabolic effects related to improved glucose tolerance, insulin sensitivity and substrate uptake, storage and oxidation in skeletal and cardiac muscle. Rodent studies have shown that taurine supplementation increases muscle taurine content and prolonged exercise causes a decline in skeletal muscle taurine content. In addition, changes in taurine concentrations have been correlated with muscle function: when muscle taurine was decreased, contractile ability declined and, when it was increased, muscle force production improved. Lastly, the knock-out of taurine transporters has been associated with low muscle taurine levels and severe impairment of skeletal muscle exercise capacity. However, none of these effects has been demonstrated in human subjects. Taurine is currently claimed to be a functional ingredient (1000-2000 mg taurine per serving) in several commercialised energy drinks, with many manufacturers claiming that taurine is ergogenic for many types of exercise. However, scientific evidence to support these claims does not exist, as most studies have examined the metabolic, cognitive and performance effects of taurine supplements in combination with many additional ingredients that have been shown to be ergogenic (eg, caffeine and carbohydrate) or have not utilised appropriate placebo control beverages. Therefore, a role for taurine alone to improve exercise performance and/or alter metabolism in humans has not been demonstrated. Recent studies have examined the plasma taurine kinetics following a single acute dose of taurine, as well as the chronic effects of 7 days of taurine supplementation on skeletal muscle taurine content and substrate metabolism during 2 h of submaximal cycling. Acute supplementation with about 1.7 g taurine caused a 13-fold increase in plasma taurine at 2 h and remained elevated for at least 4 h, but 7 days of taurine supplementation (5 g/day) did not increase the taurine content before exercise or alter skeletal muscle taurine content, or substrate utilisation during 2 h of submaximal exercise. The effects of an acute dose of taurine (1.7 g) given 1 h before a 90 min of submaximal cycle and subsequent endurance time-trial (TT) performance and whole-body metabolism in well-trained cyclists was also studied. Acute taurine ingestion had no effect on TT performance compared to the control trial. In a third trial, telling the subjects they were receiving taurine in their preexercise drink, when they did not (placebo), was also not ergogenic. Taurine also had no effect on the normal physiological and mental responses to exercise such as heart rate and rating of perceived exertion as compared with control and placebo trials. Acute taurine ingestion did produce a significant 16 percent increase in total whole-body fat oxidation during 90 min of submaximal exercise prior to the time trial, although this was not evident in the previous study. In conclusion, despite large increases in plasma taurine following the acute ingestion of a large dose of taurine, it does not enhance endurance performance in well-trained athletes and does not accumulate in skeletal muscles when consumed chronically (5 g/day for 7 days). These data suggest that supplemental taurine is not ergogenic in human subjects [12300].

One study examined the plasma taurine response to acute oral taurine supplementation and the effects of 7 days of taurin on muscle amino acid content and substrate metabolism during 2 h of cycling at approximately 60 percent peak oxygen consumption (VO2peak). There was no difference in muscle glycogen or other muscle metabolites between conditions, but there were notable interaction effects for muscle valine, isoleucine, leucine, cysteine, glutamate, alanine, and arginine amino acid content following exercise after taurin. These data indicate that acute taurin produces a 13-fold increase in plasma taurine concentration. Despite the ability to significantly elevate plasma taurine for extended periods throughout the day, 7 days of taurin does not alter skeletal muscle taurine content or carbohydrate and fat oxidation during exercise. However, taurin appears to have some impact on muscle amino acid response to exercise [08415].

Although the effect of taurine on the heart and liver is well studied, there has been no direct observation concerning the effect of taurine on spatial learning and memory at the behavior level. In one study, it was tested the effect of subacute taurine supplementation with

1787
evaluation by the Morris water maze method. Although swim distance to find the platform of taurine-supplemented rats was significantly longer than that of control rats due to increase of swimming velocity, escape latency and the efficacy of learning and memory was comparable in both groups. These results suggest that taurine supplemented orally does not affect the learning and memory function [09346].

Cystein and cystine

Cysteine is a non-essential amino acid and, together with glycine and glutamate, is an important precursor of the tripeptide glutathione. Glycine and glutamate are readily available within the body and it is thought that the limiting step in the synthesis of glutathione is the availability of cysteine. Glutathione is one of the key antioxidants within the body and is an essential component of immune function. Reid et al intravenously infused 150 mg/kg body weight of N-acetylcysteine (NAC) before electrical stimulation of the tibialis anterior to fatigue at either 10 or 40 Hz. NAC infusion increased force output during electrical stimulation at 10 Hz by 15 percent, but failed to affect performance at 40 Hz. More recent research has investigated the effect of cystine, a dipeptide of cysteine, supplemented in conjunction with theanine, on the immune response to intense exercise training. Initial results suggest that immune function improved with oral cystine/theanine supplementation during intense training periods. In conclusion, more work needs to be carried out in this area, particularly looking at oral cysteine ingestion and exercise performance and the effect of cystine supplementation on the immune response to training [10347].

The aim of one study was to ascertain the influence of cysteine derivatives on pro-antioxidant equilibrium and to compare the antioxidant effectiveness of N-acetylcysteine, alpha-lipoic acid, and taurine by using Loverro’s coefficient (pro-antioxidant ratio) in healthy men exposed to intensity-resistance exercise. Fifty-five men were randomly assigned to one of four groups: control (CON, placebo), N-acetylcysteine (NAC 1.8 g/day, 3 days), alpha-lipoic acid (LIP 1.2 g/day, 3 days), or taurine (TAU 3 g/day, 3 days). The erythrocyte superoxide dismutase (SOD), glutathione peroxidase (GPx), and catalase (CAT) activities, lipid peroxidation products (TBARS), and plasma protein thiol concentrations were evaluated. The P/A ratio was determined from the mean values of TBARS, SOD, GPx, and CAT. The applied exercise at maximal intensity induced the significant changes in pro-antioxidant equilibrium toward peroxidation, which was proved by a 25 percent increase in TBARS concentration in the CON group. The peroxidation was significantly diminished by NAC (-14 %) and LIP (-16 %), whereas TAU had no effect on the TBARS concentration. Cysteine derivatives administration prevented exercise-induced decline in SOD activity and increased in GPx activity during exercise. CAT activity changed only in the LIP group. The estimation of P/A ratio showed the lowest level of pro-antioxidant equilibrium after LIP administration. In the CON group, P/A ratio was directly correlated with the protein thiols level. These data confirm the antioxidant action of tested cysteine derivatives, particularly lipoic acid, and demonstrate the practical application of P/A ratio to evaluate the effectiveness of antioxidants in athletes [07344].

Cystine/theanine

Athletes become increasingly susceptible to infection with intense training that results in immune suppression. The immune state was investigated after administering cystine/theanine, which has been reported to have an immune reinforcement effect, to athletes before training involving a prolonged period of intense exercise. Fifteen long-distance runners were each allocated to the cystine/theanine or placebo group, and the test
food was ingested for 10 d prior to the start of training. Clinical examinations were performed before and after the training. The results indicate a significant increase in the high-sensitivity C-reactive protein (hs-CRP) and neutrophil count in the blood, as well as a decreasing tendency for lymphocytes in the placebo group, but not the cystine/theanine group. These observations suggest that the ingestion of cystine/theanine contributed to suppressing the change in inflammatory response, prevented a decrease in the immune function, and prevented infection and reduced symptoms when infected associated with continuous intense exercise [09347].

Glutathione and glutamate

Glutathione (gamma-glutamyl-cysteinyl-glycine; GSH) is the predominant low molecular weight thiol (0.5–10 mmol/L) in mammalian cells. Most GSH (85-90 %) is cytosolic, with the remainder located in organelles (including mitochondria, nuclear matrix and peroxisomes). This tripeptide is a key antioxidant within cells, critical to regulating the reactive oxygen species (ROS) concentration. Reduced glutathione may be used to remove damaging ROS such as H$_2$O$_2$ and convert it to harmless H$_2$O, generating oxidised glutathione (GSSG) via glutathione peroxidase. Disulphide formation and glutationylation are reversible forms of protein covalent modification dependent on glutathione and can provide mechanisms for regulation of metabolic, signalling and transcriptional processes, including skeletal muscle adaptation to exercise and training. The cellular redox state is crucial for molecular signalling, and glutathione is a key regulator/sensor for redox status; thus strategies aiming at increasing GSH synthesis should be beneficial to exercise performance. Exercise stimulates ROS and reactive nitrogen species (RNS) production, dependent on exercise type, duration and intensity, culminating in changes in skeletal muscle redox state. Excessive ROS and RNS production is associated with deleterious effects in many diseases including diabetes. Antioxidant supplementation strategies have been assessed for their ability to decrease ROS levels and the deleterious effects of oxidative/nitrosative damage. While excessive ROS and RNS can exert harmful effects within skeletal muscle during exercise, lower levels are crucial for adaptation of metabolic and signalling pathways in response to exercise. For example, redox changes are essential for the production and release of myokines such as interleukin 6 (IL-6), which, in part, optimises fuel provision for sustained activity. Although antioxidant supplementation may at first be considered as beneficial, the consequent reduction of ROS/RNS could have negative effects. Muscle redox state may be best improved by providing skeletal muscle cells with key natural precursors for GSH synthesis and allowing the cells to synthesise what they actually require. Exercise-induced free radical production in skeletal muscle is not detrimental to human health; thus endogenous antioxidants may be sufficient to protect against exercise-induced oxidative damage. The synthesis of GSH from glutamate, cysteine and glycine is catalysed sequentially by two key cytosolic enzymes, gamma-glutamylcysteine synthetase (GCS) and GSH synthetase. The availability of these amino acids is essential for GSH synthesis. Supplementation with cysteine precursors, such as N-acetylcysteine, increases glutathione levels. However, de novo GSH synthesis depends on glutamate, which is a constituent of the GSH molecule. It also acts as an amino acid donor in serine synthesis, which can subsequently be converted to glycine. GSH is a non-allosteric feedback inhibitor of GCS but competes with glutamate; thus high intracellular glutamate concentrations will enhance GSH synthesis. In conclusion, amino acid supplementation that increases intracellular glutamate and cysteine could improve muscle GSH synthesis. Future studies need to determine which amino acids can increase intracellular glutamate and GSH synthesis in skeletal muscle without the risk of blunting essential redox changes required for exercise adaptation. Potential amino acid candidates include branched chain amino acids (BCAA), arginine and glutamine [11283].
The major thiol-disulfide couple of reduced glutathione (GSH) and oxidized glutathione is a key regulator of major transcriptional pathways regulating aseptic inflammation and recovery of skeletal muscle after aseptic injury. Antioxidant supplementation may hamper exercise-induced cellular adaptations. The objective of one study was to examine how thiol-based antioxidant supplementation affects skeletal muscle's performance and redox-sensitive signaling during the inflammatory and repair phases associated with exercise-induced microtrauma. In a double-blind, crossover design, 10 men received placebo or N-acetylcysteine (NAC; 20 mg/kg/d) after muscle-damaging exercise (300 eccentric contractions). In each trial, muscle performance was measured at baseline, after exercise, 2 h after exercise, and daily for 8 consecutive days. Muscle biopsy samples from vastus lateralis and blood samples were collected before exercise and 2 h, 2 d, and 8 d after exercise. NAC attenuated the elevation of inflammatory markers of muscle damage (creatine kinase activity, C-reactive protein, proinflammatory cytokines), nuclear factor κB phosphorylation, and the decrease in strength during the first 2 d of recovery. NAC also blunted the increase in phosphorylation of protein kinase B, mammalian target of rapamycin, p70 ribosomal S6 kinase, ribosomal protein S6, and mitogen activated protein kinase p38 at 2 and 8 d after exercise. NAC also abolished the increase in myogenic determination factor and reduced tumor necrosis factor-α 8 d after exercise. Performance was completely recovered only in the placebo group. It was concluded that although thiol-based antioxidant supplementation enhances GSH availability in skeletal muscle, it disrupts the skeletal muscle inflammatory response and repair capability, potentially because of a blunted activation of redox-sensitive signaling pathways [13733].

Glutamine

Glutamine is a popular dietary supplement consumed for purported ergogenic benefits of increased strength, quicker recovery, decreased frequency of respiratory infections, and prevention of overtraining. From a biochemical standpoint, glutamine does play a physiologic role in each of these areas, but it remains only one of a host of factors involved. There is demonstrated a lack of evidence for definitive positive ergogenic benefits as a result of glutamine supplementation [08416].

Blood ammonia concentration increases during endurance exercise and has been proposed as a cause for both peripheral and central fatigue. It was examined the impact of glutamine and/or carbohydrate supplementation on ammonemia in high-level runners. Fifteen men in pre-competitive training ran 120 min (approximately 34 km) outdoors on 4 occasions. On the first day, the 15 athletes ran without the use of supplements and blood samples were taken every 30 min. After that, each day for 4 d before the next 3 exercise trials, it was supplemented the athletes' normal diets in bolus with carbohydrate (1 g/kg per day), glutamine (70 mg/kg per day) or a combination of both in a double-blind study. Blood ammonia level was determined before the run and every 30 min during the run. During the control trial ammonia increased progressively to approximately 70 percent above rest concentration. Following supplementation, independent of treatment, ammonia was not different for the first 60 min, but for the second hour it was lower than in the control. Supplementation in high-level, endurance athletes reduced the accumulation of blood ammonia during prolonged, strenuous exercise in a field situation [07331].

High-intensity and prolonged exercise significantly enhances the levels of plasma ammonia, a metabolite with toxic effects on the central nervous system. The main purpose of one study
was to evaluate the metabolic response of athletes to glutamine (Gln) and alanine (Ala) supplementation, since these amino acids have a significant influence on both anaplerosis and gluconeogenesis. Professional football players were assigned to groups receiving either Gln or Ala supplementation (100 mg/kg body weight); this supplementation was either short-term or long-term and was given immediately before exercise. The players were evaluated using two exercise protocols, one with intervals (n=18) and the other with continuous intensity (n=12). Both types of exercises increased ammonia, urate, urea and creatinine in blood. Chronic Gln supplementation partially protected against hyperammonemia after a football match (intermittent exercise: Gln -140 vs Ala -240 %) and after continuous exercise at 80 percent of the maximum heart rate (Gln -481 % vs placebo -778 %). Urate increased by 10-20 percent in all groups, independently of supplementation. Glutamine once a day supplementation induced a greater elevation in urate as compared to alanine at the end of the game; however, long-term supplementation provoked a lesser increment in urate. Exercise induced similar increases in creatinine as compared to their respective controls in either acute or chronic glutamine administration. Taken together, the results suggest that chronically supplemented Gln protects against exercise-induced hyperammonemia depending on exercise intensity and supplementation duration [07332].

Glutamine is a popular dietary supplement consumed for purported ergogenic benefits of increased strength, quicker recovery, decreased frequency of respiratory infections, and prevention of overtraining. From a biochemical standpoint, glutamine does play a physiologic role in each of these areas, but it remains only one of a host of factors involved. One review examines the effects of glutamine on exercise and demonstrates a lack of evidence for definitive positive ergogenic benefits as a result of glutamine supplementation [07333].

The distinction between positive and negative training adaptation is an important prerequisite in the identification of any marker for monitoring training in athletes. To investigate the glutamine responses to progressive endurance training, twenty healthy males were randomly assigned to a training group or a non-exercising control group. The training group performed a progressive (3 to 6 x 90 minute sessions per week at 70 % VO2max) six-week endurance training programme on a cycle ergometer, while the control group did not participate in any exercise during this period. Performance assessments VO2max and time to exhaustion) and resting blood samples (for hemoglobin concentration, hematocrit, cortisol, ferritin, creatine kinase, glutamine, uric acid and urea analysis) were obtained prior to the commencement of training (Pre) and at the end of week 2, week 4 and week 6. The training group showed significant improvements in time to exhaustion, and VO2max at all time points (except week 2 for VO2max while the control group performance measures did not change. In the training group, hemoglobin concentration and hematocrit were significantly lower than pretraining values at week 2 and 4, as percentage changes in plasma volume indicated a significant hemodilution (+ 6 to 9 %) was present at week 2, 4 and 6. No changes were seen in the control group. In the training group, plasma glutamine (week 2, 4 and 6), creatine kinase (week 2 and 4), uric acid (week 2 and 4) and urea (week 2 and 4) all increased significantly from pretraining levels. No changes in cortisol or ferritin were found in the training group and no changes in any blood variables were present in the control group. Plasma glutamine was the only blood variable to remain significantly above pretraining (966 ± 32 micromol) levels at week 6 (1176 ± 24 micromol) The elevation seen here in glutamine levels, after 6 weeks of progressive endurance training, is in contrast to previous reports of decreased glutamine concentrations in overtrained athletes. In conclusion, 6 weeks of progressive endurance training steadily increased plasma glutamine levels, which may prove useful in the monitoring of training responses [07334].

Some athletes can have high intakes of l-glutamine because of their high energy and protein intakes and also because they consume protein supplements, protein hydrolysates, and free
amino acids. Prolonged exercise and periods of heavy training are associated with a decrease in the plasma glutamine concentration and this has been suggested to be a potential cause of the exercise-induced immune impairment and increased susceptibility to infection in athletes. However, several recent glutamine feeding intervention studies indicate that although the plasma glutamine concentration can be kept constant during and after prolonged strenuous exercise, the glutamine supplementation does not prevent the postexercise changes in several aspects of immune function. Although glutamine is essential for lymphocyte proliferation, the plasma glutamine concentration does not fall sufficiently low after exercise to compromise the rate of proliferation. Acute intakes of glutamine of approximately 20-30 g seem to be without ill effect in healthy adult humans and no harm was reported in a study in which athletes consumed glutamine every day for 14 d. Doses of up to 0.65 g/kg body mass of glutamine (in solution or as a suspension) have been reported to be tolerated by patients and did not result in abnormal plasma ammonia levels. However, the suggested reasons for taking glutamine supplements (support for immune system, increased glycogen synthesis, anticatabolic effect) have received little support from well-controlled scientific studies in healthy, well-nourished humans.

Blood ammonia concentration increases during endurance exercise and has been proposed as a cause for both peripheral and central fatigue. It was examined the impact of glutamine and (or) carbohydrate supplementation on ammonemia in high-level runners. Fifteen men in pre-competitive training ran 120 min (approximately 34 km) outdoors on 4 occasions. On the first day, the 15 athletes ran without the use of supplements and blood samples were taken every 30 min. After that, each day for 4 d before the next 3 exercise trials, it was supplemented the athletes' normal diets in bolus with carbohydrate (1 g/kg and day), glutamine (70 mg/kg and day), or a combination of both in a double-blind study. Blood ammonia level was determined before the run and every 30 min during the run. During the control trial ammonia increased progressively to approximately 70 percent above rest concentration. Following supplementation, independent of treatment, ammonia was not different for the first 60 min, but for the second hour it was lower than in the control. Supplementation in high-level, endurance athletes reduced the accumulation of blood ammonia during prolonged, strenuous exercise in a field situation.

Different dietary proteins affect whole body protein anabolism and accretion and therefore, have the potential to influence results obtained from resistance training. One study examined the effects of supplementation with two proteins, hydrolyzed whey isolate and casein, on strength, body composition, and plasma glutamine levels during a 10 wk, supervised resistance training program. In a double-blind protocol, 13 male, recreational bodybuilders supplemented their normal diet with either whey or casein (1.5 g/kg body wt/d) for the duration of the program. Strength was assessed by 1-RM in three exercises (barbell bench press, squat, and cable pull-down). Body composition was assessed by dual energy X-ray absorptiometry. Plasma glutamine levels were determined by the enzymatic method with spectrophotometric detection. All assessments occurred in the week before and the week following 10 wk of training. Plasma glutamine levels did not change in either supplement group following the intervention.

High-intensity and prolonged exercise significantly enhances the levels of plasma ammonia, a metabolite with toxic effects on the central nervous system. The main purpose of the present study was to evaluate the metabolic response of athletes to glutamine and alanine supplementation, since these amino acids have a significant influence on both anaplerosis and gluconeogenesis. Professional football players were assigned to groups receiving either glutamine and alanine supplementation (100 mg/kg body weight); this supplementation was either short-term or long-term and was given immediately before exercise. The players were evaluated using two exercise protocols, one with intervals (n=18) and the other with...
continuous intensity (n=12). Both types of exercises increased ammonia, urate, urea and creatinine in blood. Chronic glutamine supplementation partially protected against hyperammonemia after a football match and after continuous exercise at 80 percent of the maximum heart rate. Urate increased by 10-20 percent in all groups, independently of supplementation. Glutamine once a day supplementation induced a greater elevation in urate as compared to alanine at the end of the game; however, long-term supplementation provoked a lesser increment in urate. Exercise induced similar increases in creatinine as compared to their respective controls in either acute or chronic glutamine administration. Taken together, the results suggest that chronically supplemented glutamine protects against exercise-induced hyperammonemia depending on exercise intensity and supplementation duration [08420].

Glutamine (Gln), the most abundant amino acid in the body, has recently become regarded as conditionally essential rather than non-essential. Glutamine is synthesised, stored and released predominantly by skeletal muscle: it is taken up by intestinal cells, such as enterocytes and colonocytes, by the liver and kidney and by some key immune cells. In clinical studies, the plasma concentration of glutamine is decreased in trauma and starvation: glutamine provision has been reported to have a beneficial effect on gut function, morbidity and mortality, and immune cell function. Clinical evidence suggests that glutamine provision helps recovery from surgery and maintains muscle protein mass. The normal resting, fasting plasma glutamine is 500-700 micromol/l and is often higher in athletes: the muscle concentration can reach 20 mM (60 % of the intramuscular pool). During short-term strenuous exercise, the concentration is usually markedly increased, probably due to the release of glutamine into the circulation from skeletal muscle. However, glutamine is often substantially reduced by prolonged, exhaustive exercise: this decrease often occurs concomitantly with relatively transient immunodepression. Decreased concentrations may contribute to overtraining. Glutamine supplementation after exercise reduced the self-reported incidence of illness in endurance athletes. However, when glutamine was given to athletes to combat exercise-induced depletion of circulating glutamine, no effects were observed on the immune parameters studied, apart from reduced neutrocytosis and increased circulating IL-6. It remains to be determined which other aspects of exercise-induced immunodepression might be altered by glutamine supplementation. Although the main focus of the series and this article is the ergogenic effects of supplementation, immunodepression must also be taken into account, since its elimination will allow more effective training and thus better performance. Glutamine supplementation has been well studied in both clinical and exercise situations, particularly in terms of its effects on immune function. After endurance exercise, muscle glycogen repletion is an important factor in recovery and subsequent performance. Post-exercise intake of carbohydrate provides a substrate for glycogen synthesis and also stimulates insulin secretion, which subsequently activates exercise and the glycogen synthase enzyme in muscle. Sports drinks containing glutamine as a free amino acid or part of a dipeptide are widely available but the low levels recommended are unlikely to help improve immune or muscle function. Glutamine supplementation (L-alanyl-L-glutamine dipeptide, at 0.05 and 0.2 g/kg) led to a significant ergogenic benefit by increasing time to exhaustion during a mild hydration stress. This ergogenic effect was thought likely to be mediated by an enhanced fluid and electrolyte uptake. There is also evidence of a role for glutamine, versus alanine, in protecting footballers against an exercise-induced increase in blood ammonia, which would have an impact on fatigue. The first product of glutamine metabolism, catalysed by the enzyme glutaminase, is the excitatory neurotransmitter glutamate. The latter has sometimes been used for supplementation. This may seem rather surprising, since its appearance in plasma at a high concentration correlates neurotoxicity and sometimes with clinical problems. Glutathione, for which glutamine is a precursor via glutamate, is a powerful antioxidant and, in its reduced form, is a good marker of antioxidant capacity, while an increase in its oxidised
form is a good marker of oxidative stress. Overall, there is no consensus or unifying concept to explain the efficacy of exogenous provision of glutamine alone on performance in athletes, although in combination with carbohydrate or other amino acids, significant improvements have been reported. Although there is some evidence that glutamine is effective in decreasing the self-reported incidence of upper respiratory tract illness, it has been difficult to obtain evidence of an effect on any specific aspect of the immune system. There is no doubt that it is important for the athlete to combat immunodepression, and glutamine would be particularly advantageous if it could be proved useful in this way, since it is not a banned substance. Its effects on performance per se are not convincing and, although space precludes citing every study, it is clear that more studies are needed to back up the small amount of evidence already reported [11283].

The aim of one study was to investigate whether supplementation of carbohydrate together with peptide glutamine would prevent anaerobic power decrease during repeated competitions. Twenty-eight physical education male students voluntarily participated in the study. Subjects were randomly divided on a maximal power (Max power) output value basis into four groups: 1) G group (oral ingestion of glutamine at the dose of 0.25 g/kg body mass in 250 ml of water), 2) M group (a single carbohydrate at a concentration of 50g of maltodextrin in 250 ml of water), 3) GM group (carbohydrate at a concentration of 50g of maltodextrin + glutamine at the dose of 0.25 g/kg body mass in 250 ml of water) and, 4) P group (just 250 ml of water and 30 gram sweetener). Each subject performed three times Running-based Anaerobic Sprint Test (RAST) with intervals of 1 hour. Max power, Minimal power (Min power) and fatigue were calculated for each participant. There was a significant decrease in Max and Min power in P group in time series. Furthermore, regarding the Max and Min power, there was significant difference between P and GM group in third bout indicating stronger influence of combination of maltodextrin and glutamine in comparison with pure consumption of glutamine and maltodextrin. It was concluded that it seems acute supplementation of glutamine and maltodextrin combination, 2 hours before exercise is more efficient in prevention of anaerobic power decrease than consumption of a pure carbohydrate or glutamine in repeated bouts of RAST protocol. Thus, supplementation with both carbohydrate and peptide glutamine improved the physical performance of athletes during repeated competitions [13656].

Glutamine has had its 15 min of fame, but it will not go away. In a 2012 survey of fitness and bodybuilding Internet sites, glutamine was one of the six most commonly touted supplements. These Internet sites tout glutamine as “essential for serious athletes” to “increase growth hormone” and “enhance muscle metabolism.” They claim glutamine is vital for optimal immune function. They claim you cannot get enough glutamine from food or make enough when you are training hard. Your best bet is to buy it from them. The drumbeat for glutamine that began 15 to 20 years ago was based on intriguing hypotheses. Glutamine is the most abundant free amino acid in muscle and plasma. Skeletal muscle is a major site for glutamine synthesis, and it releases glutamine into plasma at a high rate. Glutamine in muscle may buffer acids and help build glycogen and protein. Glutamine also fuels lymphocytes and macrophages. So glutamine is seen as possibly anabolic and immunity boosting. Plasma glutamine levels tend to be decreased for a few hours after prolonged exercise. A popular early hypothesis was that this decrease contributes to an “open window” of impaired immunity after marathons. So the myth was born: Glutamine supplements are vital for strong muscles and immunity [13657].

Studies in intensive care units

In ICU observational studies, low plasma glutamine levels, compared to moderate levels, have been tied to a higher mortality rate. The hypothesis was that loss of muscle led to
glutamine deficiency that weakened immune and other host defenses. But observational studies are tricky; one pitfall was that those few with the very highest glutamine levels (most had acute liver failure) also had a higher mortality rate. Self-correction is now occurring in glutamine research. The ICU observational studies that tied lower glutamine to higher mortality led to clinical trials of glutamine supplementation in critically ill ICU patients. Some trials suggested improved survival on glutamine, but the two largest ICU trials found no clear benefit from glutamine. Now comes the blockbuster study, a randomized controlled trial in a leading journal. More than 1,200 critically ill adults in 40 ICUs were randomized to receive glutamine, antioxidants, both, or placebo for up to 28 d. Glutamine had no effect on infections and did not improve clinical outcome. In fact, glutamine was tied to a slight increase in risk of death, statistically significant at 6 months. The authors concluded that glutamine “was harmful”, and an editorialist said this study allows one to reject with confidence the hypothesis that glutamine supplementation in very ill patients in the ICU improves outcome. It seems glutamine has no role in the ICU [13657].

**Glutamine, athletes, and immunity**

Glutamine has no role in sports, either, because the early hypotheses have not held up. Early studies found that plasma glutamine typically fell transiently after prolonged exercise, such as cycling nearly 4 h or running a marathon. One study suggested that two small doses of glutamine (vs placebo) after a marathon could reduce “infections,” self-reported on questionnaires, over the next week. However, such questionnaires are validated for classical viral upper respiratory infection (URI) and are less reliable for diagnosing URI in the face of allergies or stress reactions from the marathon. In other words, the pitfall is that not all “infections” after marathons are true infections. Other studies refute the hypothesis that low plasma glutamine after exercise increases the risk of infection. In a 4-week study of intensified training of swimmers, glutamine levels tended to increase, not fall, and no difference in glutamine levels was seen in swimmers who reported URI versus those who did not. In laboratory studies of athletes, glutamine supplements during exercise did not prevent the typical postexercise “immunodepression.” In other words, even though plasma glutamine stayed normal, these exercisers still developed transient decrements in lymphocyte counts and functions, in activity of natural killer cells, and in salivary immunoglobulin A levels. Experts now see no causal link between low plasma glutamine, impaired immune function, and increased risk of URI in athletes. Scientists and sports medicine physicians have known for a decade that plasma glutamine is not linked to any putative “exercise-induced immunodepression”, but glutamine sellers remain willfully ignorant on their way to the bank [13657].

**Glutamine, muscle function, and athletic performance**

The claim that glutamine can spur release of growth hormone seems to be based on one study of nine middle-aged volunteers. The mean value of plasma growth hormone, 90 min after a 2-g oral dose of glutamine, was 4-fold higher than the control (placebo) value, but sharp rises in growth hormone level after glutamine occurred in only 4 subjects, and the results were not statistically significant. It should be noted that 1 h of strenuous exercise could increase plasma growth hormone level 20-fold, so no reason exists for athletes in training to take glutamine to spur growth hormone release. Nor is there evidence that extra glutamine is anabolic. After glycogen-depleting exercise, glutamine cannot improve on glucose alone at restoring muscle glycogen. Adding glutamine to essential amino acids and carbohydrate does not enhance muscle glycogen or protein synthesis after glycogen-depleting endurance exercise. Finally, there is no good evidence that glutamine supplements improve athletic performance. When 10 trained men performed five maximal
cycling bouts, acute ingestion of glutamine did not enhance performance, and in a randomized, double-blind study of daily glutamine (vs placebo) during 6 weeks of strength training in 31 young adults, the glutamine added nothing: Gains in lean muscle mass and strength were the same on placebo as on glutamine. The bottom line is therefore still that there is no reason for athletes to buy or use glutamine supplements. Dr. George Phillips, writing 6 years ago, was right to conclude that the glutamine fad is another sad example of how marketing can trump science [13657].

Alanine

High-intensity exercise results in reduced substrate levels and accumulation of metabolites in the skeletal muscle. The accumulation of these metabolites (e.g. ADP, Pi and H+) can have deleterious effects on skeletal muscle function and force generation, thus contributing to fatigue. Clearly this is a challenge to sport and exercise performance and, as such, any intervention capable of reducing the negative impact of these metabolites would be of use. Carnosine (beta-alanyl-L-histidine) is a cytoplasmic dipeptide found in high concentrations in the skeletal muscle of both vertebrates and non-vertebrates and is formed by bonding histidine and beta-alanine in a reaction catalysed by carnosine synthase. Due to the pKa of its imidazole ring (6.83) and its location within skeletal muscle, carnosine has a key role to play in intracellular pH buffering over the physiological pH range, although other physiological roles for carnosine have also been suggested. The concentration of histidine in muscle and plasma is high relative to its K_m with muscle carnosine synthase, whereas beta-alanine exists in low concentration in muscle and has a higher K_m with muscle carnosine synthase, which indicates that it is the availability of beta-alanine that is limiting to the synthesis of carnosine in skeletal muscle. Thus, the elevation of muscle carnosine concentrations through the dietary intake of carnosine, or chemically related dipeptides that release beta-alanine on absorption, or supplementation with beta-alanine directly could provide a method of increasing intracellular buffering capacity during exercise, which could provide a means of increasing high-intensity exercise capacity and performance. One paper reviewed the available evidence relating to the effects of beta-alanine supplementation on muscle carnosine synthesis and the subsequent effects on exercise performance. In addition, the effects of training, with or without beta-alanine supplementation, on muscle carnosine concentrations were also reviewed [10411].

The influence of alanine on plasma amino acid concentrations and fuel substrates as well as cycling performance was examined. Four solutions (6 % alanine, ALA; 6 % sucrose, CHO; 6 % alanine and 6 % sucrose, ALA-CHO; and an artificially sweetened placebo, PLC) were tested using a double-blind, randomised, cross-over design. During each trial, ten cyclists ingested 500 mL of test solution 30 min before exercise and 250 mL after 15, 30, and 45 min of exercise. Participants cycled for 45 min at 75 percent VO_{2max} followed by a 15-min performance trial. Blood was collected before beverage consumption and prior to the performance trial. Alanine concentration was increased by approximately tenfold for ALA and ALA-CHO and less than twofold for CHO and PLC. Alanine ingestion increased concentrations of most gluconeogenic amino acids. Overall, alanine supplementation tended to produce favourable metabolic effects, but did not influence performance [09342].

It was examined the effect of beta-alanine supplementation plus sodium bicarbonate on high-intensity cycling capacity. Twenty males (age = 25 ± 5 years, height = 1.79 ± 0.06 m, body mass = 80.0 ± 10.3 kg) were assigned to either a placebo (P) or a beta-alanine (BA; 6.4 g/day) for 4 weeks) group based on power max, completing four cycling capacity tests at 110 percent of power max (CCT110%) to determine time to exhaustion (TTE) and total work done. A CCT110) was performed twice (habituation and baseline) before supplementation
(with maltodextrin) and twice after supplementation (with maltodextrin and with sodium bicarbonate), using a crossover design with 2 days of rest between trials, creating four study conditions (PMD, PSB, BAMD, and BASB). Blood pH, Lactate, bicarbonate and base excess were determined at baseline, before exercise, immediately after exercise, and 5 min after exercise. Data were analyzed using repeated-measures ANOVA. TTE was increased in all conditions after supplementation (+1.6 % PMD, +6.5 % PSB, +12.1 % BAMD, and +16.2 % BASB). Both BAMD and BASB resulted in significantly improved TTE compared with that before supplementation. Although further increases in TTE (4.1 %) were shown in BASB compared with BAMD, these differences were not significant. Differences in total work done were similar to those of TTE. Blood bicarbonate concentrations were significantly elevated before exercise in PSB and BASB but not in PMD or BAMD. Blood lactate concentrations were significantly elevated after exercise, remaining elevated after 5 min of recovery and were highest in PSB and BASB. It was concluded that the results show that beta-alanine improved high-intensity cycling capacity. However, despite a 6-s (about 4 %) increase in TTE with the addition of SB, this did not reach statistical significance, but magnitude-based inferences suggested a about 70 percent probability of a meaningful positive difference [11530].

It was examined the effect of beta-alanine supplementation plus sodium bicarbonate on high-intensity cycling capacity. Twenty males (age = 25 ± 5 years, height = 1.79 ± 0.06 m, body mass = 80 ± 10 kg) were assigned to either a placebo (P) or a beta-alanine (BA; 6.4 g/d for 4 weeks) group based on power max, completing four cycling capacity tests at 110 percent of power max (CCT 110 %) to determine time to exhaustion (TTE) and total work done. A CCT(110 %) was performed twice (habituation and baseline) before supplementation (with maltodextrin, MD) and twice after supplementation (with MD and with sodium bicarbonate, SB), using a crossover design with 2 d of rest between trials, creating four study conditions (PMD, PSB, BAMD, and BASB). Blood pH, Lactate, bicarbonate and base excess were determined at baseline, before exercise, immediately after exercise, and 5 min after exercise. Data were analyzed using repeated-measures ANOVA. TTE was increased in all conditions after supplementation. Both BAMD and BASB resulted in significantly improved TTE compared with that before supplementation. Although further increases in TTE (4 %) were shown in BASB compared with BAMD, these differences were not significant. Differences in total work done were similar to those of TTE. Blood bicarbonate concentrations were significantly elevated before exercise in PSB and BASB but not in PMD or BAMD. Blood lactate concentrations were significantly elevated after exercise, remaining elevated after 5 min of recovery and were highest in PSB and BASB. It was concluded that the results show that BA improved high-intensity cycling capacity. However, despite a 6-s (about 4 %) increase in TTE with the addition of SB, this did not reach statistical significance, but magnitude-based inferences suggested a about 70 percent probability of a meaningful positive difference [11531].

**L-alanine**

Dietary supplements containing L-arginine, a semi-essential amino acid, are one of the latest ergogenic aids intended to enhance strength, power and muscle recovery associated with both aerobic and resistance exercise. L-arginine is claimed to promote vasodilation by increasing nitric oxide (NO) production in the active muscle during exercise, improving strength, power and muscular recovery through increased substrate utilization and metabolite removal, such as lactate and ammonia. Research on L-arginine has recently tested this hypothesis, under the assumption that it may be the active compound associated with the vasodilator effects of NO. There were only five acute studies retrieved from the literature that evaluated exercise performance after L-arginine supplementation, three of which reported significant improvements. Regarding studies on chronic effects, eight studies
were encountered: four reported enhancements in exercise performance, whilst four reports showed no changes. Whether these improvements in exercise performance - regardless of the aerobic or anaerobic nature of the exercise - can be associated with increases in NO production, has yet to be demonstrated in future studies. Low oral doses (≤20 g) are well tolerated and clinical side effects are rare in healthy subjects. In summary, it is still premature to recommend dietary supplements containing L-arginine as an ergogenic aid for healthy physically active subjects [11284].

The ergogenic effect of L-arginine on an endurance-trained population is not well studied. The few studies that have investigated L-arginine on this population have not been conducted in a laboratory setting or measured aerobic variables. The purpose of one study was to determine if 28 days of L-arginine supplementation in trained male cyclists affects $V\text{O}_2\text{max}$ and ventilatory threshold (VT). Eighteen endurance-trained male cyclists performed a graded exercise test before and after 28 days of supplementation with L-arginine (ARG; 2 × 6 g·d) or placebo (PLA; cornstarch). The GXT was conducted on the subject’s own bicycle. $V\text{O}_2$ was continuously recorded, and VT was established by plotting the ventilatory equivalent for $O_2$ (VE/$V\text{O}_2$) and the ventilatory equivalent for $CO_2$ (VE/$V\text{CO}_2$) and identifying the point at which VE/$V\text{O}_2$ increases with no substantial changes in VE/$V\text{CO}_2$. L-arginine supplementation had no effect from initial $V\text{O}_2\text{max}$ to postsupplement $V\text{O}_2\text{max}$. Also, no effect was seen from initial VT to postsupplement VT. These results indicate that L-arginine does not impact $V\text{O}_2\text{max}$ or VT in trained male cyclists [11285].

**beta-Alanine**

Muscle carnosine synthesis is limited by the availability of beta-alanine. Thirteen male subjects were supplemented with beta-alanine for 4 weeks, 8 of these for 10 weeks. A biopsy of the vastus lateralis was obtained from 6 of the 8 at 0, 4 and 10 wks. Subjects undertook a cycle capacity test to determine total work done (TWD) at 110 percent (CCT(110%)) of their maximum power ($W_{max}$). Twelve matched subjects received a placebo. Eleven of these completed the CCT(110%) at 0 and 4 weeks, and 8, 10 weeks. Muscle biopsies were obtained from 5 of the 8 and one additional subject. Muscle carnosine was significantly increased by 59 percent and 80 percent after 4 and 10 weeks beta-alanine supplementation. Carnosine, initially 1.71 times higher in type IIa fibres, increased equally in both type I and IIa fibres. No increase was seen in control subjects. Taurine was unchanged by 10 weeks of supplementation. Four weeks of beta-alanine supplementation resulted in a significant increase in TWD (+13 %); with a further 3 percent increase at 10 weeks. TWD was unchanged at 4 and 10 weeks in the control subjects. The increase in TWD with supplementation followed the increase in muscle carnosine [07336].

beta-Alanine seems to be without adverse effects if the dose of 10 mg/kg body weight per 2-h interval, which can lead to paraesthesia, is not exceeded. It was also shown that carnosine loading leads to better performance during high-intensity exercise (cycling at 110 % of $W_{max}$ to exhaustion). With the availability of more recent studies, it becomes evident that mostly high-intensity efforts that last several minutes experience a positive influence of beta-alanine supplementation. Indeed, beta-alanine was not ergogenic for repeated sprint performance (10×5 s sprint), while both a simulated 2000-m rowing race (± 6 min) and the sprint at the end of 2-h simulated cycling race were improved by beta-alanine. It is plausible that high-intensity performance is affected in long-term vegetarians, as they are characterised with lower muscle carnosine levels (~26 %). The ergogenic mechanism of beta-alanine may reside in the attenuation of acidosis through the proton-buffering capacity of carnosine, whereas other physiological properties of carnosine (antioxidant, calcium sensitisation) cannot be excluded at present [11241].
Beta-alanine in blood-plasma when administered as A) histidine dipeptides (equivalent to 40 mg/kg bwt of beta-alanine) in chicken broth, or B) 10, C) 20 and D) 40 mg/kg bwt beta-alanine (CarnoSyn, NAI, USA), peaked at 428, 47, 374, and 833 microM. Concentrations regained baseline at 2 h. Carnosine was not detected in plasma with A) although traces of this and anserine were found in urine. Loss of beta-alanine in urine with B) to D) was <5 percent. Plasma taurine was increased by beta-alanine ingestion but this did not result in any increased loss via urine. Pharmacodynamics were further investigated with 3 x B) per day given for 15 d. Dietary supplementation with I) 3.2 and II) 6.4 g . d(-1) beta-alanine (as multiple doses of 400 or 800 mg) or III) L-carnosine (isomolar to II) for 4 w resulted in significant increases in muscle carnosine estimated at 42, 64 and 66 percent [06277].

Among the newer dietary supplements popular with athletes and fitness enthusiasts is beta-alanine, an amino acid that has a myriad of purported health and exercise benefits. Recent reviews on this topic. Beta-alanine is an amino acid that, when combined with histidine, forms the dipeptide carnosine within skeletal muscle. Carnosine and beta-alanine each have multiple purposes within the human body; one review focuses on their roles as ergogenic aids to exercise performance and suggests how to best quantify the former's merits as a buffer. Carnosine normally makes a small contribution to a cell's total buffer capacity; yet beta-alanine supplementation raises intracellular carnosine concentrations that in turn improve a muscle's ability to buffer protons. Numerous studies assessed the impact of oral beta-alanine intake on muscle carnosine levels and exercise performance. Beta-alanine may best act as an ergogenic aid when metabolic acidosis is the primary factor for compromised exercise performance. Blood lactate kinetics, whereby the concentration of the metabolite is measured as it enters and leaves the vasculature over time, affords the best opportunity to assess the merits of beta-alanine supplementation's ergogenic effect. Optimal beta-alanine dosages have not been determined for persons of different ages, genders and nutritional/health conditions. A recent meta-analysis shows a heightened exercise capacity, yet no significant improvement in performance, from oral beta-alanine supplementation. Meta-analysis results included a median beta-alanine intake of 179 g per intervention led to a median improvement of less than 3 percent. The disparity in results from these earlier reviews clearly indicate the types of studies and exercise bouts previously employed have not allowed oral beta-alanine supplementation to be optimally examined and utilized for its ergogenic properties. It is clear from examinations of cellular biochemistry that exercise which evokes intracellular H+ accrual may benefit most from oral beta-alanine intake. Yet some reviews offered limited information on exercise-induced cellular conditions (metabolic acidosis) that led to increased beta-alanine and carnosine research, as well as little quantitative evidence of the latter's prowess to continue to act as a potent buffer in the face of successively larger intramuscular pH decrements. Far from a mere recitation and review of prior study outcomes, one paper offered insights as to how beta-alanine may best be used, as well as how its ergogenic properties can be objectively and accurately quantified through continued exercise-based research. Paraesthesia is to date the only side effect from oral beta-alanine ingestion. The severity and duration of paraesthesia episodes are dose-dependent. It may be unwise for persons with a history of paraesthesia to ingest beta-alanine. As for any supplement, caution should be exercised with beta-alanine supplementation [12431].

The benefits associated with histidine dipeptides and muscle buffering capacity has been known for more than 20 years. However, the ergogenic role of beta-alanine when combined with histidine became popular before the 2008 Olympic games. Several studies published during the early part of the past decade suggested that beta-alanine ingestion by itself, or when combined with creatine, may significantly enhance anaerobic athletic performance (e.g. resistance exercise, repeated sprints) to a greater magnitude than a placebo or to creatine by
itself. These studies have indicated that beta-alanine can enhance the quality of a workout and sport performance by delaying skeletal muscle fatigue. This has resulted in a surge in its popularity over the last years. Recently, the benefits of beta-alanine supplementation on nonathletic and/or clinical populations has become of interest within the medical community. Its potential therapeutic role, especially in the aging population, may prove to be valuable. This article will examine the physiology of beta-alanine. The popularity of beta-alanine stems from its unique ability to enhance intramuscular buffering capacity and thereby attenuating fatigue. One review provided an overview of the physiology that underlies the mechanisms of action behind beta-alanine, examine dosing schemes, and examine the studies that have been conducted on the efficacy of this supplement. The ergogenic benefits of beta-alanine supplementation thus are most evident in activities that elicit a strong intramuscular acidotic condition (intense exercise between 60 and 240 s) by delaying the onset of skeletal muscle fatigue. A delay in fatigue during repeated or prolonged sprinting and an enhanced volume of resistance training (greater number of repetitions performed) are common responses observed following beta-alanine ingestion [12432].

It was examined the isolated and combined effects of beta-alanine (BA) and sodium bicarbonate (SB) on high-intensity intermittent upper-body performance in judo and jiu-jitsu competitors. Thirty-seven athletes were assigned to one of four groups: (1) placebo (PL)+PL; (2) BA+PL; (3) PL+SB or (4) BA+SB. BA or dextrose (placebo) (6.4 g/day) was ingested for 4 weeks and 500 mg7kg BM of SB or calcium carbonate (placebo) was ingested for 7 days during the 4th week. Before and after 4 weeks of supplementation, the athletes completed four 30-s upper-body Wingate tests, separated by 3 min. Blood lactate was determined at rest, immediately after and 5 min after the 4th exercise bout, with perceived exertion reported immediately after the 4th bout. BA and SB alone increased the total work done in 7 and 8 percent, respectively. The co-ingestion resulted in an additive effect (+14). BA alone significantly improved mean power in the 2nd and 3rd bouts and tended to improve the 4th bout. SB alone significantly improved mean power in the 4th bout and tended to improve in the 2nd and 3rd bouts. BA+SB enhanced mean power in all four bouts. PL+PL did not elicit any alteration on mean and peak power. Post-exercise blood lactate increased with all treatments except with PL+PL. Only BA+SB resulted in lower ratings of perceived exertion.. Chronic BA and SB supplementation alone equally enhanced high-intensity intermittent upper-body performance in well-trained athletes. Combined BA and SB promoted a clear additive ergogenic effect [13657].

Beta-alanine may benefit short duration, high-intensity exercise performance. The aim of one randomised, double-blind, placebo controlled study was to examine the effects of beta-alanine supplementation on aspects of muscular performance in highly-trained cyclists. Sixteen highly-trained cyclists (mean±SD; age 24 ± 7 years) supplemented with either beta-alanine (n=8, 65 mg/kg BM) or a placebo (n=8, dextrose monohydrate) over four weeks. Pre- and post-supplementation cyclists performed: 1) a four-minute maximal cycling test to measure average power and 2) 30 reciprocal maximal isokinetic knee contractions at a fixed angular velocity of 180°·sec⁻¹ to measure average power/repetition, total work done (TWD) and fatigue index (%). Blood pH, lactate (La⁻) and bicarbonate concentrations were measured pre- and post-isokinetic testing at baseline and following the supplementation period. β-alanine supplementation was 44% likely to increase average power output during the four-minute cycling time-trial when compared to the placebo, although this was not statistically significant. Isokinetic average power/repetition was significantly increased post-beta-alanine supplementation, while fatigue index was significantly reduced. TWD was 89 percent likely to be improved following beta-alanine supplementation, however this was not statistically significant. There were no significant differences in blood pH, lactate and HCO₃⁻ between groups. Four weeks of beta-alanine supplementation resulted in worthwhile changes in time-trial performance and short-duration muscular force production in highly-
trained cyclists [13659].

Beta-alanine supplementation has been shown to improve exercise performance in short-term, high-intensity efforts. The aim of one study was to assess if beta-alanine supplementation could improve 800 m track running performance in male recreational club runners (n=18). Participants completed duplicate trials (2 pre-supplementation, 2 post-supplementation) of an 800 m race, separated by 28 days of either beta-alanine (n=9; 80 mg/kg BM/day) or placebo (n=9) supplementation (single blind design). Using ANCOVA (pre-supplementation times as covariate), post-supplementation race times were significantly faster following beta-alanine, with post- versus pre-supplementation race times being faster after beta-alanine but not placebo. These improvements were supported by a moderate effect size and a “very likely” (99 %) benefit in the beta-alanine group after supplementation. Split times (ANCOVA) at 400 m were significantly faster post-supplementation in the beta-alanine group, compared with placebo. This was supported by large effect sizes and a “very likely” (99 %) benefit at the 400 and 800 m splits when comparing pre- to post-supplementation with beta-alanine. Additionally, the first and second halves of the race were faster post- compared to pre-supplementation following beta-alanine. No significant differences between groups or pre- and post-supplementation were observed for post-race blood lactate and pH. Thus, overall, 28 days of beta-alanine supplementation improved 800 m track performance in recreational club runners [13660].

Beta-alanine (BA) is a popular ergogenic supplement because it can induce muscle carnosine loading. It was hypothesize that, by analogy with creatine supplementation, an inverse relationship between urinary excretion and muscle loading is present, and the latter is stimulated by carbohydrate- and protein-induced insulin action. In study A, the effect of a 5-week slow-release BA (SRBA) supplementation (4.8 g/day) on whole body BA retention was determined in seven men. It was further determined whether the coingestion of carbohydrates and proteins with SRBA would improve retention. In study B (34 subjects), it was explored the effect of meal timing on muscle carnosine loading (3.2 g/day) during 6-7 weeks). One group received pure BA (PBA) in between the meals; the other received PBA at the start of the meals, to explore the effect of meal-induced insulin release. Further, it was compared with a third group receiving SRBA at the start of the meals. Orally ingested SRBA has a very high whole body retention (97 %-98 %) that is not declining throughout the 5-week supplementation period, nor is it influenced by the coingestion of macronutrients. Thus, a very small portion (1 %-2 %) is lost through urinary excretion, and equally only a small portion is incorporated into muscle carnosine (about 3 %), indicating that most ingested BA is metabolized (possibly through oxidation). Second, in soleus muscles, the efficiency of carnosine loading is significantly higher when PBA is coingested with a meal (+64 %) compared with in between the meals (+41 %), suggesting that insulin stimulates muscle carnosine loading. Finally, the chronic supplementation of SRBA versus PBA seems equally effective [13658].

To critically review the methodological quality and synthesize information from systematic reviews and high quality studies on the effects of beta alanine (BA) on exercise and athletic performance a search strategy was developed in accordance with the standards for the reporting of scientific literature via systematic reviews. Five databases were thoroughly searched from inception to November 2012. Inclusion criteria were English language, human studies, used BA to increase exercise or athletic performance, systematic reviews or randomized controlled trials and were published in a peer-reviewed journal. Included studies were systematically graded for their methodological quality by rotating pairs of reviewers and the results were qualitatively synthesized. One systematic review and nineteen randomized trials were included in this review. There is one systematic review with several methodological weaknesses that limit the confidence in its results. There are moderate to
high quality studies that appear to support that BA may increase power output and working capacity, decrease the feeling of fatigue and exhaustion, and have of positive effect on body composition and carnosine content. The reporting of side effects from BA supplementation in the athletic population was generally under-reported. It was concluded that there appears to be some evidence from this review that supplementation with BA may increase athletic performance. However, there is insufficient evidence examining the safety of BA supplementation and its side effects. It is therefore recommended to err on the side of caution in using BA as an ergogenic aid until there is sufficient evidence confirming its safety [13659].

beta-Alanine supplementation has become a common practice among competitive athletes participating in a range of different sports. Although the mechanism by which chronic beta-alanine supplementation could have an ergogenic effect is widely debated, the popular view is that beta-alanine supplementation augments intramuscular carnosine content, leading to an increase in muscle buffer capacity, a delay in the onset of muscular fatigue and a facilitated recovery during repeated bouts of high-intensity exercise. beta-Alanine supplementation appears to be most effective for exercise tasks that rely heavily on ATP synthesis from anaerobic glycolysis. However, research investigating its efficacy as an ergogenic aid remains equivocal, making it difficult to draw conclusions as to its effectiveness for training and competition. The aim of one review was to update, summarise and critically evaluate the findings associated with beta-alanine supplementation and exercise performance with the most recent research available to allow the development of practical recommendations for coaches and athletes. A critical review of the literature reveals that when significant ergogenic effects have been found, they have been generally shown in untrained individuals performing exercise bouts under laboratory conditions. The body of scientific data available concerning highly-trained athletes performing single competition-like exercise tasks indicates that this type of population receives modest but potentially worthwhile performance benefits from beta-alanine supplementation. Recent data indicate that athletes may not only be using beta-alanine supplementation to enhance sports performance, but also as a training aid to augment bouts of high-intensity training. beta-Alanine supplementation has also been shown to increase resistance training performance and training volume in team-sport athletes, which may allow for greater overload and superior adaptations compared to training alone. The ergogenic potential of beta-alanine supplementation for elite athletes performing repeated high-intensity exercise bouts, either during training or during competition in sports which require repeated maximal efforts (e.g. rugby and soccer) needs scientific confirmation [13660].

Beta-alanine (BA) is a non-essential amino acid that combines with L-histidine, to form the dipeptide carnosine. BA is thought to be the rate-limiting step in the synthesis of carnosine. Carnosine acts as an intracellular buffer during high-intensity exercise, and elevations in muscle carnosine concentration have been demonstrated to enhance cycling capacity, ventilatory threshold, and delay fatigue. A meta-analysis has shown a significant ergogenic effect of BA supplementation during high intensity exercise lasting 60–240 s in duration. However, the efficacy of BA supplementation during single exercise durations shorter than 60 s durations is not clear. Although the efficacy of BA on repeated sprint performance is not very well known, studies examining BA and resistance training performance have indicated significant increases in training volume, suggesting that BA ingestion would be beneficial for repetitive high intensity exercise activities [13608].

It was aimed to manipulate physiological determinants of severe exercise performance. We hypothesized that beta-alanine supplementation would increase intramuscular carnosine and buffering capacity and dampen acidosis during severe cycling, that high-intensity interval training (HIT) would enhance aerobic energy contribution during severe cycling, and that HIT
preceded by beta-alanine supplementation would have greater benefits. Sixteen active men performed incremental cycling tests and 90-s severe (110 % peak power) cycling tests at three time points: before and after oral supplementation with either beta-alanine or placebo, and after an 11-days HIT block (9 sessions, 4 × 4 min), which followed supplementation. Carnosine was assessed via MR spectroscopy. Energy contribution during 90-s severe cycling was estimated from the O₂ deficit. Biopsies from m. vastus lateralis were taken before and after the test. Beta-alanine increased leg muscle carnosine. Buffering capacity and incremental cycling were unaffected, but during 90-s severe cycling, beta-alanine increased aerobic energy contribution concurrent with reduced O₂ deficit and muscle lactate accumulation while having no effect on pH. beta-Alanine also enhanced motivation and perceived state during the HIT block. There were no between-group differences in adaptations to the training block, namely increased buffering capacity and glycogen storage. It was concluded that beta-alanine did not affect buffering considerably, but has beneficial effects on severe exercise metabolism as well as psychological parameters during intense training phases [13661].

Carnosine (beta-alanyl-l-histidine) is present in high concentrations in human skeletal muscle. The ingestion of beta-alanine, the rate-limiting precursor of carnosine, has been shown to elevate the muscle carnosine content. It was aimed to investigate, using proton magnetic resonance spectroscopy (proton MRS), whether oral supplementation with beta-alanine during 4 weeks would elevate the calf muscle carnosine content and affect exercise performance in 400-m sprint-trained competitive athletes. Fifteen male athletes participated in a placebo-controlled, double-blind study and were supplemented orally for 4 weeks with either 4.8 g/day beta-alanine or placebo. Muscle carnosine concentration was quantified in soleus and gastrocnemius by proton MRS. Performance was evaluated by isokinetic testing during five bouts of 30 maximal voluntary knee extensions, by endurance during isometric contraction at 45 percent maximal voluntary contraction, and by the indoor 400-m running time. beta-Alanine supplementation significantly increased the carnosine content in both the soleus (+47 %) and gastrocnemius (+37 %). In placebo, carnosine remained stable in soleus, while a small and significant increase of +16 percent occurred in gastrocnemius. Dynamic knee extension torque during the fourth and fifth bout was significantly improved with beta-alanine but not with placebo. Isometric endurance and 400-m race time were not affected by treatment. In conclusion, proton MRS can be used to noninvasively quantify human muscle carnosine content; muscle carnosine is increased by oral beta-alanine supplementation in sprint-trained athletes; carnosine loading slightly but significantly attenuated fatigue in repeated bouts of exhaustive dynamic contractions; and the increase in muscle carnosine did not improve isometric endurance or 400-m race time [07337].

One study examined the effects of 28 days of beta-alanine supplementation on the physical working capacity at fatigue threshold (PWCFT), ventilatory threshold (VT), maximal oxygen consumption (VO₂max), and time-to-exhaustion (TTE) in women. Twenty-two women (age 27 ± 6 years) participated and were randomly assigned to either the beta-alanine or Placebo (PL) group. Before (pre) and after (post) the supplementation period, participants performed a continuous, incremental cycle ergometry test to exhaustion to determine the PWCFT, VT, VO₂max, and TTE. There was a 14, 13 and 3 percent increase in VT, PWCFT, and TTE, respectively, for the beta-alanine group, with no changes in the PL. There were no changes for VO₂max in either group. Results of this study indicate that beta-alanine supplementation delays the onset of neuromuscular fatigue and the ventilatory threshold at submaximal workloads, and increase in TTE during maximal cycle ergometry performance. However, beta-alanine supplementation did not affect maximal aerobic power (VO₂max). In conclusion, beta-alanine supplementation appears to improve submaximal cycle ergometry performance and TTE in young women, perhaps as a result of an increased buffering capacity due to elevated muscle carnosine concentrations [07338].
**Physiology of beta-alanine**

beta-Alanine is a nonessential nonproteogenic amino acid that is synthesized in the liver. It will also be consumed in many of our foods, such as beef, chicken, and turkey. When beta-alanine is ingested as part of a meal, it is generally in the form of a histidine-containing dipeptide such as anserine, balenine, or carnosine. It is carnosine that is predominant in the human skeletal muscle. The hydrolysis of these dipeptides yields beta-alanine, which is then absorbed into the skeletal tissue for the resynthesis of carnosine. The ergogenic properties of beta-alanine by itself appear to be very limited, but when combined with histidine to form carnosine in the skeletal muscle, it does appear to have ergogenic effects. The primary role of carnosine is in the maintenance of acid-base homeostasis through enhanced intramuscular hydrogen ion (H⁺) buffering capacity. Increasing intramuscular carnosine concentration through beta-alanine supplementation has demonstrated an ergogenic potential for endurance, strength, and power athletes. In a recent meta-analysis, beta-alanine proved to be ergogenic for maximal exercise lasting 60 to 240 s [12432].

**Efficacy of beta-alanine supplementation**

The mechanism of action emanating from beta-alanine ingestion suggests that it would be most effective in performances involving high intensity activity. The investigations that have focused on this aspect of athletic performance have consistently reported positive results in the ergogenic benefit of A-alanine supplementation. However, the lack of significant strength improvement is consistent with other studies that have failed to show significant improvements in strength following beta-alanine supplement durations lasting between 4 and 10 weeks. These results are not surprising considering the physiological changes that are influenced by elevations in muscle carnosine concentrations. An improved intramuscular buffering system has its greatest effect on fatiguing-type exercises by extending the duration of exercise but does not appear to have a direct effect on strength development during these relatively short-duration training protocols. Such training durations may not be of sufficient length to stimulate significant strength improvements, especially in experienced resistance-trained. The benefits of beta-alanine ingestion and endurance exercise appear to be inconclusive. While there is limited evidence to suggest an ergogenic effect of beta-alanine supplementation on endurance performance, the use of beta-alanine supplementation may improve cardiovascular fitness and increase total work done in recreationally active individuals. Decreases in muscle carnosine concentrations may pose potential health risks. Carnosine acts as an antioxidant, whereby it may scavenge reactive oxygen species, aldehydes, ketones, and inflammatory cells. A deficiency of muscle carnosine concentrations may increase oxidative stress-induced lipid and protein oxidation, increase inflammation, and possibly impair insulin signaling in skeletal muscle [12432].

**Side effects associated with beta-alanine supplementation**

The only known adverse effect associated with A-alanine supplementation is flushing (also sometimes experienced as paresthesia). Paresthesia is a sensation of numbing or tingling in the skin and often appears when high doses of beta-alanine are ingested. It generally disappears within 1 h following ingestion. If A-alanine is mixed with a carbohydrate and electrolyte drink, the appearance of this adverse effect seems negligible [12432].

**beta-Alanine dosing scheme**

It was examined the effect of three different dosing regimens (10, 20, and 40 mg/kg body weight). The two highest doses yielded the greatest increase in plasma beta-alanine concentrations, but these doses also were associated with uncomfortable adverse effects (e.g. paresthesias as a tingling-like sensation felt in the skin) that prohibit those dosages from being used. The kinetics of the A-alanine response to the low dosing scheme was a time to peak in plasma A-alanine concentration of 30 to 40 min following ingestion, a
concentration half-life (time at which there is a 50% reduction in peak concentration) of 25 min, and a return-to-baseline concentration by 3 h after ingestion. According to this kinetic profile, the appropriate dosing regimen should be 0.8 g of A-alanine taken every 3 to 4 h. This would provide a daily dosing regimen of 4.8 to 6.4 g/day. Recent studies have examined the use of time-release capsule technology and have demonstrated that dosages of 1.6 g per ingestion four times per day also can be consumed without any adverse effects and result in a 40 percent increase in muscle carnosine concentrations. This latter method appears to be a more practical dosing pattern that has slower absorption kinetics, improved whole-body retention, and sensory side effects that cannot be differentiated from placebo. On the basis of the available evidence, it is not clear whether a ceiling effect exists regarding increases in muscle carnosine content and A-alanine supplementation. Limitations may be more related to the adverse effects associated with higher dosing regimens. With the use of slow-release capsules, the rate of A-alanine release into circulation is slowed, allowing less excretion through the urine, resulting in a greater percentage of A-alanine retained for carnosine synthesis in the muscle [12432].

Just like any dietary supplement, optimal beta-alanine dosages are based on factors such as a person’s age, gender and nutritional/health practices. Unfortunately most studies have used young- or college-age men. Results suggest ergogenic effects are more likely at higher dosages. In contrast upon cessation of beta-alanine intake carnosine levels decline in a linear fashion at a relatively slow rate of 2 percent per-week until pre-supplementation values of the dipeptide are restored. High initial intramuscular carnosine levels do not apparently limit a cell’s ability to accrue further increases of the dipeptide. Some believe persons with naturally lower absolute carnosine concentrations (those with high percentages of type I muscle fibers, women, vegetarians, elderly) respond best to oral beta-alanine ingestion. A single 400 mg beta-alanine dose produced favorable changes in blood-based markers, but did not improve exercise performance as compared to a placebo intervention. Such a dose might represent first pass liver metabolism that must be overcome before deposition into muscle cells occurs. For 30-day interventions devoid of physical activity a 4.8 g/day, but not a 1.2 g/day, beta-alanine dosage had an ergogenic effect on resistive exercise performance. Thus the minimal β-alanine dose needed for an ergogenic effect may reside between 1.2 and 4.8 g/day in healthy men. Dosages higher than 6.4 g/day have yet to be studied [12431].

Precautions

Just like any dietary supplement, beta-alanine may be abused if not consumed in a proper fashion; in addition the manufacturers do not typically specify the production purity and presence of trace contaminants, which has received little prior attention. Beta-alanine precautions relate to its potential to induce paraesthesia, characterized by heightened sensitivity of nociceptive neurons that transmit neuropathic pain, which lead to flushing and prickly sensations on the skin. The severity of paraesthesia episodes is dose-dependent but generally last 60 min after ingestion. In some cases beta-alanine intake was curtailed or terminated due to the severity of the paraesthesia. When beta-alanine was consumed as part of a chicken broth elixir at the 40 mg/kg body mass dose no side effects occurred, yet when that same dosage was given as an oral dietary supplement some subjects incurred paraesthesia. Given this finding, it appears in addition to the peak dosage given, the occurrence of beta-alanine-induced paraesthesia episodes may relate to the manner of its administration. It was suggested individual beta-alanine doses should mimic those incurred from a normal diet to limit the risk of paraesthesia. The same project also assessed chronic beta-alanine administration in healthy men. Several dosing strategies were examined; one of which entailed intake of a 10 mg/kg body mass dose three times per day for two weeks. The dosing protocol elicited few side effects that included occasional mild flushing. Two other strategies entailed 3.2 and 6.4 g/day given to healthy men for four weeks in 400–800 mg doses. The four-week protocols produced a few cases of mild paraesthesia and a sore throat.
in one subject. Thus it appears paraesthesia-like symptoms begin at dosages above 10 mg/kg body mass. The prevalence and severity of paraesthesia relate to peak beta-alanine levels in the bloodstream which led to the demand for time-release versions of the supplement. Despite recent studies, unanswered questions still remain. While numerous trials examined its role as an ergogenic aid, the potential of oral beta-alanine intake to improve buffer capacity has yet to be fully quantified. It is thus important to measure, from both in-vitro and in-vivo trials, for a given oral beta-alanine dosage the amount of carnosine accretion, and magnitude of increase in intracellular buffering capacity. Since lactate offers an indication of the degree of H+ accrual and acidosis, measurements of blood lactate concentrations over time foretells concurrent intracellular changes in response to periods of exercise and recovery. In theory beta-alanine intake should permit higher work capacities before acidosis-induced exercise cessation, despite attainment of greater peak blood lactate levels. New trials should compare changes to blood lactate values from supramaximal exercise bouts performed with and without prior beta-alanine supplementation. Until such studies are conducted on physical activity paradigms that entail successive bouts of supramaximal exercise, the true extent of ergogenic effects from beta-alanine will remain unresolved. Future recommendations also include determination of optimal beta-alanine doses for persons based upon their age, gender and nutritional/health practices. The occurrence of paraesthesia in a variety of human subjects, from both standard and time-released versions of the supplement, should continue to be assessed [12431].

**Combined with bicarbonate**

Despite the large variety of so-called ergogenic supplements used by the sporting community, only few of them are effectively supported by scientific proof. One of the recent evidence-based supplements that entered the market is beta-alanine. Beta-alanine is the rate-limiting precursor for the synthesis of the dipeptide carnosine (beta-alanyl-L-histidine) in human muscle. The chronic daily ingestion of beta-alanine can markedly elevate muscle carnosine content, which results in improved exercise capacity, especially in sports that include high-intensity exercise episodes. The use of beta-alanine is exponentially growing in recent years. One chapter aimed to discuss the scientific basis and physiological background of beta-alanine and its synthesis product carnosine, and translate these scientific findings to practical applications in sports [13663].

Enhanced carnosine levels have been shown to be ergogenic for high-intensity exercise performances, although the role of carnosine in the control of muscle function is poorly understood. Therefore, the aim of this study was to investigate the effect of long-term supplementation with increasing doses of carnosine and beta-alanine on muscle carnosine, anserine, and taurine levels and on in vitro contractility and fatigue in mice. Male Naval Medical Research Institute mice (n= 66) were control fed or supplemented with either carnosine (0.1 %, 0.5 %, or 1.8 %) or beta-alanine (0.6 or 1.2 %) in their drinking water for 8-12 wk. Soleus and extensor digitorum longus (EDL) were tested for in vitro contractile properties, and carnosine, anserine, and taurine content were measured in EDL and tibialis anterior by high-performance liquid chromatography. Only supplementation with 1.8 percent carnosine and 1.2 percent beta-alanine resulted in markedly higher carnosine (up to +160 %) and anserine levels (up to +46 %) compared with control mice. Beta-alanine supplementation (1.2 %) resulted in increased fatigue resistance in the beginning of the fatigue protocol in soleus (+2 %-% 4 %) and a marked leftward shift of the force-frequency relation in EDL (10 %-% 31 % higher relative forces). It was concluded that comparable with humans, beta-alanine availability seems to be the rate-limiting step for synthesis of muscle histidine-containing dipeptides in mice. Moreover, muscle histidine-containing dipeptides loading in mice moderately and muscle dependently affects excitation-contraction coupling and fatigue [13664].
One study aimed to investigate if combining beta alanine (BA) and sodium bicarbonate (NaHCO₃) supplementation could lead to enhanced repeated-sprint performance in team-sport athletes, beyond what is possible with either supplement alone. Participants (n=24) completed duplicate trials of a repeated-sprint test (3 sets; 6 × 20 m departing every 25 seconds, 4 minutes active recovery between sets) and were then allocated into 4 groups as follows: BA only (n=6; 28 days BA, acute sodium chloride placebo); NaHCO₃ only (n=6; 28 days glucose placebo, acute NaHCO₃); BA/NaHCO₃ (n=6; 28 days BA, acute NaHCO₃); placebo only (n=6; 28 days glucose placebo, acute sodium chloride placebo), then completed duplicate trials postsupplementation. Sodium bicarbonate alone resulted in moderate effect size and "likely" and "very likely" benefit for overall total sprint times (TST) and for each individual set and for first sprint (sets 2 and 3) and best sprint time (sets 2 and 3). Combining BA and NaHCO₃ resulted in "possible" to "likely" benefits for overall TST and for sets 2 and 3. First sprint (set 3) and best sprint time (sets 2 and 3) also showed "likely" benefit after this trial. The BA and placebo groups showed no differences in performance after supplementation. In conclusion, these results indicate that supplementation with acute NaHCO₃ improved repeated-sprint performance more than either a combination of NaHCO₃ and BA or BA alone [13665].

Lack of effect on sprint
Recent research has shown that beta-alanine (BA) supplementation can increase intramuscular carnosine levels. Carnosine is an intramuscular buffer, and it has been linked to improvements in performance, specifically during bouts of high-intensity exercise that are likely limited by muscle acidosis. Therefore, the purpose of one study was to examine the effect of BA supplementation on sprint endurance at 2 different supramaximal intensities. Twenty-one anaerobically trained (4 rugby players, 11 wrestlers, and 60 recreationally strength trained athletes) college-aged men participated in a double-blind, placebo controlled study. The subjects performed an incremental VO₂max test and 2 sprint to exhaustion tests set at 115 and 140 percent of their VO₂max on a motorized treadmill before (PRE) and after (POST) a 5-week supplementation period. During this time, the subjects ingested either a BA supplement or placebo (PLA) with meals. The subjects ingested 4 g/day of BA or PLA during the first week and 6 g/day the following 4 weeks. Capillary blood samples were taken before and after each sprint to determine blood lactate response to the sprint exercise. No significant group (BA, PLA) × intensity), group by time, or group × intensity × time interactions were observed for time to exhaustion. In addition, similar nonsignificant observations were made for lactate response to the sprint group. From the results of this study, it was concluded that beta-alanine supplementation did not have a significant effect on sprint endurance at supramaximal intensities [13666].

Running
Beta-alanine supplementation has been shown to improve exercise performance in short-term, high-intensity efforts. The aim of one study was to assess if beta-alanine supplementation could improve 800 m track running performance in male recreational club runners (n=18). Participants completed duplicate trials (2 presupplementation, 2 postsupplementation) of an 800 m race, separated by 28 days of either beta-alanine (n=9; 80 mg/kg BM/day) or placebo (n=9) supplementation. Using ANCOVA (presupplementation times as covariate), postsupplementation race times were significantly faster following beta-alanine, with post- versus presupplementation race times being faster after beta-alanine but not placebo. These improvements were supported by a moderate effect size and a very likely (99 %) benefit in the beta-alanine group after supplementation. Split times (ANCOVA) at 400 m were significantly faster postsupplementation in the beta-alanine group, compared with placebo. This was supported by large effect sizes and a very likely (99 %) benefit at the 400 and 800 m splits when comparing pre- to postsupplementation with beta-alanine. In addition, the first and second halves of the race were faster post- compared with presupplementation.
following beta-alanine (1st half likely 78% chance of benefit; 2nd half very likely 98% chance of benefit). No significant differences between groups or pre- and postsupplementation were observed for postrace blood lactate and pH. It was concluded that overall, 28 days of beta-alanine supplementation (80 mg/kg BM/day) improved 800 m track performance in recreational club runners [13667].

**Biking**

Beta-alanine may benefit short-duration, high-intensity exercise performance. The aim of one randomized double-blind placebo-controlled study was to examine the effects of beta-alanine supplementation on aspects of muscular performance in highly trained cyclists. Sixteen highly trained cyclists (age 24 ± 7 years) supplemented with either beta-alanine (n=8, 65 mg/kg BM) or a placebo (n=8; dextrose monohydrate) over 4 weeks. Pre- and postsupplementation cyclists performed a 4-minute maximal cycling test to measure average power and 30 reciprocal maximal isokinetic knee contractions at a fixed angular velocity of 180°-sec-1 to measure average power/repetition, total work done (TWD), and fatigue index (%). Blood pH, lactate (La-) and bicarbonate (HCO₃⁻) concentrations were measured pre- and postsisokinetic testing at baseline and following the supplementation period. Beta-alanine supplementation was 44 percent likely to increase average power output during the 4-minute cycling time trial when compared with the placebo, although this was not statistically significant. Isokinetic average power/repetition was significantly increased post beta-alanine supplementation compared with placebo (85% likely benefit), while fatigue index was significantly reduced (95% likely benefit). TWD was 89 percent likely to be improved following beta-alanine supplementation; however, this was not statistically significant. There were no significant differences in blood pH, lactate, and bicarbonate between groups. Four weeks of beta-alanine supplementation resulted in worthwhile changes in time-trial performance and short-duration muscular force production in highly trained cyclists [13668].

**Alanine plus creatine**

It has been examined the combination of both creatine and beta-alanine supplements. The hypothesis was that this combination of supplements would provide a significant benefit for strength/power athletes. Results of one study demonstrated that this combination significantly improved the quality of the workout more so than creatine alone. Specifically, improvements in training volume were found to be associated with significantly greater gains in lean body mass and decreases in fat mass [12432].

The effect of beta-alanine (beta-Ala) alone or in combination with creatine monohydrate (Cr) on aerobic exercise performance is unknown. The purpose of this study was to examine the effects of 4 weeks of beta-Ala and Cr supplementation on indices of endurance performance. Fifty-five men (25 years) participated in a double-blind, placebo-controlled study and randomly assigned to one of 4 groups; placebo (PL, n=13), creatine (Cr, n=12), beta-alanine (beta-Ala, n=14), or beta-alanine plus creatine (CrBA, n=16). Prior to and following supplementation, participants performed a graded exercise test on a cycle ergometer to determine VO₂peak, time to exhaustion (TTE), and power output, VO₂, and percent VO₂peak associated with VT and LT. No significant group effects were found. However, within groups, a significant time effect was observed for CrBA on 5 of the 8 parameters measured. These data suggest that CrBA may potentially enhance endurance performance [07339].

The effects of creatine and creatine plus beta-alanine on strength, power, body composition, and endocrine changes were examined during a 10-wk resistance training program in collegiate football players. Thirty-three male subjects were randomly assigned to either a placebo (P), creatine (C), or creatine plus beta-alanine (CA) group. During each testing session subjects were assessed for strength (maximum bench press and squat), power
Wingate anaerobic power test, 20-jump test), and body composition. Resting blood samples were analyzed for total testosterone, cortisol, growth hormone, IGF-1, and sex hormone binding globulin. Changes in lean body mass and percent body fat were greater in CA compared to C or P. Significantly greater strength improvements were seen in CA and C compared to P. Resting testosterone concentrations were elevated in C, however, no other significant endocrine changes were noted. Results of this study demonstrate the efficacy of creatine and creatine plus beta-alanine on strength performance. Creatine plus beta-alanine supplementation appeared to have the greatest effect on lean tissue accretion and body fat composition [06278].

The purpose of one study was to examine the effects of 28 days of beta-alanine (b-Ala) and creatine monohydrate (CrM) supplementation on the onset of neuromuscular fatigue by using the physical working capacity at neuromuscular fatigue threshold (PWCFT) test in untrained men. Fifty-one men (mean age 25) volunteered to participate in this 28-day, double-blind, placebo-controlled study and were randomly assigned to 1 of 4 groups: placebo (PLA; 34 g dextrose; n=13), CrM (5.25 g CrM plus 34 g dextrose; n=12), b-Ala (1.6 g b-Ala plus 34 g of dextrose; n=12), or b-Ala plus CrM (CrBA; 5.25 g CrM plus 1.6 g b-Ala plus 34 g dextrose; n=14). The supplement was ingested 4 times per day for 6 consecutive days, then twice per day for 22 days before posttesting. Before and after the supplementation, subjects performed a continuous incremental cycle ergometry test while a surface electromyographic signal was recorded from the vastus lateralis muscle to determine PWCFT. The adjusted mean posttest PWCFT values (covaried for pretest PWCFT values) for the b-Ala and CrBA groups were greater than those for the PLA group. However, there were no differences between the CrM versus PLA, CrBA versus b-Ala, CrM versus b-Ala, or CrM versus CrBA groups. These findings suggested that b-Ala supplementation may delay the onset of neuromuscular fatigue. Furthermore, there appeared to be no additive or unique effects of CrM versus b-Ala alone on PWCFT [06279].

The effect of beta-alanine (beta-Ala) alone or in combination with creatine monohydrate (Cr) on aerobic exercise performance is unknown. The purpose of one study was to examine the effects of 4 weeks of beta-Ala and Cr supplementation on indices of endurance performance. Fifty-five men (25 years) participated in a double-blind, placebo-controlled study and randomly assigned to one of 4 groups; placebo (PL, n=13), creatine (Cr, n=12), beta-alanine (beta-Ala, n=14), or beta-alanine plus creatine (CrBA, n=16). Prior to and following supplementation, participants performed a graded exercise test on a cycle ergometer to determine VO2peak, time to exhaustion (TTE), and power output, VO2, and percent VO2peak associated with VT and LT. No significant group effects were found. However, within groups, a significant time effect was observed for CrBA on 5 of the 8 parameters measured. These data suggest that CrBA may potentially enhance endurance performance [06280].

Methionine

Methionine is an indispensable amino acid that acts as a substrate, much like the other indispensable amino acids, for building functional muscle proteins. It is clear, however, that methionine also holds a unique role, when compared against the other indispensable amino acids, as it serves as a methyl group donor for DNA/RNA intermediates and for the synthesis of cysteine. Daily methionine requirement, reported as a constituent of the requirement for total sulphur amino acids, is 13-15 mg/kg/day with the risk for toxicity manifesting only at levels exceeding >10-fold excess in humans. Daily requirements of methionine are easily obtained in the diet due to its widespread abundance in meats, eggs, cheeses, fruits and vegetables. However, vegan athletes may need increased self-awareness of daily methionine intake. Supplemental methionine have very little effect for enhancement of the
performance, provided the athlete is healthy and consuming a mixed diet containing an adequate amount of energy to meet training needs. Indeed, methionine is fundamental, together with arginine and glycine, for the endogenous synthesis of creatine. However, there is no evidence to suggest that additional crystalline methionine to normal dietary intake would be more beneficial or even helpful, than oral intake of creatine monohydrate; a supplement that has been shown to increase muscle strength and hypertrophy after resistance training [11523].

**Threonine**

Threonine is one of the nine essential amino acids required by humans. As such, threonine cannot be synthesised endogenously, and thus threonine must be obtained through diet or nutritional supplementation. Foods high in threonine include cottage cheese, poultry, fish, meat, lentils and sesame seeds. In animals, threonine is a primary component of intestinal mucin protein and plasma γ-globulin required for maintaining gut function. Threonine supplementation in chickens, pigs and mice has been shown to elevate serum antibodies against various viruses, providing support for a role of dietary threonine in modulating immune function. In rats, threonine deficiency has been found to depress the synthetic rate of phospholipid and nucleoprotein phosphorus fractions in the liver, resulting in an increase in the deposition of liver fat.3 As far as the author is aware, there is no published research to support threonine supplementation in healthy humans, and as such, there is currently no evidence to suggest that additional threonine can improve athletic performance. However, based on the aforementioned animal research, there may be some potential for threonine supplementation to support immune function, which may be beneficial for athletes, particularly during periods of strenuous training when immune function has been shown to be depressed [12427].

**Tryptophan**

Tryptophan (C\textsubscript{11}H\textsubscript{12}N\textsubscript{2}O\textsubscript{2}) is an essential amino acid which contains an indole functional group and, uniquely among amino acids, binds to albumin in the blood. Mobilisation of fatty acids during exercise leads to an increase in non-esterified fatty acids (NEFA), which compete for the same binding site. The increase in NEFA results in tryptophan becoming unbound. This leads to an increase in the plasma concentration of free tryptophan and thus to an increase in the plasma concentration ratio of free tryptophan : large neutral amino acids, particularly BCAA.5 Tryptophan is a precursor of the neurotransmitter 5-hydroxytryptamine (5-HT, also known as serotonin) which is involved in sleep, mood changes and fatigue. There is evidence that an increase in free and total tryptophan across the blood–brain barrier leads to an increased rate of synthesis of 5-HT and kynurenic acid.6 Central fatigue (emanating from the brain) is an important aspect of exercise-induced fatigue in addition to muscle (peripheral) fatigue. The suppression of voluntary movement due to fatigue is a result of modulation of motor-neuron pathways in both the central and peripheral nervous systems. It has been well documented that this is triggered by tryptophan. Tryptophan supplementation has been prescribed for many years in the general community to alleviate depression. It has also been investigated in relation to sports performance. Two studies have claimed a beneficial effect of acute tryptophan supplementation on exercise capacity, hypothesising that its mood-enhancing effect might reduce the perception of pain or discomfort during exercise. However, other studies have failed to show this effect.10 In fact, given the known role of tryptophan as a key substance in the initial reactions leading to fatigue and perception of fatigue, it seems more likely that tryptophan supplementation and a
consequent increase in the plasma concentration of tryptophan might lead to premature fatigue in, for example, endurance events. Indeed, this has been shown in rats where suppression of tryptophan uptake in the brain, via pretreatment with 2-amino-2-norbornanecarboxylic acid, has been seen to diminish central fatigue and to improve running performance. The availability of tryptophan has been observed to be an important factor in immune system function; however, this has not been studied in the context of exercise. In addition, the potential role of tryptophan as a sleep agent to promote recovery after exercise is a current topic of interest but this has not has not been studied specifically in athletes. Finally, it is important to be aware that, in the late 1980s, cases of eosinophilia-myalgia syndrome (EMS) occurred, including some deaths, in many people using tryptophan supplements. This was generally, but not unanimously, attributed to contamination during synthesis by one manufacturer. As a result, the sale of tryptophan as an isolated over-the-counter (OTC) supplement was banned in most countries. However, OTC tryptophan was reintroduced in many countries in the mid-2000s. In summary, there is currently no evidence that tryptophan supplementation has any beneficial effects on athletes. Indeed tryptophan is known to be a key substance in the initial reactions leading to fatigue and perception of fatigue [12427].

**Tyrosine**

Tyrosine (4-hydroxyphenylalanine) is an amino acid that can be synthesised in the body from phenylalanine. Tyrosine shares a common transport molecule with large neutral amino acids at the blood–brain barrier; therefore an increase in the tyrosine ratio causes an increase in brain tyrosine that would lead to an increase in brain dopamine (DA) and norepinephrine (NE) concentration. Since both DA and NE play a key role in a variety of stress-related behaviors, it is not surprising that tyrosine has been the focus of considerable military interest for its cognitive antistress effects. A series of preclinical, animal studies clearly indicate that tyrosine reduces many of the adverse effects of acute stress on cognitive performance in a wide variety of stressful environments. Although it has been difficult to demonstrate conclusively that tyrosine has beneficial effects in humans, in part due to ethical concerns, most of the evidence suggests that tyrosine has utility as an acute treatment to prevent stress-related declines in cognitive function. Tyrosine affects the same neurotransmitter systems as the amphetamines and related drugs, which are potent performance-enhancing compounds, although they have many side effects. Studies examining acute tyrosine supplementation could not show benefits either on prolonged exercise capacity or performance in temperate conditions. A recent study showed that supplementing tyrosine 1 h pre-exercise is associated with increased exercise capacity in the heat [12427].

**Valine**

Valine is an EAA which, together with leucine and isoleucine, is classified as a BCAA. The investigation of valine, in isolation from other BCAA, has received little attention. Valine is involved as a precursor for anaplerosis of the succinyl-CoA in the tricarboxylic acid (TCA) cycle but it has been shown, in combination with other BCAA, that it does not alter the TCA cycle pool expansion during exercise. This limits the use of valine in delaying the decrease of the TCA cycle flux during exercise and thus of local muscle fatigue. Alternatively, BCAA have been shown to be effective in stimulating muscle protein synthesis; however, in isolation, valine has been shown to induce an inferior anabolic signalling response in vitro when compared with leucine and other EAA. As previously reviewed, BCAA may also have a role in reducing central fatigue. Valine alone has been shown to support the central fatigue hypothesis by attenuating the exercise-induced rise in 5-hydroxytryptamine in the
hippocampus of rats. At present, despite marketing claims, there is little evidence to support the use of valine as an ergogenic aid in isolation from other BCAA and EAA [13676].

**CBEX**

Besides beta-alanine supplementation, CBEX is also used, mainly in Japan, to elevate muscle carnosine stores. CBEX, obtained via hot water extraction of chicken breast, is a rich source of HCD, like anserine (1.4 g/100 ml) and carnosine (0.6 g/100 ml). An increase in the muscle carnosine content is likely to occur as a result of chronic CBEX supplementation. Long-term CBEX supplementation enhanced the time to exhaustion at the last spurt of a relatively high-intensity endurance performance. It was shown that the acute supplementation with CBEX (0.4 g carnosine + 1.1 g anserine) 30 min before 10×5 s repeated sprints, decreased the bicarbonate buffering in blood but did not affect performance. The effect of acute supplementation with histidine-containing dipeptides on blood buffering and high-intensity exercise performance needs further investigation [11241].

**Carnosine (beta-alanyl-l-histidine)**

Chronic oral beta-alanine supplementation can elevate muscle carnosine (beta-alanyl-L-histidine) content and improve high-intensity exercise performance. However, the regulation of muscle carnosine levels is poorly understood. The uptake of the rate-limiting precursor beta-alanine and the enzyme catalyzing the dipeptide synthesis are thought to be key steps. The aims of this study were to investigate the expression of possible carnosine-related enzymes and transporters in both human and mouse skeletal muscle in response to carnosine-altering stimuli. Human gastrocnemius lateralis and mouse tibialis anterior muscle samples were subjected to HPLC and qPCR analysis. Mice were subjected to chronic oral supplementation of beta-alanine and carnosine or to orchidectomy (7 and 30 days, with or without testosterone replacement), stimuli known to, respectively, increase and decrease muscle carnosine and anserine. The following carnosine-related enzymes and transporters were expressed in human and/or mouse muscles: carnosine synthase (CARN5), carnosinase-2 (CNDP2), the carnosine/histidine transporters PHT1 and PHT2, the beta-alanine transporters TauT and PAT1, beta-alanine transaminase (ABAT) and histidine decarboxylase (HDC). Six of these genes showed altered expression in the investigated interventions. Orchidectomy led to decreased muscle carnosine content, which was paralleled with decreased TauT expression, whereas CARN5 expression was surprisingly increased. Beta-alanine supplementation increased both muscle carnosine content and TauT, CARN5 and ABAT expression, suggesting that muscles increase beta-alanine utilization through both dipeptide synthesis (CARN5) and deamination (ABAT) and further oxidation, in conditions of excess availability. Collectively, these data show that muscle carnosine homeostasis is regulated by nutritional and hormonal stimuli in a complex interplay between related transporters and enzymes [12430].

The effects of a submaximum single physical load with a mixed aerobic-anaerobic character (combined rowing test) on the intensity of lipid peroxidation (LPO) processes, antioxidant state of the organism, and rheological properties of blood have been studied in a group of athletes. The administration of natural antioxidants significantly decreased the LPO stress induced by the physical load, reduced the suppression of the antioxidant system of the organism, and normalized the LPO-disturbed hemorheological parameters. Antioxidants such as carnosine, cytamine, and apilac can be used as non-doping means for the accelerated recovery and increase in the physical work capacity in athletes [07357].
Carnosine is an abundant dipeptide in human skeletal muscle with proton buffering capacity. There is controversy as to whether training can increase muscle carnosine and thereby provide a mechanism for increased buffering capacity. This study investigated the effects of 5 weeks sprint training combined with a vegetarian or mixed diet on muscle carnosine, carnosine synthase mRNA expression and muscle buffering capacity. Twenty omnivorous subjects participated in a 5 week sprint training intervention (2-3 times per week). They were randomized into a vegetarian and mixed diet group. Measurements (before and after the intervention period) included carnosine content in soleus, gastrocnemius lateralis and tibialis anterior by proton magnetic resonance spectroscopy ($^1$H-MRS), true-cut biopsy of the gastrocnemius lateralis to determine in vitro non-bicarbonate muscle buffering capacity, carnosine content (HPLC method) and carnosine synthase (CARN) mRNA expression and 6 × 6 s repeated sprint ability (RSA) test. There was a significant diet × training interaction in soleus carnosine content, which was non-significantly increased (+11 %) with mixed diet and non-significantly decreased (-9 %) with vegetarian diet. Carnosine content in other muscles and gastrocnemius buffer capacity were not influenced by training. CARN mRNA expression was independent of training, but decreased significantly in the vegetarian group. The performance during the RSA test improved by training, without difference between groups. It was found a positive correlation between an invasive and non-invasive method for muscle carnosine quantification. In conclusion, the study shows that 5 weeks sprint training has no effect on the muscle carnosine content and carnosine synthase mRNA.

The dipeptide carnosine ($\beta$-alanyl-$l$-histidine) is one of a number of histidine containing dipeptides (HCDs) including anserine ($\beta$-alanyl-$l$-$1$-methylhistidine) and balanine ($\beta$-alanyl-$l$-$3$-methylhistidine). Carnosine is abundant in human muscle tissue: around 20-25 mmol/kg dry muscle was previously considered normal for human skeletal muscle. However, the concentration of carnosine in type II muscle fibres is 1.5-2 times higher than type I. The histidine located imidazole ring in the carnosine molecule has a $pK_a$ of 6.83. As this lies within the transit pH range between rest and exercise of skeletal muscle, carnosine is therefore an effective intracellular buffer. Carnosine is synthesised in situ in muscle by carnosine synthase from beta-alanine and histidine, and degraded by an extracellular dipeptidase, carnosinase. Synthesis in muscle is limited by the availability of beta-alanine produced from uracil degradation in the liver, augmented by ingestion of beta-alanine containing HCDs found in meat. Deprived of a dietary source, vegetarian subjects have lower muscle carnosine concentrations, 10-14 mmol/kg. It has been found that 4 weeks’ dietary supplementation of beta-alanine increased carnosine skeletal muscle concentrations by 40-60 percent, and shown an 80 percent increase after 10 weeks with values exceeding 40 mmol/kg. The increase occurred equally in types I and II muscle fibres, despite initially higher levels in type II. When beta-alanine supplementation was stopped, the muscle carnosine concentration declined slowly back towards the basal level with a half-life of approximately 9 weeks. While strength-trained athletes appear to have higher muscle carnosine concentrations, training alone of up to 12 weeks’ duration had no effect. In addition, acute training had no effect on the increase in muscle carnosine seen with beta-alanine supplementation. The capacity to undertake strenuous bicycle exercise increases with the increase in muscle carnosine following supplementation. Total work done in a cycle exercise test performed at 110 percent power max (expected duration approximately 2.5 min) increased 13 percent after 4 weeks (mean increase in muscle carnosine, 59 %) and 16 percent after 10 weeks (mean increase in muscle carnosine, 80 %). It was suggested that this was the result of the increase in muscle buffering capacity. Further evidence for this comes from a report that beta-alanine supplementation attenuates the fall in blood pH during high-intensity exercise, without affecting blood lactate or bicarbonate concentration. beta-Alanine supplementation has already become an ergogenic aid widely used by athletes at the highest level of international competition. Supplementation doses are typically based on
levels obtained from the ingestion of meats, such as turkey and chicken breast, which are rich in HCDs containing beta-alanine [09343].

Intramuscular carnosine buffers protons (H) in skeletal muscle. It was examined the effects of supplementation with chicken breast meat extract (CBEX) containing carnosine and anserine on hormonal responses to resistance exercise. Twenty-two men were assigned to a CBEX drink group (CBEX containing total 2 g of carnosine and anserine) (n=14) or a placebo drink group (n=8). The subjects ingested the prescribed drink (100 mL) twice daily for 30 days without physical training. Before and after the supplementation period, the subjects completed 5 sets of bilateral knee extension exercises (with a 90-s rest between sets). The magnitude of the increase in exercise-induced free testosterone did not change significantly after supplementation in either group. The blood lactate response to exercise was significantly attenuated after supplementation in both groups. In the CBEX group, the plasma epinephrine and norepinephrine concentrations after exercise were significantly lower after supplementation. The serum growth hormone response to exercise was also significantly reduced in the CBEX group after supplementation. No significant differences in exercise-induced strength reduction (fatigue index) were observed in the 2 groups after supplementation. These results suggest that short-term supplementation with CBEX attenuates the exercise-induced epinephrine, norepinephrine, and growth hormone responses [10245].

Carnosine is a dipeptide with a high concentration in mammalian skeletal muscle. It is synthesized by carnosine synthase from the amino acids L-histidine and beta-alanine, of which the latter is the rate-limiting precursor, and degraded by carnosinase. Recent studies have shown that the chronic oral ingestion of beta-alanine can substantially elevate (up to 80%) the carnosine content of human skeletal muscle. Interestingly, muscle carnosine loading leads to improved performance in high-intensity exercise in both untrained and trained individuals. Although carnosine is not involved in the classic adenosine triphosphate-generating metabolic pathways, this suggests an important role of the dipeptide in the homeostasis of contracting muscle cells, especially during high rates of anaerobic energy delivery. Carnosine may attenuate acidosis by acting as a pH buffer, but improved contractile performance may also be obtained by improved excitation-contraction coupling and defence against reactive oxygen species. High carnosine concentrations are found in individuals with a high proportion of fast-twitch fibres, because these fibres are enriched with the dipeptide. Muscle carnosine content is lower in women, declines with age and is probably lower in vegetarians, whose diets are deprived of beta-alanine. Sprint-trained athletes display markedly high muscular carnosine, but the acute effect of several weeks of training on muscle carnosine is limited. High carnosine levels in elite sprinters are therefore either an important genetically determined talent selection criterion or a result of slow adaptation to years of training. Beta-Alanine is rapidly developing as a popular ergogenic nutritional supplement for athletes worldwide, and the currently available scientific literature suggests that its use is evidence based. However, many aspects of the supplement, such as the potential side effects and the mechanism of action, require additional and thorough investigation by the sports science community [10246].

In this narrative review, it was presented and discussed the current knowledge available on carnosine and beta-alanine metabolism as well as the effects of beta-alanine supplementation on exercise performance. Intramuscular acidosis has been attributed to be one of the main causes of fatigue during intense exercise. Carnosine has been shown to play a significant role in muscle pH regulation. Carnosine is synthesized in skeletal muscle from the amino acids L-histidine and beta-alanine. The rate-limiting factor of carnosine synthesis is beta-alanine availability. Supplementation with beta-alanine has been shown to increase muscle carnosine content and therefore total muscle buffer capacity, with the potential to
elicit improvements in physical performance during high-intensity exercise. Studies on beta-alanine supplementation and exercise performance have demonstrated improvements in performance during multiple bouts of high-intensity exercise and in single bouts of exercise lasting more than 60 s. Similarly, beta-alanine supplementation has been shown to delay the onset of neuromuscular fatigue. Although beta-alanine does not improve maximal strength or VO2max, some aspects of endurance performance, such as anaerobic threshold and time to exhaustion, can be enhanced. Symptoms of paresthesia may be observed if a single dose higher than 800 mg is ingested. The symptoms, however, are transient and related to the increase in plasma concentration. They can be prevented by using controlled release capsules and smaller dosing strategies. No important side effect was related to the use of this amino acid so far. In conclusion, beta-alanine supplementation seems to be a safe nutritional strategy capable of improving high-intensity anaerobic performance [10247].

Carnosine is found in high concentrations in skeletal muscles, where it is involved in several physiological functions. The muscle carnosine content measured within a population can vary by a factor 4. The aim of one study was to further characterize suggested determinants of the muscle carnosine content (diet, gender and age) and to identify new determinants (plasma carnosinase activity and testosterone). It was investigated a group of 149 healthy subjects, which consisted of 94 men (12 vegetarians) and 55 women. Muscle carnosine was quantified in M. soleus, gastrocnemius and tibialis anterior using magnetic resonance proton spectroscopy and blood samples were collected to determine CNDP1 genotype, plasma carnosinase activity and testosterone concentrations. Compared to women, men have 36, 28 and 82% higher carnosine concentrations in M. soleus, gastrocnemius and tibialis anterior muscle, respectively, whereas circulating testosterone concentrations were unrelated to muscle carnosine levels in healthy men. The carnosine content of the M. soleus is negatively related to the subjects’ age. Vegetarians have a lower carnosine content of 26% in gastrocnemius compared to omnivores. In contrast, there is no difference in muscle carnosine content between omnivores with a high or low ingestion of β-alanine. Muscle carnosine levels are not related to the polymorphism of the CNDP1 gene or to the enzymatic activity of the plasma carnosinase. In conclusion, neither CNDP1 genotype nor the normal variation in circulating testosterone levels affects the muscular carnosine content, whereas vegetarianism, female gender and increasing age are the factors associated with reduced muscle carnosine stores [11282].

Carnosine (beta-alanyl-L-histidine) and its methylated analogues anserine (beta-alanyl-N1-methylhistidine) and balenine (beta-alanyl-N3-methylhistidine) are histidine-containing dipeptides (HCDs) present abundantly in mammalian skeletal muscles. Carnosine is the only HCD found in human skeletal muscles, whereas all three HCDs are present in the omnivorous human diet. In an attempt to understand the role of carnosine in human muscle, it was searched for a carnosine loading protocol. They showed that beta-alanine supplementation (4-6 g/day) for several weeks (4-10 weeks) resulted in elevated muscle carnosine levels (up to 80 %) [11241].

Because carnosine is located in other excitable tissues other than skeletal muscle, such as the brain and heart, it appears to have additional physiological roles. Some studies have suggested that carnosine may serve as a neuroprotector, possibly aiding in the treatment and prevention of neurodegenerative disorders induced by oxidative stress and antiaging activity. Carnosine is composed of the amino acids beta-alanine and histidine. However, its ability to be absorbed from the circulation by muscle is limited; therefore, it needs to be synthesized within the skeletal muscle. Because the skeletal muscle has a relatively low concentration of beta-alanine, but a high concentration of histidine and carnosine synthetase (the enzyme responsible for carnosine synthesis), beta-alanine becomes the rate-limiting step in carnosine synthesis. Supplementing with beta-alanine (3.2 to 6 g/day) for 4 weeks
has resulted in increases of carnosine concentrations within the skeletal muscle between 37 and 64 percent). Recently, it was demonstrated that 1.6 g/day was sufficient to increase muscle carnosine over a 2-week period. It was concluded that the increase in carnosine is dependent on the total beta-alanine consumed over time and is not dependent on baseline muscle carnosine, the muscle fiber type, or daily amount of supplemented beta-alanine. Carnosine is found primarily in human fast-twitch (type II) skeletal muscle and is estimated to contribute up to 40 percent of the skeletal muscle’s buffering capacity of H^+ that are produced during a high-intensity exercise. The increase in Ca^{2+} sensitivity from greater carnosine concentrations within the skeletal muscle has been demonstrated to enhance the excitation-contraction coupling, potentially reducing the rate of fatigue during muscle performance [12432].

Carnosine is a dipeptide of beta-alanine and L-histidine found in high concentrations in skeletal muscle. Combined with beta-alanine, the pKa of the histidine imidazole ring is raised to 6.8, placing it within the muscle intracellular pH high-intensity exercise transit range. Combination with beta-alanine renders the dipeptide inert to intracellular enzymic hydrolysis and blocks the histidinyl residue from participation in proteogenesis, thus making it an ideal, stable intracellular buffer. For vegetarians, synthesis is limited by beta-alanine availability; for meat-eaters, hepatic synthesis is supplemented with beta-alanine from the hydrolysis of dietary carnosine. Direct oral beta-alanine supplementation will compensate for low meat and fish intake, significantly raising the muscle carnosine concentration. This is best achieved with a sustained-release formulation of beta-alanine to avoid paresthesia symptoms and decreasing urinary spillover. In humans, increased levels of carnosine through beta-alanine supplementation have been shown to increase exercise capacity and performance of several types, particularly where the high-intensity exercise range is 1-4 min. Beta-alanine supplementation is used by athletes competing in high-intensity track and field cycling, rowing, swimming events and other competitions [13669].

Carnosine was first discovered in skeletal muscle, where its concentration is higher than in any other tissue. This, along with an understanding of its role as an intracellular pH buffer has made it a dipeptide of interest for the athletic population with its potential to increase high-intensity exercise performance and capacity. The ability to increase muscle carnosine levels via beta-alanine supplementation has spawned a new area of research into its use as an ergogenic aid. The current evidence base relating to the use of beta-alanine as an ergogenic aid is reviewed here, alongside our current thoughts on the potential mechanism(s) to support any effect. There is also some emerging evidence for a potential therapeutic role for carnosine, with this potential being, at least theoretically, shown in ageing, neurological diseases, diabetes and cancer. The currently available evidence to support this potential therapeutic role is also reviewed here, as are the potential limitations of its use for these purposes, which mainly focusses on issues surrounding carnosine bioavailability [13670].

Little research has been done on the physiological and performance effects of altitude training on team-sport athletes. Therefore, this study examined changes in 2000-m time-trial running performance (TT), hemoglobin mass (Hbmass), and intramuscular carnosine content of elite Australian Football (AF) players after a preseason altitude camp. Thirty elite AF players completed 19 days of living and training at either moderate altitude (about 2130 m; ALT, n=21) or sea level (CON, n=9). TT performance and Hbmass were assessed preintervention (PRE) and postintervention (POST1) in both groups and at 4 weeks after returning to sea level (POST2) in ALT only. Improvement in TT performance after altitude was likely 1.5 percent (± 4.8-90 % CL) greater in ALT than in CON, with an individual responsiveness of 0.8 percent. Improvements in TT were maintained at POST2 in ALT. Hbmass after altitude was very likely increased in ALT compared with CON (2.8 % ± 3.5 %),
with an individual responsiveness of 1.3 percent. Hbmass returned to baseline at POST2. Intramuscular carnosine did not change in either gastrocnemius or soleus from PRE to POST1. A preseason altitude camp improved TT performance and Hbmass in elite AF players to a magnitude similar to that demonstrated by elite endurance athletes undertaking altitude training. The individual responsiveness of both TT and Hbmass was approximately half the group mean effect, indicating that most players gained benefit. The maintenance of running performance for 4 weeks, despite Hbmass returning to baseline, suggests that altitude training is a valuable preparation for AF players leading into the competitive season [13671].

Carnosine occurs in high concentrations in human skeletal muscle and assists working capacity during high-intensity exercise. Chronic beta-alanine (BA) supplementation has consistently been shown to augment muscle carnosine concentration, but the effect of training on the carnosine loading efficiency is poorly understood. The aim of one study was to compare muscle carnosine loading between trained and untrained arm and leg muscles. In a first study (n=17), reliability of carnosine quantification by proton magnetic resonance spectroscopy (1H-MRS) was evaluated in deltoid and triceps brachii muscles. In a second study, participants (n=35; 10 nonathletes, 10 cyclists, 10 swimmers, and 5 kayakers) were supplemented with 6.4 g/day of slow-release BA for 23 days. Carnosine content was evaluated in soleus, gastrocnemius medialis, and deltoid muscles by 1H-MRS. All the results are reported as arbitrary units. In the nonathletes, BA supplementation increased carnosine content by 47 percent in the arm and 33 percent in the leg muscles (not significant). In kayakers, the increase was more pronounced in arm (deltoid) vs. leg (soleus + gastrocnemius) muscles whereas the reverse pattern was observed in cyclists. Swimmers had significantly higher increase in carnosine in both deltoid and gastrocnemius muscle compared with nonathletes. It was shown that carnosine content can be reliably measured by 1H-MRS in deltoid muscle, carnosine loading is equally effective in arm versus leg muscles of nonathletes, and carnosine loading is more pronounced in trained versus untrained muscles [13672].

Carnosine (beta-alanyl-L-histidine) was discovered in 1900 as an abundant non-protein nitrogen-containing compound of meat. The dipeptide is not only found in skeletal muscle, but also in other excitable tissues. Most animals, except humans, also possess a methylated variant of carnosine, either anserine or ophidine/balenine, collectively called the histidine-containing dipeptides. One review aimed to decipher the physiological roles of carnosine, based on its biochemical properties. The latter include pH-buffering, metal-ion chelation, and antioxidant capacity as well as the capacity to protect against formation of advanced glycation and lipoxidation end-products. For these reasons, the therapeutic potential of carnosine supplementation has been tested in numerous diseases in which ischemic or oxidative stress are involved. For several pathologies, such as diabetes and its complications, ocular disease, aging, and neurological disorders, promising preclinical and clinical results have been obtained. Also the pathophysiological relevance of serum carnosinase, the enzyme actively degrading carnosine into L-histidine and beta-alanine, is discussed. The carnosine system has evolved as a pluripotent solution to a number of homeostatic challenges. L-Histidine, and more specifically its imidazole moiety, appears to be the prime bioactive component, whereas beta-alanine is mainly regulating the synthesis of the dipeptide. This paper summarizes a century of scientific exploration on the (patho)physiological role of carnosine and related compounds. However, far more experiments in the fields of physiology and related disciplines (biology, pharmacology, genetics, molecular biology, etc.) are required to gain a full understanding of the function and applications of this intriguing molecule [13673].
Beta-alanine (BA) supplementation has been shown to delay neuromuscular fatigue as a result of increased muscle carnosine concentrations. Carnosine has also been found in brain and cardiac tissue. The physical working capacity test at heart rate threshold (PWC_{HRT}) is a global estimate of the onset of fatigue during exercise, influenced by central and peripheral factors. The purpose of this study was to determine the effects of 28 days of BA supplementation on the PWC_{HRT}.

Thirty subjects (age 21 ± 2 years) were randomly assigned to BA (n=15) or placebo (PL, n=15) groups. Testing included eight to nine total visits: an enrolment day, physical screening, peak oxygen consumption (VO_{2peak}) and two PWC_{HRT} assessments over 4 days. Significant differences existed between BA and PL for PWC_{HRT}, but not for VO_{2peak}, time to exhaustion (TTE) or ventilatory threshold (VT). Results suggest that BA may increase heart rate training threshold. These results, in combination with one previous study reporting a potential effect of BA on HR, suggest that future studies should evaluate both central and peripheral aspects of fatigue with BA intake [13674].

**With and without sodium bicarbonate**

To examine the effect of beta-alanine only and beta-alanine with sodium bicarbonate supplementation on 2,000-m rowing performance 20 well-trained rowers (age 23 ± 4 years) were assigned to either a placebo or beta-alanine (6.4 g/d for 4 weeks) group. A 2,000-m rowing time trial (TT) was performed before supplementation (Baseline) and after 28 and 30 days of supplementation. The post supplementation trials involved supplementation with either maltodextrin or sodium bicarbonate in a double-blind, crossover design, creating four study conditions (placebo with maltodextrin; placebo with sodium bicarbonate; beta-alanine with maltodextrin; beta-alanine with sodium bicarbonate). Blood lactate, pH, bicarbonate, and base excess were measured pre-TT, immediately post-TT and at TT+5 min. Performance data were analyzed using magnitude based inferences. Beta-alanine supplementation was very likely to be beneficial to 2,000-m rowing performance, with the effect of sodium bicarbonate having a likely benefit. There was a small but possibly beneficial additional effect when combining chronic beta-alanine supplementation with acute sodium bicarbonate supplementation compared with chronic beta-alanine supplementation alone. Sodium bicarbonate ingestion led to increases in plasma pH, base excess, bicarbonate, and lactate concentrations. It was concluded that chronic beta-alanine and acute sodium bicarbonate supplementation alone had positive effects on 2,000-m rowing performance. The addition of acute sodium bicarbonate to chronic beta-alanine supplementation may further enhance rowing performance [13675].

**Effect of training**

Chronic training does appear to have a profound effect on muscle carnosine concentrations. One of the primary physiological adaptations from anaerobic conditioning programs is an enhanced buffering capacity. It has been demonstrated that highly trained anaerobic athletes have a greater buffering capacity and a significantly greater skeletal muscle concentration of carnosine than endurance trained athletes and untrained subjects. Sprinters also have been reported to have muscle carnosine concentrations ranging between 17 and 25 mmol/kg of dry muscle, which is significantly higher than that typically found in endurance athletes, untrained individuals, and the elderly. There is a positive relationship is reported between muscle carnosine concentrations and mean power during a 30-s sprint. Considering that most of the available evidence to date indicates that neither short-term nor long-term high-intensity training regimens can elevate muscle carnosine concentrations, the method that appears to best increase muscle carnosine content is supplementing with beta-alanine [12432].
Citrulline

Citrulline is a non-essential alpha-amino acid (C_6H_13N_3O_3) found in protein-rich foods of both animal and plant origin. The body uses it to synthesise arginine, a precursor of nitric oxide (NO) production. In fact, citrulline supplementation appears to be more effective in increasing plasma arginine concentration than the ingestion of arginine itself. Citrulline is also an intermediate in the urea cycle, an important pathway that removes ammonia from muscle and liver cells. Despite some reported benefits of citrulline supplementation in clinical populations, few studies have investigated its potential benefits for athletic performance. Surprisingly, one study found a potentially blunted NO production and a reduction in treadmill time to exhaustion after ingestion by healthy volunteers of 3 and 9 g L-citrulline over 24 h before testing. However, a field study showed that ingesting 6 g citrulline malate before a cycling event increased post-race NO concentration in polymorphonuclear neutrophils compared with a control group, potentially reducing exercise-induced immunodepression. Currently, there is no conclusive evidence that citrulline ingestion enhances athletic performance [10251].

Low calorie diets are designed to reduce body weight and fat mass, but they also lead to a detrimental loss of lean body mass, which is an important problem for overweight people trying to lose weight. In this context, a specific dietary intervention that preserves muscle mass in people following a slimming regime would be of great benefit. Leucine (LEU) and Citrulline (CIT) are known to stimulate muscle protein synthesis (MPS) in post-prandial and post-absorptive state, respectively. This makes them interesting bioactive components to test in the context of dietary restriction. It was tested the concept of combining LEU and CIT in adult female rats. It was postulated that the sequential administration of LEU (mixed in chow) and CIT (given in drinking water before a rest period) could be beneficial for preservation of muscle function during food restriction. Sixty female rats (22 weeks old) were randomized into six groups: one group fed ad libitum with a standard diet (C) and five food-restricted groups (60 % of spontaneous intake for 2 weeks) receiving a standard diet (R group), a CIT-supplemented diet (0.2 or 1 g/kg/day, CIT0.2 group and CIT1 group, respectively), a LEU-supplemented diet (1.0 g/kg/day) or a CIT + LEU-supplemented diet (CIT + LEU 1.0 g/kg/day each). At the end of the experiment, body composition, muscle contractile properties and muscle protein synthesis (MPS) rate were studied in the tibialis anterior muscle. Dietary restriction tended to decrease MPS and decrease muscle strength. Only CIT administration (1 g/kg) was able to restore MPS and increase muscle maximum tetanic force and muscle strength LEU had no effect and CIT + LEU supplementation had few effects, limited to adipose mass and fatigue force. The results of this study highlight the ability of CIT alone to preserve muscle function during dietary restriction. Surprisingly, LEU antagonized some effects of CIT. The mechanisms involved in this antagonistic effect warrant further study [13680].

Aspartate and asparagine

Aspartate is a non-essential amino acid (C_4H_7NO_4). The normal daily requirement of L-aspartate in humans is approximately 2 g. It is found mainly in meat, fish, seafood (0.6-2.6 g/100 g), cheese (1.2-2.9 g/100 g) and eggs (1.3-1.5 g/100 g); less in plant sources. The main purported ergogenic effects of aspartate supplementation are increased exercise endurance and attenuation of exercise-induced hyperammonaemia. Six rat studies showed increased endurance time from 15 percent to 111 percent; six rat and one dog studies showed no positive effect on endurance exercise. In humans, the first supplementation study
showed 51 percent increased time to exhaustion. Two studies reported increased endurance time during cycling exercise (15 %, 16 %) versus five studies with no effects on endurance exercise. No correlation has been found between the dosage of aspartate and increments of exercise time. Claims of glycogen-sparing, reduced hyperammonaemia or a higher rate of free fatty acid oxidation are not confirmed by the aspartate literature. Aspartate has not been shown to increase muscle endurance or strength. When combined with asparagine (C₆H₁₀N₂O₃), aspartate supplementation resulted in a significantly longer time to exhaustion in rats with lower blood lactate levels and skeletal muscle and liver glycogen degradation. However, a recent study performed in 15 triathletes did not confirm the results obtained in rats [09135].

**Aspartame**

Aspartame (C₁₄H₁₈N₂O₅) is an example of an intense or non-nutritive sweetener and an ingredient of many thousands of drink and food products consumed worldwide. It is a methyl ester of a dipeptide composed of the amino acids aspartic acid and phenylalanine, which are constituents of all protein-containing foods. Aspartame is about 180 times sweeter than sucrose with, for most individuals, minimal bitterness and a good quality of sweet taste. Being composed of amino acids, it has an energy value of 4 kcal/g; however, at the concentrations needed to sweeten foods and drinks, its nutritive value is negligible. In products it may be blended with one or more other intense sweeteners or with sugars, including sucrose, fructose and glucose. The safety of aspartame has been the subject of much, often ill-informed, debate. After ingestion, aspartame is broken down to its constituent amino acids and methanol, and some further minor products. Even at high dietary intakes of aspartame, the amount of methanol produced is too small to be harmful. Because high intakes of phenylalanine are undesirable for those born with phenylketonuria, products with aspartame may contain information such as “Contains a source of phenylalanine.” By replacing sugars in products, intense sweeteners can potentially aid control of energy intake and weight, but the extent of any benefit would appear to be dependent on the context of use. Additionally, aspartame reduces appetite independent of its sweet taste by a physiological action which is currently unknown. Aspartame, and other intense sweeteners, are used in sport drinks to allow adjustment of nutrient profile and tonicity, while maintaining a pleasant level of sweetness. The flavour and sweetness of such products are important for motivating consumption, and thereby achieving desired levels of hydration and nutrient intake [09344].

**Glycine**

Glycine is the smallest amino acid; it is non-essential and can be synthesised from serine. Glycine is present in most proteins and is particularly highly concentrated in collagen. Consequently, one of the highest food sources of glycine is gelatin. Glycine is also one of the three amino acid components of glutathione, which is a key component of the body’s defences against oxidative stress; however, it is thought that glycine availability is not the limiting step in glutathione synthesis. Glycine ingestion increases plasma concentrations of insulin in a similar way to other amino acids. Glycine is also an inhibitory neurotransmitter. There is little research on supplementation with glycine. Research has looked at its potential role in decreasing inflammation. Sport specific research has focused on combining glycine with other nutrients. Glycine-propionyl-L-carnitine (GPLC) has been shown to influence exercise performance, decrease oxidative stress and potentially increase vasodilation through increases in plasma nitrate. At present, there is insufficient evidence to suggest the use of glycine as a supplement to enhance sporting performance. However, further research
on the effectiveness of GPLC is warranted [11241].

**Glycine-arginine-alpha-ketoisocaproic acid**

Oral supplementation with glycine-arginine-alpha-ketoisocaproic acid (GAKIC) has previously been shown to improve exhaustive high-intensity exercise performance. There are no controlled studies involving GAKIC supplementation in well-trained subjects. The aim of one study was to examine the effects of GAKIC supplementation on fatigue during high-intensity, repeated cycle sprints in trained cyclists. After at least 2 familiarization trials, 10 well-trained male cyclists completed 2 supramaximal sprint tests each involving 10 s separated by 50-s rest intervals on an electrically braked cycle ergometer. Subjects ingested 11.2 g of GAKIC or placebo (Pl) during a period of 45 min before the 2 experimental trials, administered in a randomized and double-blind fashion. In contrast to previous studies in untrained individuals, the results suggested that GAKIC has no ergogenic effect on repeated bouts of high-intensity exercise in trained individuals [11242].

Glycine-arginine-alpha-ketoisocaproic acid (GAKIC) is a relatively new supplement that athletes and fitness enthusiasts ingest to enhance performance during anaerobic exercise. Therefore, the purpose of this study was to investigate the potential ergogenic effects of GAKIC ingestion during multiple bouts of resistance exercise. Seven resistance-trained men participated in a randomized, counterbalanced, double-blind study. Participants were randomly assigned to placebo or GAKIC (10.2 g) and performed 5 sets of 75 percent of 1-repetition maximum leg press to failure. Total load volume was calculated by multiplying the 75 percent of 1-repetition maximum mass lifted by the sum of repetitions to failure. One week later, participants ingested the other supplement (placebo or GAKIC) and performed the same exercise protocol. Blood lactate, glucose, and heart rate were determined preexercise and immediately postexercise. GAKIC supplementation significantly increased leg-press total load volume. Heart rate and blood lactate were significantly increased postexercise compared with preexercise but were not significantly different between GAKIC and placebo. No significant changes were detected for one-repetition maximum and blood glucose. These novel findings suggest that GAKIC increases total work performed during repeated bouts of lower-body resistance exercise. Thus, the data suggest that GAKIC ingestion before weight training may increase the training volume of athletes and resistance-trained individuals [13704].

Glycine-arginine-alpha-ketoisocaproic acid (GAKIC) has been proposed to increase anaerobic high-intensity exercise performance in male subjects. However, the effects of GAKIC ingestion in female subjects have not been studied. Therefore, the purpose of this study was to investigate the effects of GAKIC supplementation on total load volume (i.e., mass lifted) and metabolic parameters during repeated bouts of submaximal leg extensions in college-age females. Nine resistance-trained females participated in a randomized, counterbalanced, double-blind study. Subjects were randomly assigned to placebo or GAKIC (10.2 g) and performed six sets of 50 percent of one repetition maximum leg extensions (two legs simultaneously) to failure. One week later, subjects ingested the other supplement and performed the same exercise protocol. Furthermore, blood lactic acid, blood glucose, and heart rate were also measured preexercise and 5 s after the completion of the exercise protocol (postexercise). GAKIC supplementation significantly increased leg extension total load volume. Heart rate and blood lactic acid were significantly increased postexercise compared to preexercise, but were not significantly different between GAKIC and placebo. Blood glucose was significantly decreased postexercise compared to preexercise, but was not significantly different between GAKIC and placebo. Collectively, these findings suggest
that GAKIC increased lower body resistance performance in trained college-age females; however, these findings are not necessarily generalizable [13705].

**alpha-Ketoglutarate**

AKG is a five-carbon dicarboxylic acid produced in the citric acid cycle from the oxidative decarboxylation of isocitrate. AKG plays a central role in the oxidation of glutamine and glutamate in the small intestine and the rate of AKG formation is important in determining the overall rate of the citric acid cycle. AKG functions as an energy donor, ammonium scavenger, provides a source of glutamine that stimulates protein synthesis, inhibits protein catabolism in muscle and constitutes an important metabolic fuel for cells of the gastrointestinal tract. The majority of studies investigating the effects of AKG have been conducted in animals, however, in humans, AKG has been shown to increase plasma levels of several hormones such as insulin, growth hormone and insulin-like growth factor I significantly, although the mechanisms responsible are poorly understood. Research investigating the effects of AKG on athletic performance is scant and the limited studies that have been conducted have examined the effects of AKG co-ingestion with L-arginine and/or with creatine. Twelve grams of L-arginine α-ketoglutarate (AAKG) per day in three daily doses of 4 g (2 g L-arginine and 2 g AKG) over 8 weeks was found to be safe, well tolerated and positively influenced 1RM bench press and Wingate peak power performance but did not affect body composition or aerobic capacity. Creatine and AAKG supplementation (0.1 g/kg/day creatine+0.075 g/kg/day) for 10 days was found to improve upper body muscle endurance and peak power output on repeated Wingate tests compared to a placebo. These findings, however, should be interpreted with caution because studies investigating the effects of creatine and L-arginine supplementation without the addition of AKG have found positive effects on exercise performance. Currently, there is insufficient evidence to support the use of AKG supplementation to inhibit protein degradation in the muscle, increase muscle mass, promote positive training adaptations and enhance athletic performance. Further research is necessary to investigate the effects of AKG supplementation alone and AKG co-ingestion with other nutrients [11288].

**alpha-Ketoisocaproate**

KIC is a metabolite of the amino acid leucine. beta-Hydroxymethylbutyrate (HMB) is produced from KIC by the enzyme KIC dehydrogenase, and this route of HMB formation is dependent on liver KIC dioxygenase. KIC has been found to have protein-sparing and antinflammatory properties through inhibition of muscle proteolysis and enhancement of protein synthesis. alpha-Ketoisocaproic acid (alpha-KIC) supplementation has been suggested to enhance exercise performance by attenuating exercise-induced muscle soreness and promoting energy supply to the muscle. More specifically, it has been purported that the liver can convert KIC to ketone bodies thereby increasing the energy supply during exercise and alpha-KIC supplementation has also been suggested to spare glucose utilisation by the muscle. Very few studies have examined the effects of alpha-KIC supplementation alone on athletic performance. Acute alpha-KIC supplementation at doses of 1.5 and 9.0 g ingested immediately prior to exercise failed to improve moderate- and high-intensity exercise performance in resistance trained men. Other studies have investigated the co-ingestion of alpha-KIC with other nutrients. alpha-KIC, glycine and L-arginine co-ingestion has been found to enhance high-intensity exercise performance. alpha-KIC and HMB co-ingestion was found to attenuate exercise-induced muscle damage and preserve fat-free mass. However, it is unclear whether these benefits could be attributed to α-KIC supplementation or the other
compounds. At present, there is insufficient evidence to support the use of alpha-KIC supplementation in enhancing exercise performance [11288].

**Proline**

Proline is not considered essential in adult humans, although early work demonstrated a potential benefit of proline when arginine was limiting. Proline is readily available in dairy, meat and eggs, and most plant proteins but can also be synthesised endogenously by two pathways, one arising from ornithine and arginine, or one from glutamine and glutamate. Although the glutamate pathway is considered to be the major route, it is not known how much body proline is derived from the diet or made de novo. Since proline and hydroxyproline (formed post-translationally) comprise approximately 25 percent of the amino acids in collagen, proline is important to skin, bone, cartilage, tendons, ligaments and connective tissues. Proline is degraded via proline oxidase (dehydrogenase) to glutamate or ornithine, and the final fates include polyamines, arginine and entry into the TCA cycle. Proline is an osmoprotectant, a source of superoxide (in the immune system), and plays a role in sensing both energy availability and maintaining protein homeostasis. Hydroxyprolines are present in proteins other than collagen where they play a role in oxygen sensing while hydroxyproline, released from protein degradation, is an antioxidant. Given the importance of proline in growth and wound repair, including the muscle hypertrophy of training, it has been proposed that proline may be conditionally essential. Indeed, proline has been marketed as a supplement for bodybuilders and weight lifters, and for recovery after strenuous exercise. However, there is no direct evidence to support these claims. It is notable that, while circulating proline concentrations decrease during burn injury, dietary supplementation with proline has no effect on plasma proline levels in such patients. Very few studies have looked directly at proline supplementation, though in patients with gyrate atrophy, supplements of up to 488 mg/kg/d are well tolerated. It is, however, not possible to make any claims about the safety or even effectiveness of proline supplements due to an almost complete lack of data. An alternative approach to increase proline availability would be to provide proline precursors (glutamine, ornithine, arginine) as dietary supplements but again there is little evidence that these are effective or even result in increased proline synthesis [12405].

**Amino acids and creatine**

It was aimed to examine the acute hormonal and performance responses to resistance exercise with and without prior consumption of an amino acid/creatine/energy supplement. Eight men performed a resistance-exercise protocol at baseline (BL), 20 min after consuming a supplement (S) consisting of essential amino acids, creatine, taurine, caffeine, and glucuronolactone or a maltodextrin placebo (P). Venous blood samples were obtained before and immediately after (IP), 15 min (15P), and 30 min (30P) after each protocol. Area under the curve of resistance-exercise volume revealed that BL was significantly less than S (10 %) and P (9 %). For fatigue rate, only S was significantly lower than BL. Total testosterone (TT) and growth hormone (GH) were significantly elevated at IP and 15P in all conditions. The GH response was significantly lower, however, in S and P than in BL. The TT and GH responses did not differ between S and P. These results indicated that a supplement consisting of amino acids, creatine, taurine, caffeine, and glucuronolactone can modestly improve high-intensity endurance; however, the anabolic-hormonal response was not augmented [07345].

**Fat**

1823
One study compared the fat metabolism between "a single bout of prolonged exercise" and "repeated bouts of exercise" of equivalent exercise intensity and total exercise duration. Seven men performed three trials: a single bout of 60-min exercise (Single); two bouts of 30-min exercise, separated by a 20-min rest between exercise bouts (Repeated); and rest. Each exercise was performed with a cycle ergometer at 60 percent of maximal oxygen uptake. In the Single and Repeated trials, serum glycerol, growth hormone, plasma epinephrine, and norepinephrine concentrations increased significantly during the first 30-min exercise bout. In the Repeated trial, serum free fatty acids (FFA), acetoacetate, and 3-hydroxybutyrate concentrations showed rapid increases during a subsequent 20-min rest period. During the second 30-min exercise bout, FFA and epinephrine responses were significantly greater in the Repeated trial than in the Single trial. Moreover, the Repeated trial showed significantly lower values of insulin and glucose than the Single trial. During the 60-min recovery period after the exercise, FFA, glycerol, and 3-hydroxybutyrate concentrations were significantly higher in the Repeated trial than in the Single trial. The relative contribution of fat oxidation to the energy expenditure showed significantly higher values in the Repeated trial than in the Single trial during the recovery period. These results indicate that repeated bouts of exercise cause enhanced fat metabolism compared with a single bout of prolonged exercise of equivalent total exercise duration [07362].

Medium-chain triglycerides (MCT) are triglycerides with a fatty acid chain length varying between 6 and 10 carbon atoms. MCT differ from long-chain triglycerides as they are relatively soluble in water and, hence, rapidly hydrolysed and absorbed. MCT are transported in the blood through the portal system, consequently they bypass adipose tissue that makes them less susceptible to hormone-sensitive lipase and deposition into adipose tissue stores. Due to these properties, MCT have been researched for both benefits to exercise performance and health. One review aimed to assess whether MCT are beneficial in either of these situations. MCT have been proposed as a means to maximizing an athlete's ability to maintain their glycogen stores so they can be more competitive. However, only two studies to date have shown an improvement in exercise performance. From a health perspective, MCT increase fat oxidation and energy expenditure as well as reduce food intake and beneficially alter body composition. Results indicate that MCT feeding is ineffective in improving exercise performance and future work should focus on the health benefits and applications of MCT [10518].

Fatty acids are a major component of most diets and can be synthesised endogenously in the human body. They are found in all cells and tissues and are transported between tissues in the bloodstream. Fatty acids are usually linked to other structures, frequently but not exclusively by ester linkages, to form more complex lipids such as triglycerides, phospholipids and sphingolipids. Non-esterified fatty acids (NEFAs), often called "free fatty acids", circulate in the bloodstream and are an important source of energy for skeletal muscle and heart cells. All fatty acids have a common general structure (a hydrocarbon chain (termed the acyl chain) with a carboxyl group at one end and a methyl group at the other)\(^1\): the reactive carboxyl group readily forms ester links. Individual fatty acids are distinguished by the length of their hydrocarbon chain, and by the absence, presence, number and configuration (cis or trans) of double bonds within that chain. Fatty acids have systematic and trivial names, and there are also several shorthand nomenclatures based upon structural features. Saturated and monounsaturated fatty acids can be synthesised de novo from precursors such as glucose. This occurs mainly in the liver and is promoted by insulin. The simplest polyunsaturated fatty acids (PUFAs), linoleic acid (18:2n-6) and alpha-linolenic acid (18:3n-3), cannot be synthesised in animals including humans. However, they can be synthesised in plants, often abundantly. Because they have important roles in animals but cannot be synthesised de novo, linoleic and alpha-linolenic acids are essential in the diet.
Essential fatty acid deficiency is manifested by typical nutrient deficiency symptoms. However, this condition is rare in humans, being avoided at relatively low intakes of the essential fatty acids. Animals can metabolise essential fatty acids further, inserting additional double bonds (desaturation) and extending the hydrocarbon chain (elongation). Through these processes, linoleic acid can be converted to arachidonic acid (20:4n-6) and alpha-linolenic acid to EPA (20:5n-3). Further metabolism to longer-chain, more unsaturated derivatives is possible (eg, of EPA to DHA (22:6n-3)), although the extent of this conversion is not clear in humans. There is competition between the n-6 and n-3 fatty acid families for metabolism, and so the ratio or balance between these fatty acids appears important. Fat makes an important contribution to dietary energy intake, typically providing 30-40 percent in most Western diets. Most fat occurs as fatty acids esterified into triglycerides. All diets contain many different fatty acids, the relative abundance reflecting the fatty acid composition of the foods eaten. Triglycerides must be extensively hydrolysed before the body can assimilate their constituent fatty acids. This hydrolysis is catalysed by lipase enzymes, chiefly pancreatic lipase, operating in the small intestine. The process of triglyceride digestion is very efficient in most humans. After entering the absorptive cells (enterocytes), fatty acids with hydrocarbon chains of <12 carbons are absorbed directly into the portal blood. However, transport of longer chain fatty acids is more complex. They are first re-esterified into triglycerides, then packaged with phospholipids and apolipoproteins to form chylomicrons, which are secreted into the lymphatic circulation and then enter the bloodstream, having bypassed the liver. Fatty acids within chylomicrons are targeted for uptake and storage in adipose tissue, promoted by lipoprotein lipase action at the endothelial surface. Fatty acids taken up are re-esterified to triglycerides within the adipose tissue and stored in this form. These processes are promoted by insulin. Hydrolysis of stored triglyceride releases the fatty acids, which enter the bloodstream in the non-esterified form: this is promoted by adrenaline, noradrenaline and other stress hormones. Some triglyceride stored within skeletal muscle serves as a local reservoir of fatty acids. The principal roles of fatty acids are as energy sources and membrane constituents. Many types of fatty acid can fill these roles. Certain fatty acids have additional, specific roles, such as serving as precursors for the synthesis of bioactive lipid mediators (eg, prostaglandins), and influencing membrane and intracellular signalling processes, the activation of transcription factors and gene expression. Through these different actions, fatty acids are able to influence cellular functions and thus physiological responses. Fatty acids are oxidised by the process of beta-oxidation which occurs within mitochondria. Oxidation of fatty acids generates more energy than the oxidation of glucose (about 9 cal/g vs about 4 cal/g). Two key points control the rate of fatty acid oxidation:

- intracellular fatty acid concentration which, in turn, is determined by their concentration in the blood, so that a rise in circulating NEFA concentration increases fatty acid oxidation in the tissues using them
- transport of NEFAs (as their coenzyme A esters) from the cytosol into the mitochondria via the carnitine acyl transferase system.

NEFAs become important energy sources during starvation, endurance exercise and other situations where carbohydrate supply is limiting. Glucose and NEFA oxidation is inversely related, so that energy demands of different tissues in different physiological situations can be met by an appropriate, but changing, fuel supply. Importantly, the oxidation of fatty acids requires concurrent glucose oxidation because the movement of acetyl-coenzyme A from fatty acid beta-oxidation into the Krebs cycle needs a supply of oxaloacetate provided from pyruvate, derived from glucose. Fatty acid oxidation cannot maintain the same power output as glucose oxidation, and so performance is decreased as fatty acids contribute increasingly to meeting the demand for energy. It is well known that endurance training regimens can enhance the number of mitochondria and enzyme activities of the Krebs cycle and the beta-
oxidation pathway, so improving NEFA utilisation as a fuel. However, other strategies that have been investigated do not enhance fatty acid oxidation. Among these are “fat loading” (high fat consumption), which may bring about metabolic alterations but does not improve performance, perhaps even impairing the ability to undertake high-intensity exercise when required during an endurance event. Oral L-carnitine has poor bioavailability, and when consumed by itself, it has little impact on tissue carnitine content; only if future studies can resolve this problem will it be able to have a role in increasing fatty acid oxidation. Caffeine promotes NEFA release from stored triglycerides, but this appears to have a limited role in explaining its effects as an ergogenic aid. Increased dietary intake of fatty acids normally consumed in low amounts (eg, long-chain n-3 PUFAs like EPA and DHA) results in the incorporation of these fatty acids into cell membranes, and this might be one mechanism by which dietary fat affects cell function, physiological responses and health. One study suggested that differing fatty acid profiles of skeletal muscle between trained and untrained individuals, despite similar dietary fatty acid composition was a direct consequence of changes in fatty acid metabolism due to increased physical activity. There is no role for supplements aimed at providing saturated or monounsaturated fatty acids or linoleic acid, since these are all consumed in significant amounts from a mixed healthy diet, and the former two classes of fatty acid can be synthesised de novo. There may be a role for supplements aimed at providing those fatty acids which are consumed in lower amounts from the diet and which have general or specific physiological functions or roles in human health or athletic performance. Examples would be alpha-linolenic acid, found in significant amounts in certain plant oils (eg, flaxseed), which acts to increase the status of its derivative EPA: EPA status increase is linearly related to the amount of alpha-linolenic acid provided. Also the long-chain highly unsaturated n-3 PUFAs EPA and DHA found in fish oils and similar supplements and conjugated linoleic acids may be an option [10519].

One study compared the fat metabolism between “a single bout of 30-min exercise” and “three bouts of 10-min exercise” of the same intensity (60 % maximal oxygen uptake) and total exercise duration (30 min). Nine healthy men participated in three trials: (1) a single 30-min bout of exercise (Single), (2) three 10-min bouts of exercise, separated by a 10-min rest (Repeated) and (3) rest (Rest). Each exercise was performed with a cycle ergometer at 60 percent of maximal oxygen uptake, followed by 180-min rest. Blood lactate concentration increased significantly after exercise in the Single and Repeated trials, but the Single trial showed a significantly higher value during the recovery period. No significant difference was observed in the responses of plasma glycerol concentration. The Repeated trial produced a smaller increase in the ratings of perceived exertion during the exercise. During the exercise, no significant difference was observed in respiratory exchange ratio (RER) between the Single and Repeated trials. However, the RER values during the recovery period were significantly lower in the Repeated trial than in the Single and Rest trials, indicating higher relative contribution of fat oxidation in the Repeated trial. These results suggest that the repetition of 10-min of moderate exercise can contribute to greater exercise-induced fat oxidation compared with a single 30-min bout of continuous exercise [11286].

Fish oil and conjugated linoleic acid (CLA) belong to a popular class of food supplements known as “fat supplements”, which are claimed to reduce muscle glycogen breakdown, reduce body mass, as well as reduce muscle damage and inflammatory responses. Sport athletes consume fish oil and CLA mainly to increase lean body mass and reduce body fat. Recent evidence indicates that this kind of supplementation may have other side-effects and a new role has been identified in steroidogenensis. Preliminary findings demonstrate that fish oil and CLA may induce a physiological increase in testosterone synthesis. The aim of this review is to describe the effects of fish oil and CLA on physical performance (endurance and resistance exercise), and highlight the new results on the effects on testosterone
biosynthesis. In view of these new data, it can be hypothesized that fat supplements may improve the anabolic effect of exercise \[13706\].

**Medium-chain triglycerides**

Medium-chain triglycerides (MCTs) are fats in which the fatty acids joined to the glycerol backbone are 6-14 carbon molecules in length. These fats are digested and metabolised differently from the long-chain fatty acids that make up most of our dietary fat intake. Specifically, MCTs can be digested within the intestinal lumen with less need for bile and pancreatic juices than long-chain triglycerides, with the liberated medium chain fatty acids (MCFAs) being absorbed via the portal circulation. MCFAs are then taken up into the mitochondria without the need for carnitine-assisted transport. MCT supplements derived from palm kernel and coconut oil are used in clinical nutrition situations as an energy source for patients who have various digestive or lipid metabolism disorders. Sports related applications of MCTs includes their use by body builders as an easily absorbed and oxidized fuel source that is less likely to deposit as body fat. There has been little investigation of such chronic use apart from some evidence that it may be associated with deterioration in blood lipid profiles. The best studied use of MCTs by athletes is as a source of rapidly accessible fat that can be consumed during exercise to increase fat availability during endurance and ultra-endurance events. In such events, there is both time to consume a fat source and the potential benefits if this leads to a sparing of muscle glycogen use. The maximum rate of oxidation of MCTs occurs after about 120-180 min of exercise and co-ingestion with carbohydrate can increase this rate, possibly by increasing the rate of MCT absorption.\[17\] The literature on supplementation with MCT and carbohydrate during ultra-endurance exercise is inconsistent, with the results appearing to depend on the amount of MCT that can be ingested and the prevailing hormonal conditions. Studies in which the intake of large amounts of MCT raised plasma free fatty acid concentrations and allowed glycogen sparing reported enhancement of a performance trial undertaken at the end of prolonged exercise.\[18\] However, these metabolic (and performance) benefits may be compromised when exercise is commenced with higher insulin levels, as is the case following a carbohydrate-rich pre-exercise meal. The effectiveness of MCT is mostly limited by the inability of subjects to tolerate the substantial amount of MCT oils required to have a metabolic impact. A total intake of about 30 g appears to be the limit of gastrointestinal tolerance of MCT, which would limit its fuel contribution to 3-7 percent of the total energy expenditure during typical ultra-endurance events. Gastrointestinal reactions to larger intakes range from insignificant\[18\] to performance-limiting.\[19\] Differences in gastrointestinal tolerance between or within studies may reflect differences in the type and intensity of exercise, the mean chain length of MCTs found in the supplements or increased tolerance in some athletes due to chronic exposure to MCTs. Despite some support for use during prolonged exercise, MCTs appear to have limited application to most sporting situations [11393].

**Maximal lipid oxidation**

For patients with metabolic diseases, as with other diseases, exercise training is a fully recognized therapy. Such training helps obese patients stabilize weight after slimming. For patients with type 2 diabetics, it is both a prevention and a glucose-lowering treatment and reduces health care costs. It was proposed a targeted training for individuals at the level of maximal lipid oxidation (LIPOX_{max}) with a protocol of exercise calorimetry (four 6-min workloads) based on Brooks and Mercier's crossover concept. Calorimetric interpretation of gas exchange at the fifth and sixth minutes of each stage shows a bell-shaped curve for lipid oxidation that peaks at LIPOXmax, a point that varies considerably among individuals. As well, glucose oxidation is a linear function of power (carbohydrate cost of the watt). Such a
calculation predicts fairly actual lipid oxidation over 45 min at the same level. Other protocols, with 3-min workloads used in sports medicine, are not reliable for patients with metabolic diseases. For obese adults and teenagers, as well as those with type 2 diabetes, 2 months' training at the LIPOXmax (three sessions at 45 min per week) results in a net loss of fat mass, with preserved fat-free mass, and increased ability to oxidize lipids. At the end of this period, training can be "re-targeted" to be more effective and, possibly, associated with other strategies with stronger exercise intensities. Therefore, metabolic training is a viable option for patients with metabolic diseases, but the full concept is still evolving. However, the major challenge remains to transform inactive individuals into active ones.

In cyclists

The objective of one work was to determine whether the young cyclists follow the optimal fats and minerals intake, based on the recommended dietary guidelines. The appropriate intake of fats, fibre, and minerals (sodium, calcium, magnesium, potassium) in their diets; may reduce the risk to develop hypertension and cardiovascular diseases, in the long-term. The correct rehydration is essential in cycling during summer. Nutrients intake questionnaire of 7 consecutive days, applied to 34 young cyclists. The evaluation results are compared with the enKid study of Spanish young people. The diet has been evaluated at the beginning of the cyclist season. A percentage of cyclists in the present study, consume excessive quantities of cholesterol (94 % of cyclists), saturated fats (74 %), and sodium (47 %); while they do not consume the recommended quantities of unsaturated fats (100 %); fibre (67 %), calcium (29 %), magnesium (10 %) and potassium (44 %). This work contributes to the knowledge of the diets followed by very active young people. Their diets show nutritional unbalances; therefore the need to educate the cyclists, their parents and coaches, to follow diets based on the Mediterranean diet; rich in vegetable, fruits, fish, nuts, and olive oil, in order to increase the intake of MUFA, PUFA and minerals, that will protect them against possible risk of cardiovascular diseases.

Fish oil

Both fish oil supplementation and physical exercise are able to induce benefits to mental health by providing an improvement in cognitive performance and enhancing neuropsychology and protection against neurological lesions. The aim of one study was to investigate the cognitive effects in rats of the: a diary and prolonged fish oil supplementation (85 mg/kg/day) initiated from prenatal period to the midlife (300 day/old); moderate physical exercise in treadmill initiated from adolescent period to midlife, and association of fish oil supplementation and moderate physical exercise protocol during the same period. Animals were submitted to the habituation in the open-field, object recognition and to the plus-maze discriminative avoidance tasks. The results demonstrated that a diary and prolonged fish oil supplementation can facilitate the persistence of the long-term habituation and recognition memories without, however, affecting the discriminative avoidance memory. Conversely, although the program of physical exercise exerted no effects on habituation or objects recognition, it was able to potentiate the persistence of the discriminative avoidance memory. Such promnestic effects (induced by both fish oil supplementation and physical exercise) were not accompanied by alterations in emotionality or locomotor activity. The findings suggest that fish oil supplementation, initiated from prenatal period to midlife, and physical exercise program applied throughout the life induced distinctly a better cognitive performance.
Fish oil (FO) supplementation prevents the development of obesity and insulin resistance, and upregulate the expression of UCP3 in skeletal muscle in rodents. This may represent indirect evidence that FO promotes fat oxidation and/or alter energy efficiency. The aim of one study was to evaluate whether such effects can be observed in humans. The metabolic effects of FO were assessed during exercise in order to obtain a direct measurement of energy efficiency. Eight healthy male volunteers were studied with and without supplementation with 7.2 g/day FO (including 1.1 g/day eicosapentaenoic acid and 0.7 g/day docosahexaenoic acid) during 14 days. Their VO$_2$ max was measured on cycle ergometer. Thereafter, energy metabolism (substrate oxidation, energy expenditure and energy efficiency) was assessed during a 30 min cycling exercise at 50 percent VO$_2$ max performed 2 h 30 after a standardized, high carbohydrate breakfast. VO$_2$ max was 39 ± 2 after FO and 38 ± 2 (mL/kg and min) in control conditions, which was a non-significant difference. Basal plasma glucose, insulin and NEFA concentrations, and energy metabolism were similar with FO and in controls. During exercise, the increases in plasma NEFA concentrations, energy expenditure, glucose and lipid oxidation, and the decreases in glycaemia and insulinemia were not altered by FO intake. Energy efficiency was similar in both groups. In order to ascertain that the absence of effects of FO was not due to consumption of a carbohydrate meal immediately before exercise, 4 of the 8 subjects were re-studied in fasting conditions, FO also failed to alter energy efficiency in this subset of studies. It was concluded that FO supplementation did not significantly alter energy metabolism and energy efficiency during exercise in healthy humans.

To investigate the effects of docosahexaenoic-(DHA)-rich fish oil (FO) supplementation on lymphocyte function before and after a marathon race 22 athletes participated in a study. Eight marathon runners were supplemented with 3 g of FO daily for 60 d (FO group), and 13 athletes were not supplemented (C group). The following measures of lymphocytes were taken before and after the marathon: cell proliferation, cytokine production (IL-2, IL-10, TNF-alpha, and IL-4), and signs of cell death. In the C group, the marathon had no effect on lymphocyte proliferation, DNA fragmentation, or mitochondrial membrane polarization; however, the marathon increased phosphatidylserine externalization (by 2.5-fold), induced a loss of plasma membrane integrity (by 20 %), and decreased IL-2, TNF-alpha, and IL-10 production (by 55 %, 95 %, and 50 %, respectively). FO supplementation did not prevent lymphocyte death induced by the marathon, as indicated by cell viability, DNA fragmentation, and phosphatidylserine externalization. However, FO supplementation increased lymphocyte proliferation before and after the marathon, and before the race, FO supplementation decreased IL-2, TNF-a, and IL-10 production in concanavalin-A-stimulated lymphocytes (by 55 %, 95 %, and 58 %, respectively) compared with cells from the C group. The production of cytokines was not altered before or after the race in the FO group. DHA-rich FO supplementation increased lymphocyte proliferation and prevented a decrease in cytokine production, but it did not prevent lymphocyte death induced by participation in the marathon. Overall, DHA rich-FO supplementation has beneficial effects in preventing some of the changes in lymphocyte function induced by marathon participation.

**Omega-3 fatty acids**

Polyunsaturated fatty acids are popular dietary supplements advertised to contribute to weight loss by increasing fat metabolism in liver, but the effects on overall muscle metabolism are less established. It was evaluated the effects of conjugated linoleic acid (CLA) or combination omega 3 on metabolic characteristics in muscle cells. Human rhabdomyosarcoma cells were treated with either DMSO control, or CLA or combination omega 3 for 24 or 48 hours. RNA was determined using quantitative reverse transcriptase polymerase chain reaction (qRT-PCR). Mitochondrial content was determined using flow cytometry and immunohistochemistry. Metabolism was quantified by measuring extracellular
acidification and oxygen consumption rates. Omega 3 significantly induced metabolic genes as well as oxidative metabolism (oxygen consumption), glycolytic capacity (extracellular acidification), and metabolic rate compared with control. Both treatments significantly increased mitochondrial content. It was concluded that omega 3 fatty acids appear to enhance glycolytic, oxidative, and total metabolism. Moreover, both omega 3 and CLA treatment significantly increase mitochondrial content compared with control [12431].

Human beings evolved consuming a diet that contained about equal amounts of omega-6 and omega-3 essential fatty acids. Today, in Western diets, the ratio of omega-6 to omega-3 fatty acids ranges from approximately 10:1 to 20:1 instead of the traditional range of 1:1 to 2:1. Studies indicate that a high intake of omega-6 fatty acids shifts the physiologic state to one that is prothrombotic and proaggregatory, characterized by increases in blood viscosity, vasospasm, and vasoconstriction, and decreases in bleeding time. omega-3 Fatty acids, however, have anti-inflammatory, antithrombotic, antiarrhythmic, hypolipidemic, and vasodilatory properties. Excessive radical formation and trauma during high-intensity exercise leads to an inflammatory state that is made worse by the increased amount of omega-6 fatty acids in Western diets, although this can be counteracted by eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). For the majority of athletes, especially those at the leisure level, general guidelines should include EPA and DHA of about 1 to 2 g/d at a ratio of EPA:DHA of 2:1 [07366].

Increased dietary LCn-3PUFA (long-chain n-3 polyunsaturated fatty acid) intake stimulates muscle protein anabolism in individuals who experience muscle loss due to aging or cancer cachexia. However, it is not known whether LCn-3PUFAs elicit similar anabolic effects in healthy individuals. To answer this question, we evaluated the effect of 8 weeks of LCn-3PUFA supplementation (4 g of Lovaza®/day) in nine 25-45-year-old healthy subjects on the rate of muscle protein synthesis (by using stable isotope-labelled tracer techniques) and the activation (phosphorylation) of elements of the mTOR (mammalian target of rapamycin)/p70S6K (p70 S6 kinase) signalling pathway during basal post-absorptive conditions and during a hyperinsulinaemic-hyperaminoacidaemic clamp. We also measured the concentrations of protein, RNA and DNA in muscle to obtain indices of the protein synthetic capacity, translational efficiency and cell size. Neither the basal muscle protein fractional synthesis rate nor basal signalling element phosphorylation changed in response to LCn-3PUFA supplementation, but the anabolic response to insulin and amino acid infusion was greater after LCn-3PUFA (i.e. the muscle protein fractional synthesis rate during insulin and amino acid infusion increased). In addition, the muscle protein concentration and the protein/DNA ratio (i.e. muscle cell size) were both greater after LCn-3PUFA supplementation. It was concluded that LCn-3PUFAs have anabolic properties in healthy young and middle-aged adults [11438].

The effect of fish-oil supplementation (FO-S) on the immune responses of elite swimmers was investigated. In a randomized placebo-controlled trial, swimmers received either fish-oil capsules (n=10) containing long chain polyunsaturated fatty acids (FA) of n-3 (LCPUFA n-3) or placebo capsules (n=10), both for 6 weeks. Plasma FA, immunological markers, insulin and cortisol were evaluated. The FO-S resulted in an increase in LCPUFA n-3 and a decrease in arachidonic n-6 FA in plasma and a reduction in the production of interferon-gamma by cultured cells. A reduction in the production of tumor necrosis factor-alpha was observed in both groups. An increase in interleukin-2 production and no significant difference in interleukin-4 were also observed. FO-S was able to attenuate the exercise-induced increases in prostaglandin E2. Circulating concentrations of insulin did not change, while cortisol and glucose showed increase after the study period. These results suggest that FO-S influence exercise-associated immune responses in competitive swimmers [07367].
Long-distance migrants have evolved specific adaptations that make their athletic records possible. Unique mechanisms explaining their amazing capacity for endurance exercise have now been uncovered, particularly with respect to energy storage, mobilization, transport and utilization. Birds are champions of migration because flying offers a key compromise: it allows more rapid movement than swimming, but has a lower cost of transport than running. High efficiency for muscle contraction, pointed wings, low wingloading, travelling in V-formations, storing fuel as energy-dense lipids and atrophy of non-essential organs are some of their strategies to decrease the cost of transport. The ability to process lipids rapidly also emerges as a crucial component of the migrant phenotype. High lipid fluxes are made possible by lipoprotein shuttles and fatty acid binding proteins that accelerate lipid transport and by upgrading the metabolic machinery for lipolysis and lipid oxidation. Preparation for long flights can include natural doping on n-3 polyunsaturated fatty acids from unique invertebrate diets. Muscle performance is improved by restructuring membrane phospholipids and by activating key genes of lipid metabolism through peroxisome proliferator-activated receptors (PPARs). The physiological secret to long migrations does not depend on a single 'magic' adaptation but on the integration of multiple adjustments in morphology, biomechanics, behavior, nutrition and metabolism. Research on the physiology of migrants improves the fundamental knowledge of exercise biology, but it also has important implications for wildlife conservation, treating obesity and improving the performance of human athletes [09350].

Wild semipalmated sandpipers (Calidris pusilla) eat n-3 fatty acids to prime their muscles for long migrations. Sedentary bobwhite quails (Colinus virginianus) were used as a model to investigate the mechanisms for this natural doping. The goal of one study was to characterize the stimulating effects of n-3 eicosapentaenoic acid (EPA) and n-3 docosahexaenoic acid (DHA) on oxidative capacity. Mechanisms linked to changes in membrane composition and in gene expression for peroxisome proliferator-activated receptors (PPAR) were investigated. Dietary n-3 fatty acids stimulated the activities of oxidative enzymes by 58-90% (citrate synthase, cytochrome oxidase, carnitine palmitoyl transferase and hydroxyacyl dehydrogenase), and sedentary quails showed the same changes in membrane composition as sandpipers preparing for migration. EPA and DHA have the same doping effect. The substitution of n-6 arachidonic acid by n-3 EPA in membrane phospholipids plays an important role in mediating the metabolic effects of the diet, but results provide no significant support for the involvement of PPARs (as determined by changes in gene expression). The fatty acid composition of mitochondrial membranes and sarcoplasmic reticulum can be monitored by measuring total muscle phospholipids because all phospholipids are equally affected by diet. Only extreme regimes of endurance training can lead to increments in oxidative capacity matching those induced here by diet. As they prepare for long migrations, semipalmated sandpipers improve their physical fitness by eating! Choosing n-3 fatty acid doping over endurance training strikes us as a better strategy to boost aerobic capacity when rapid storage of energy is critical [09351].

The purpose of one study was to test the influence of 2.4 g/d fish oil n-3 polyunsaturated fatty acids (n-3 PUFA) over 6 weeks on exercise performance, inflammation, and immune measures in 23 trained cyclists before and after a 3-d period of intense exercise. Participants were randomized to n-3 PUFA (n=11; 2,000 mg eicosapentaenoic acid, EPA, 400 mg docosahexaenoic acid, DHA) or placebo (n = 12) groups. They ingested supplements under double-blind methods for 6 weeks before and during a 3-day period in which they cycled for 3 hr/d at about 57 percent W,max with 10-km time trials inserted during the final 15 min of each 3-hr bout. Blood and saliva samples were collected before and after the 6 weeks supplementation period, immediately after the 3-hr exercise bout on the third day, and 14 hr postexercise and analyzed for various immune-function and inflammation parameters. Supplementation with n-3 PUFA resulted in a significant increase in plasma EPA and DHA.
but had no effect on 10-km time-trial performance; preexercise outcome measures; exercise-induced increases in plasma cytokines, myeloperoxidase, blood total leukocytes, serum C-reactive protein, and creatine kinase; or the decrease in the salivary IgA:protein ratio. In conclusion, 6 weeks supplementation with a large daily dose of n-3 PUFAs increased plasma EPA and DHA but had no effect on exercise performance or in countering measures of inflammation and immunity before or after a 3-day period of 9 hr of heavy exertion [09352].

The authors evaluated the role of a high-protein, low-calorie, polyunsaturated fatty-acid (PUFA)-supplemented diet on anthropometric parameters, erythrocyte-membrane fatty-acid composition, and plasma antioxidant defenses of nonprofessional volleyball athletes. The athletes were divided in two groups: One (n=5) followed the Mediterranean diet, and the other (n=6) followed a high-protein, low-calorie diet with a 3-g/day fish-oil supplementation. All the athletes had anthropometric measurements taken, both at the beginning and at the end of the study, which lasted for 2 months. Body-mass index and total body fat were significantly diminished in the second group, while they remained unchanged in the first. Plasma total antioxidant activity (TAA) was significantly increased in the plasma of both groups, with no differences between the groups, suggesting that physical activity, not the different diets, is the main contributor to the increase of plasma TAA. The second group showed a significant increase in erythrocyte-membrane PUFA content and in the unsaturation index value (UI) because of the fish-oil supplementation. A high-protein, low-carbohydrate, fish-oil-supplemented diet seems to be useful only when the aim of the diet is to obtain weight loss in a short-term period. The significant increase in the UI of erythrocyte membranes indicates the potential for harm, because a high intake of PUFA might increase susceptibility to lipid peroxidation not counterbalanced by a higher increase in TAA. Adherence to the Mediterranean diet seems to be the better choice [08423].

Docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA) have beneficial effects on cardiovascular function. It was tested the hypotheses that dietary supplementation with DHA (2 g/day) + EPA (3 g/day) enhances increases in stroke volume (SV) and cardiac output (CO) and decreases in systemic vascular resistance (SVR) during dynamic exercise in healthy subjects. It was concluded that safflower oil treatment had no effects on MAP, HR, SV, CO or SVR at rest or during exercise. DHA + EPA-induced increases in stroke volume and cardiac output imply that dietary supplementation with these fatty acids can increase oxygen delivery during exercise, which may have beneficial clinical implications for individuals with cardiovascular disease and reduced exercise tolerance [08424].

The purpose of one investigation was to determine the effects of eicosapentaenoic and docosahexaenoic acid (EPA and DHA) supplementation on resting and exercise-induced inflammation and oxidative stress in exercise-trained men. Fourteen men supplemented with 2224 mg EPA + 2208 mg DHA and a placebo for 6 weeks in a random order, double blind cross-over design (with an 8 week washout) prior to performing a 60 minute treadmill climb using a weighted pack. Blood was collected pre and post exercise and analyzed for a variety of oxidative stress and inflammatory biomarkers. Blood lactate, muscle soreness, and creatine kinase activity were also measured. Treatment with EPA/DHA resulted in a significant increase in blood levels of both EPA and DHA, while no differences were noted for placebo. Resting levels of CRP and TNF-alpha were significantly lower with EPA/DHA compared to placebo. Resting oxidative stress markers were not different. There was a mild increase in oxidative stress in response to exercise. No interaction effects were noted. However, a condition effect was noted for CRP and TNF-alpha, with lower values with the EPA/DHA condition. It was concluded that EPA/DHA supplementation increases blood levels of these fatty acids and results in decreased resting levels of inflammatory biomarkers in exercise-trained men, but does not appear necessary for exercise-induced attenuation in either inflammation or oxidative stress. This may be due to the finding that trained men
Fish oils contain the long-chain highly unsaturated ω-3 (n-3) fatty acids EPA and DHA, although EPA and DHA amounts and their ratio vary according to origin (type of fish, season, location where the fish is caught, etc). Many commonly available fish oils contain about 30 percent EPA plus DHA; more concentrated preparations are available. Most fish oils present fatty acids in triglyceride form, although some supplements provide them as phospholipids, free fatty acids or ethyl esters. All forms have good bioavailability. Fish liver oils, such as cod liver oil, contain higher amounts of vitamins A and D. Typical daily intakes of EPA and DHA are likely to be <200 mg/day, perhaps much less than this, which is below the recommendations made (about 500 mg/day). Thus, supplements can make a substantial contribution to meeting the recommended n-3 intake. When fish oil supplements are consumed, EPA and DHA become enriched within blood lipids, cells and tissues, and influence many aspects of metabolism and physiology; the changes induced are considered to lead to improved health or lowered risk of disease. A daily intake of at least several hundred milligrams of EPA and DHA is apparently required to induce health benefits, but clear threshold doses and dose–response relationships are not established.

Exercise- or athlete-specific benefits of fish oils are not clear because of inconsistencies in the scientific literature. They may improve metabolic changes that occur with exercise and reduce exercise-induced inflammation. Enhanced cardiac function during exercise, perhaps resulting in better oxygen delivery to tissues, has been described following fish oil supplementation in healthy non-athletes. Other studies report no effect of fish oil on maximum aerobic power, anaerobic threshold or exercise performance in athletes. One study reported that fish oil reduced exercise-induced delayed onset muscle soreness, but another study found no effect. These studies typically used moderate (1.8 g/day) to high (4 g/day) doses of EPA plus DHA over several weeks or months, but many studies have studied a small number of subjects. One area yielding some positive results for fish oil supplementation is exercise-induced bronchoconstriction (EIB). A high dose (3.2 g EPA plus 2.0 g DHA daily) for 3 weeks markedly improved lung function postexercise in non-atopic elite athletes with EIB and in asthmatic athletes. Cell culture work suggests that EPA rather than DHA may be responsible, and the benefit may involve novel EPA-derived mediators. Although there are plentiful supplies of body fat on even the leanest athletes, the best efforts of sports scientists to find a way to use supplements to achieve and translate enhanced fat oxidation into performance benefits have not been successful. Therefore, general supplementation of dietary fat by athletes is not warranted. However, interest in supplementation with key fatty acids remains: for example, the fish oil n-3 series, proposed to enhance activities including cardiac function, anti-inflammatory responses and EIB management [10519].

The aim of one investigation was to assess the effects of 6 weeks of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) supplementation on resting and exercise-induced lipid peroxidation and antioxidant status in judoists. Subjects were randomly assigned to receive a placebo or a capsule of polyunsaturated fatty acids (PUFAs; 600 mg EPA and 400 mg DHA). Blood samples were collected in preexercise and postexercise conditions (judo-training session), both before and after the supplementation period. The following parameters were analyzed: α-tocopherol, retinol, lag phase , maximum rate of oxidation (Rmax) during the propagating chain reaction, maximum amount of conjugated dienes (CDmax) accumulated after the propagation phase, nitric oxide (NO) and malondialdehyde (MDA) concentrations, salivary glutathione peroxidase activity, and the lipid profile. Dietary data were collected using a 7-day dietary record. A significant interaction effect between supplementation and time (p < .01) on triglycerides was noted, with values significantly lower in the n-3 long-chain-PUFA (LCPUFA) group after supplementation than in the placebo group. Significant interaction effects between supplementation and time on resting MDA
concentrations and Rmax were found, with elevated values in the n-3 LCPUFA group after supplementation and no change in the placebo group's levels. The authors observed a significantly greater NO and oxidative-stress increase with exercise (MDA, Rmax, CDmax, and NO) in the n-3 LCPUFA group than with placebo. No main or interaction effects were found for retinol and α-tocopherol. These results indicate that supplementation with n-3 LCPUFAs significantly increased oxidative stress at rest and after a judo-training session [10520].

Based on the findings of epidemiological data and recent clinical trials, omega-3 fatty acids seem to have a preventive and therapeutic effect on depression. It was examined the effect of omega-3 fatty acids on the forced-swimming test (FST) in two groups of Sprague-Dawley rats after a six-week treatment with two different diets. Behavioral responses were observed and recorded during the 5-min test. The fatty acid composition from the whole brain tissue and the RBC membrane of the rats were analyzed. Comparing to control diet, omega-3 fatty acid diet significantly decreased the immobility time and increased behaviors of swimming and climbing during the FST. The group in omega-3 fatty acid diet had higher levels of docosahexaenoic acid (DHA, 50% increase) and alpha-linolenic acid (ALA, 63% increase) in the brain, and of eicosapentaenoic acid (EPA, 27% increase) in the peripheral RBC membrane. The level of brain DHA is negatively correlated to the immobility time and is positively correlated to the swimming time. The result shows that omega-3 fatty acids have a beneficial effect on preventing the development of depression-like behaviors in rats with the FST [06269].

**Multi-ingredient performance supplements (MIPS)**

Multi-ingredient performance supplements (MIPS) intended for consumption in close proximity to resistance exercise are extremely popular among young males and athletes. The composition of MIPS varies widely, but the principle ingredients generally include creatine monohydrate, caffeine, beta alanine, the branched chain amino acids (BCAAs) leucine, isoleucine, and valine, as well as L-citrulline, and L-arginine. Resistance training (RT) enhances muscle protein synthesis and hypertrophy while increasing strength and power. Some multi-ingredient performance supplements have been shown to augment the physiological improvements associated with RT. The purpose of one study was to investigate the impact of specific pre- and post-workout MIPS on anabolic hormones, body composition, muscle strength, and power in resistance-trained men participating in a periodized RT program. Twenty-four 24 years) resistance-trained men completed 6 wks of periodized RT (3 times a week). Participants were assigned to one of two groups based upon maximal voluntary contraction of the quadriceps (Biodex) to lean mass (LM) ratio. Group 1 (n=13; MIPS) consumed one serving of NO-Shotgun® (whey protein, casein protein, branched-chain amino acids, creatine, beta alanine, and caffeine) before each workout and one serving of NO-Synthesize® (whey protein, casein protein, branched-chain amino acids, creatine, and beta alanine; Vital Pharmaceuticals, Inc., Davie, FL) immediately after each workout and on non-RT days. Group 2 (n=11; Placebo; PLA) consumed a flavor-matched isocaloric maltodextrin placebo. Serum insulin-like growth factor 1, human growth hormone, testosterone, body composition (DXA), circumferences, 1-repetition maximal strength (1RM) of the upper (chest press) and lower body (leg press), and anaerobic power (Wingate test) were assessed before and after the intervention. Statistical analysis included a 2 x 2 (group x time) ANOVA with repeated measures. There was a main time effect (p = 0.035) for testosterone to increase, but no differences between groups were observed. There were no differences in the other blood hormones. Group x time interactions were observed for LM. Only a main effect of time was noted for circumference measures. Both groups increased upper and lower body 1RM strength to a similar degree. MIPS significantly increased peak
anaerobic power while PLA remained unchanged. Consumption of MIPS during the course of a periodized RT program facilitated training-induced improvement in LM in trained males, whereas the consumption of PLA did not. MIPS improved measures of anaerobic power while PLA did not [12452].

To investigate the effects of an acute multinutrient supplement on game-based running performance, peak power output, anaerobic by-products, hormonal profiles, markers of muscle damage, and perceived muscular soreness before, immediately after, and 24 h following competitive rugby union games 12 male rugby union players ingested either a comprehensive multinutrient supplement (SUPP), or a placebo (PL) for 5 d. Participants then performed a competitive rugby union game (with global positioning system tracking), with associated blood draws and vertical jump assessments pre, immediately post and 24 h following competition. SUPP ingestion resulted in moderate to large effects for augmented 1st half very high intensity running (VHIR). Further, moderate increases in 2nd half VHIR distance and VHIR mean speed in SUPP condition were also apparent. Postgame aspartate aminotransferase (AST) and creatine kinase (CK) measures demonstrated increased values in the SUPP condition, while AST and CK values correlated with 2nd half VHIR distance. Elevated C-reactive protein (CRP) was observed postgame in both conditions; however, it was significantly blunted with SUPP. It was concluded that multinutrient supplement may assist in the maintenance of VHIR during rugby union games, possibly via the buffering qualities of multinutrient supplement ingredients. However, correlations between increased work completed at very high intensities and muscular degradation in multinutrient supplement conditions, may mask any anticatabolic properties of the supplement [10234].

The purpose of one study was to examine changes in performance and metabolic parameters in collegiate soccer players during preseason preparation and to determine the impact of a nutraceutical blend proposed to reduce oxidative stress. Male Division I college soccer players (n=22) performed a progressive maximal treadmill test at the beginning and end of preseason to assess changes in VO\(_{2\text{max}}\), velocity at lactate threshold (VLT), time-to-exhaustion, lipid hydroperoxide (LPO), 8-isoprostane, and creatine kinase (CK) response. After baseline testing, athletes were randomly assigned to receive the nutraceutical blend (EXP; n=12) or an isocaloric equivalent (CON; n=10) for 20 days of preseason training. Delta VO\(_{2\text{max}}\), DeltaVLT, and Delta time-to-exhaustion were improved across groups, but no significant effect of supplementation on performance was seen. Changes in resting levels of CK from the beginning to end of preseason were significantly lower in EXP than in CON. Additionally, EXP demonstrated a significant decrease in the magnitude of the 8-isoprostane response at trial 2 compared with trial 1. A similar pattern was seen for LPO. Preseason training in male college soccer players resulted in significant improvements in VO\(_{2\text{max}}\), VLT, and time-to-exhaustion. Supplementing with a proprietary antioxidant and nutraceutical blend may enhance some of these effects as indicated by magnitude of the responses. However, it appears that the most notable effects of supplementation were seen for reduced CK and oxidative stress, at least with short-term supplementation [10235].

The purpose of one study was to determine the effects of the pre-workout supplement Assault™ (MusclePharm, Denver, CO, USA) on upper and lower body muscular endurance, aerobic and anaerobic capacity, and choice reaction time in recreationally-trained males. Subjective feelings of energy, fatigue, alertness, and focus were measured to examine associations between psychological factors and human performance. Twelve recreationally-trained males participated in a 3-week investigation. Subjects reported to the human performance laboratory on three separate occasions. All participants completed a baseline/familiarization day of testing that included a maximal graded exercise test for the determination of aerobic capacity (VO\(_{2\text{max}}\)), one-rep maximum (1-RM) for bench and leg press to determine 75 percent of 1-RM, choice reaction tests, and intermittent critical velocity
familiarization. Choice reaction tests included the following: single-step audio and visual, one-tower stationary protocol, two-tower lateral protocol, three-tower multi-directional protocol, and three-tower multi-directional protocol with martial arts sticks. Subjects were randomly assigned to ingest either the supplement (SUP) or the placebo (PL) during visit 2. Subjects were provided with the cross-over treatment on the last testing visit. Testing occurred 20 min following ingestion of both treatments. Significant main effects for the SUP were observed for leg press, perceived energy, alertness, focus, choice reaction audio single-step, choice reaction multi-direction 15 s, and multi-direction for 30 s. It was concluded that ingesting the SUP before exercise significantly improved agility choice reaction performance and lower body muscular endurance, while increasing perceived energy and reducing subjective fatigue. These findings suggest that the SUP may delay fatigue during strenuous exercise [12463].
NUTRITIONAL SUPPLEMENTS: TRACE ELEMENTS, VITAMINS AND OTHER OXIDANTS

The purpose of one study was to assess the effect of relative exercise intensity on various plasma trace elements in euhydrated endurance athletes. Twenty-seven well-trained endurance athletes performed a cycloergometer test: after a warm-up of 10 min at 2.0 W/kg, workload increased by 0.5 W/kg every 10 min until exhaustion. Oxygen uptake, blood lactate concentration, and plasma ions (Zn, Se, Mn and Co) were measured at rest, at the end of each stage, and 3, 5 and 7 min post-exercise. Urine specific gravity was measured before and after the test, and subjects drank water ad libitum. No significant differences were found in Urine specific gravity between, before, and after the test or in any plasma ion level as a function of intensity. There were weak significant correlations of Zn and Se with blood lactate concentration but no relationships were established between blood lactate concentration and VO$_2$, fat oxidation, carbohydrate oxidation, energy expenditure from fat, from carbohydrates and total energy expenditure and plasma ion levels. Acute exercise at different submaximal intensities in euhydrated well-trained endurance athletes does not provoke a change in plasma trace element levels, suggesting that plasma volume plays an important role in the homeostasis of these elements during exercise [11287].

Iron

Iron status was assessed in 70 female athletes aged 18-25 years participating in collegiate cross-country track, tennis, softball, swimming, soccer, basketball, and gymnastics. No significant differences in mean hemoglobin, hematocrit, serum iron, total iron-binding capacity, transferrin saturation, and ferritin were found among teams. The mean concentrations of each parameter for each of the teams were within the normal ranges. However, several athletes from different sports had suboptimal iron status indexes. Of 17 athletes with a serum ferritin concentration < 15 microg/L, 8 (4 freshmen, 2 sophomores, 2 unknown) also exhibited low serum iron concentrations (< 60 microg/dL) and low transferrin saturation (< 16 %). Thirteen (6 freshmen, 3 sophomores, 2 juniors, 2 seniors) of 51 (25 %) athletes failed to consume two-thirds of the Recommended Dietary Allowance for iron and exhibited suboptimal serum concentrations of ferritin, iron, and/or transferrin saturation. Of nine athletes taking iron supplements, one exhibited suboptimal iron status. In summary, nonanemic iron depletion was present among female collegiate athletes involved in many different sports and in all years of participation (freshmen, sophomore, junior, and senior athletes). Female athletes should continue to be individually and routinely evaluated for nutritional deficiencies throughout their collegiate athletic careers [06291].

Decrements in iron status have been reported in female soldiers during military training. Diminished iron status adversely affects physical and cognitive performance. It was determined whether iron supplementation could prevent decrements in iron status and improve measures of physical performance and cognitive status in female soldiers during basic combat training. In this 8-wk randomized, double-blind, placebo-controlled trial, soldier volunteers (n=219) were provided with capsules containing either 100 mg ferrous sulfate or a placebo. Iron status indicator assays were performed pre- and post-training. Two-mile running time was assessed post-training; mood was assessed by using the Profile of Mood States questionnaire pre- and post-training. The training course affected iron status: red blood cell distribution width and soluble transferrin receptor were significantly elevated, and serum ferritin was significantly lowered after training. Iron supplementation significantly
attenuated the decrement in iron status; group-by-time interactions were observed for serum ferritin and soluble transferrin receptor. Iron supplementation resulted in significantly improved vigor scores on the Profile of Mood States post-training and in faster running time in volunteers reporting to training with iron deficiency anemia. Thus, iron supplementation may prove to be beneficial for mood and physical performance during the training period [09363].

Iron is an ubiquitous metal of vital importance to normal physiologic processes, is one of these substances. Although the risk of iron deficiency or depletion in athletes is limited to specific situations, namely the female sex, increased training stress, increased iron losses, and poorly balanced vegetarian diets, iron-supplementation therapy is commonplace in athletes to counterbalance physiological or pathological anemia and to prevent physiological dysfunction. Iron supplementation may be initiated on the basis of unproven evidence of performance improvement or it may accompany the administration of erythropoiesis-stimulating substances, as iron bioavailability is crucial in enhancing for example the efficacy of rHuEpo. While an athlete who is iron deficient may not be overtly anemic, he or she may have a hemoglobin level that is less than optimal. Correcting iron deficiency anemia is not blood doping and may improve an athlete's performance. However, taking excessive oral iron supplements cannot increase hemoglobin above the reference range and may occasionally result in iron overload, which is associated with serious metabolic risks. While transferrin saturation is considered an indicator of an underlying genetic defect associated with primary hemochromatosis, the linear relationship between body iron load and serum ferritin makes the measurement of ferritin concentration a suitable approach to assess the total body iron content and detect potential misuse, especially in endurance athletes. Serum ferritin measurement, ordinarily performed in athletes entering elite training programs to identify hematologic and iron-related abnormalities, allows early recognition of iron overload, which may persist for a long time in most athletes after retirement from competition and cessation of excessive iron supplementation [10353].

One study examined iron status and nutrient intake in highly active (physical activity per week, PPA) and sedentary women. Participants completed a 7-day weighed-food record (energy, protein, fiber, alcohol, and micronutrients), 7-day pedometer/activity log, and fasting blood draw (hemoglobin, hematocrit, red blood cell indices, C-reactive protein, serum iron, percent transferrin saturation, total iron-binding capacity, ferritin, transferrin receptor, sTfR, and sTfR index). Significantly lower serum ferritin and mean cell hemoglobin concentrations were found in active than in sedentary women. Significantly higher mean sTfR and sTfR index values were found in the active women. No significant differences were found between groups for the other blood markers. Serum ferritin concentrations (storage iron) indicated iron depletion (stage I) in 21 percent of active and 18 percent of sedentary participants. Nonetheless, 50 percent of active and 18 percent of sedentary participants were iron depleted as evidenced by the sTfR index (ratio of functional-to-storage iron). Elevated sTfR concentrations (functional iron) were observed in 25 percent of active and 3 percent of sedentary participants. Although the active women reported significantly greater iron but similar heme iron intakes, they had higher mean sTfR, higher sTfR index, and lower serum ferritin concentrations than the sedentary women. Assessment of iron status may require measures not commonly used in routine assessments [09364].

Iron deficiency is the most prevalent nutritional disorder in the world and is particularly pertinent in athletes. An altered iron status may range in severity from iron depletion (serum ferritin (SF) <35 microg/L, haemoglobin (Hb) >115 g/L, transferrin saturation >16 %) to iron deficiency anaemia (SF <12 microg/L, Hb <11.5 g/L, transferrin saturation <16 %). It is recognised that optimal physical performance is dependent on the efficient delivery and
utilisation of oxygen by the exercising muscle. Iron is a fundamental element to both of these processes due to its role as the functional component of haemoglobin and myoglobin, as well as being a critical constituent of mitochondrial enzymes and cytochromes that promote oxidative phosphorylation. Insufficient iron stores may thus lead to feelings of lethargy and decrements in athletic performance. There are several reasons why athletes may present with low iron levels, including plasma volume expansion, low dietary iron intake, low iron bioavailability and excessive iron excretion/loss. Furthermore, female athletes are at greater risk of iron deficiency, due to menstrual blood loss and suboptimal dietary intake. During exercise, iron losses can occur from several avenues such as red blood cell haemolysis, haematuria and sweating. Such iron loss mechanisms are dependent on the exercise mode, intensity and duration. Additionally, recent research has demonstrated that the hormone hepcidin may also have an impact on an athlete’s iron stores in the acute postexercise period. As a result of these aforementioned mechanisms of iron loss in athletes, iron replacement in this population is of utmost importance. However, the human body has no internal mechanism to generate its own iron stores, and as such, dietary intake and/or supplementation is the only solution to replacing these iron losses. To maintain sufficient iron stores, it is recommended that a dietary iron intake of 8 mg/day for men and 18 mg/day for women is consumed. The food choices used to attain this daily iron requirement may vary, and will include the ingestion of the more efficiently absorbed haem iron (derived from meat sources; accounting for about 20% of the daily dietary iron intake), and the less efficiently absorbed non-haem iron (derived from plant foods such as spinach, leafy greens, lentils and beans; accounting for about 80 percent of the daily dietary iron intake). With regard to iron supplementation, previous research has demonstrated that an oral iron supplement provided at a dose of 100 mg of ferrous sulphate per day may increase SF levels by 30-50 percent over a 6-8-week period. The absorption of this iron supplement is considered to be more efficient when taken in conjunction with ascorbic acid (i.e. orange juice) and less efficient when taken with caffeinated products (i.e. tea and coffee). As a result, the practitioner may wish to consider the prescription of an oral iron supplement that also contains Vitamin C (i.e. ferro-gradumet C). Although it is recommended, and commonly practiced, to prescribe oral iron supplementation at 100 mg of ferrous sulphate on a daily basis, an ill-tolerance of this supplement may result in side effects such as gastrointestinal distress, constipation and/or black-coloured stools. In the event of such a response, the supplementation protocol may be reduced in consultation with the sports physician, to represent a dosage more tolerable to the individual athlete. Alternatively, the use of intramuscular iron injections may be considered. Ideally, the supplementation regime should be monitored by a blood test every 8-12 weeks in order to screen the athlete’s SF levels. Once the SF has returned to a level that suggests a healthy iron status, the supplementation should cease, since the oxidative nature of excessive iron stores may be toxic to the body. Such a consequence also highlights the dangers of unsupervised and unwarranted iron supplementation. Although it is accepted that the consumption of an oral iron supplement might be effective in improving the physical performance of iron-deficient, anaemic athletes, there is still much debate on the efficacy of such a regime in enhancing the physical performance of iron-deficient, non-anaemic athletes. Some studies have demonstrated significant improvements in running energy efficiency, 15 km running time-trial time and maximal oxygen uptake as a result of oral iron supplementation in iron-deficient, non-anaemic athletes. However, other studies have demonstrated that there is no improvement in athletic performance, despite a regime of oral iron supplementation significantly increasing the SF levels. The likely contrast in such outcomes may result from the different performance parameters and athlete characteristics measured within these studies, thus suggesting that more research is warranted in this area. However, despite the equivocal research to suggest the influence of an oral iron supplement given to iron-depleted, non-anaemic athletes, it is still encouraged that iron supplementation continues to be prescribed to such populations on the basis of preventing iron depletion from potentially progressing to iron deficiency anaemia. As established above, the use of an oral
Iron supplement may take at least 6 to 8 weeks to improve the iron status of an athlete. However, should a faster increase in iron status be required (due to impending competition, extreme fatigue, etc), the use of an intramuscular iron injection may be considered by the sports physician. When comparing such a technique to the ingestion of oral iron tablets, it has been shown that 5×2 mL intramuscular injections of Ferrum H (equivalent to 100 mg of elemental iron), provided over a 10-day period, resulted in a significantly faster and greater increase in SF levels when compared to the ingestion of an oral iron tablet (105 mg of elemental iron), which was consumed over a 30-day period. Although a significantly faster way to improve the iron status of an athlete, to date, the evidence for an improvement in athletic performance from such a regime is negligible, and more research is required into this area of iron supplementation. Additionally, intravenous iron infusions are obviously an even faster method of increasing iron status. However, intravenous infusions are considered a banned method by the World Anti-Doping Agency (WADA) and unless one can justify this method over oral or intramuscular iron replacement. In conclusion, iron-deficient, non-anaemic athletes should, in the first instance, increase their dietary intake of iron (preferably in the form of haem iron) on the advice of a sports dietitian. In addition, depending on the SF levels, clinical symptoms of fatigue, poor performance and response to dietary intake, oral iron supplementation or intramuscular iron injections should be considered in consultation with a sports physician. Finally, there appears to be no indication for iron supplementation in the absence of iron deficiency, and there certainly may be adverse effects with ongoing, unsupervised, iron supplementation [11288].

Iron supplementation for the iron-depleted nonanemic athlete is a controversial issue. Athletes may be iron deficient due to poor dietary intake, significant or obligatory blood loss, or deficiency via increased need secondary to intense physical activity. Athletes who are found to be anemic secondary to iron deficiency do benefit and show improved performance with appropriate iron supplementation. There is contradictory evidence for iron supplementation and improving performance in the iron-depleted nonanemic athlete. An athlete's iron status is usually monitored via serum ferritin. Currently, there is no standardized ferritin level at which supplementation is recommended, nor is there a consensus as to the appropriate maintenance of ferritin. Screening endurance athletes or female athletes in general for iron deficiency and also educating these athletes regarding the importance of a balanced diet to maximize performance would seem prudent and beneficial. Based on the literature, supplementation for the iron-depleted nonanemic athlete does not appear to be justified to solely improve performance [07378].

To evaluate the effect of iron supplementation on physical performance in children (0-18 years) through systematic review of randomised controlled trials (RCTs). RCTs with interventions that included oral or parenteral iron supplementation, fortified formula milk, or cereals were evaluated. The physical performance outcomes studied were heart rate, treadmill endurance times, blood lactate, and oxygen consumption. A total of three studies were included, in all of which iron was supplemented in the form of oral medicinal iron. At 5, 6 and 7 miles per hour running speeds, the pooled weighted mean difference (WMD) in the heart rate (per minute) between the iron and the placebo, following exercise was -7, -6, and -8 respectively. After excluding the study with nonanemic subjects, the corresponding figures were -13, -14, and -13), respectively. Oxygen consumption, estimated in two studies, showed no significant difference between the treatment groups. Blood lactate levels were estimated in one study only at two different doses of iron, and were significantly lower in iron supplemented group in comparison to placebo both before (7.7 and 7.6 mg/dL versus 8.4 mg/dL) and after (14.4 and 14.4 mg/dL versus 16.5 mg/dL) exercise. Treadmill endurance time was significantly better in iron supplemented group when compared with placebo in one study. It was concluded that iron supplementation may have a positive effect on the physical performance of children, as evaluated through the post exercise heart rate in anemic
subjects, blood lactate levels and treadmill endurance time. In view of the limited data availability, this finding cannot be considered conclusive [07379].

To determine the effect of iron supplementation on iron status and endurance capacity 20 iron-deficient (serum ferritin, sFer<16 microg/l; serum transferrin receptor, sTfR>8.0 mg/l; or sTfR/log sFer index >4.5), nonanemic (hemoglobin, Hb>120 g/l, women; >130 g/l, men) men and women (18-41 years) were recruited via fliers and newspaper advertisements; 20 of 31 eligible subjects participated. A 30 mg measure of elemental iron as ferrous sulfate or placebo was given daily for 6 weeks. Dietary iron intake and physical activity did not differ between groups before or after supplementation. Iron supplementation significantly increased sFer compared to placebo, but did not affect Hb or hematocrit. Iron supplementation prevented the decline in ventilatory threshold (VT) observed in the placebo group from pre- to post-supplementation; this effect was greater in individuals with lower sFer before intervention. Changes in sFer from pre- to post-treatment were positively correlated with changes in VT, independent of supplementation. The iron group significantly increased gross energetic efficiency during the submaximal test. Changes in sFer were negatively correlated with changes in average respiratory exchange ratio during the submaximal test. It was concluded that iron supplementation significantly improves iron status and endurance capacity in iron-deficient, nonanemic trained male and female subjects [07380].

This case study examines the impact of low serum ferritin (sFe) on physiological assessment measures and performance in a young female 1500-m runner undertaking approximately 95-130 km/wk training. The study spans 4 race seasons and an Olympic Games. During this period, 25 venous blood samples were analyzed for sFe and hemoglobin (Hb); running economy, VO$_{2\text{max}}$, and lactate threshold were measured on 6 occasions separated by 8-10 mo. Training was carefully monitored including 65 monitored treadmill training runs (targeting an intensity associated with the onset of blood lactate accumulation) using blood lactate and heart rate. Performances at competitive track events were recorded. All data were compared longitudinally. Mean sFe was 24.5 ± 7.6 microg/L (range 10-47), appearing to be in gradual decline with the exception of 2 data points (37 and 47 microg/L) after parenteral iron injections before championships, when the lowest values tended to occur, coinciding with peak training volumes. Each season, 1500-m performance improved, from 4:12.8 in year 1 to 4:03.5 in year 4. VO$_{2\text{max}}$ (69.8 ± 2.0 mL/kg/min) and running economy (%VO$_{2\text{max}}$ at a fixed speed of 16 km/h; max 87.8%, min 80.3%) were stable across time and lactate threshold improved (from 14 to 15.5 km/h). Evidence of anemia (Hb <12 g/dL) was absent. These unique data demonstrate that in 1 endurance athlete, performance can continue to improve despite an apparent iron deficiency. Raising training volume may have caused increased iron utilization; however, the effect of this on performance is unknown. Iron injections were effective in raising sFe in the short term but did not appear to affect the long-term pattern [13709].

**Screening**

The aim of one prospective, cohort study was to determine the clinical and performance related utility of hematological and iron-related screening in elite athletes. Three hundred and three male and 273 female elite athletes underwent routine medical screening over a three-year period. In association with a standard medical consultation, a full blood count and iron-related variables were measured. Ten male athletes had a serum ferritin less than 30 ng/mL and satisfied AIS criteria for iron supplementation. In only one case was a disorder identified which was not expected following the clinical history and examination. Fifty-two female athletes had a serum ferritin less than 30 ng/mL and satisfied AIS criteria for iron supplementation. In the females, there were no instances in which a medical condition was
identified which was not expected following the clinical history and examination. In both groups, clinically non-significant abnormalities were generally minor or isolated reductions in hemoglobin and/or hematocrit, and alterations in red cell parameters or single measures of iron status. It was concluded that screening for hematological and iron-related abnormalities in athletes has a low yield. Due to the critical nature of the effects of anaemia and low serum ferritin on some aspects of performance it is reasonable to perform a haemoglobin and a serum ferritin on male and female athletes entering an elite training program. Isolated abnormalities which are close to the limits of their normal ranges and not accompanied by symptoms or signs of illness can almost certainly be ignored [07381].

Boron

Boron, an element with the atomic number 5, is an essential nutrient for plants, but the physiological role in humans is not fully understood. Boron can be considered as an ultra trace element therefore requirements are micrograms per day. Dietary daily human intake is estimated to range from 2.1 to 4.3 mg of boron per kilogram body weight per day. Boron enters the food chain via its incorporation into plant structure and subsequent consumption by humans. There is little evidence of boron deficiency in humans, however, oral boron supplementation is used in the general health and sports markets. Boron has been linked to increased endogenous testosterone levels, but there is little evidence in the literature using an athletic population to support this. Research investigating boron supplementation in postmenopausal women (after a boron-restricted diet) focused on mineral, estrogen and testosterone metabolism. A supplementation of 3 mg of boron per day was associated with an increase in testosterone levels. No proposed mechanism for increased testosterone was reported; however, the authors suggested that maintenance of adequate boron levels in postmenopausal women might prevent calcium loss and bone demineralisation. Few studies have investigated the effects of boron supplementation on increasing testosterone levels in an athletic population. In a randomised placebo-controlled design including participants who regularly weight-trained for at least 1 year (however, no data were reported describing the trained status of the participants). The volunteers were given either 2.5 mg/day of boron (n=10) or placebo (n=9) for a 7-week period. The results suggested an increase in strength (based on one repetition maximum, squat and bench press), increases in lean tissue and testosterone in both groups. However, there was no evidence that the boron supplementation had any additional effect. Therefore, the changes could be regarded as only due to a training effect. A 10-month boron supplementation study in young female athletes, versus sedentary women, produced a modest effect on mineral status. This included a decrease in serum phosphorus and increased urinary calcium excretion which was greater in athletes than in controls. There is currently little evidence to support the use of boron supplementation in the athletic population [09344].

Boron possesses widespread properties in biochemistry and nutrition. Acute supplementation with 11.6 mg of boron resulted in a significant increase in plasma boron concentration. Given such a fast bioavailability, the objective was to determine whether acute (hourly or daily), and weekly supplementation could have any significant biological effects on the steroid hormones and further on some inflammatory biomarkers. Eight healthy male volunteers attended the laboratory on three occasions (days 0, 1 and 7). On the first day (day 0), a blood sample collection at 8.00 A.M was followed by ingestion of placebo with the breakfast. On the next day (supplementation day 1), similar procedure was followed by ingestion of a capsule containing 10mg of boron. On both occasions blood was collected every 2h for the next 6h. Subjects were requested to consume a capsule of 10mg boron every day with their breakfast, and on the day 7, the blood collection was carried out at 8.00
A.M. again. Boron in plasma increased significantly following hours and weekly consumption. Six hours supplementation showed a significant decrease on sex hormone binding globulin high sensitive CRP, and TNF-alpha level. After one week (in samples taken at 8.00 A.M, only), the mean plasma free testosterone increased and the mean plasma estradiol decreased significantly. Dihydrotestosterone, cortisol and vitamin D was elevated. Also, concentrations of all three inflammatory biomarkers decreased after supplementation. Of note, despite decreased proinflammatory cytokines, based on recent clinical data, this must be the first human study report to show an increase level of free testosterone after boron consumption [11289].

Calcium

Exercise-induced sweat calcium losses have been reported as substantial in male athletes. The first aim of the study was to quantify the increase in 24-h total dermal calcium losses and the net changes in calcium retention in active sportswomen after a 1-h strenuous exercise session. A second aim was to determine the effectiveness of calcium supplementation to offset any calcium loss. Twenty-six premenopausal sportswomen completed three 8-d intervention phases in a randomized-order, crossover design. The three phases were placebo+no exercise (control), placebo+exercise, and 400 mg of calcium as calcium carbonate (TUMS Ultra) twice daily + exercise. The supervised exercise was 1 h/day cycling at 65-70 percent of heart rate reserve. A controlled diet of approximately 450 mg/day of calcium and 24-h pooled urine and fecal collections allowed determination of calcium balance on days 5-8 of each phase. Twenty-four-hour dermal collections were made at the end of each phase using a whole-body washdown procedure. Exercise increased dermal calcium losses, which was no longer significant when calcium supplementation was provided. Higher urinary calcium excretion during calcium supplementation is suggestive of higher net calcium absorption. Exercise did not affect urinary calcium excretion indicating lack of compensation for dermal losses. Net calcium retention was positive only during the exercise+calcium supplementation intervention period. It was concluded that calcium supplementation can correct for negative calcium balance attributable to low calcium dietary intake and additional dermal losses from exercise [07387].

Calcium plays a major role in forming and maintaining healthy bone tissue. Food sources of calcium include milk and milk products, such as yogurt and cheese, foods prepared with milk, vegetables, fruits, fish with bones, dried beans and calciumfortified foods and supplements. Low-fat or non-fat versions of milk and milk products have the same amount of calcium as whole milk but a lower fat content. In some countries, a few foods such as cereal and orange juice are fortified with calcium. In addition, vegetables and some fruits can also provide calcium. If adequate calcium is not consumed from foods or beverages, a supplement can help meet calcium needs. Absorption of calcium reaches a plateau at doses of about 500 mg. Doses spaced throughout the day appear to result in a greater total calcium absorption than if one larger dose is taken only once during the day. Since many nutrients in addition to calcium and vitamin D play a role in bone health, it is important that athletes consume a well-balanced diet containing a variety of food, rather than just focusing on one or two bone-related nutrients. A diet that contains vegetables, fruits, low-fat milk and milk products, whole grains and adequate levels of protein and calories to maintain a healthy body weight can provide the nutrients needed for the formation and maintenance of healthy bones. For otherwise healthy athletes, if calcium or vitamin D needs are not met from foods and beverages, then supplements are recommended at levels that meet but do not exceed recommended intakes for these nutrients when added to intakes from foods [10252].
Cobalt

Soluble cobalt (Co) supplements with recommended daily doses up to 1000 microg Co/day are increasingly being marketed to consumers interested in healthy living practices. For example, some athletes may consider using Co supplements as blood doping agents, as Co is known to stimulate erythropoiesis. However, the distribution and excretion kinetics of ingested Co are understood in a limited fashion. It was used a Co-specific biokinetic model to estimate whole blood and urine Co levels resulting from oral exposure or ingestion of Co in amounts exceeding typical dietary intake rates. Following 10 days of Co supplementation at a rate of 400 to 1000 microg/day, predicted adult Co concentrations range from 1.7 to 10 microg/L in whole blood, and from 20 to 120 microg/L in urine. Chronic supplementation (≥ 1 year) at a rate of 1000 microg Co/day is predicted to result in blood levels of 5.7 to 13 microg/L, and in urine levels from 65 to 150 microg/L. The model predictions are within those measured in humans following ingestion of known doses. The methodology presented in this paper can be used to predict urinary or blood Co levels following acute or chronic occupational incidental ingestion, medicinal therapy, supplemental intake, or other non-occupational exposures [12444].

Copper

The importance of the mineral copper for human health can be deduced from its role as a cofactor in numerous metalloenzymes involved in antioxidant defence, oxygen transport and utilisation, immune function, catecholamine and connective tissue synthesis. Copper deficiency in adults has been described as secondary to malabsorption, zinc supplementation and excessive soft drink consumption. Severe copper deficiency is associated with wide ranging clinical manifestations: iron resistant anaemia, pancytopenia, neuropathy, hypercholesterolaemia and osteoporosis. However, copper toxicity has been associated with water contamination over 1.6 mg/l. Dietary requirements for adults have been set at 1.2 mg/day in the UK (tolerable upper intake 10 mg/day) with no specific recommendations for athletes. Copper status studies in male and female athletes across a variety of sports via blood/dietary analysis have yielded mixed results, but confirm that self-reported dietary intakes cannot reliably predict actual micronutrient status. Copper deficiency affects immune function. Indeed, athletes who restrict total energy and nutrient intake for long periods to reduce their body mass may be at greater risk of copper deficiency and its associated immunological effects. Copper supplementation may help to reduce loss of bone mineral density. It is advised that copper status should be assessed in athletes with chronically restricted energy intakes, who report persistent fatigue, frequent infections and stress fractures. Despite potential for poor copper status in some athletes, copper supplementation should not be undertaken without clinical justification, given the fact that it can be toxic [10251].

Chromium

Chromium picolinate, a complex of trivalent chromium (a trace mineral) and picolinic acid, has been heavily marketed for both muscle building and fat loss, but the overwhelming majority of the data do not support these purported benefits [13676].

Chromium enhances insulin signaling and insulin-mediated glucose uptake in cultured cells. It was investigated the effect of chromium on glycogen synthesis and insulin signaling in
humans. Sixteen overweight men (BMI 31) were randomly assigned to supplement with 600 microg/d chromium as picolinate (Cr; n=8) or a placebo (Pl; n=8). After 4 weeks of supplementation, subjects performed a supramaximal bout of cycling exercise to deplete muscle glycogen, which was followed by high-glycemic carbohydrate feedings for the next 24 h. Muscle biopsies were obtained at rest, immediately after exercise, and 2 and 24 h after exercise. Elevations in glucose and insulin during recovery were not different, but the lactate response was significantly higher in Cr. There was a significant depletion in glycogen immediately after exercise, an increase at 2 h, and a further increase above rest at 24 h. The rate of glycogen synthesis during the 2 h after exercise was not different between groups. Glycogen synthase activity was significantly increased immediately after exercise in both groups. Muscle phosphatidylinositol 3-kinase (PI 3-kinase) activity decreased immediately after exercise and increased at 2 h, with a trend for a lower PI 3-kinase response in Cr. Thus, chromium supplementation did not augment glycogen synthesis during recovery from high-intensity exercise and high-carbohydrate feeding, although there was a trend for lower PI 3-kinase activity [06292].

Chromium (Cr$^{3+}$) is a required trace mineral that potentiates the effect of insulin. A small number of patients on total parenteral nutrition have developed severe chromium deficiencies and subsequently presented with symptoms of diabetes. However, this was reversed with chromium supplementation. Chromium levels in food are quite low, with the highest levels found in egg yolk, Brewer's yeast and beef. Although physical activity may increase chromium losses, and intestinal chromium absorption is low (0.5-2.0 %), chromium deficiencies are uncommon, and supplementation is generally not warranted. The adequate intake of chromium is 35 and 25 μg/day for adult (19–50 years) men and women, respectively. Chromium picolinate, a complex of trivalent chromium and picolinic acid, is better absorbed (2-5 %) than dietary chromium. As a dietary supplement, chromium picolinate has been heavily marketed for muscle building, fat loss and, more recently, to reduce insulin resistance/type 2 diabetes risk. Based on these claims, sales of chromium picolinate supplements have soared and representing 6 percent of mineral supplement sales (second behind calcium) in the USA. The overwhelming majority of the data does not support the purported benefits of chromium picolinate supplementation, and thus, supplementation is not recommended. Adverse events related to chromium picolinate supplementation in humans are rare and based on case studies, but negative effects on iron status were noted in one double-blind placebo-controlled trial. Data are not available regarding the safety of high-dose, long-term chromium picolinate ingestion. There is currently little evidence to support the use of chromium picolinate supplementation by athletes [10253].

**Magnesium**

Magnesium (Mg) is an essential biological element that is predominantly located in bones (approx 52 %), muscle cells (28 %), soft tissue (19 %), serum (0.3 %; concentration range 0.75–1.1 mmol/L) and red blood corpuscles (0.5 %). Important food sources of Mg include vegetables, fish, nuts and whole grains. Serum acts as a transit pathway between bone stores and actively metabolising tissues and is not representative of the body's Mg status. Intracellular Mg is under hormonal control in some cell types and regulated by a secondary active transport system, the Na$^+$-Mg$^{2+}$-exchanger. In both extra- and intracellular compartments, the equilibrium between ionised Mg$^{2+}$ and bound Mg is established. Only Mg$^{2+}$ is available to react in physiological and biochemical processes during cellular homeostasis by binding to organic substances such as proteins, nucleic acids and nucleotides. In general, Mg$^{2+}$ is an important regulator of three main complexes: enzyme activation, for example during energy metabolism; stabilising membrane function and
integrity; and cell signalling, for example, intracellular calcium signals. There is interest in the effect of exercise on magnesium status. Acute exercise induces hypomagnesaemia (10 out of 18 studies) while total intracellular Mg content of blood cells seems to be unchanged (7 out of 12 studies). Ionised intracellular Mg was seen to decrease after high-intensity exercise while ionised Mg$^{2+}$ increased. Results from animal studies suggest that Mg$^{2+}$ is shifted from plasma into muscle and adipose tissue. Meanwhile, longitudinal and cross-sectional studies suggest that chronic exercise training may be followed by Mg$^{2+}$ depletion and that athletes are prone to Mg$^{2+}$ deficiency; this is most likely due to Mg losses in sweat and urine. Dietary restrictions, especially in athletes participating in sports requiring weight control, may aggravate the situation. One study has reported depleted Mg$^{2+}$ status in a group of athletes compared with a control group, as indicated by enhanced retention of an intravenous dose of Mg$^{2+}$ during a Mg$^{2+}$ loading test. Mg$^{2+}$ deficiency is characterised by an enhanced neuromuscular excitability, including symptoms such as cardiac arrhythmias, headache, nervousness, and cramps of both smooth and skeletal muscle. The latter, however, have to be differentiated from exercise induced muscle cramps for which Mg supplementation has not been proven to be effective for so far. A recent review indicates no significant effect of Mg supplementation on exercise performance; this is the case for athletes with balanced Mg status, although single studies indicate that Mg supplementation may improve exercise economy (lower VO$_{2max}$ values at given intensity; better lactate clearance). However, Mg supplementation should be considered in athletes with Mg deficiency based on findings from animal experiments and in humans which suggest that magnesium deficiency can compromise exercise capacity. Magnesium supplements include both inorganic and organic compounds of which the latter seemed to have a better bioavailability. A range between 350 and 400 mg/day is recommended as the upper limit. In the case of individuals with renal insufficiency, the daily dose will need to be reduced. Common side effects include gastrointestinal problems such as nausea and diarrhoea. Intravenous application may cause hypotension and cardiac arrhythmias [11393].

The effects of magnesium supplementation on plasma magnesium, zinc, and copper levels were determined in young adult tae-kwon-do athletes and sedentary controls at rest and exhaustion. After a 4-week supplementation period with 10 mg/day/kg Mg, the plasma magnesium, copper, and zinc levels significantly increased in sedentary and training (90-120 min training 5 days a week) subjects when compared to nonsupplemented controls [07384].

The effects of magnesium supplementation on blood parameters were studied during a period of 4 weeks in adult tae-kwon-do athletes at rest and exhaustion. Thirty healthy subjects of ages ranging in age from 18 to 22 years were included in the study. The subjects were separated into three groups, as follows: Group 1 consisted of subjects who did not train receiving 10 mg/kg/d magnesium. Group 2 included subjects equally supplemented with magnesium and exercising 90-120 min/d for 5 day/week. Group 3 were subject to the same exercise regime but did not receive magnesium supplements. The leukocyte count (WBC) was significantly higher in groups 1 and 2 than in the subjects who did not receive any supplements. There were no significant differences in the WBC of the two groups under magnesium supplementation. The erythrocyte, hemoglobin, and trombocyte levels were significantly increased in all groups, but the hematocrit levels did not show any differences between the groups although they were increased after supplementation and exercise. These results suggest that magnesium supplementation positively influences the performance of training athletes by increasing erythrocyte and hemoglobin levels [07385].

The effects of a 1-month exercise program and magnesium supplementation on the adrenocorticotropic hormone and cortisol levels were studied in young tae-kwon-do and sedentary subjects both at rest and exhaustion. The hormone levels were compared before and after supplementation with 10 mg of magnesium (as magnesium sulfate) per kilogram of
body weight. Both exercise and magnesium supplements caused significant increases of the adrenocorticotropic hormone. The cortisol levels were increased in training subjects receiving supplements but not so in subjects that either trained or received magnesium supplements in an independent manner. The cortisol levels measured in resting individuals were higher in the supplemented and non-supplemented athletes than those in sedentary subjects. The results of this study show that exercise and/or magnesium supplementation causes a rise of the adrenocorticotropic hormone, whereas cortisol is increased only as a result of combined exhaustion and magnesium supplements [07386].

One study was performed to determine how the magnesium supplementation for a 4-week period affects the glucose and insulin levels at rest and at exhaustion in sportsmen. It was a 4-week study performed on 30 healthy male subjects varying between 18-22 ages. Glucose and insulin parameters of the groups were measured 4 times; at rest and exhaustion in the beginning of the research and at rest and exhaustion after the end of 4 weeks application period. Glucose levels in exhaustion measurements both before and after the supplementation significantly increased compared to resting levels. Significant difference was determined in the glucose values of 1st and 2nd groups supplemented with magnesium in comparison to their first measurements. Insulin values a decrease in all of the 3 groups occurred with exercise both before and after the supplementation [08395].

Potassium

Potassium (K⁺) is the major intracellular cation in the body, with about 98 percent of the body potassium stores located inside the cells with a concentration maintained at about 145 mM. Its major functions are to promote contractility of ciac, smooth and skeletal muscle and to influence the regulation of nerve conduction through the influx of sodium (Na⁺) and efflux of K⁺ on either side of the nerve terminal, occurring at the rate of $10^7$ ions per second. On the surface of a nerve terminal, there are voltage-dependent channels for K⁺. In humans, at least 15 different K⁺-specific voltage-dependent channels have been identified. The Na⁺/K⁺ ATPase, also known as the Na pump, is the primary active transporter system that maintains the high K⁺ and low Na⁺ intracellular concentrations. The plasma membrane ATPase of all mammalian cells catalyses the reaction: ATP→ADP+Pi with obligatory requirements for Na⁺ and K⁺ and Mg²⁺ required for the dephosphorylation of ATP. Muscle has an especially high activity of this P-type Na⁺ pump which has been estimated to use 60 to 70 percent of the ATP synthesised in nerve and muscle cells. For active individuals/athletes, sweat is the major route of loss of K⁺ with an average of 5 mEq/l loss. Early work indicated that the loss of K⁺ from active muscle could contribute to fatigue during prolonged or intense exercise. Potassium efflux from muscles is greater during high intense/short duration exercise and could result in decreased membrane excitability and cause intracellular acidosis. However, the International Olympic Committee (IOC) Consensus on Nutrition for Athletes states that there is no convincing justification for the specific addition of electrolytes other than sodium to fluids consumed for postexercise recovery. Indeed, a sports drink containing 25 mM K⁺ and 60 mM Na⁺ did not have an additive effect on restoring hydration over a drink containing Na⁺. In addition, exercise in the heat was not associated with losses of Ca⁺, Mg²⁺ and K⁺ among tennis players. Potassium should be consumed as a normal component of the diet rather than as a supplement. Foods containing more than 300 mg K⁺/serving include banana, potato, orange juice, avocado, lima beans, cantaloupe, peaches, tomato, chicken, salmon, tuna, turkey and unsalted nuts. Some carbohydrate-electrolyte sports drinks provide higher amounts of K⁺ (90mg) than others (10-30mg) per 8 fl oz (240ml). Consuming supplemental forms of K⁺ could result in hyperkalaemia which could lead to cardiac arrhythmias and even cardiac arrest. The adequate intake from the diet for adults, age 14 to >70 years in the US, is
4.7 g/d but the average intake is about 2.5 g/d. Individuals with kidney failure or compromised kidney function would need to seek a physician's advice before taking any K+ supplement or consuming potassium-rich foods [12458].

**Selenium**

Both obesity and acute high-intensity exercise increase oxidant stress levels. One study investigated whether selenium (Se) supplementation could be a potential effective therapy to reduce obesity-associated oxidant stress and exercise-induced oxidant stress. Ten normal-weight (NW) (22.80 ± 0.41 kg/m²) and ten overweight (OW) healthy subjects (28.00 ± 0.81 kg/m²) were assessed during a randomized double-blind Se supplementation study (200 microg sodium selenite/day for 3 weeks) with a 3-week placebo control and inversion of treatment periods. Blood levels of lipid hydroperoxide (LH), superoxide dismutase (SOD), erythrocyte glutathione (GSH), and total antioxidant status (TAS), were measured at rest, pre-, and postexercise (30 min 70 % VO₂max, before and after treatment (pretreatment (week 0 and 12) and post-treatment (week 3 or 15)). At rest, compared to placebo, Se supplementation had no significant effect on LH, SOD, GSH, and TAS levels. However, Se supplementation decreased LH levels in the OW group, immediately postexercise compared to placebo treatment. Postexercise, with or without Se supplementation, no changes in TAS, SOD, and GSH levels were observed in both the NW and OW group. The study has highlighted a potential benefit of Se in reducing LH levels postexercise in OW individuals. Given that oxidant stress is a predictor of coronary events, it is imperative to better understand oxidant stress-related responses to lifestyle factors (in particular "high-risk" population groups) and potential antioxidant therapy [12446].

To investigate the ameliorative potential of sodium selenite and zinc sulfate on intensive-swimming-induced testicular disorders, 48 Wistar male rats (age, 4 months; mass, 146 g) were randomly divided into 4 groups: the unexercised-control group (n=12); the exercised group (n=12); the control supplemented group (n=12); and the exercised supplemented group (n=12). For 10 weeks, the exercised rats underwent a protocol that consisted of 4 hour swimming per day for 6 days per week; the control rats did not exercise. For 10 weeks, both the supplemented groups received an oral daily dose of a combination of sodium selenite and zinc sulfate (6 and 3 mg/kg body mass, respectively). After 10 weeks, a significant reduction was seen in rats in the exercised group, compared with rats in both control groups, in paired testicular masses; in epididymal sperm count; in testicular delta5, 3beta-hydroxysteroid dehydrogenase (HSD) and 17beta-HSD; in plasma levels of testosterone, luteinizing hormone, follicle-stimulating hormone, and prolactin; in the numbers of preleptotene spermatocytes, midpachytene spermatocytes, and stage 7 spermatids of the stage VII seminiferous epithelium cycle; and in fertility performance. As well, a significant increase was seen in the exercised group, compared with both control groups, in plasma corticosterone levels and in testicular content of malondialdehyde and catalase activity. At the same time, there was a significant reduction in the exercised group, compared with both control groups, in plasma concentrations of zinc and selenium; in the testicular content of glutathione (GSH), the glutathione and glutathione disulphide (GSSG) ratio, ascorbic acid, and alpha-tocopherol; and in testicular activities of superoxide dismutase, glutathione-peroxidase, and glutathione-S-transferase in the testes. No significant changes were seen in the number of spermatogonia-A from the stage VII seminiferous epithelium cycle or the testicular content of GSSG among the groups. Sodium selenite and zinc sulfate supplementation significantly protected against exercise-induced testicular gamatogenic and spermatogenic disorders, prevented testicular oxidative stress, and increased antioxidant status. It can be concluded that intensive-swimming-induced oxidative stress causes
dysfunctions in the male reproductive system, which can be protected by the coadministration of sodium selenite and zinc sulfate [08396].

Vanadium

Vanadium is a trace element that is probably an essential nutrient, although deficiency states in humans have not been described and its precise biological role is yet to be fully defined. It is commonly found in mushrooms, green beans and cereals, with the usual dietary daily intake around 10-60 microg. As a supplement, in the form of vanadyl sulphate (VOSO₄), vanadium has been used for muscle development in weight training athletes at doses up to 60 mg/day, on the basis that muscle growth and body composition are enhanced. There is little evidence to support this practice. Of the five studies identified which investigated the effect of vanadyl sulphate supplementation on anthropometry and/or body composition, all failed to demonstrate a significant effect. For performance enhancement, the only study to demonstrate an improvement was probably due to the treatment group being at a lower baseline fitness than the control group. However, the cationic species of vanadium (VO²⁺) is known to interact with muscle tissue actin at specific binding sites, altering protein conformation and function. The significance of this is unclear, but does suggest some biological basis behind the claims for vanadium effects on muscle. At supraphysiological levels, in vitro and animal studies indicate that vanadate and other vanadium compounds, do exert measurable biological effects. The effects on glucose transport activity and pancreatic β-cell function, via phosphatases and kinases, are the subject of current research into a potential role as antidiabetic therapeutics. The role of vanadium as a transcription modulator of genes in the area of oxidative stress, and oncogenesis has also been described, suggesting a possible future use as an anticancer agent. Vanadium in sulphate form has low toxicity or side effects. One study into the adverse effects of vanadium supplements failed to find any haematological or biochemical changes in 31 athletes taking 0.5 mg/kg/day of vanadyl sulphate. In summary, it would appear that vanadium compounds are biologically active but not in the areas associated with supplement consumption by weightlifting athletes [13676].

Zinc

One study aims to examine the effect of zinc supplementation on free-radical formation and antioxidant system in individuals who are actively engaged in wrestling as a sport. The study registered a total of 40 male subjects, of whom 20 were wrestlers and 20 were sedentary individuals. The subjects were equally allocated to four groups: group 1, zinc-supplemented sportsmen group; group 2, sportsmen group without supplementation; group 3, zinc-supplemented sedentary group; group 4, sedentary group without supplementation. Blood samples were collected from all subjects twice, once at the beginning of the study and once again at the end of 8-week procedures. The blood samples collected were analyzed to determine the levels of malondialdehyde (MDA), serum glutathione (GSH), serum glutathione peroxidase (GPx) activity, serum superoxide dismutase (SOD) activity (ELISA colorimetric method) and zinc (colorimetric method). No difference was found between MDA levels of the study groups in the beginning of the study. The significantly highest MDA value at the end of the study was obtained in group 4. MDA levels in group 2 were established to be significantly higher than those in groups 1 and 3. GSH level, GPx, and SOD activities and zinc level measured in the beginning of the study were not different between groups. Measurements performed at the end of the study showed that groups 1 and 3 (zinc-supplemented groups) had the significantly highest GSH level, GPx, and SOD activities and zinc level. These
parameters were not different in the groups without supplementation (groups 2 and 4). Results obtained at the end of the study indicate that zinc supplementation prevents production of free radicals by activating the antioxidant system. In conclusion, physiologic doses of zinc supplementation to athletes may beneficially contribute to their health and performance [10254].

One study aimed to examine the effect of zinc supplementation on free-radical formation and antioxidant system in individuals who are actively engaged in wrestling as a sport. The study registered a total of 40 male subjects, of whom 20 were wrestlers and 20 were sedentary individuals. The subjects were equally allocated to four groups: group 1, zinc-supplemented sportsmen group; group 2, sportsmen group without supplementation; group 3, zinc-supplemented sedentary group; group 4, sedentary group without supplementation. Blood samples were collected from all subjects twice, once at the beginning of the study and once again at the end of 8-week procedures. The blood samples collected were analyzed to determine the levels of malondialdehyde (MDA), serum glutathione (GSH), serum glutathione peroxidase (GPx) activity, serum superoxide dismutase (SOD) activity (ELISA colorimetric method) and zinc (colorimetric method). No difference was found between MDA levels of the study groups in the beginning of the study. The highest MDA value at the end of the study was obtained in group 4. These parameters were not different in the groups without supplementation. Results obtained at the end of the study indicate that zinc supplementation prevents production of free radicals by activating the antioxidant system. In conclusion, physiologic doses of zinc supplementation to athletes may beneficially contribute to their health and performance [09365].

The aim of one study was to determine how exercise affects thyroid hormones and testosterone levels in sedentary men receiving oral zinc for 4 weeks. The study included 10 volunteers (mean age, 19 years) who did not exercise. All subjects received supplements of oral zinc sulfate (3 mg/kg/day) for 4 weeks and their normal diets. The thyroid hormone and testosterone levels of all subjects were determined at rest and after bicycle exercise before and after zinc supplementation. TT3, TT4, FT3, and total and free testosterone levels decreased after exercise compared to resting levels before supplementation. Both the resting and fatigue hormone values were higher after 4 weeks of supplementation than the resting and fatigue values before supplementation. The results indicate that exercise decreases thyroid hormones and testosterone in sedentary men; however, zinc supplementation prevents this decrease. Administration of a physiologic dose of zinc can be beneficial to performance [07382].

One study evaluated levels of plasma zinc, copper, and leptin, body composition, and their relationship in nine male judo athletes under two different training conditions. Body composition and biochemical measurements (hematological indexes, plasma zinc, plasma copper, and plasma leptin) were analyzed 24 h after intense training and following a 5-d period without training (no-training). Plasma leptin and plasma zinc increased with no-training. Plasma zinc correlated negatively with percent fat mass and positively with plasma leptin in the no-training condition. Plasma copper did not change during the study and correlated positively with plasma leptin and with percent fat mass after training. Percent fat mass was associated negatively with plasma zinc in the no-training condition. Moreover, percent fat mass was negatively associated with the Zn/Cu plasma ratio under both training conditions. These results are consistent with the possible function of zinc as a lipid-mobilizing factor and of copper as a limiting factor in energy metabolism [07383].
The essential trace mineral zinc (Zn) serves multiple biological functions – catalytic, structural, regulatory and substrate – in support of metabolic, endocrine, signal transduction, cellular control, protein stabilization and immune networks and pathways. Overall, approximately 3000 Zn proteins are encoded in the human genome and Zn is a cofactor to more than 300 enzymes; these include superoxide dismutase, alkaline phosphatase and alcohol dehydrogenase, in the liver, and carbonic anhydrase III, AMP deaminase and the matrix metalloproteinases, in skeletal muscle. As one of the most widely distributed metals in the body, 85 percent of Zn resides in muscle and bones, 11 percent in skin and the liver and the remainder in all the other tissues. This clearly demonstrates the overall importance of Zn and would suggest that it may be important in physical performance. The best food sources of Zn are oysters, wheat germ, liver, beef, melon, squash seeds and cocoa [13710].

Improvement in physical performance or aspects of physical performance by administration of Zn can be demonstrated in one of three ways: showing that providing Zn to persons who are Zn deficient restores/improves performance, demonstrating that providing Zn to healthy individuals with adequate Zn status improves some aspect of performance, or showing that Zn supplementation counters a particular health risk that could compromise performance. With regard to Zn deficiency, the multiple functions of Zn suggest that repletion should restore decrements in performance through a variety of mechanisms. One of the earliest mechanisms proposed was related to Zn’s influence on testosterone (T) and growth hormone (GH). In both human and animal studies, it has been clearly shown that a Zn deficiency can adversely affect plasma levels of T, GH and insulin-like growth factor 1 (IGF-1). Specifically, Zn deficiency in rats is associated with lower plasma luteinising hormone and T concentrations, as well as alterations in steroid metabolism and sex steroid hormone receptors when compared to Zn sufficient rats. Moreover, administration of Zn to animals and humans with either Zn deficiency or retarded growth increased serum T and IGF-1 levels [13710].

Studies in humans with Zn deficiency led investigators to evaluate whether administration of Zn would elicit/invoke biological increases in GH, IGF-1 and testosterone. Most studies have indicated that supplemental Zn promotes growth and an anabolic environment only under conditions of Zn deficiency; no effects on plasma testosterone in Zn-sufficient and/or normal growth humans have been noted. It was demonstrated that providing 30 mg of Zn per day for 4 weeks had no effect on testosterone. It was also reported that Zn supplementation for 4 weeks prevented decreases in testosterone caused by fatiguing exercise. However, the dose/serving size used was very high (3 mg/kg/day of Zn sulphate) or about 85 mg/day for a 70 kg person, and higher than the tolerable upper intake level of Zn for adults (40 mg/day). In addition, doses/serving sizes over 100 mg/day have been found to be associated with health problems – headache, abdominal cramps and nausea – as well as resulting in a copper deficiency, which can cause anaemia, leucopaenia and neutropaenia. Importantly, they did not measure performance or show that maintaining serum T conferred any performance benefit [13710].

In addition to the Zn effects on anabolic pathways, others have suggested that Zn supplementation may improve blood rheology, in particular erythrocyte deformability and factors regulating blood viscosity. However, the evidence for any clear performance benefit is weak, and the effects may be specific to those with Zn deficiency, as determined by low serum Zn levels. Importantly, although inconsistent findings have been reported with regard to serum Zn concentrations in athletes, dietary intake of Zn is often below the recommended dietary allowance (8 and 11 mg/day for adult women and men respectively, sedentary or fit) in many athletes and other special populations [13710].

1851
Finally, zinc supplementation may mitigate performance decrements by mediating health barriers, such as the common cold. Although the data are not strong, several studies have indicated that Zn supplementation may provide more rapid relief from cold symptoms and/or shorten the duration of a cold [13710].

**Zinc monomethionine aspartate**

ZMA is a popular nutritional supplement which regularly features in the nutritional supplementation regimens of many athletes, been reported to suffer from Zn and magnesium deficiency. Studies conducted in clinical populations and animals have shown growth retardation, blunted testosterone and IGF-1 concentrations with Zn deficiency. Plasma magnesium concentrations have been shown to be associated with plasma cortisol concentrations, which are believed to lead to inferior gains in muscle mass and strength following resistance training. Collectively, this suggests that Zn and magnesium deficiency may have deleterious effects on skeletal muscle adaptations and exercise performance. With this in mind, it was investigated the hormonal and training responses of US football players following 7 weeks of ZMA supplementation. It was observed a significant increase in the plasma concentrations of Zn and magnesium after ZMA supplementation, together with a significant increase in plasma testosterone and IGF-1. Those athletes who received ZMA also showed improved muscle strength when compared to the placebo group. However, in contrast, two subsequent studies conducted in athletes using similar levels of ZMA supplementation from the same source found no effects. It was also shown that 8 weeks of ZMA supplementation, combined with resistance training, resulted in no significant differences in the plasma concentrations of Zn or magnesium in anabolic (testosterone, IGF-1 and GH) or catabolic hormones (cortisol), gains in muscle mass and strength or cycling anaerobic capacity when compared to placebo. Manufacturers claim that some versions of ZMA improve the quality of sleep. Despite many athletes using ZMA as a sleep aid, no study until now has investigated the effect of ZMA on sleep quality. At present, there is little evidence to support the use of ZMA as an anabolic nutritional intervention or to improve sleep quality [13710].

**Phosphate**

Research into supplementation with sodium phosphate has not investigated the effects of a repeated supplementation phase. Therefore, this study examined the potential additive effects of repeated sodium phosphate (SP) supplementation on cycling time-trial performance and peak oxygen uptake (VO\(_{2\text{peak}}\)). Trained male cyclists (n=9) completed baseline 1,000-kJ time-trial and VO\(_{2\text{peak}}\) tests separated by 48 hr, then ingested either 50 mg/kg fat-free mass/day of tribasic SP or a combined glucose and NaCl placebo for 6 d before performing these tests again. A 14-d washout period separated the end of one loading phase and the start of the next, with 2 SP and 1 placebo phase completed in a counterbalanced order. Although time-trial performance was shorter in SP1 and SP2, effect sizes and smallest-worthwhile-change values did not differ in comparison with baseline and placebo. However, mean power output was greater than placebo during time-trial performance at the 250 kJ and 500kJ time points after the second SP phase. Furthermore, mean VO\(_{2\text{peak}}\) values were greater after the SP1 (3.5-4.3 %), with further improvements found in SP2 (7.1-7.7 %), compared with baseline and placebo. In summary, repeated SP supplementation, ingested either 15 or 35 d after initial loading, can have an additive effect on VO\(_{2\text{peak}}\) and possibly time-trial performance [13711].
Nitrate

Several recent studies indicate that supplementation of the diet with inorganic nitrate results in a significant reduction in pulmonary O\textsubscript{2} uptake during sub-maximal exercise, an effect that appears to be related to enhanced skeletal muscle efficiency. The physiological mechanisms responsible for this effect are not completely understood but are presumably linked to the bioconversion of ingested nitrate into nitrite and thence to nitric oxide. Nitrite and/or nitric oxide may influence muscle contractile efficiency perhaps via effects on sarcoplasmic reticulum calcium handling or actin-myosin interaction, and may also improve the efficiency of mitochondrial oxidative phosphorylation. A reduced O\textsubscript{2} cost of exercise can be observed within 3 h of the consumption of 5-6 mmol of nitrate, and this effect can be preserved for at least 15 days provided that the same ‘dose’ of nitrate is consumed daily. A reduced O\textsubscript{2} cost of exercise following nitrate supplementation has now been reported for several types of exercise including cycling, walking, running, and knee extension exercise. Dietary nitrate supplementation has been reported to extend the time to exhaustion during high-intensity constant work rate exercise by 16-25 percent and to enhance cycling performance over 4, 10, and 16.1 km by 1-2 percent in recreationally active and moderately trained subjects. Although nitrate appears to be a promising “new” ergogenic aid, additional research is required to determine the scope of its effects in different populations and different types of exercise [13712].

One study examined if an elevated nitrate intake would improve VO\textsubscript{2} kinetics, endurance, and repeated sprint capacity in elite endurance athletes. Ten highly trained cyclists (72 ± 4 mL O\textsubscript{2}/kg/min, mean ± standard deviation) underwent testing for VO\textsubscript{2} kinetics (3 × 6 min at 298 ± 28 W), endurance (120 min preload followed by a 400-kcal time trial), and repeated sprint capacity (6 × 20 s sprints, recovery 100 s) during two 6-day periods in randomized order with a daily ingestion of either 0.5 L beetroot (BR) juice to increase nitrate levels or a 0.5 L placebo (PLA) drink with blackcurrant juice. Plasma NO\textsubscript{x} (nitrate + nitrite) levels were higher in BR (147 ± 102 and 159 ± 103 μM after 4 and 6 days of beverage intake, respectively) compared with PLA (41 ± 10 and 40 ± 7 microM). VO\textsubscript{2} kinetics and exercise economy were the same in BR and PLA. Time-trial performance was similar with an average completion time of 18:20 and 18:37 min:s in BR and PLA, respectively, with average power outputs of 290 ± 43 W in BR and 285 ± 44 W in PLA. Peak and mean power during repeated sprinting were similar in BR and PLA. In contrast to observations in moderately trained subjects intake of BR juice had no effect on VO\textsubscript{2} kinetics and performance in elite cyclists [13713].

Vitamins, in general

Master athletes are more than 35 years of age and continue to train as hard as their young counterparts despite the aging process. All life long, they are capable of accomplishing exceptional sporting performances. For these participants in endurance events, matching energy intake and expenditure is critical to maintain health and performance. The proportions of carbohydrate, fat, and protein must be optimized to provide enough calories to sustain the energy requirements of competition or training, and for recovery. In addition, endurance athletes must include adequate vitamins and minerals in their diets to maintain healthy immune function. Vitamins and minerals may be sufficient in the diets of endurance athletes, who have a high energy intake. This would make it unnecessary to use vitamin and mineral supplements. Furthermore, one major limitation for these athletes is the management of oxidative stress, which, when in excess, can be deleterious for the organism. For individuals exposed to oxidative stress, micronutritional supplementations rich in vitamins and minerals
can be also an alternative strategy. Although these supplementations are increasingly used by master athletes, very few data are available on their effects on oxidative stress, muscle recovery, and physical performance. The potential benefits of supplement use in athletes are thus questionable. Some studies indicate no benefits, while others highlight potential negative side effects of vitamin supplementation. Additional studies are warranted in order to design adapted prescriptions in antioxidant vitamins and minerals [13714].

A double-blind study investigated the effects of vitamin and mineral complex supplementation on the neuromuscular function of the knee-extensor muscles after a prolonged trail running race. Twenty-two well-trained endurance runners took either placebo (Pl group) or vitamins and minerals (Vm group) for 21 d before the race and for 2 d after the race. Maximal voluntary contractions (MVC) and surface EMG activity of the vastus lateralis (VL) muscle were recorded before (pre) and 1 h (post), 24 h (post 24) and 48 h (post 48) after the race. Central activation ratio (CAR), neural (M-wave), and contractile (muscular twitch) properties of the quadriceps muscles were analyzed using electrical stimulation techniques. The knee-extensor MVC was significantly reduced after exercise for both groups, but MVC recovery was greater for Vm than Pl after 48 h. The reduced MVC after exercise was associated with a significant reduction in maximal EMG normalized to the M-wave in VL muscle and in CAR for both groups. Characteristics of the muscular twitch were not significantly altered for either groups, whereas M-wave duration increased significantly after exercise. It was concluded that the reduction of MVC immediately after the race appeared to result from peripheral mechanisms such as a failure in muscle membrane excitation and, to a lesser extent, from reduced central activation. The cause of the depressed MVC 24 h after the race seemed to be located within the muscle itself. A dietary supplementation of a vitamin and mineral complex does not attenuate the loss of contractile function immediately after the running exercise, and it may accelerate the recovery of maximal force capacity [06283].

Ultraendurance exercise training places large energy demands on athletes and causes a high turnover of vitamins through sweat losses, metabolism, and the musculoskeletal repair process. Ultraendurance athletes may not consume sufficient quantities or quality of food in their diet to meet these needs. Consequently, they may use oral vitamin and mineral supplements to maintain their health and performance. We assessed the vitamin and mineral intake of ultraendurance athletes in their regular diet, in addition to oral vitamin and mineral supplements. Thirty-seven ultraendurance triathletes (24 men and 13 women) completed a 7-day nutrition diary including a questionnaire to determine nutrition adequacy and supplement intake. Compared with dietary reference intakes for the general population, both male and female triathletes met or exceeded all except for vitamin D. In addition, female athletes consumed slightly less than the recommended daily intake for folate and potassium; however, the difference was trivial. Over 60 percent of the athletes reported using vitamin supplements, of which vitamin C (98 %), vitamin E (78 %), and multivitamins (52 %) were the most commonly used supplements. Almost half (48 %) the athletes who used supplements did so to prevent or reduce cold symptoms. Only one athlete used supplements on formal medical advice. Vitamin C and E supplementation was common in ultraendurance triathletes, despite no evidence of dietary deficiency in these 2 vitamins [10526].

**Vitamin B**

The B-vitamins are water-soluble vitamins that play crucial roles in energy metabolism. There are eight B-vitamins: thiamine (B₁), riboflavin (B₂), niacin (B₃), pantothenic acid (B₅) pyridoxine (B₆), biotin (B₇), involved in energy-producing pathways; folic acid (B₉), cobalamin
involved in synthesising new cells, red blood cells and in cell repair. The richest sources of B-vitamins are unprocessed foods such as whole grains, green leafy vegetables, nuts, dairy products and animal foods such as meat and eggs but, in many countries, foods such as cereals and bread are fortified with these vitamins. It has been reported that inadequate intake and deficiencies in B-vitamins could impair athletic performance. Studies examining dietary intakes of B-vitamins in athletes have found that males typically report higher intakes than females because of their overall higher energy intake. Female athletes on an energy restricted diet and/or who exhibit disordered eating practices have lower intakes of riboflavin, folate and pyridoxine. Limited data on B-vitamin status in athletes exist: the few studies available have examined the status of thiamin, riboflavin, pyridoxine, folic acid and cobalamin. Some studies reported thiamin status to be adequate and, moreover, that exercise training does not appear to alter thiamin status. Similarly, studies on cobalamin also observed adequate status in athletes. However, data have also demonstrated altered cobalamin metabolism in recreational athletes compared with non-exercising controls. Data on riboflavin are mixed, with some studies reporting poor status in athletes and it has been suggested that riboflavin requirements may be higher than the recommended nutritional intake (RNI) for athletes than for the general population. Similarly, poor pyridoxine status in male and female athletes has been documented in some studies. Exercise training has been found to increase pyridoxine requirements due to greater losses and turnover suggesting that athletes undergoing heavy training might require more pyridoxine than current RNI. Studies examining folate status have produced mixed findings, with some researchers reporting adequate status in athletes and others reporting poor folate status. Few studies have investigated the effects of vitamin B supplementation on exercise performance in athletes. Thiamine supplementation does not appear to enhance exercise performance when adequate status is present, similarly, 10 weeks of folate supplementation in female marathon runners had no effect on running performance. Although no studies directly investigated the effects of riboflavin on performance in athletes, it was reported that dieting and exercise increase the intake of riboflavin needed to maintain adequate status. Several researchers have shown that exercise modifies pyridoxine metabolism with one study reporting losses of 1 mg during a marathon race. However, there are no studies on the effects of pyridoxine supplementation on performance per se. High folate and cobalamin intakes in conjunction with regular exercise may reduce plasma homocysteine concentrations which, in turn, can lower the risk factor for cardiovascular disease. Further well-controlled studies are required to investigate the effects of B-vitamin supplementation on exercise performance in athletes, and on physical activity and health, against a background of both adequate and inadequate status [13715].

Vitamin D

The prevalence of seasonal variation in vitamin D status was examined in 20 FA Premier League soccer players residing at a latitude of 53°N. Serum 25-hydroxyvitamin D (25(OH)D) levels decreased between August (104.4 ± 21.1 nmol/L, range 68-151) and December (51.0 ± 19.0 nmol/L), range 22-86), such that levels for 65 percent of the sample were insufficient (<50 nmol/L) in winter. Strategies to augment vitamin D(3) availability may therefore be advantageous for UK soccer players so as to maintain muscle function [12443].

A surprisingly high prevalence of vitamin D insufficiency and deficiency has recently been reported worldwide. Although very little is known about vitamin D status among athletes, a few studies suggest that poor vitamin D status is also a problem in athletic populations. It is well recognized that vitamin D is necessary for optimal bone health, but emerging evidence is finding that vitamin D deficiency increases the risk of autoimmune diseases and
nonskeletal chronic diseases and can also have a profound effect on human immunity, inflammation, and muscle function (in the elderly). Thus, it is likely that compromised vitamin D status can affect an athlete's overall health and ability to train (i.e. by affecting bone health, innate immunity, and exercise-related immunity and inflammation). Although further research in this area is needed, it is important that sports nutritionists assess vitamin D (as well as calcium) intake and make appropriate recommendations that will help athletes achieve adequate vitamin D status: serum 25(OH)D of at least 75 or 80 nmol/L. These recommendations can include regular safe sun exposure (twice a week between the hours of 10 a.m. and 3 p.m. on the arms and legs for 5-30 min, depending on season, latitude, and skin pigmentation) or dietary supplementation with 1,000-2,000 IU vitamin D3 per day. Although this is significantly higher than what is currently considered the adequate intake, recent research demonstrates these levels to be safe and possibly necessary to maintain adequate 25(OH)D concentrations [08406].

Vitamin D insufficiency is prevalent in various populations worldwide but with scarce data on physically active individuals. Vitamin D is important to athletes, affecting bone mass, immunity, and physical performance. This study evaluated the prevalence of vitamin D insufficiency and deficiency among young athletes and dancers. Data on 98 athletes and dancers (age, 15 ± 3 years: 53 % men), who had undergone screening medical evaluations, were extracted from medical records. Mean serum 25(OH)D concentration was 25 ± 8 ng/mL. Seventy-three percent of participants were vitamin D insufficient. Prevalence of vitamin D insufficiency was higher among dancers (94 %), basketball players (94 %), and Tae Kwon Do fighters (67 %) and among athletes from indoor versus outdoor sports (80 % vs 48 %). 25(OH)D levels adjusted for age and sex correlated with serum ferritin and season. In this study, conducted among young athletes and dancers from various disciplines in a sunny country, a high prevalence of vitamin D insufficiency was identified. A higher rate of vitamin D insufficiency was found among participants who practice indoors, during the winter months, and in the presence of iron depletion. Given the importance of vitamin D to athletes for several reasons, we suggest that athletes and dancers be screened for vitamin D insufficiency and treated as needed [10412].

While vitamin D deficiency is well recognized in Middle Eastern women as a result of cultural norms of remaining covered, Middle Eastern men are an under-reported group. Vitamin D is now known to have multiple effects, including an impact on muscle function, thereby increasing the relevance for sportsmen. The aim of one study was to evaluate serum 25-hydroxyvitamin D (25(OH)D) levels in young male Middle Eastern athletes in a cross-sectional study. Ninety-three Middle Eastern men presenting to hospital for an annual screening undertook a blood test to evaluate their vitamin D status. Ninety-one percent of athletes were found to be deficient in 25(OH)D (serum concentration <20 ng/ml). Athletes with severe deficiencies were significantly younger than those with less marked deficiency. A subset of athletes underwent bone mineral density assessment and 59 percent were shown to have at least one Z-score less than -1; despite this, however, no athletes reported a stress fracture. There was no correlation between 25(OH)D concentration and sunlight exposure, skin coverage and skin colouring. Thus, the study revealed that 25(OH)D deficiency is very common among otherwise healthy Middle Eastern male athletes. Given the potentially significant long- and short-term effects of 25(OH)D deficiency, serum 25(OH)D evaluation should be part of the routine assessment in this region [10528].

Vitamin D plays a major role in bone health by helping to maintain skeletal calcium balance in bone tissue. Vitamin D also helps to maintain adequate amounts of serum calcium for bone formation by actions on the intestines and kidney, allowing normal functioning of parathyroid hormone to help maintain serum calcium at normal levels. Sources of vitamin D include sunlight and dietary intake. Vitamin D is synthesised in the skin with exposure to
sunlight. For some individuals, who get enough exposure during the warmer months, the sun can provide adequate levels of vitamin D throughout the entire year. Athletes are among the groups of people who have been shown to be unable to get adequate levels of vitamin D from exposure to sunlight, especially if they live in northern latitudes, have dark skin pigmentation or participate in an indoor sport. These individuals should obtain intake from foods or supplements. Liver, cod liver oil, fatty fish and egg yolks all contain vitamin D. In some countries, a few foods, such as milk and cereals, are fortified with vitamin D. However, the nutrient composition should be checked, since some products make claims for vitamin D levels that are unlikely to make a substantial contribution to total needs. For athletes living in northern latitudes, especially athletes who exercise indoors, vitamin D status should be assessed [10252].

Vitamin D is an important factor for calcium and phosphorus homeostasis. A negative relationship has been observed between vitamin D status and diseases such as cancer, arthritis, diabetes, and muscle fiber atrophy. However, the relationship between vitamin D and prevention of skeletal muscle damage has not been clearly elucidated. The purpose of this study was to investigate the effects of vitamin D on exercise-induced muscle changes. Rats were divided into 3 groups: (1) sedentary control (C: n=10), (2) high-intensity exercise (HE: n=10), and (3) high-intensity exercise with vitamin D supplementation (HED: n=10; i.p. 1000 IU/kg body weight). Rats were trained for 30 min/day on treadmills (5 days/week for 8 weeks) with the running speed gradually increased up to 30 m/min at a 3° incline. At the end of the training period, the running speed was 38 m/min at a 5° incline. The high-intensity exercise significantly increased plasma creatine kinase (CK) and lactate dehydrogenase (LDH) activity. In addition, IL-6 and TNF-alpha levels as well as phosphorylation of AMPK, p38, ERK1/2, IKK, and IκB were significantly increased. Vitamin D-treated rats showed a significant decrease in plasma CK level, phosphorylation of AMPK, p38, ERK1/2, IKK, and IκB, and gene expression of IL-6 and TNF-alpha. Furthermore, the protein expression of vitamin D receptor (VDR) was highly increased in the muscles of HED-treated rats, respectively. Therefore, it was concluded that vitamin D may play a pivotal role in exercise-induced muscle damage and inflammation through the modulation of MAPK and NF-kappaB involved with VDR [13718].

Vitamin D is well known for its role in calcium regulation and bone health, but emerging literature tells of vitamin D's central role in other vital body processes, such as: signaling gene response, protein synthesis, hormone synthesis, immune response, plus, cell turnover and regeneration. The discovery of the vitamin D receptor within the muscle suggested a significant role for vitamin D in muscle tissue function. This discovery led researchers to question the impact that vitamin D deficiency could have on athletic performance and injury. With over 77 percent of the general population considered vitamin D insufficient, it's likely that many athletes fall into the same category. Research has suggested vitamin D to have a significant effect on muscle weakness, pain, balance, and fractures in the aging population; still, the athletic population is yet to be fully examined. There are few studies to date that have examined the relationship between vitamin D status and performance, therefore, this review will focus on the bodily roles of vitamin D, recommended 25(OH)D levels, vitamin D intake guidelines and risk factors for vitamin D insufficiency in athletes. In addition, the preliminary findings regarding vitamin D's impact on athletic performance will be examined [13719].

As research has progressed, the importance and versatility of vitamin D in the body has become quite evident, therefore the prevalence of vitamin D insufficiency has been heavily examined in recent years. Research suggests vitamin D's active role in immune function, protein synthesis, muscle function, inflammatory response, cellular growth and regulation of skeletal muscle. In addition, a common symptom of clinical vitamin D deficiency is muscle
weakness. Due to the many essential roles of vitamin D within the body, it has been suggested that physical performance may be influenced by serum vitamin D status, especially in those who are clinically deficient [13719].

Vitamin D insufficiencies are estimated to affect over one billion people worldwide. The Third National Health and Nutrition Examination Survey (NHANES III) data showed a significant increase in vitamin D insufficiency in the USA over the last 30 years, with over 77 percent of Americans considered vitamin D insufficient. The alarming rates of insufficiency and the vast metabolic properties of vitamin D have led researchers to examine the influence of vitamin D, not only on disease prevention, but also on physical performance and injury. Vitamin D has been identified in most tissues within the body, including skeletal muscle, which has led to further examination of vitamin D’s influence on athletes and physical performance. Because athletes and sports medicine physicians are primarily concerned with performance, the risk of vitamin D insufficiency among athletes has received growing interest and is under current examination by many researchers. In the last decade, researchers have examined 25(OH)D levels among various groups of athletes, ranging from gymnasts to runners to jockeys. Some findings have suggested that vitamin D levels in athletes are comparable to those of the general population; however, results depended largely on geographical location and type of sport (indoor vs. outdoor). It is apparent that the athlete is at an equal risk for vitamin D insufficiency, therefore the potential impact of vitamin D status on performance is now under examination. There are few studies to date that have examined the relationship between vitamin D status and performance, therefore, this review will focus on the bodily roles of vitamin D, recommended serum 25(OH)D level, vitamin D intake guidelines and risk factors for vitamin D insufficiency in athletes. In addition, the preliminary findings regarding vitamin D’s impact on athletic performance will be examined [13719].

It is well recognised that vitamin D plays an important role in calcium regulation and bone health. Emerging evidence, however, also suggests that vitamin D plays important roles in immune and inflammatory modulation and skeletal muscle function, and therefore has the potential to impact upon the health, training and performance of athletes. Although vitamin D is thought of as a “vitamin”, required amounts can be obtained entirely from cutaneous synthesis via exposure to ultraviolet-B (UVB) radiation in sunlight. Cutaneous synthesis of vitamin D, however, is dependent on factors including time of exposure, season, latitude, cloud cover, smog, skin pigmentation, sunscreen coverage and age. Vitamin D is not synthesised during the winter at latitudes greater than 35-37° north or south because insufficient UVB photons reach the earth’s surface during these months. Vitamin D is also obtained in the diet from limited natural and fortified sources. Dietary vitamin D includes vitamin D3 (cholecalciferol, derived from animal sources) and vitamin D2 (ergocalciferol, derived from UVB exposure of fungi and yeast ergosterols). Both forms are readily absorbed (about 50 % bioavailable), except in individuals with malabsorptive disorders. It is well recognised that suboptimal vitamin D status is widespread among the general population worldwide. Among athletes, the prevalence of deficiency varies by sport, training location, skin colour and individual lifestyle habits. For example, a high prevalence of vitamin D deficiency has been observed in gymnasts training in East Germany and Finland, with 37-68 percent of these athletes having serum 25(OH)D concentrations under 10-15 ng/mL (25-38 nmol/L), and in Middle Eastern sportsmen training in Qatar of whom 91 percent have serum 25(OH)D concentrations under 20 ng/mL (50 nmol/L), resulting in high rates of deficiency. In contrast, a low prevalence of insufficiency/deficiency and better overall status has been documented in college athletes training in a high altitude region of the USA. The proportion of athletes found to maintain optimal vitamin D status is observed to be 15-76 percent among some outdoor training populations. Muscle pain and weakness are well-documented but frequently forgotten symptoms of severe vitamin D deficiency improve with vitamin D repletion. Recent evidence from animal and in vitro studies are finding that vitamin D is
important for calcium handling across the sarcolemma and expression of proteins involved in muscle contraction. Although published data on vitamin D status or vitamin D supplementation on muscle performance are not yet available in athletes, provocative evidence from the Russian and German literature at the turn of the 20th century suggests that UVB exposure makes a positive impact upon athletic performance. These studies, however, did not simultaneously measure markers of vitamin D status (which were not yet understood) and were also not conducted using the rigorous scientific standards employed today. Vitamin D supplementation may benefit the health and performance of many athletes but should not be routinely recommended without assessment. Serum 25(OH)D concentration, the best indicator of vitamin D status, should first be evaluated along with anthropometric measurements (including body fat estimation), dietary intake and lifestyle and environmental factors that potentially impact status. Both body fat and body size are important to consider because they are inversely correlated with vitamin D status. This is due to either sequestration or volumetric dilution of ingested or cutaneously synthesized vitamin D by the larger fat mass which increases supplemental dose in larger or fatter athletes. Following assessment, recommendations for achieving/maintaining optimal vitamin D status can be tailored to the individual athlete’s current serum 25(OH)D concentration, diet, lifestyle habits, belief system, lifestyle habits and, if present, clinical symptoms. Habitual exposure to arms, legs and back several times a week for 5 mins (for fair-skinned individuals) to 30 mins (for darker-skinned individuals) at close to solar noon without sunscreen usually leads to sufficient vitamin D synthesis in summer months. Individuals with limited sun exposure require supplementation with at least 1500-2000 IU/day vitamin D to keep 25(OH)D concentrations in the sufficient but not necessarily the optimal range. Higher supplemental doses may be required in those with little sun exposure, regular sunscreen use, dark-pigmented skin and/or excess adiposity. Athletes who live or train at latitudes above/below 35-37° north or south should supplement with at least 600 IU/day during winter, rainy or cloudy seasons even if they maintain adequate stores during sunnier seasons. Regular consumption of vitamin D-fortified foods is not likely to result in sufficient status in the absence of UVB exposure. Although specific guidelines for supplemental vitamin D are not yet established, a rule-of-thumb is to increase supplemental vitamin D by 1000 IU over 3-4 months for every 10 ng/mL elevation in 25(OH)D desired. Thus, a “normal-weight” athlete with a serum 25(OH)D concentration of 20 ng/mL would require an additional 2000 IU daily to increase stores to 40 ng/mL in 3-4 months. Higher doses than estimated, using this rule-of-thumb, may be needed to improve status in some athletes, particularly when adipose stores are high or the starting serum 25(OH)D concentration extremely low. Genetic differences also influence response to supplementation. Supplemental vitamin D can be taken either daily or as a larger bimonthly or monthly dose (i.e. 50 000 IU/month and 1667 IU/day). To replenish stores more rapidly, athletes with deficient status may benefit from short-term, high-dose ‘loading’ regimens under the supervision of a physician. Examples of high-dose regimens include 50 000 IU/week for 8-16 weeks or 10 000 IU/day for several weeks. While supplementation with either D3 and D2 are effective at doses of 1000 IU/day, D3 is recommended for higher supplemental doses (50 000 IU) due to its greater potency at raising and maintaining serum 25(OH)D concentrations. It is interesting to note that Vitamin D deficiency can produce some symptoms similar to those in chronic fatigue syndrome and fibromyalgia. There is still debate about the distinction between deficiency and insufficiency of Vitamin D. On the other hand, taking high doses of Vitamin D supplementation exemplifies the situation in supplementation where more is not necessarily better. It is suggested that supplementation with Vitamin D should be carefully monitored, due to risk of toxicity if allowed to accumulate unchecked. While D3 is recommended for higher doses, it comes from sheep’s wool lanolin and thus is not suitable for vegan athletes. There is good evidence in the literature that Vitamin D, in moderate doses, may be helpful to some athletes [13720].
Despite a wide number of studies performed on the general population, little is known about the Vitamin D status of athletes. A particular influence of many factors, including skin pigmentation, early- or late-day training, indoor training, geographic location and extensive sunscreen use, has been observed in this specific population. The need of supplementation with Vitamin D in athletes is not defined or, when supplementation is needed, even the optimal amount of Vitamin D to be used is not specified. The periodic measurement of Vitamin D is the only procedure capable to define athletes’ status. Although various methods for the measurement of Vitamin D are routinely used, they often give discordant and poorly reproducible results; thus, it is necessary to standardize the various methods, in order to have comparable results. In conclusion, current available data indicate both that little is known about the Vitamin D status of athletes and that is still unclear if supplementation could be desirable. Finally, it must be pointed out that all the papers about Vitamin D status should indicate in detail the method used for really allowing a correct interpretation of data [13721].

One study implemented a two-part design to assess the vitamin D concentration of a large cohort of non-vitamin D supplemented UK-based athletes and 30 age-matched healthy non-athletes and to examine the effects of 5000 IU/day vitamin D(3) supplementation for 8-weeks on musculoskeletal performance in a placebo controlled trial. Vitamin D concentration was determined as severely deficient if serum 25(OH)D < 12.5 nmol/L, deficient 12.5-30 nmol/L and inadequate 30-50 nmol/L. demonstrate that 62 percent of the athletes (38/61) and 73 percent of the controls (22/30) exhibited serum total 25(OH)D < 50 nmol/L. Additionally, vitamin D supplementation increased serum total 25(OH)D from baseline, whereas the placebo showed no significant change. There was a significant increase in 10 m sprint times and vertical-jump in the vitamin D group whereas the placebo showed no change. The current data supports previous findings that athletes living at Northerly latitudes (UK = 53° N) exhibit inadequate vitamin D concentrations (<50 nmol/L). Additionally the data suggests that inadequate vitamin D concentration is detrimental to musculoskeletal performance in athletes. Future studies using larger athletic groups are now warranted [13722].

There is an increasing body of evidence for a multiplicity of roles for the vitamin D endocrine system throughout the human body. Such evidence has developed from an appreciation for the existence of a nuclear receptor (vitamin D receptor, VDR) for the biologically active form of vitamin D (1,25-dihydroxyvitamin D3) and its expression in a large number of tissues. The active metabolite is a potent secosteroid hormone that interacts with more than 200 genes via the VDR, giving it a wide range of actions. One tissue regulated by vitamin D is skeletal muscle. Indeed, in those with a clinical vitamin D deficiency, skeletal muscle myopathy (presenting as a proximal muscle weakness) is often observed. “Normalisation” of 25 hydroxyvitamin D (25[OH]D) concentrations in patients with myopathy has been shown to reverse the myopathy. Histological and electromyographic investigations in vitamin D deficient sample populations have demonstrated muscle fibre atrophy, a reduction in motor unit potentials and muscle weakness. A type II fibre atrophy has also been observed in the non-hemiplegic vastus lateralis muscle of elderly stroke patients, which was corrected with vitamin D supplementation. Vitamin D deficiency is common in the general public and athletic populations and may impair skeletal muscle function. It must be stressed that the recommended “optimum” concentrations are defined in relation to adequate bone function/metabolism and there are currently no accepted guidelines to the optimum levels to maximize neuromuscular performance. Interpretation of existing data is also complicated by the variations in biochemical methods used to measure 25[OH]D. In this regard, recent recommendations state that both vitamins D2 and D3 should be assessed using high performance liquid chromatography (HPLC) mass spectrometry (Tandem MS) to allow an accurate assessment of total 25[OH]D concentration. Despite the equivocal definitions of vitamin D deficiency, it would appear that a large proportion of individuals worldwide are at risk of low 25[OH]D concentrations that may result in subsequent health risks including
myopathy. It was therefore assessed the effects of vitamin D3 supplementation on serum 25(OH)D concentrations and physical performance. Thirty club-level athletes were block randomized (using baseline 25(OH)D concentrations) into one of three groups receiving either a placebo (PLB), 20 000 or 40 000 IU/week oral vitamin D3 for 12 weeks. Serum 25(OH)D and muscle function (1-RM bench press and leg press and vertical jump height) were measured presupplementation, 6 and 12 weeks postsupplementation. Vitamin D deficiency was defined in accordance with the US Institute of Medicine guideline (<50 nmol/L). Fifty-seven percent of the subject population were vitamin D deficient at baseline (mean ± SD value 51±24 nmol/L). Following 6 and 12 weeks supplementation with 20 000 IU (79 ± 14 and 85 ± 10 nmol/l, respectively) or 40 000 IU vitamin D3 (98 ± 14 and 91 ± 24 nmol/L, respectively), serum vitamin D concentrations increased in all participants, with every individual achieving concentrations greater than 50 nmol/L. In contrast, vitamin D concentration in the PLB group decreased at 6 and 12 weeks (37 ± 18 and 41 ± 22 nmol/L, respectively). Increasing serum 25(OH)D had no significant effect on any physical performance parameter. It was concluded that both 20 000 and 40 000 IU vitamin D3 supplementation over a 6-week period elevates serum 25(OH)D concentrations above 50 nmol/L, but neither dose given for 12 weeks improved our chosen measures of physical performance [13723].

Vitamin D is an essential nutrient obtained from the diet and exposure to sunlight. Roles for vitamin D have been established in the function of the cardiovascular, immune, and musculoskeletal systems. An electronic database search was conducted using EMBASE (1967 to August 2012), MEDLINE (1966 to August 2012), SPORTDiscus™ (1975 to August 2012), and the Scientific Electronic Library Online (SciELO) (1998 to August 2012) with no limits of language of publication. Articles that described vitamin D and performance were considered eligible for this review. Recent studies suggest that vitamin D maintains physical performance in athletes and other active populations, e.g. maximal oxygen consumption may be related to vitamin D status. Poor vitamin D status affects muscle strength, and vitamin D may participate in protein synthesis through the actions of the vitamin D receptor in muscle tissue. Vitamin D may protect against overuse injuries, such as stress fracture, through its well-documented role in calcium metabolism [13724].

**Vitamin D and muscle tissue**

The autocrine pathway appears to be of utmost importance and has recently received a great deal of attention in regards to vitamin D’s influence on skeletal muscle function. Vitamin D receptor (VDR) sites have been identified in virtually every tissue within the body. VDR regulates expression in hundreds of genes that perform essential bodily functions. The discovery of VDR within the muscle suggested a significant role for vitamin D in muscle tissue and has since been identified as a regulator of skeletal muscle. There are two proposed mechanisms by which vitamin D status may influence muscular strength. One possible explanation involves the direct role of 1,25-dihydroxyvitamin D [1,25(OH)2D] on VDRs within the muscle cells. A second explanation suggests that vitamin D modifies the transportation of calcium in the sarcoplasmic reticulum by increasing the efficiency or number of calcium binding sites involved in muscle contraction. This indirect mechanism however, has only been examined in rat models. On the contrary, one study disputes the evidence for the presence of VDRs within the skeletal muscle cells and suggests that the immunocytochemical staining to detect VDR may be responsible for the false positives results in previous studies. Furthermore, it has been suggested that vitamin D supplementation in individuals with low vitamin D status may improve muscle strength. This is believed to be due to an increase in the size and amount of type II (fast twitch) muscle fibers associated with vitamin D supplementation. It should be noted that type II fibers are predominant in power and anaerobic activities, and are recruited first to prevent falls,
associated with muscle strength in the aging population. Various researchers have found vitamin D to have a significant effect on muscle weakness, pain, balance and fractures in aging individuals. It is difficult, however to compare the results given the variety of outcome measures and differences in populations used in the studies. Several observational studies have suggested that vitamin D status influences muscular strength and function in the elderly. Contrary to these findings, it was in 2002 found no association between baseline vitamin D status and changes in performance measures over a four year period. Replacing vitamin D stores in the elderly population may be protective against fall risk and declining physical function. Few studies to date have examined this relationship in the adolescent population. However, it was examined the relationship between 25(OH)D status and bone mass, bone turnover, and muscle strength in Chinese adolescent females (n=301) and found that poor vitamin D status (<20 ng/mL) was associated with reduced forearm strength, (using a handgrip dynamometer) when compared to individuals with adequate vitamin D levels (>20 ng/mL). It was also suggested that 25(OH)D levels were positively associated with muscle power, and jump height in postmenarchal females (n=91), however physical activity levels were not taken into consideration. These findings in regard to muscle tissue and function suggest that vitamin D status may have a significant effect on muscle performance and injury prevention, therefore possibly influencing athletic performance. However, further research is warranted to determine the magnitude of effect of vitamin D on muscle strength and performance [13719].

**Vitamin D recommendations (intake abd desirable levels)**

Although the sun is the most plentiful source of vitamin D, there are also some dietary sources. Some common foods contain significant levels of vitamin D, naturally, including salmon, fatty fish, egg yolks, plus, fortified products also exist, such as, milk, cereal and orange juice. While these dietary sources may appear significant, the process of absorbing dietary vitamin D is only about 50 percent efficient; therefore, much of the nutrient value is lost in digestion. The lack of dietary vitamin D is yet another factor that increases the risk of vitamin D insufficiency. Most experts agree that a higher intake of vitamin D, through dietary sources, ultraviolet B (UVB) exposure, and supplementation, is necessary to obtain optimal serum vitamin D levels. In November of 2010, the Institute of Medicine (IOM) released new recommendations for dietary intake of vitamin D, 400-600 IU/day for children and adults (0-70 years), 800 IU/day for older adults (>70 years). These values are only slightly higher than past recommendations. Many experts argue that while IOM intake recommendations may adequately prevent clinical vitamin D deficiency, they are significantly lower than the level necessary to achieve optimal vitamin D status. The Recommended Dietary Allowance (RDA) for Vitamin D, according to the National Institute of Medicine (IOM) is compared to the Endocrine Society’s recommended intake. Many believe that the RDA is grossly underestimated, including the Endocrine Society, who released vitamin intake guidelines that are significantly higher. The Endocrine Society recommends 400-1000 IU/day for infants, 600-1000 IU/day in children (1-18 years) and 1500-2000 IU/day in adults, in addition to sensible sun exposure. Another area of debate among vitamin D researchers is the terminology and reference values used to define optimal vitamin D status, deficiency, and insufficiency. Optimal serum 25(OH)D concentrations have yet to be defined; however, most researchers have similar reference values. Vitamin D deficiency is often defined as <20 ng/mL (50 nmol/L), and insufficiency defined as 20-32 ng/mL (50-80 nmol/L) and optimal levels are >40 ng/mL (100 nmol/L). The term insufficiency “appears to be the currently favored term for the range of marginal deficiency and is the theoretical serum concentration that is not high enough to protect against certain chronic diseases.” Optimal levels of serum 25(OH)D are no exception to the controversy. When serum levels reach >32 ng/mL, parathyroid hormone (PTH) levels become stable and reduce the risk of secondary hypoparathyroidism, which is commonly associated with low vitamin D status. In addition,
intestinal calcium absorption is enhanced, reducing the risk of secondary bone disease. These basic vitamin D functions are efficiently demonstrated at 25(OH)D levels >32 ng/mL; however, superior benefits are observed at even greater levels. For example, only at 25(OH)D levels >40 ng/mL, does vitamin D begin to be stored in the muscle and fat for future use. Therefore, at levels <40 ng/mL, the body relies on a daily replenishment of vitamin D to directly satisfy its daily requirements, which is not likely to be present in the common diet. At levels <40 ng/mL, there appears to be just enough circulating 25(OH)D available for all of the immediate metabolic needs; however, stored vitamin D is not likely available for the advanced processes involved in the critical autocrine pathways. It is estimated that the body requires 3000–5000 IU of vitamin D per day to meet the needs of “essentially every tissue and cell in the body.” The IOM recommends 600 IU of vitamin D for most adults (18–70 years of age) to prevent clinical vitamin D deficiency, defined as 25(OH)D ≤ 20 ng/mL. In contrast, most expert’s recommendations are much higher than 600 IU per day, because their recommendations are designed to help reach optimal 25(OH)D levels of at least 40 ng/mL. Intake levels recommended by most experts not only allow support for daily metabolic requirements, but also allow for vitamin D storage and increased availability, which appears to reduce the risk of many diseases and possibly enhance performance. The recommended daily vitamin D intake, according to most experts, is at least 1000 IU per day to maintain optimal 25(OH)D status; however, more is required if levels begin suboptimal. With over 77 percent of Americans considered insufficient in vitamin D, it is apparent that the current recommendations are suboptimal. Intake recommendations increase with age, pregnancy, and lactation. In addition, experts recommend much higher initial dosages if 25(OH)D levels begin deficient, ranging from 2000 to 200,000 IU, until optimal 25(OH)D levels are met, then 1000-2000 IU/day for maintenance. A commonly prescribed treatment to quickly correct vitamin D deficiency is a weekly dose of 50,000 IU of vitamin D for eight weeks. The tolerable upper limit for vitamin D has been set by the IOM at 4000 IU for adults, compared to 10,000 IU/day by the Endocrine Society. Leading experts have claimed that a daily intake of 10,000 IU would take months, or even years to manifest symptoms of toxicity. A recent publication found no cases of toxicity with daily intakes of 30,000 IU per day for an extended period of time. Regardless of the current dietary intake value, the amount of vitamin D produced from 15 min of unprotected sun exposure is 10,000 to 20,000 IU, in a light-skinned individual, making most experts believe toxicity to be a rare and unlikely event. During the months that UVB rays are available from the sun, five to 15 min of unprotected sun exposure between the hours of 10 a.m. and 3 p.m. appear to provide adequate amounts of vitamin D. There have never been any reported cases of vitamin D toxicity from overexposure to the sun; however, symptoms of intoxication, such as hypercalcemia, have been observed when 25(OH)D levels are greater than 150 ng/mL. Serum 25(OH)D levels in individuals living close to the equator and working outdoors are often around 50 ng/mL, supporting the theory that vitamin D toxicity from the sun is extremely unlikely, and suggesting that any toxicities would result only from over supplementation. Regardless, many experts agree than 1000 IU/day in the absence of proper sun exposure can maintain 25(OH)D levels of at least 32 ng/mL [13719].

Vitamine D status of athletes

The distance from the equator, season, and time of day dictate whether vitamin D is available from the sun. Production of vitamin D from the sun is also dictated by cloud cover, pollution, sunscreen, skin pigment and age. During the summer months, UVB radiation from the sun can be absorbed in adequate amounts to synthesize vitamin D. However, during winter months, the angle of the sun prevents UVB radiation from reaching latitudes greater than 35-37 degrees, therefore, vitamin D cannot be synthesized from in these areas. Research has suggested that low levels of vitamin D are widespread in populations living south of the 35th parallel. Even if one spends ample time in the sun, sunscreen with a sun protection factor (SPF) of 15 results in a 99 percent decrease in vitamin D absorption.
Individuals who spend ample time outdoors may still need vitamin D supplementation to maintain adequate levels during the winter. Many outdoor athletes avoid peak sunlight hours, opting to practice early in the morning or late at night, which greatly reduces UVB exposure, putting them at considerable risk of vitamin D insufficiency. Various studies have found many athletes to be at high risk for vitamin D insufficiencies. It was in 2009 revealed that 90 percent of Middle Eastern sportsmen were vitamin D deficient between April and October. Although these sportsmen were training at favorable latitudes, Qatar (25.4°N), they averaged less than 30 min of sun exposure per day. Another study conducted at favorable latitude (Israel 31.8°N), suggested that 73 percent of athletes were vitamin D insufficient. The majority (83 %) of female, Australian indoor athletes were also found to be vitamin D insufficient. In contrast, a study conducted at less favorable latitude (41.3°N), revealed vitamin D insufficiency in 63 percent of indoor/outdoor athletes during winter, compared to the fall (12 %) and spring (20 %) in indoor and outdoor athletes. Finally, a study conducted even further from the equator (46.9°N), using exclusively outdoor athletes, found 25-30 percent with vitamin D insufficiency from fall to winter. Storlie et al. suggested that 1000 IU/day of vitamin D was not enough to prevent seasonal decline of vitamin D status in this cohort. Although the results are variable, geographical location (latitude) and gender do not appear to be the major risk factors for vitamin D insufficiency in athletes. Lack of sun exposure appears to be the main risk factor, putting indoor athletes and those who avoid peak daylight hours, regardless of latitudinal location, at the greatest risk for vitamin D insufficiency [13719].

**Vitamin D and athletic performance**

Original research concerning vitamin D and athletic performance dates back to the early twentieth century, but current performance trials are quite limited and inconclusive. Russian and German researchers were the first to report the convincing effects of ultraviolet light irradiation for improving athletic performance and decreasing chronic sports related pain. These early European researchers suggested significant improvements in time trials, cardiovascular fitness, and strength with treatment of UVB irradiation prior to performance. German Olympic officials considered these effects significant enough for UVB radiation (vitamin D) to be considered an ergogenic aid. In support of this concept, many athletes claim to peak in physical fitness during the time of year that vitamin D (UVB) levels are at their highest, summer and fall. Unfortunately, there are limited experimental studies available and even fewer that demonstrate a performance enhancement from vitamin D supplementation. However, research examining the aging population (>65 years of age) suggests benefits from vitamin D supplementation. Multiple performance studies in older adults have related low vitamin D levels to decreased reaction time, poor balance, and an increased risk of falling. Furthermore, vitamin D supplementation (800 IU/ day) in older adults showed improvements in strength, and walking distance, and a decrease in general discomfort. These favorable results in older adults support the need for further research on athletic performance and vitamin D. The current research available to support vitamin D’s influence on performance is quite limited. An (n=39), unpublished thesis examined 25(OH)D and maximal oxygen uptake (VO2max) to determine vitamin D’s effect on aerobic fitness in physically active college males. Higher 25(OH)D levels were associated with an increased VO2max, compared to those with lower vitamin D levels. These findings suggest that a favorable vitamin D status may improve aerobic performance. In 2013 it was examined, young, United Kingdom (UK, 53°N) based athletes (n=30), and examined the effects that vitamin D supplementation (20-40,000 IU/week for 12 weeks) had on muscle performance (1-RM bench press, leg press and vertical jump height). Subjects were assigned to a placebo, 20,000 IU/week or 40,000 IU/week of vitamin D for 12 weeks. Muscle performance and 25(OH)D was measured at six and 12 weeks, revealing that six weeks of supplementation was enough to correct vitamin D deficiency, however, it was not enough to
obtain optimal vitamin D levels >40 ng/mL. Contrary to the findings in the elderly population, no significant improvements in muscle performance were observed after 6 or 12 weeks of vitamin D supplementation, although serum 25(OH)D levels significantly increased over this time, from an average of 20 ng/mL to 32-39 ng/mL. In this study, lower baseline concentrations appeared to respond greater to supplementation, therefore, future studies may find more substantial results by dividing subjects into groups based on their baseline levels. Although final 25(OH)D concentrations obtained by the athletes were no longer considered deficient (>20 ng/mL), researchers hypothesized that higher total serum levels may be necessary to document enhanced muscle performance in young athletes. To explain the lack of response, the author suggested that skeletal muscle may require higher serum concentrations for a response, compared to other tissues. The significant response shown in elderly subjects, however, may be explained by sarcopenia. If the elderly were actively losing muscle mass, they may have a more sensitive response to vitamin D supplementation in the skeletal muscle. The authors suggested that more convincing results may be observed by giving supplemental doses of vitamin D to increase serum 25(OH)D above 40 ng/mL. A larger (n=61 athletes, n=31 healthy control subjects) UK-based vitamin D supplementation trial resulted in higher mean 25(OH)D levels, as a result of 5000 IU/day of vitamin D3 for eight weeks and found promising muscle performance results. This supplementation regime significantly increased mean 25(OH)D levels from (mean ± SD) 11.62 ± 10.02 ng/mL to 41.27 ± 10.02 ng/mL, whereas a placebo group showed no significant changes. The supplementation group also displayed significant improvements in 10-meter sprint times and vertical jump (with no improvements in 1-RM bench and squat tests) compared to the placebo group. One athlete’s 25(OH)D levels increased from 22.40 ng/mL to 55.69 ng/mL and showed improvements in all performance areas, this is only one athlete however. These findings support the aforementioned hypothesis that higher serum 25(OH)D levels (>40 ng/mL) may generate more convincing performance improvements. Findings also suggest that a daily dose of vitamin D (5000 IU/day) may be superior in raising 25(OH)D levels when compared to a weekly dose (40,000 IU/week). Based off of these two preliminary studies and guidelines from leading experts, 25(OH)D levels above 40 ng/mL are likely necessary to significantly improve anaerobic athletic performance. There are no studies available that have examined the effect of vitamin D on aerobic or endurance athletic performance. To maintain 25(OH)D levels of 40 ng/mL, vitamin D supplementation, especially during the winter months, is warranted. The 25(OH)D goal of 40 ng/mL is recommended for athletes because at this level, vitamin D begins to be stored in the muscle and fat for future use. Furthermore, at levels below 32 ng/mL, vitamin D is not likely to be readily available for the advanced processes involved in the autocrine pathways, which is the pathway that is most likely to influence performance. This level is also supported by the two comparable Close et al. studies, where the study achieving 25(OH)D levels greater than 40 ng/mL showed significant effects on performance. Besides the two UK based performance trials recent research on vitamin D and athletes has focused on the prevalence of vitamin D insufficiency among athletes, not the effects on performance. Although performance trials are limited, various other studies have resulted in alternative findings to support vitamin D’s positive impact on performance. Although the results of performance trials are not yet convincing enough to support vitamin D as a direct performance enhancer, obtaining optimal 25(OH)D levels can reduce the risk of debilitating stress fracture among athletes, which may indirectly influence performance through prevention of injury. In addition, because of its active role in muscle, resolution of vitamin D insufficiency has the potential to impact performance [13719]

Summer versus winter

Serum 25-hydroxyvitamin D is produced by the exposure of the skin to sunlight. Therefore athletes who train indoors, such as dancers, are vulnerable to vitamin D deficiency. The purpose of the study was to evaluate the serum 25-hydroxyvitamin D status in UK
professional dancers during periods of reduced and increased sunlight exposure (i.e. winter vs summer), and to assess the impact on bone metabolism and risk of injury. Nineteen elite classical ballet dancers (age 26 years; height 1.66 m; mass 54 kg) were monitored over a 6 month period for 25-hydroxyvitamin D, PTH and blood serum bone turnover markers (CTX and PINP) along with injury data. Repeated measure ANOVA and Wilcoxon and Chi-square analyses were used. Significant changes were noted between the winter and summer test dates for 25-hydroxyvitamin D, PTH, and PINP. The oral contraceptive had a significant effect on serum 25-hydroxyvitamin D, PTH and CTX. Soft tissue injuries were significantly lower in summer compared to winter period. It was concluded that professional ballerinas characterized by a high incidence of low serum 25-hydroxyvitamin D levels which improve marginally in the summer. These dancers also demonstrate a higher injury incidence in the winter. Oral contraception seems to increase serum 25-hydroxyvitamin D levels and has a positive effect on bone metabolism [13725].

Experimental

Vitamin D is an important factor for calcium and phosphorus homeostasis. A negative relationship has been observed between vitamin D status and diseases such as cancer, arthritis, diabetes, and muscle fiber atrophy. However, the relationship between vitamin D and prevention of skeletal muscle damage has not been clearly elucidated. The purpose of one study was to investigate the effects of vitamin D on exercise-induced muscle changes. Rats were divided into 3 groups: (1) sedentary control (C: n=10), (2) high-intensity exercise (HE: n=10), and (3) high-intensity exercise with vitamin D supplementation (HED: n=10; i.p. 1000 IU/kg body weight). Rats were trained for 30 min/day on treadmills (5 days/week for 8 weeks) with the running speed gradually increased up to 30 m/min at a 3° incline. At the end of the training period, the running speed was 38 m/min at a 5° incline. The high-intensity exercise significantly increased plasma creatine kinase (CK) and lactate dehydrogenase (LDH) activity. In addition, IL-6 and TNF-alpha levels as well as phosphorylation of AMPK, p38, ERK1/2, IKK, and IkappaB were significantly increased. Vitamin D-treated rats showed a significant decrease in plasma CK level, phosphorylation of AMPK, p38, ERK1/2, IKK, and IkB, and gene expression of IL-6 and TNF-α. Furthermore, the protein expression of vitamin D receptor (VDR) was highly increased in the muscles of HED-treated rats, respectively. Therefore, it was concluded that vitamin D may play a pivotal role in exercise-induced muscle damage and inflammation through the modulation of MAPK and NF-kappaB involved with VDR [13726].

Vitamin A

One study aimed to examine the effects of both physical activity and vitamin A supplementation on trace element metabolism in individuals engaged in taekwondo. The study registered seven healthy male national taekwondo players. The subjects were supplemented with oral administration of 100 mg vitamin A (retinol) for 6 weeks, and concurrently, they were subjected to taekwondo training 5 days a week. Before starting the vitamin A supplementation, blood samples were taken from the subjects twice, once at rest and once after exhaustion. Similarly, at the end of the 6-week vitamin A supplementation, two blood samples were taken from the subjects, once at rest and once after exhaustion, in order to determine (by atomic emission) and compare serum cobalt, molybdenum, calcium, cadmium, chromium, copper, manganese, sodium, nickel, phosphorus, sulfur, iron, boron, and zinc (mg/L) levels. Values of boron and nickel dropped significantly after 6-week vitamin A supplementation. Reduced levels of boron and nickel we obtained in the present study are believed to result from the antioxidant effect of long-term vitamin A supplementation [10250].
Coenzyme Q10

Coenzyme Q10 (originally known as ubiquinone), a coenzyme in the electron shuttle system of the inner mitochondrial membrane, is part of the total antioxidant defence system. It protects different cell structures from free oxygen radicals produced during oxygen stress such as severe physical exercise. Therefore athletes have used antioxidant supplements to strengthen antioxidant defence during training and competition. However, it was recently proposed that free radicals may have useful functions in the body, particularly in the signalling pathways associated with exercise stimulus. Thus, free radical production may be a prerequisite for training effects in muscle. On the basis of available findings, and recent general caution about antioxidant supplementation combined with exercise, it is not recommended that athletes take coenzyme Q10 supplements [10251].

The theoretically beneficial effects of coenzyme Q10 (Q10) on exercise-related oxidative stress and physical capacity have not been confirmed to our knowledge by interventional supplementation studies. The aim of one study was to investigate further whether Q10 supplementation at a dose recommended by manufacturers influences these factors. Using a randomized, double-blind, controlled design, we investigated the effect on physical capacity of 8 wk of treatment with a daily dose of 90 mg of Q10 (n=12) compared with placebo (n=11) in moderately trained healthy men 19 to 44 years old. Two days of individualized performance tests to physical exhaustion were performed before and after the intervention. Primary outcomes were maximal oxygen uptake, workload, and heart rate at the lactate threshold. Secondary outcomes were creatine kinase, hypoxanthine, and uric acid. No significant differences between the groups were discerned after the intervention for maximal oxygen uptake, workload at lactate threshold, or heart rate at lactate threshold were found, neither any differences between the groups were detected for hypoxanthine or uric acid (serum markers of oxidative stress) or creatine kinase (a marker of skeletal muscle damage). It was concluded that although in theory Q10 could be beneficial for exercise capacity and in decreasing oxidative stress, the present study could not demonstrate that such effects exist after supplementation with a recommended dose [12445].

Folate

Adequate folate intake is important for athletes and active individuals because of its role in red blood cell (RBC) production and tissue repair and maintenance. Folate plays a significant part in cell division, especially in tissues with rapid turnover such as RBCs. Folate deficiency leads to anaemia, caused by failure of the red cell precursors to develop into functional RBCs. The result is abnormally large RBCs that cannot effectively transport oxygen or remove carbon dioxide. For many countries, the recommended dietary allowance (RDA) for folate is 400 µg/day for individuals aged >19 years. Folate is found in many foods but is especially high in leafy green vegetables, nuts, legumes and liver. The bioavailability of folate in food is about 50 percent but is reduced by prolonged cooking. Many foods, such as breakfast cereals, are fortified with synthetic folic acid (50-100 % of the RDA for folate), which is highly bioavailable (85 %). Some countries have also made fortification of folic acid in enriched breads, flours and other grain products compulsory. Thus, the diets contain a mixture of food folate and synthetic folic acid with differing levels of bioavailability. Overall, the diets of active males appear to be adequate in folate as long as energy intake is adequate. Conversely, the apparent intake of dietary folate is consistently below recommendations for active females, which can be due to energy restriction for weight loss.
1868

and/or under-reporting of food intake in food records. However, in female marathon runners, although folate supplementation (5 g/day for 10 weeks in conjunction with iron) improved blood folate levels, there was no effect on performance [10527].

Adequate folate intake is important for athletes and active individuals because of its role in red blood cell (RBC) production and tissue repair and maintenance. Folate plays a significant part in cell division, especially in tissues with rapid turnover such as RBCs. Folate deficiency leads to anaemia, caused by failure of the red cell precursors to develop into functional RBCs. The result is abnormally large RBCs that cannot effectively transport oxygen or remove carbon dioxide. For many countries, the recommended dietary allowance (RDA) for folate is 400 microg/day for individuals aged >19 years. Folate is found in many foods but is especially high in leafy green vegetables, nuts, legumes and liver. The bioavailability of folate in food is about 50 percent, but reduced by prolonged cooking. Many foods, such as breakfast cereals, are fortified with synthetic folic acid (50-100 % of the RDA for folate), which is highly bioavailable (about 85 %). Some countries have also made fortification of folic acid in enriched breads, flours and other grain products compulsory. Thus, our diets contain a mixture of food folate and synthetic folic acid with differing levels of bioavailability. Overall, the diets of active males appear to be adequate in folate as long as energy intake is adequate. Conversely, the apparent intake of dietary folate is consistently below recommendations for active females, which can be due to energy restriction for weight loss and/or under-reporting of food intake in food records. However, in female marathon runners, although folate supplementation (5 g/day for 10 weeks in conjunction with iron) improved blood folate levels, there was no effect on performance [11279].

Vitamin K

Vitamin K is of interest to sports performance through its identified potential either to prevent or enhance the healing of bone injury. Vitamin K is a co-enzyme involved in the gamma-carboxylation of certain proteins in bone, including osteocalcin. Vitamin K is found in plant-based food as phylloquinone (K1) and can be synthesised by bacteria as menaquinones (K2). Current recommended dietary intakes for vitamin K are based on a diet sufficient to promote normal blood clotting and it is possible that this is inadequate for optimal bone health. Low vitamin K status has also been linked with increased risk of hip fracture. Reduction in the number of bone injuries or the time taken to recover from these could be a significant performance enhancer in sport by reducing training time lost to injury. The impact of vitamin K on bone health has been examined mostly in postmenopausal women. In a recent meta-analysis the impact of supplementation was assessed against bone loss and fracture risk with the conclusion that vitamin K2 supplementation may decrease fracture risk and that both K1 and K2 reduced bone loss. Another meta-analysis examined the relationship between vitamin K supplementation and bone mineral density (BMD). It was concluded that supplementation with K1 may improve bone density at the lumbar spine but not at the femoral neck, although there was a large heterogeneity in results between studies. Doses studied varied between 1 and 45 mg/day which are well above the current Australian adequate intake of 60-70 microg/day. In both meta-analyses the majority of studies were undertaken in postmenopausal Asian women, which means this may not be generalised to other population groups such as athletes. To date only two studies have been conducted in athletic populations. The first found that K1 supplementation (10 mg/day for 4 weeks) improved markers of bone formation in athletes. Five of eight athletes were classed as deficient in vitamin K at baseline and supplementation had a larger effect on bone markers in these athletes. It is unclear as to why there was such a high incidence of deficiency in this group and whether this is representative of status in athlete populations generally. In another

1868
undertook a 2-year follow-up study looking at supplementation (10 mg/day, K1) in 115 female runners. Menstrual status was assessed and bone loss was measured by BMD. No benefit of supplementation was found. Limitations of the study were infrequent follow-up (6 monthly contact) and no adherence measures. While research relating to vitamin K is interesting, further studies are required before it is routinely considered in the management of bone health in athletes [13715].

Vitamin C

Prolonged physical exertion and environmental heat stress may elicit postexercise depression of immune cell function, increasing upper respiratory tract infection (URTI) susceptibility. It was investigated the effects of acute and short-term vitamin C compared with placebo supplementation on URTI susceptibility, salivary immunoglobulin A, and cortisol responses in healthy individuals following prolonged exercise-heat stress. Twelve participants were randomized in a double-blind design. For 12 days, participants consumed 3 x 500 mg tablets per day, with testing completed at baseline, then following acute (1 d) and short-term (8 d) supplementation. There was a significant linear trend in postexercise cortisol attenuation in the vitamin C group at baseline. No differences were detected in ratio of salivary sIgA to protein or URTI symptoms between groups. These data suggest that vitamin C supplementation can decrease postexercise cortisol in individuals performing exercise similar to that of a half-marathon or marathon in hot conditions. However, no changes in sIgA and URTI were evident, possibly due to previous moderate training and reduced physical and psychological stress compared with athletes participating in ultramarathons [09355].

Epidemiological data suggest that diets rich in antioxidants protect against diseases associated with free radical damage, including cancer, cardiovascular disease and diabetes. Early observations also suggested that vitamin supplements with antioxidant properties, like vitamins C and E, could also prevent or ameliorate pre-eclampsia, but most large randomized clinical trials have failed to show any benefit. Vitamin C given orally, even at high doses, does not achieve sustained serum levels that might be required for effective antioxidant activity. This may explain the failure of the numerous clinical trials involving its use in pre-eclampsia, cancers, cardiovascular diseases, etc. Vitamin C supplementation to stave off pre-eclampsia, cancer and other diseases is a 'nutraceutical' industry-driven myth which should be abandoned. We do not dispute a role for oxidative stress in the pathophysiology of pre-eclampsia, nor the possibility of amelioration of the disease by an anti-oxidant given at the right time and in the correct dosage. It was advocated to make a case that the massive and expensive clinical trials of vitamins C and E should cease until further rigorous scientific research is undertaken [11405].

Ascorbic acid is highly concentrated in the brain, being considered as a neuromodulator. This study investigated the effect of ascorbic acid in the tail suspension test (TST) and in the forced swimming test (FST) in mice and the contribution of the monoaminergic system to its antidepressant-like effect. Moreover, the effects of fluoxetine, imipramine and bupropion in combination with ascorbic acid in the TST were investigated. Ascorbic acid (0.1-10 mg/kg, i.p., 1-10 mg/kg p.o. or 0.1 nmol/mice i.c.v.) produced an antidepressant-like effect in the TST, but not in the FST, without altering the locomotor activity. The effect of ascorbic acid (0.1 mg/kg, i.p.) in the TST was prevented by i.p. pre-treatment with NAN-190 (0.5 mg/kg), ketanserin (62.5 microg/kg), yohimbine (1 mg/kg), prazosin (2 mg/kg), haloperidol (0.2 mg/kg), sulpiride (50 mg/kg), but not with SCH23390 (0.05 mg/kg, s.c.). Additionally, ascorbic acid (1 mg/kg, p.o.) potentiated the effect of subeffective doses (p.o. route) of fluoxetine (1 mg/kg), imipramine (0.1 mg/kg), or
bupropion (1 mg/kg) in the TST. The combined treatment of ascorbic acid with antidepressants produced no alteration in the locomotion in the open-field test. In conclusion, the results show that administration of ascorbic acid produces an antidepressant-like effect in TST, which is dependent on its interaction with the monoaminergic system. Moreover, ascorbic acid caused a synergistic antidepressant-like effect with conventional antidepressants. Therefore, the present findings warrant further studies to evaluate the therapeutical relevance of ascorbic acid for the treatment of depression and as a co-adjuvant treatment with antidepressants [09356].

The risk of upper respiratory infections (URIs) is increased in people who are under heavy physical stress, including recreational and competitive swimmers. Additional treatment options are needed, especially in the younger age group. The aim of one study was to determine whether 1 g/day vitamin C supplementation affects the rate, length, or severity of URIs in adolescent swimmers. It was carried out a randomized, double-blind, placebo-controlled trial during three winter months, among 39 competitive young swimmers (mean age 14 ± 2 years) in Jerusalem, Israel. Vitamin C had no effect on the incidence of URIs (rate ratio 1.01; 95 % confidence interval 0.70 to 1.46). The duration of respiratory infections was 22 percent shorter in vitamin C group, but the difference was not statistically significant. However, it was found a significant interaction between vitamin C effect and gender, so that vitamin C shortened the duration of infections in male swimmers by 47 percent, but had no effect on female swimmers. The effect of vitamin C on the severity of URIs was also different between male and female swimmers, so that vitamin C was beneficial for males, but not for females. The study indicates that vitamin C does not affect the rate of respiratory infections in competitive swimmers [11293].

To test the hypothesis that antioxidants can attenuate high-intensity interval training-induced improvements in exercise performance two groups of recreationally active males performed a high-intensity interval running protocol, four times per week for 4 weeks. Group 1 (n=8) consumed 1 g of vitamin C daily throughout the training period, whereas Group 2 (n=7) consumed a visually identical placebo. Pre- and posttraining, subjects were assessed for VO$_{2\text{max}}$, 10 km time trial, running economy at 12 km/h and distance run on the YoYo intermittent recovery tests level 1 and 2 (YoYoIRT1/2). Subjects also performed a 60 min run before and after training at a running velocity of 65 percent of pretraining VO$_{2\text{max}}$ so as to assess training-induced changes in substrate oxidation rates. Training improved VO$_{2\text{max}}$, 10 km time trial, running economy, YoYoIRT1 and YoYoIRT2 in both groups, although there was no difference between groups in the magnitude of training-induced improvements in any of the aforementioned parameters. Similarly, training also decreased mean carbohydrate and increased mean fat oxidation rates during submaximal exercise in both groups, although no differences existed between training conditions. It was concluded that daily oral consumption of 1 g of vitamin C during a 4 week high-intensity interval training period does not impair training-induced improvements in the exercise performance of recreationally active males [11294].

Vitamin C, also known as ascorbate and ascorbic acid is synthesized by all animals except humans, monkeys, guinea pigs, bats, and several bird species. The chief biologic function of vitamin C is as a water-soluble reducing agent (i.e. electron donor). Vitamin C has the potential to reduce cytochromes a and c of the electron transport chain, as well as molecular oxygen itself. Arguably the most important reaction requiring ascorbic acid as a cofactor involves the hydroxylation of proline residues in collagen. As such, vitamin C is required for the maintenance of normal connective tissue and wound healing. Vitamin C also is needed for the remodeling of bone, because of the presence of collagen in the organic matrix. A number of other metabolic reactions require vitamin C to act as a cofactor; notable among those are the synthesis of epinephrine from tyrosine, and the synthesis of the bile acids.
Also, vitamin C is suspected to have involvement in the process of adrenal steroidogenesis. Other putative biochemical uses of vitamin C include a role in antioxidant protection, thyroxin synthesis, amino acid metabolism, strengthening resistance to infection, and aiding in the absorption of iron. The work of Nobel Prize laureate Linus Pauling stimulated public interest in megadoses of this vitamin to prevent infection with the viruses responsible for the common cold; research on this topic over the past 20 years has offered conflicting results. The classic vitamin C deficiency disease is scurvy, due to the role of the vitamin in the post-translational modification of collagens. Vitamin C deficiency symptoms include small cell-type anemia, atherosclerotic plaques, and pinpoint hemorrhages; bone fragility and joint pain; poor wound healing and frequent infections; bleeding gums and loosened teeth; muscle degeneration and pain, hysteria and depression; and rough skin and blotchy bruises. An excessive intake of vitamin C (e.g. gram doses) may cause diarrhea, abdominal bloating, overabsorption of iron, hyperoxalemia (in dialysis patients), and hemolysis (in patients with glucose-6 phosphate dehydrogenase deficiency). A tolerable upper intake level for vitamin C was set at 2000 mg/d by the Food and Nutrition Board in 2000. The current RDA is 90 mg for men, and 75 mg for women (with an additional 35 mg added for smokers), and at these doses, vitamin C bioavailability is close to 100 percent. Significant food sources include citrus fruits, cabbage-type vegetables, dark green vegetables, cantaloupe, lettuce, tomatoes, potatoes, papayas, and mangoes. Despite its abundance in foods, it is important to note that vitamin C is easily destroyed by light, heat, and oxygen [06284].

Exercise involving lengthening muscle actions, such as downhill running, results in delayed onset muscle soreness (DOMS), which may be attributable to reactive oxygen species (ROS). Although exercise causes oxidative stress, any link between ROS and DOMS remains speculative. There is emerging evidence to suggest that ROS play an important physiological role, assisting in the recovery process and protecting the cell from future damage; however, this has not been fully established. Despite this uncertainty as to the precise role of ROS, attempts to prevent post-exercise ROS production through antioxidant intervention are still common. The study investigated the effects of ascorbic acid supplementation on ROS production and DOMS following downhill running. Subjects were assigned to two groups. The ascorbic acid group (group AA) received 1 g ascorbic acid 2 h pre-, and for 14 d post-downhill running, whilst the placebo group (Pl group) received a placebo. Blood samples were drawn pre-supplement, pre- and post-exercise, and then 1, 2, 3, 4, 7 and 14 d post-exercise for analysis of ascorbate, malonaldehyde and total glutathione. DOMS was assessed using a visual analogue scale and pressure algometry. Muscle function was assessed using isokinetic dynamometry. Plasma ascorbate was elevated throughout in group AA compared with the Pl group. Downhill running resulted in DOMS in both groups. Muscle function was impaired post-exercise in both groups, although a delayed recovery was noted in group AA. Malonaldehyde increased 4 d post-exercise in the Pl group only. Ascorbic acid supplementation attenuates ROS production following downhill running, without affecting DOMS. Furthermore, ascorbic acid supplementation may inhibit the recovery of muscle function [06285].

An increased systemic concentration of stress hormones (of the hypothalamic-pituitary adrenal axis) and some cytokines may contribute to the depression of immune cell function typically observed after prolonged exercise. The aim of the present study was to determine the effect of 2 weeks of supplementation with vitamin C (VC) on cortisol, adrenocorticotropic hormone, interleukin-6, oxidative stress and neutrophil responses to a single bout of endurance exercise. Nine healthy endurance-trained males exercised for 2.5 h at 60 percent VO\textsubscript{2max} after 2 weeks of placebo (PLA) or VC (1,000 mg/day) supplementation. All participants completed both trials utilising a randomised crossover design with a minimum 14 day washout period between trials. There was a significant trial x time interaction effect for plasma cortisol concentration which tended to be lower in the VC trial but post hoc analysis
found no specific between trial differences. There was a significantly lower post-exercise
neutrophilia in the VC trial, compared with the PLA trial. There was no trial x time interaction
for measures of neutrophil function (bacteria-stimulated elastase release, fMLP or PMA-
stimulated oxidative burst). However, there was a trend for higher fMLP-stimulated neutrophil
oxidative burst in the VC compared with PLA trial (trial x time interaction). These results
suggest that supplementation with VC for a period of up to 2 weeks provides little to no
protection against the depression of neutrophil function which typically occurs after
endurance exercise [06286].

Vitamin C is an essential component of the diet and may reduce the adverse effects of
exercise-induced reactive oxygen species, including muscle damage, immune dysfunction,
and fatigue. While supplement sales remain high, the debate as to whether athletes need
supplemental vitamin C continues. Vitamin C certainly plays an important role in immune
function, collagen synthesis, and cortisol synthesis, and it removes free radical intermediates
that initiate damaging cell reactions. Numerous studies have demonstrated an increase in
reactive oxygen species (ROS) or their byproducts with moderate to high intensity exercise.
As signaling molecules, ROS can modify target proteins by oxidizing thiol groups, forming
disulfide bonds that reversibly alter protein structure and function, therefore supplementing
with vitamin C may be expected to enhance athletic performance by reducing the potential
negative consequences of ROS. On the other hand, ROS released in exercise instigates cell
signaling for training adaptations, which vitamin C blocks. Supplementation with vitamin C
may therefore impair performance. The studies included in one review used the search terms
vitamin C, exercise, and athletes. Additional studies were sourced from reference lists in
related articles and books on the topic cited from 1985 to January 2012, with an initial list of
42 articles, with 12 of these included in the final review. From a total of 12 studies, vitamin C
in doses >1 g/day impaired sport performance substantially in four of four studies, possibly
by reducing mitochondrial biogenesis, while a further four studies demonstrated impairments
that were not statistically significant. Doses of about 0.2 g/day of vitamin C consumed
through five or more servings of fruit and vegetables may be sufficient to reduce oxidative
stress and provide other health benefits without impairing training adaptations [12437].

Of the human studies, the results are more varied; of the four studies supplementing with
vitamin C alone, three studies reported performance impairment and one reported
improvement, although all were nonsignificant. In the untrained humans, while the results are
mixed, the magnitude of the performance appears to be greater than in the trained, although
the results are insignificant. Overall, of the seven studies that supplemented with vitamin C
alone, three demonstrated significant performance impairments. Those studies
demonstrating a performance improvement were all nonsignificant outcomes. Regarding the
dose of vitamin C, of the four studies demonstrating significant performance decrements,
three adopted large supplemental doses of vitamin C (>0.5 g/kg daily) and two used a long-
term supplement protocol (>8 weeks). In particular, vitamin C prevented transcription of
genes involved in mitochondrial biogenesis (PGC1>) and the training-induced increase in
cytochrome C concentration (a marker of mitochondrial content) and messenger RNA
(mRNA) expression of the antioxidant enzymes superoxide dismutase and glutathione
peroxidase. It is shown that the exercise-induced rise in ROS is necessary for physiological
adaptations, including PGC1>, to training. The inhibition of mitochondrial growth is one
mechanism by which vitamin C impairs performance, given the important role that the
mitochondria play in aerobic energy metabolism. In addition to the retardation of
mitochondrial growth, ROS has been shown to regulate various intermediate activation
factors, responsible for optimal muscle cell function. ROS increases kinase activity (including
ERK, JNK, and p38) while reducing phosphatase activity (including PTEN and calcineurin),
resulting in the activation of transcription factors (p53, NK-JB, and ATF2). Physiological
changes that occur following moderate ROS production include increases in mitochondrial
growth factors, cell survival proteins (B-cell lymphoma 2), reduction in muscle atrophy and proteins involved in cell death signaling pathways (Bcl-2), and amplification of immune function. It is likely that supplementing with vitamin C may blunt numerous transcription factors responsible for adaptation to training not just PGC1. Distinct from the effects of vitamin C on mitochondrial growth, one study has demonstrated reductions in vascular function with mixed antioxidants. Reductions in exercise-induced redistribution of blood flow to skeletal muscles have been shown to reduce exercise capacity. Thus, vitamin C may reduce exercise-induced blood flow, reducing exercise capacity and performance [12437].

**Optimal vitamin C intake for athletes**

The US recommended intake of vitamin C for healthy individuals of 60 mg/day is based on the needs of nonactive healthy individuals, therefore not necessarily appropriate for athletes. For athletes with low vitamin C concentrations at baseline, will supplementing alter performance outcomes? While it is natural to presume that athletes with low baseline levels will benefit, this issue has not been well answered. Certainly in the general population, patients with ulcers and low vitamin C concentrations who supplemented with 500 mg daily demonstrated improved healing compared with controls. At present, it is safe to advise athletes to aim at the higher end of the recommended fruit and vegetable servings, in an attempt to consume adequate vitamin C, folate, magnesium, potassium, fiber, vitamins A, and other as-yet unidentified phytochemicals. Chronically megadosing with vitamin C is not recommended, although a moderate intake of 0.2 g daily consumed in the form of fruit and vegetables can be justified for health reasons. The impact vitamin C has on sport performance will depend on the exercise duration, dosage period, and background diet of the athlete. As far as the ideal vitamin C dose is concerned, it could be speculated that higher intakes taken for short period of time, such as onset of illness or during training camps, may provide benefit [12437].

**Vitamin C and E**

The antioxidant vitamins C (ascorbic acid) and E (alpha, beta, gamma, and delta tocopherols and tocotrienols) are involved in protecting cellular organelles from oxidative damage. Exercise can increase free radical production by 2- to 4-fold and produce changes in redox status which may exert oxidative stress on muscles and other tissues leading to alteration of lipids, proteins, and genetic material. Short-term exercise results in temporary increases in concentrations of oxidized products, but habitual exercise may result in an augmented endogenous antioxidant system and a reduction in oxidized products. Supporting endogenous antioxidant defense systems with additional oral doses of antioxidants has received much attention as a strategy to reduce oxidative stress, decrease muscle damage, and improve exercise performance. Indeed, a significant number of athletes, including elite athletes, consume vitamin supplements seeking beneficial effects on performance. However, recently, there is a growing evidence of the negative effects of antioxidant supplementation on exercise performance in both animal and human studies. In light of the results of these prolific studies, it was concluded that vitamin C and/or E interfere with the adaptive responses to endurance exercise training. More studies followed trying to delineate the possible effects of antioxidant supplementation on adaptations in exercise performance and/or redox homeostasis. In this context, it was performed the present literature analysis to evaluate whether antioxidant vitamin C and/or E supplementation affect the favorable adaptations of exercise. The detrimental outcomes associated with unregulated and excessive production of free radicals remains a physiological concern that has implications to health, medicine and performance. Available evidence suggests that physiological
adaptations to exercise training can enhance the body's ability to quench free radicals and circumstantial evidence exists to suggest that key vitamins and nutrients may provide additional support to mitigate the untoward effects associated with increased free radical production. However, controversy has risen regarding the potential outcomes associated with vitamins C and E, two popular antioxidant nutrients. Recent evidence has been put forth suggesting that exogenous administration of these antioxidants may be harmful to performance making interpretations regarding the efficacy of antioxidants challenging. The available studies that employed both animal and human models provided conflicting outcomes regarding the efficacy of vitamin C and E supplementation, at least partly due to methodological differences in assessing oxidative stress and training adaptations. Based on the contradictory evidence regarding the effects of higher intakes of vitamin C and/or E on exercise performance and redox homeostasis, a permanent intake of non-physiological dosages of vitamin C and/or E cannot be recommended to healthy, exercising individuals [12438].

Vitamin C and E supplementation has been shown to attenuate the acute exercise-induced increase in plasma interleukin-6 (IL-6) concentration. Here, we studied the effect of antioxidant vitamins on the regulation of IL-6 expression in muscle and the circulation in response to acute exercise before and after high-intensity endurance exercise training. Twenty-one young healthy men were allocated into either a vitamin (VT; vitamin C and E, n=11) or a placebo (PL, n=10) group. A 1-h acute bicycling exercise trial at 65 percent of maximal power output was performed before and after 12 weeks of progressive endurance exercise training. In response to training, the acute exercise-induced IL-6 response was attenuated in PL, but not in VT. However, no clear difference between groups was observed (group × training). Endurance exercise training also attenuated the acute exercise-induced increase in muscle-IL-6 mRNA in both groups. Oxidative stress, assessed by plasma protein carbonyls concentration, was overall higher in the VT compared with the PL group (group effect). This was accompanied by a general increase in skeletal muscle mRNA expression of antioxidative enzymes, including catalase, copper-zinc superoxide dismutase, and glutathione peroxidase 1 mRNA expression in the VT group. However, skeletal muscle protein content of catalase, copper-zinc superoxide dismutase, or glutathione peroxidase 1 was not affected by training or supplementation. In conclusion, the results indicate that, although vitamin C and E supplementation may attenuate exercise-induced increases in plasma IL-6 there is no clear additive effect when combined with endurance training [12439].

In order to study the effects of vitamin E and vitamin C supplementation on the bioenergetic index, 36 male physical education students were selected nonrandomly and assigned to a different supplementation protocol. The average age was 23 years. The period of supplementation lasted 3 weeks. The subjects from group 1 consumed a daily dose of 400 mg of vitamin E, subjects from group 2 ingested 1000 mg of vitamin C, subjects from group 3 ingested 400 mg of vitamin E along with 1000 mg of vitamin C, and subjects from group 4 (control group) consumed a placebo. The tests applied were the running anaerobic sprint test (RAST) and the Cooper 12-min run test. The results indicate that there were no significant differences between groups during the study in anaerobic power assessed by RAST. It was found a significant difference between group's, however, in aerobic power. It was concluded that daily consumption of vitamin E, vitamin C, and a combination of vitamin E and vitamin C for a period of 3 week significantly improved aerobic power [07369].

Like every redox-active compound vitamin E may exert pro-oxidative and antioxidative effects depending on the reaction partners present. In this work we evaluated the intensity of oxidative stress produced by a physical exercise through swimming as well as of protecting action of antioxidant vitamins E and C. Antioxidant systems include antioxidant enzymes: superoxide-dismutase (SOD), catalase (CAT), glutathion peroxidase (GSH-Px), as well as of
components with an antioxidant action of the reduced glutathion type (GSH) and vitamins E and C. We determine the activities of these enzymes in the erythrocytes and heart homogenate. Our results points out a protective effect against oxidative stress produced by swimming in animals treated with vitamins E and C, which are expressed through the diminution of the malondialdehyde (MDA) quantity both in erythrocytes and in the heart, and through the conservation of GSH content in both products. CAT and GSH-Px activities decrease while that of SOD increases on both tissues, but with different intensities in accordance with the variation of protection degree performed by the vitamin couple on these tissues. The obtained data underline the necessity of intensifying the means of endogenous anti-radical defence with exogenous antioxidant vitamins C and E. This study highlights the need of a proper vitamin supplement in organism under stress [07370].

In order to study the effects of vitamin E and vitamin C supplementation on the bioenergetic index, 36 male physical education students were selected nonrandomly and assigned to a different supplementation protocol. The average age was 22 years. The period of supplementation lasted 3 weeks. The subjects from group 1 consumed a daily dose of 400 mg of vitamin E, subjects from group 2 ingested 1000 mg of vitamin C, subjects from group 3 ingested 400 mg of vitamin E along with 1000 mg of vitamin C, and subjects from group 4 (control group) consumed a placebo. The tests applied were the running anaerobic sprint test (RAST) and the Cooper 12-min run test. The results indicate that there were no significant differences between groups during the study in anaerobic power assessed by RAST. It was found a significant difference between group’s, however, in aerobic power. It was concluded that daily consumption of vitamin E, vitamin C, and a combination of vitamin E and vitamin C for a period of 3 week significantly improved aerobic power [07371].

Intense and exhaustive exercise (IEE) is associated with oxidative stress in skeletal muscle, and it was recently reported that intestine is sensitive to IEE. In one study, it was investigated the possible relationship between the effects of IEE on morphology and oxidative markers in the ileum and isolated mitochondria. Mice were ascribed either to a control group comprising two subgroups, one sedentary and another exercised for 10 days (E10), or to a corresponding supplemented control group again comprising two subgroups, one sedentary and another exercised for 10 days (E10-V). The IEE program consisted of a single daily treadmill running session at 85 percent of V\(_{\text{max}}\), until animal exhaustion. Vitamins C (10 mg/kg) and E (10 mg/kg) were concurrently intraperitoneally administered 2 h before the exercise sessions. IEE was shown to cause impairment of ileum internal membrane mitochondria verified by ultramicrography analysis, and increase in ileum carbonyl content (117 %) and reduction in antioxidant capacity (36 %), and increase in mitochondria carbonyl content (38 %), increase in the percentage of ruptured mitochondria (25 %), increase in superoxide dismutase activity (186 %), and reduction in citrate synthase activity (40 %) compared with control animals. Observations in the vitamin-supplemented exercised animals (E10-V) were healthy appearance of myocyte mitochondria, decrease in ileum carbonyl content (66 %) and increase in antioxidant capacity (53 %), decrease in mitochondria carbonyl content (43 %), decrease in the percentage of ruptured mitochondria (30 %), slight increase in superoxide dismutase activity (7 %), and significant increase in citrate synthase activity (121 %) compared with E10 animals. Therefore, the present results strongly corroborate the hypothesis that IEE leads to marked disturbances in intestinal mitochondria, mainly in redox status, and affects whole intestinal redox status [09357].

There is a considerable commercial market, especially within the sports community, claiming the need for antioxidant supplementation. One argument for antioxidant supplementation in sports is that physical exercise is associated with increased reactive oxygen and nitrogen species (RONS) production, which may cause cell damage. However, RONS production may also activate redox sensitive signaling pathways and transcription factors, which
subsequently may promote training adaptation. The aim was now to investigate the effects of combined vitamin C and E supplementation to healthy individuals on different measures of exercise performance after endurance training. Using a double-blinded placebo-controlled design, moderately trained young men received either oral supplementation with vitamins C and E (n=11) or placebo (n=10) before and during 12 weeks of supervised, strenuous bicycle exercise training of a frequency of 5 days/week. Muscle biopsies were obtained before and after training. After the training period, maximal oxygen consumption, maximal power output, and workload at lactate threshold all increased significantly in both groups. Also, glycogen concentration, citrate synthase (CS), and beta-hydroxyacyl-CoA dehydrogenase (beta-HAD) activity in muscle were significantly higher in response to training in both groups. However, there were no differences between the two groups with regard to any of the physiological and metabolic variables measured. The results suggest that administration of vitamins C and E to individuals with no prior vitamin deficiencies has no effect on physical adaptations to strenuous endurance training [09358].

Exercise practitioners often take vitamin C supplements because intense muscular contractile activity can result in oxidative stress, as indicated by altered muscle and blood glutathione concentrations and increases in protein, DNA, and lipid peroxidation. There is, however, considerable debate regarding the beneficial health effects of vitamin C supplementation. One double-blind and randomized study was designed to study the effect of vitamin C on training efficiency in rats and in humans. Fourteen men (27-36 years old) were trained for 8 week. Five of the men were supplemented daily with an oral dose of 1 g vitamin C. In the animal study, 24 male Wistar rats were exercised under 2 different protocols for 3 and 6 week. Twelve of the rats were treated with a daily dose of vitamin C (0.24 mg/cm² body surface area). The administration of vitamin C significantly hampered endurance capacity. The adverse effects of vitamin C may result from its capacity to reduce the exercise-induced expression of key transcription factors involved in mitochondrial biogenesis. These factors are peroxisome proliferator-activated receptor co-activator 1, nuclear respiratory factor 1, and mitochondrial transcription factor A. Vitamin C also prevented the exercise-induced expression of cytochrome C (a marker of mitochondrial content) and of the antioxidant enzymes superoxide dismutase and glutathione peroxidase. This means that vitamin C supplementation decreases training efficiency because it prevents some cellular adaptations to exercise [08397].

In order to study the effects of vitamin E and vitamin C supplementation on the bioenergetic index, 36 male physical education students were selected nonrandomly and assigned to a different supplementation protocol. The period of supplementation lasted 3 weeks. The subjects from group 1 consumed a daily dose of 400 mg of vitamin E, subjects from group 2 ingested 1000 mg of vitamin C, subjects from group 3 ingested 400 mg of vitamin E along with 1000 mg of vitamin C, and subjects from group 4 (control group) consumed a placebo. The tests applied were the running anaerobic sprint test (RAST) and the Cooper 12-min run test. The results indicate that there were no significant differences between groups during the study in anaerobic power assessed by RAST. It was found a significant difference between group's, however, in aerobic power and it was concluded that daily consumption of vitamin E, vitamin C, and a combination of vitamin E and vitamin C for a period of 3 week significantly improved aerobic power [08398].

The need for energy in strenuous exercises necessitates an increase in oxygen consumption and production of reactive oxygen species. It seems that supplementation of vitamins C and E reduces exercise-induced oxidative stress. Therefore, one study aimed to investigate the effects of vitamin C and E supplementation on muscle damage and oxidative stress in female athletes. The study was a four-week randomized, double-blind clinical trial, conducted on 64 trained female athletes recruited in the Isfahan sports club. They were randomly assigned to
one of the following four groups: (a) vitamin C (250 mg/day), (b) vitamin E (400 IU), (c) vitamin C + vitamin E, and the control (placebo). Aspartate transaminase (AST), creatine kinase (CK), and lactate dehydrogenase (LDH) for assessing muscle damage, and malondialdehyde, were measured before and after the intervention. In the between-groups comparison, only creatine kinase significantly changed at the end of the period. However, in the intergroup comparison creatine kinase was significantly decreased in group 1. As for Aspartate aminotransferase, no significant difference was spotted in any of the comparisons. Lactate dehydrogenase was significantly decreased in group 2. Finally, the study revealed a significant decrease in oxidative stress markers in groups 1, 3, and 4. It was concluded that it is induced from the results that vitamin C and E supplementation plays a role in reducing muscle damage markers of aerobic exercises [13716].

Effects on running

Exercise-induced oxidative stress is implicated in muscle damage and fatigue which has led athletes to embark on antioxidant supplementation regimes to negate these effects. one study investigated the intake of vitamin C (VC) (1 g), blackcurrant (BC) juice (15 mg VC, 300 mg anthocyanins) and placebo in isocaloric drink form on training progression, incremental running test and 5-km time-trial performance. Twenty-three trained female runners (age, 31 years) completed three blocks of high-intensity training for 3 weeks and 3 days, separated by a washout (4 wks). Changes in training and performance with each treatment were analysed with a mixed linear model, adjusting for performance at the beginning of each training block. Markers of oxidative status included protein carbonyl, malondialdehyde (in plasma and in vitro erythrocytes), ascorbic acid, uric acid and erythrocyte enzyme activity of superoxide dismutase, catalase and glutathione peroxidase were analysed. There was a likely harmful effect on mean running speed during training when taking VC (1.3 %). Effects of the two treatments relative to placebo on mean performance in the incremental test and time trial were unclear, but runners faster by 1 SD of peak speed demonstrated a possible improvement on peak running speed with BC juice (1.9 %). Following VC, certain oxidative markers were elevated: catalase at rest (23 %), protein carbonyls at rest (27 %) and superoxide dismutase post-exercise (8.3 %). In conclusion, athletes should be cautioned about taking VC chronically, however, BC may improve performance in the elite [13717].

Side effects

Vitamins A (retinol), D, E, and K are stored in the liver and in body fat stores hence they do not need to be taken every day. Some are toxic if an excess amount is consumed. In a recent meta-analysis of primary and secondary treatment with antioxidant supplements, beta-carotene, vitamin A and E were also found to increase mortality but there was no convincing evidence for harmful effects of selenium or vitamin C [08399]. Despite the fact that water-soluble vitamins (i.e. C, B) are excreted in the urine rather than stored in the body, there is evidence suggesting that vitamin C, especially in combination with iron [08400] can cause damage to the gastrointestinal tract (GI) and initiate or aggravate symptoms associated with chronic GI disorders. A high intake of iron, especially in combination with manganese doubles the risk for Parkinson’s disease [08401]. Unnecessary cobalt ingestion results in enhanced oxidative stress leading to organ damage and dysfunction in liver and kidney, and also impairs thyroid activity and myocardial function [08402]. In addition to the potential hazard of positive doping tests [08403, 08404], contamination may also pose health risks such as lead contamination in calcium products [08405].

Vitamines A, C, and E
Micronutrients, including vitamin supplements, are widely used in the general population and by athletes. A variety of claims or areas of interest have promoted the use of vitamin supplements, with antioxidant claims becoming a popular interest over the past two decades. While the antioxidant issue has typically targeted the prevention of ageing or various diseases associated with oxidative damage, it has also been recognised that exercise is a stimulator of the generation of oxygen radical species. Hence, there has been interest in whether athletes might have additional needs for antioxidant vitamins to counteract such damage. Vitamins A, C and E are often being discussed together because all three have antioxidant properties, though they differ in many other respects. Recent research has focused on these vitamins’ antioxidant prospects because exercise induces free radical (ROS, reactive oxygen species) release which leads to cellular damage, fatigue and overtraining. Literally hundreds of studies on antioxidant vitamin supplementation (AVS) and exercise have been published. Systematic training causes the body to develop adaptations naturally to the increase in exercise-induced ROS, but it has been hypothesised that AVS may provide additional benefits. Studies validate as well as refute this possibility. Validating this possibility, in one study nine sedentary and nine active young adult males were given 50 mg/day V-A+1000 mg/day V-C+800 mg/day V-E for 2 months and performed a treadmill ergometer VO2max test before and after the treatment period. Before supplementation, sedentary subjects (but not trained subjects) exhibited exercise-induced increased white blood cell and granulocyte levels and increased erythrocyte aggregation and deformability; after supplementation, these phenomena did not occur. Both sedentary and trained subjects showed an elevated erythrocyte lipid peroxidation after the VO2max test pre-supplementation but not post-supplementation. This study suggested that AVS augmented the already increased antioxidant capacity found in trained individuals. In a study of adolescent male basketball players undergoing intense training for 35 days, athletes dosed with 500 mg/day V-C+150 mg/day V-E demonstrated higher plasma content of V-A (retinol), V-C and V-E concomitant with elevated erythrocyte glutathione peroxidase (GSH-Px) and reduced glutathione (GSH; both important antioxidant molecules) compared with non-treated controls. Refuting the prospect of AVS providing additional physiological benefits in trained athletes, a different study supplemented 21 sedentary young adult males with 500 mg/day V-C+400 IU/day V-E for 16 weeks. After the first 4 weeks, subjects also performed endurance training for 12 weeks. With results from previous studies, the researchers noted that, although AVS reduced plasma IL-6 levels in response to an acute exercise bout (cycle Pmax test) before training, AVS did not show the same effect after training. Plasma IL-6 levels were, in fact, higher in the supplemented/trained group than the placebo/trained group, indicating that either the supplement only worked in the sedentary condition or that the supplement attenuated the effects of training. Using a model of eccentric training, another team of researchers supplemented 14 young adult males with 1 g/day V-C+400 IU/day V-E for 11 weeks combined with 7 weeks of resistance training and found no differences in acute exercise-induced plasma GSH or other markers of antioxidant capacity and redox status compared with similarly trained but non-supplemented controls. The effects of AVS on performance have also been studied. Using subjects discussed previously, one team showed that maximal performance parameters and muscle biopsy-determined glycogen, citrate synthase and beta-hydroxyacyl-CoA activity levels were no different in AVS-supplemented versus non-supplemented groups. One study of eight active men given 1 g/day V-C for 4 weeks concomitant with aerobic training showed that AVS had no impact on running performance. Another team reported that 10 well-trained young adult male runners given either 500 mg/day V-C+100 IU/day V-E or placebo for 2 weeks in a cross-over design showed no differences in 8 km time trial performance. Intriguingly, this latter study used an environmental chamber that simulated a hot, humid, ozone-polluted environment for the time trials and also reported that total plasma antioxidant V-C and V-E concentrations were higher, whereas plasma and nasal lavage CC (Clara cell protein; a marker for lung cell
damage) levels were lower in the AVS-treated compared with non-treated trials. Addressing just V-C, it appears that those studies dosing athletes at 1 g/day or greater demonstrate negative effects on performance more often than not. Although the data together may appear equivocal, it would be premature to draw any conclusions regarding the effectiveness or lack of AVS in athletes. Experimental parameters (including subject, exercise and dosing characteristics) are variable across studies, rendering it difficult to make direct comparisons. Regardless of this, athletes who consume well-balanced meals congruent with contemporary guidelines should be receiving adequate supplies of these vitamins. Several have opined that athletes should not be likely to receive any additional benefits from exceeding recommended daily intakes (RDI) and that additional supplementation may only be necessary in cases of extreme, prolonged physical exertion under adverse environmental conditions. Nevertheless, multivitamin supplements are readily available to athletes, vary widely in their vitamin doses, and often contain antioxidant vitamins at RDI or greater levels. For example, in an impromptu survey of a dozen different multivitamin supplements available at a central Iowa grocery store in mid-September, V-A content ranged from 1750-6100 IU (35-120 % RDI), V-C 60-250 mg (100-417 % RDI) and V-E 22.5–200 IU (75-667 %). Over-supplementation (toxicity) is more likely to occur with the fat-soluble vitamins. Excess antioxidant vitamins may be detrimental to athletes when they interfere with normal levels of ROS-mediated intracellular signalling, disrupting redox balance and interfering with normal muscle cell function and performance. The current data only suggest that AVS, in the doses used across studies, either improved or had no effect on physiologically relevant markers of antioxidant capacity and either decreased or had no effect on performance outcomes. There is no question that athletes experience increased oxidative stress as a result of their activity levels, but the issue of whether or not athletes need higher dietary antioxidants than less active counterparts remains under debate. There are hypotheses as well as data to support a beneficial use, a neutral outcome in people who are already achieving intakes at recommended levels from dietary sources, and even a detrimental effect on training adaptations. Athletes consuming a balanced diet commensurate with their caloric needs, including vegetables, fruits and whole grains, are likely receiving adequate levels of antioxidant vitamins. For those athletes “errring on the side of caution”, food-based sources of antioxidant vitamins may be preferable to supplement-based sources because the possibility of toxicity is lower when foods are utilised. Although daily multivitamin supplements are generally regarded as safe, over-supplementation may result in disrupted redox balance or diminished performance. Further studies may help to clarify which of these outcomes is the most likely, given the various scenarios of training, environment and diet in which athletes may find themselves [12440].

Vitamin E

The purpose of one study is to determine the effect following exercise to exhaustion of vitamin E supplementation on oxidative stress in athletic students. Twenty male students voluntarily participated in the study and were randomly assigned (double blind) to either a vitamin E (daily dose of 450 mg of a-tocopherol for a period of 8 weeks) or a placebo group (took capsules containing 450 mg of lactose for 8 weeks). Before and after 8 weeks blood samples were collected at rest and after exercise to exhaustion. Oxidative stress markers were malondialdehyde (MDA), carbonylated proteins (CP) and creatine kinase (CK). Also, the effect of vitamin E on ergometer cycling time, as an example of endurance performance, was evaluated. ANOVA and independent t-tests indicated that vitamin E supplementation did not significantly change MDA, CP and CK values at rest, after exercise to exhaustion, and cycling time, but plasma volume after exercise to exhaustion significantly decreased. It was concluded that although vitamin E supplementation had no effect on exercise performance or capacity in athletic students, further investigation is required using larger numbers of subjects and measures of vitamin E before unequivocal conclusion can be stated [06287].

During endurance exercise, oxygen consumption by the skeletal muscle can increase 100-200 times. It was previously found that during an ultramarathon race (50 km, forest trail through hilly terrain) compared with a day of rest, vitamin E disappeared faster (as measured using 2H-labelled alpha-tocopherol) and lipid peroxidation increased. Therefore, it was hypothesized that prior supplementation with antioxidants (vitamins E and C) would decrease oxidative stress during distance running and, therefore, decrease lipid peroxidation and inflammation, decrease DNA damage, decrease muscle damage and/or improve recovery. To test these hypotheses, it was carried out a randomized, double-blind study in runners (11 females, 11 males) who were participants in an annual ultramarathon race. It was found that supplementation with both vitamins E and C only prevented increases in lipid peroxidation, but had no apparent effect on DNA damage, inflammation or muscle damage. These results suggest that the mechanism of oxidative damage is operating independently of the inflammatory and muscle damage responses [06288].

One study investigated whether vitamin E can attenuate eccentric exercise-induced soleus muscle injury as indicated by the amelioration of in situ isometric force decline following a low-frequency fatigue protocol (stimulation at 4 Hz for 5 min) and the ability of the muscle to recover 3 min after the termination of the fatigue protocol. Adult male Wistar rats were divided into vitamin E-supplemented or placebo-supplemented groups studied at rest, immediately post-exercise or 48 h post-exercise. Daily dl-alpha-tocopheryl acetate intraperitoneal injections of 100 mg/kg body mass for 5 consecutive days prior to exercise doubled its plasma levels. Fatigue index and recovery index expressed as a percentage of the initial tension. FI at 0 h post- and 48 h post-exercise respectively was 88 percent and 89 percent in the vitamin E groups versus 76 percent and 80 percent in the placebo groups. RI was 99 percent and 100 percent in the vitamin E groups versus 82 percent and 84 percent in the placebo groups. Complementally to the traditionally recorded maximal force, low-frequency fatigue measures may be beneficial for assessing injury-induced decrease in muscle functionality [12441].

The aim of one study was to determine the direction of change in performance variables at fixed blood lactate concentrations following vitamin E (VE) supplementation. In a paired-matched design twelve (male: n=8; female: n=4) trained runners were allocated to a VE (n=6; 268 mg/d) or placebo (n=6; glucose) group for 35 days. Participants completed a discontinuous incremental exercise test, pre and post supplementation, to determine peak
oxygen uptake (\(\text{VO}_{2\text{peak}}\)) running velocity and percentage of peak oxygen uptake (%(\text{VO}_{2\text{peak}})) at the lactate threshold (TLAC) and the onset of blood lactate accumulation (OBLA). Participants maintained a standardised training regime throughout the supplementation period. VE supplementation failed to significantly enhance velocity at TLAC and OBLA compared to a placebo treatment. Analogously, VE did not significantly enhance %(%(\text{VO}_{2\text{peak}})) at TLAC and OBLA compared to a placebo treatment. Whilst VE supplementation did not enhance performance it did not impair performance compared to a placebo. Training significantly enhanced velocity at TLAC and OBLA. No training-induced improvements in %\(\text{VO}_{2\text{peak}}\) at TLAC and OBLA were observed. It was thus concluded that daily VE supplementation for 35 days does not enhance or impair physiological performance at fixed blood lactate concentrations. Long-term VE supplementation for the purposes of performance enhancement is not recommended [12442].

**Dietary antioxidants, in general**

Physical exercise induces oxidative stress and tissue damage. Although a basal level of reactive oxygen species (ROS) is required to drive redox signaling and numerous physiologic processes, excess ROS during exercise may have adverse implications on health and performance. Antioxidant nutrients may be helpful in that regard. Caution should be exercised against excess antioxidant supplements, however. This article presents a digest for sports practitioners. The following three recommendations are made:

- it is important to determine the individual antioxidant need of each athlete performing a specific sport
- multinutrient preparations, as opposed to megadoses of any single form of nutrient, seem to be a more prudent path to choose
- for outcomes of antioxidant supplementation, performance should not be the only criteria

Overall well being of the athlete, faster recovery, and minimization of injury time could all be affected by antioxidant therapy [06289].

Athletes should match their energy intake with expenditure in order to maintain lean body mass. It is also important to consume adequate amounts of antioxidant vitamins and minerals to maintain health. To assess the dietary habits of six nationally ranked Australian swimmers physical training load and dietary intake (24 h food recall) and were recorded on a daily basis during a 4 day intensive physical training period. The results showed no significant difference between energy intake and expenditure or the amount of carbohydrate consumed compared to the Australian recommended daily intake (RDI). Athletes reported a significantly greater intake of vitamin A, vitamin C, vitamin E, and protein than the RDI. It was concluded that these elite swimmers have an adequate dietary intake to allow for optimal physical training and performance [12447].

Exercise has been noted in some, but not all, studies to elicit an oxidative stress. The discrepancy in findings may be related to differences in exercise intensity across protocols, as well as to differences in training status of participants. It was compared blood oxidative stress biomarkers in exercise-trained men after three different bouts of exercise of varying intensity and duration, as well as a nonexercise condition. On different days, men (n=12, 21-35 years) performed aerobic cycle exercise (60 min at 70 % HR reserve) and cycle sprints (five 60-s sprints at 100 % maximum wattage obtained during graded exercise testing and ten 15-s sprints at 200% maximum wattage obtained during graded exercise testing). Blood
was collected before and 0, 30, and 60 min after exercise and analyzed for malondialdehyde, hydrogen peroxide (H₂O₂), advanced oxidation protein products, and nitrate/nitrite (NO(x)). As indicators of antioxidant status, Trolox equivalent antioxidant capacity, superoxide dismutase, catalase, and glutathione peroxidase were measured. No differences were noted in malondialdehyde, hydrogen peroxide advanced oxidation protein product, or NO(x) between conditions or across time. Antioxidant capacity was generally highest at 30 and 60 min after exercise and lowest at 0 min after exercise. It was concluded that in trained men, and considering the limitations of the current design (e.g. inclusion of selected oxidative stress and antioxidant biomarkers measured in blood only), strenuous bouts of exercise do not result in a significant increase in blood oxidative stress during the 1-h postexercise period. These findings may be related to attenuation in reactive oxygen species production as an adaptation to chronic exercise training and/or a protective effect of the antioxidant system in response to acute strenuous exercise [12448].

One study examined the acute effects of a single dose of an antioxidant (AO; Lactaway® containing pycnogenol) on time to fatigue (TTF). Nine trained cyclists performed on two separate occasions a continuous protocol of 5 min at 50 percent of peak power output (PPO), 8 min at 70 percent of PPO, and then cycled to fatigue at 95 percent PPO. Four hours prior to the exercise protocol, the subjects consumed the supplement or a placebo (counterbalanced, double blind protocol). Cyclists, on average, rode for 80 s more in the Lactaway trial than they did in the placebo trial. There was considerable evidence (chances ≥95 %) for substantial positive treatment effects for TTF and the other performance-related variables (excluding [BLa] at 95 % PPO). Other studies are necessary to confirm these results and identify the mechanisms underlying the observed effects [12449].

To compare the effects of a 3-week supplementation between two different mixtures of antioxidants (AOX) and placebo on aerobic exercise performance in acute normobaric hypoxia. Seventeen subjects were randomly assigned in a double blind fashion to receive a broad-based AOX supplement containing beta-carotene, ascorbic acid, d-alpha-tocopherol-succinate, N-acetylcysteine, riboflavin, zinc, and selenium (AO group), or a combination of alpha-ketoglutaric acid (alpha-KG) and 5-hydroxymethylfurfural (5-HMF) (CS group), or placebo (PL group). Before and after supplementation subjects performed two incremental cycle-exercise tests until exhaustion. The first test was conducted under normoxic conditions (LA, FiO₂ of 21 %, 547 m) and the second after the 3-week supplementation period under normobaric hypoxic conditions (AHA, FiO₂ of 13 %, 4300m). In CS peak cycling performance (peak power) declined from LA to AHA 7.3% (90% CI: 2.2-12.4) less compared to PL and 7 percent less compared to AO. Better maintenance of aerobic exercise capacity in CS was associated with an attenuated reduction in maximal heart rate in hypoxia. It was concluded that aerobic exercise performance was less impaired in acute normobaric hypoxia after 3 weeks with supplementation of alpha-KG and 5-HMF compared to a broad-based AOX supplement or placebo [13727].

**Theoretical aspects on the cellular level**

Dietary antioxidant supplements are readily available and routinely consumed by the general public. Reasons for supplementation include compensation for dietary insufficiencies, treatment of primary mitochondrial disorders, improved health and overall wellbeing, and the prevention of diseases associated with aging including cancer. Despite estimates that 40 percent of the adult population in the US consumes some form of antioxidants scientific support for their purported benefits is currently inadequate and some reports even suggest that antioxidants may be detrimental to some health outcome. Exercise is believed to result in a transient increase in reactive oxygen species (ROS) production that results from increased demand for ATP, produced by mitochondrial oxidative phosphorylation, to support
increased muscle contractile activity. This increase in ROS may play a role in activating signaling pathways that mediate long-term adaptations to exercise, such as increased mitochondrial biogenesis, that is associated with improved insulin sensitivity. Conversely, excessive ROS production may place muscle in a condition of oxidative stress that adversely affects performance and adaptation. Consequently, the hypothesis has emerged that the consumption of antioxidants during endurance training could attenuate physiological adaptations in muscle (increased antioxidant defense enzyme activity and mitochondrial biogenesis). The latter concept has been controversial since some reports have shown that antioxidant supplementation counteracted the beneficial effects of exercise, reduced performance, and inhibited mitochondrial adaptations to exercise, but others have not [13728].

Important factors that may contribute to differences between reported outcomes include; the complex interactions between antioxidants, the potential for antioxidants to become pro-oxidant, non-redox cellular effects of the “antioxidants”, and/or temporal differences between the state of training (early adaptive or elite acute extreme performance). Although there are many different compounds that fall under the umbrella term “antioxidant”, vitamin E, vitamin C, coenzyme Q₁₀ (CoQ₁₀) and α-lipoic acid are more commonly studied. CoQ₁₀ is an electron-shuttling compound that is vital to the mitochondrial electron transport chain and has potent antioxidant properties. Vitamin E (alpha-tocopherol) is an important component of biological membranes where it is thought to participate in scavenging lipid peroxide radicals, though it may exert some molecular effects independent of its antioxidant properties. alpha-Lipoic acid is an essential cofactor for mitochondrial α-ketoacid dehydrogenases (e.g. pyruvate dehydrogenase) and is crucial for several mitochondrial metabolic pathways. It is also regarded as potent mitochondrial antioxidant and has been studied in numerous oxidative stress-related pathological conditions such as ischemia/reperfusion injury and diabetes. It also has direct effects on skeletal muscle, increasing resting energy expenditure, insulin sensitivity, and glucose uptake. This is mediated primarily through the activation of AMP-activated protein kinase (AMPK), a major energy (ATP/AMP) sensor in the cell, that regulates mitochondrial biogenesis through peroxisome proliferator-activated receptor gamma coactivator 1alpha (PGC-1alpha). Despite the potential effects of these and other antioxidant compounds on metabolism and energetic adaptation, there is no evidence that mitochondrial function can be directly altered by dietary antioxidant supplementation alone. While many of these antioxidants display potent radical scavenging properties in vitro, experiments conducted in vivo are mixed and some studies indicate that they may function as pro-oxidants, rather than antioxidants [13728].

Clinical studies
The beneficial effects of exercise and a healthy diet are well documented in the general population but poorly understood in elite athletes. Previous research in subelite athletes suggests that regular training and an antioxidant-rich diet enhance antioxidant defenses but not performance. To investigate whether habitual diet and/or exercise (training status or performance) affect antioxidant status in elite athletes antioxidant blood biomarkers were assessed before and after a 30-min ergometer time trial in 28 male and 34 female rowers. The antioxidant blood biomarkers included ascorbic acid, uric acid, total antioxidant capacity (TAC), erythrocyte-superoxide dismutase, glutathione peroxidase (GPx), and catalase. Rowers completed a 7-day food diary and an antioxidant-intake questionnaire. Effects of diet, training, and performance on resting biomarkers were assessed with Pearson correlations, and their effect on exercise-induced changes in blood biomarkers was assessed by a method of standardization. With the exception of GPx, there were small to moderate increases with exercise for all markers. Blood resting TAC had a small correlation with total antioxidant intake, and the exercise-induced change in TAC had a trivial to small association with dietary antioxidant intake from vitamin C, vegetables, and vitamin A. Most other dietary
intakes had trivial associations with antioxidant biomarkers. Years of training had a small inverse correlation with TAC and a small association with the exercise-induced change in TAC. Training status correlates more strongly with antioxidant status than diet does [13729].

To ascertain whether reactive oxygen species (ROS) contribute to training-induced adaptation of skeletal muscle, we administered ROS-scavenging antioxidants (AOX; 140 mg/L of ascorbic acid, 12 mg/L of coenzyme Q10 and 1% N-acetyl-cysteine) via drinking water to 16 C57BL/6 mice. Sixteen other mice received unadulterated tap water (CON). One cohort of both groups (CON(EXE) and AOX(EXE)) was subjected to treadmill exercise for 4 weeks (16-26 m/min, incline of 5°-10°). The other two cohorts (CON(SED) and AOX(SED)) remained sedentary. In skeletal muscles of the AOX(EXE) mice, GSSG and the expression levels of SOD-1 and PRDX-6 were significantly lower than those in the CON(EXE) mice after training, suggesting disturbance of ROS levels. The peak power related to the body weight and citrate synthase activity was not significantly influenced in mice receiving AOX. Supplementation with AOX significantly altered the mRNA levels of the exercise-sensitive genes HK-II, GLUT-4 and SREBF-1c and the regulator gene PGC-1alpha but not G6PDH, glycogenin, FABP-3, MCAD and CD36 in skeletal muscle. Although the administration of AOX during endurance exercise alters the expression of particular genes of the ROS metabolism, it does not influence peak power or generally shift the metabolism, but it modulates the expression of specific genes of the carbohydrate and lipid metabolism and PGC-1alpha within murine skeletal muscle [13730].

The beneficial effects of exercise and a healthy diet are well documented in the general population but poorly understood in elite athletes. Previous research in subelite athletes suggests that regular training and an antioxidant-rich diet enhance antioxidant defenses but not performance. To investigate whether habitual diet and/or exercise (training status or performance) affect antioxidant status in elite athletes antioxidant blood biomarkers were assessed before and after a 30-min ergometer time trial in 28 male and 34 female rowers. The antioxidant blood biomarkers included ascorbic acid, uric acid, total antioxidant capacity (TAC), erythrocyte- superoxide dismutase, glutathione peroxidase (GPx), and catalase. Rowers completed a 7-d food diary and an antioxidant-intake questionnaire. Effects of diet, training, and performance on resting biomarkers were assessed with Pearson correlations, and their effect on exercise-induced changes in blood biomarkers was assessed by a method of standardization. With the exception of GPx, there were small to moderate increases with exercise for all markers. Blood resting TAC had a small correlation with total antioxidant intake, and the exercise-induced change in TAC had a trivial to small association with dietary antioxidant intake from vitamin C, vegetables, and vitamin A. Most other dietary intakes had trivial associations with antioxidant biomarkers. Years of training had a small inverse correlation with TAC and a small association with the exercise-induced change in TAC. It was concluded that training status correlates more strongly with antioxidant status than diet does [13731].

Physical exercise has many benefits, but it might also have a negative impact on the body, depending on the training level, length of workout, gender, age and fitness. The negative effects of physical exercise are commonly attributed to an imbalance between the levels of antioxidants (both low molecular weight antioxidants and antioxidant enzymes) and reactive oxygen and nitrogen species due to excessive production of free radicals during physical exercise. In this critical review, we look for answers for three specific questions regarding the interrelationship between physical exercise and oxidative stress (OS), namely

- the dependence of the steady-state level of OS on fitness
- the effect of intensive exercise on the OS
- the dependence of the effect of the intense exercise on the individual fitness
All these questions have been raised, investigated and answered, but the answers given on the basis of different studies are different. In one review, it was tried to explain the reason(s) for the inconsistencies between the conclusions of different investigations, commonly based on the concentrations of specific biomarkers in body fluids. It was thought that most of the inconsistencies can be attributed to the difference between the criteria of the ill-defined term denoted OS, the methods used to test them and in some cases, between the qualities of the applied assays. On the basis of our interpretation of the differences between different criteria of OS, it was considered possible answers to three well-defined questions. Possible partial answers are given, all of which lend strong support to the conclusion that the network responsible for homeostasis of the redox status is very effective. However, much more data are required to address the association between exercise and OS and its dependence on various relevant factors [13732].

*Redox state in athletes*

The purpose of one study was to assess the influence of sport-specific and nonspecific bouts of exercise on athletes' redox state. Blood samples were collected from 14 handball players immediately before and after graded exercise test on the cycle ergometer and handball training. Levels of superoxide anion radical (O$_2^-$), hydrogen peroxide (H$_2$O$_2$), nitrites (NO$_2^-$) as markers of nitric oxide, index of lipid peroxidation (TBARs), glutathione (GSH), superoxide dismutase (SOD), and catalase (CAT) activity were determined. Exercise intensity was assessed by a system for heart rate (HR) monitoring. Average athletes' HR was not significantly different between protocols, but protocols differed in total time and time and percentage of time that athletes spent in every HR zone. The laboratory exercise test induced a significant increase of H$_2$O$_2$ and TBARs as well as the decrease of the SOD and CAT activity, while after specific handball training, levels of NO$_2^-$ were increased and SOD activity decreased. It seems that unaccustomed short intensive physical activity may induce oxidative stress in trained athletes, while sport-specific activity of longer duration and proper warm-up period may not. Further research should show whether the change of protocol testing and the implementation of various supplementations and manual methods can affect the redox equilibrium [12450].

*In rugby players*

One study investigated the biochemical and anthropometric characteristics in elite athletes of rugby union based in the south of France during the different periods of the competition to identify metabolic and biochemical adaptations to particular lifestyle conditions. Participants included 35 players in 2008 and 43 players in 2009. Biochemical variables [creatinine, uric acid, creatine kinase (CK), alanine aminotransferase, aspartate aminotransferase, C-reactive protein] were evaluated. Specific protein levels (albumin, acid alpha-glycoprotein, prealbumin), vitamins (A, E, C), antioxidant enzymes (glutathione peroxidase (GPX), superoxide dismutase (SOD)) oligoelements (Zn, Se, Cu, erythrocyte magnesium), homocysteine (Hcy), carnitine and the distribution of amino acids were specifically determined for our study during a pre-competition period (September 2008 and 2009). Globally, no deficit was observed for vitamins, oligonutrients and amino acids levels. The high SOD and GPx activities in rugby players suggest a presence of oxidative stress of exercise. The evaluation of renal function should be used with caution because of the interaction between creatinine and lean body mass. In addition, a profound effect of intense exercise on the CK values was reported to establish specific reference values for athletes. The analysis of the biological variation allows optimization of the interpretation of the changes from an increased or decreased baseline value from a season to the other one. The conclusions of the study were that there was a necessity of rugby-specific reference intervals.
for CK and creatinine parameters and the use of enzymatic creatinine for Modification of Diet in Renal Disease (MDRD) and CKD-EPI, or cystatin C to improve glomerular filtration rate estimation. Moreover, it should be taken into account the oxidative stress testifying of a bad recovery, and there is a need to better take care the nutritional status of the players by adapting needs and amino acids supplementations but also to consider a follow-up of oxidative stress and antioxidants according the results [12451].

**Phlebodium decamanum**

Strenuous exercise induces muscle damage due to a highly increased generation of free radicals and inflammatory response and therefore, in this type of exercise, it is important to reduce both oxidative stress and inflammation, at least their negative aspects. The purpose of this study was investigate, for the first time, whether a purified, standard water-soluble fraction obtained from Phlebodium decamanum could reduce the over-expression of inflammation and oxidative stress induced by strenuous exercise. The physical test consisted of a constant run that combined several degrees of high effort (mountain run and ultra-endurance), in permanent climbing. Biochemical parameters, oxidative stress and inflammatory mediators were assessed. The results showed that oral supplementation of P. decamanum during high-intensity exercise effectively reduces the degree of oxidative stress (decreased 8-hydroxy-2'-deoxyguanosine and isoprostanes generation, increased antioxidant enzyme activities in erythrocyte and total antioxidant status in plasma). The data obtained also indicate that this supplementation is efficient in reducing the inflammatory response through the decrease of TNF-alpha and increase of sTNF-RII, but kept the levels of IL-6 and IL-1ra. In conclusion, oral supplementation of P. decamanum extract during high-intensity exercise effectively reduces the degree of oxidative stress and has anti-inflammatory protective effects, preventing the over-expression of TNF-alpha but keeping the levels and effects of IL-6. These findings provide a basis for similar Phlebodium supplementation for both professional and amateur athletes performing strenuous exercise in order to reduce the undesirable effects of the oxidative stress and inflammation signalling elicited during high-intensity exercise [12453].

**Resveratrol**

Resveratrol is a natural polyphenolic flavonoid antioxidant which may provide numerous health benefits such as the prevention of cancer, cardiovascular disease and ischaemic injuries, as well as enhancing stress resistance. It is a freely available food supplement and is found in the seeds and skins of grapes, red wine, mulberries, peanuts and rhubarb. Interest in resveratrol in sports medicine arose after animal studies assessed endurance performance of mice and found a dose-dependent increase in exercise tolerance, improved motor skills and increased number and activity of mitochondria in muscle cells. Resveratrol-treated mice had a significantly higher maximum VO\textsubscript{2} rate, suggestive of an increased oxidative capacity. Resveratrol intake increases the ratio of oxidative to non-oxidative type muscle fibres and increases muscle strength in resveratrol-treated mice. The resveratrol effects also seem to be dependent on the length of intake, as one of the actions proposed is a gene switch. There are no established doses for resveratrol but it has been shown in humans that resveratrol administration with doses of 250 mg and 500 mg, resulted in a dose-dependent increase in cerebral blood flow during task performance and enhanced oxygen extraction. Doses of 1600 mg per day in a 70 kg participant are regarded as safe, even long term. Resveratrol as a food supplement in sports medicine has not received much attention despite some basic scientific evidence that this substance could have multiple indications.
related to high-performance sports. Therefore, further studies are required to confirm whether there are similar effects in humans [12470].

Resveratrol (RES) is a well-known phytocompound and food component which has antioxidative and multifunctional bioactivities. However, there is limited evidence for the effects of RES on physical fatigue and exercise performance. The purpose of one study was to evaluate the potential beneficial effects of trans-RES on fatigue and ergogenic functions following physiological challenge. Male ICR mice from four groups (n=8 per group) were orally administered RES for 21 days at 0, 25, 50, and 125 mg/kg/day, which were respectively designated the vehicle, RES-25, RES-50, and RES-125 groups. The anti-fatigue activity and exercise performance were evaluated using forelimb grip strength, exhaustive swimming time, and levels of serum lactate, ammonia, glucose, and creatine kinase (CK) after a 15-min swimming exercise. The exhaustive swimming time of the RES-25 group was significantly longer than that of vehicle group. A trend analysis revealed that RES treatments increased the grip strength. RES supplementation also produced dose-dependent decreases in serum lactate and ammonia levels and CK activity and also an increase in glucose levels in dose-dependent manners after the 15-min swimming test. The mechanism was related to the increased energy utilization (as blood glucose), and decreased serum levels of lactate, ammonia, and CK. Therefore, RES could be a potential agent with an anti-fatigue pharmacological effect [13734].

Resveratrol and quercetin

Resveratrol and quercetin function as antioxidants and anti-inflammatories in vitro, but these mechanisms have been minimally examined in combination in exercising humans. The purpose of this investigation was to examine supplementation as a countermeasure against oxidative stress and inflammation in response to exercise. Fourteen athletes were randomly assigned, in a double-blind crossover design, to a resveratrol and quercetin combination (RQ) (120 mg resveratrol and 225 mg quercetin for 6 days and 240 mg resveratrol and 450 mg quercetin on day 7 just prior to exercise) or to placebo (P). There was a 1-week washout between trials. Blood was taken at baseline, pre-exercise, immediately after exercise, and 1 h after exercise. Plasma was analyzed for oxidative stress (F2-isoprostanes and protein carbonyls), antioxidant capacity (ferric-reducing ability of plasma (FRAP), Trolox equivalent antioxidant capacity (TEAC), oxygen radical absorptive capacity (ORAC)), and inflammation (cytokine interleukin (IL)-8 and C-reactive protein (CRP)). Statistical design utilized a 2 × 3 ANOVA and Student's t test. Pre-exercise values were not different from baseline for any measure. The postexercise increase in F2-isoprostanes was significantly less with RQ (68 %) than with P (137 %). Protein carbonyls, FRAP, ORAC, and TEAC significantly increased after exercise but were not affected by treatment. IL-8 and CRP increased significantly immediately after exercise but were not affected by treatment. These data indicate that RQ significantly reduces exercise-induced lipid peroxidation without associated changes in inflammation or plasma antioxidant status [13735].

N-Acetylcysteine

N-acetylcysteine (NAC) is a reduced thiol donor that supports cellular resynthesis of glutathione, a major antioxidant in skeletal muscle and other human tissues. Glutathione
buffers reactive oxygen species (ROS) produced by muscle. ROS levels increase substantially during strenuous exercise, overwhelming glutathione buffering and depressing contractile function. This contributes to the development of muscle fatigue. NAC opposes this process. By supporting glutathione resynthesis, NAC slows the rise of ROS activity in exercising muscle and delays fatigue. This was first demonstrated in humans by our group in studies of tibialis anterior, an ankle dorsiflexor muscle, during repetitive electrical stimulation. Subsequent studies confirmed that NAC inhibits fatigue during volitional exercise tasks, for example, loaded breathing and handgrip exercise. The studies of greatest physiological relevance were those who showed that NAC delays fatigue of trained athletes during strenuous cycling exercise. Despite performance benefits in the laboratory, several issues limit NAC use as an ergogenic aid. First, only pharmacological doses of 140–150 mg/kg have been shown to limit fatigue. It is not known if lower doses are effective. Secondly, doses that delay fatigue are safe but can have uncomfortable side effects including nausea and diarrhoea. Finally, NAC may have negative effects on athletic training. Data are emerging to suggest that chronic antioxidant supplementation blunts the positive effects of transient oxidative stress, a signal that appears to be essential for muscle adaptation to exercise. Thus, while effects of high-dose NAC are intriguing, it is too soon to conclude that NAC supplementation is beneficial for athletes. Future directions for research include studies to optimize NAC dosage, balancing efficacy versus side effects, and to evaluate novel thiol donors for their effects on fatigue [11523].

Allopurinol

The aim of one research was to examine the impact of the xanthine oxidase (XO) inhibitor allopurinol on the skeletal muscle activation of cell signaling kinases and adaptations to mitochondrial proteins and antioxidant enzymes following acute endurance exercise and endurance training. Male Sprague-Dawley rats performed either acute exercise (60 min of treadmill running, 27 m/min, 5 % incline) or 6 wk of endurance training (5 days/week) while receiving allopurinol or vehicle. Allopurinol treatment reduced XO activity to 5 percent of the basal levels, with skeletal muscle uric acid levels being almost undetectable. Following acute exercise, skeletal muscle oxidized glutathione (GSSG) significantly increased in allopurinol- and vehicle-treated groups despite XO activity and uric acid levels being unaltered by acute exercise. This suggests that the source of ROS was not from XO. Surprisingly, muscle GSSG levels were significantly increased following allopurinol treatment. Following acute exercise, allopurinol treatment prevented the increase in p38 MAPK and ERK phosphorylation and attenuated the increase in mitochondrial transcription factor A (mtTFA) mRNA but had no effect on the increase in peroxisome proliferator-activated receptor-gamma coactivator-1alpha (PGC-1alpha), nuclear respiratory factor-2, GLUT4, or superoxide dismutase mRNA. Allopurinol also had no impact on the endurance training-induced increases in PGC-1alpha, mtTFA, and mitochondrial proteins including cytochrome c, citrate synthase, and beta-hydroxyacyl-CoA dehydrogenase. In conclusion, although allopurinol inhibits cell signaling pathways in response to acute exercise, the inhibitory effects of allopurinol appear unrelated to exercise-induced ROS production by XO. Allopurinol also has little effect on increases in mitochondrial proteins following endurance training [13736].

Other antioxidants

High levels of reactive oxygen species (ROS) produced in skeletal muscle during exercise have been associated with muscle damage and impaired muscle function. Supporting endogenous defence systems with additional oral doses of antioxidants has received much
attention as a noninvasive strategy to prevent or reduce oxidative stress, decrease muscle damage and improve exercise performance. Over 150 articles have been published on this topic, with almost all of these being small-scale, low-quality studies. The consistent finding is that antioxidant supplementation attenuates exercise-induced oxidative stress. However, any physiological implications of this have yet to be consistently demonstrated, with most studies reporting no effects on exercise-induced muscle damage and performance. Moreover, a growing body of evidence indicates detrimental effects of antioxidant supplementation on the health and performance benefits of exercise training. Indeed, although ROS are associated with harmful biological events, they are also essential to the development and optimal function of every cell. The aim of this review is to present and discuss 23 studies that have shown that antioxidant supplementation interferes with exercise training-induced adaptations. The main findings of these studies are that, in certain situations, loading the cell with high doses of antioxidants leads to a blunting of the positive effects of exercise training and interferes with important ROS-mediated physiological processes, such as vasodilation and insulin signalling. More research is needed to produce evidence-based guidelines regarding the use of antioxidant supplementation during exercise training. It was recommend that an adequate intake of vitamins and minerals through a varied and balanced diet remains the best approach to maintain the optimal antioxidant status in exercising individuals [11589].

Various nutritional, behavioral, and pharmacological interventions have been previously shown to extend life span in diverse model organisms, including Saccharomyces cerevisiae, Caenorhabditis elegans, Drosophila melanogaster, mice, and rats, as well as possibly monkeys and humans. This review aims to summarize published evidence that several longevity-promoting interventions may converge by causing an activation of mitochondrial oxygen consumption to promote increased formation of reactive oxygen species (ROS). These serve as molecular signals to exert downstream effects to ultimately induce endogenous defense mechanisms culminating in increased stress resistance and longevity, an adaptive response more specifically named mitochondrial hormesis or mitohormesis. Consistently, we here summarize findings that antioxidant supplements that prevent these ROS signals interfere with the health-promoting and life-span-extending capabilities of calorie restriction and physical exercise. Taken together it is suggested that ROS act as essential signaling molecules to promote metabolic health and longevity [1403].

Acute antioxidant supplementation may modulate oxidative stress and some immune perturbations that typically occur following prolonged exercise. The aims of one study were to examine the effects of acutely consuming dark chocolate (high polyphenol content) on plasma antioxidant capacity, markers of oxidative stress and immunoendocrine responses to prolonged exercise. Fourteen healthy men cycled for 2.5 h at about 60 percent maximal oxygen uptake 2 h after consuming 100 g dark chocolate (DC), an isomacronutrient control bar (CC) or neither (BL) in a randomised-counterbalanced design. Dark chocolate enhanced pre-exercise antioxidant status and reduced by trend 1 h post-exercise plasma free (F_{2}-isoprostane) compared with CC (also, F_{2}-isoprostane increased post-exercise in CC and BL but not DC trials). Plasma insulin concentration was significantly higher pre-exercise and 1 h post-exercise in the DC compared with the CC trial. There was a better maintenance of plasma glucose concentration on the DC trial, which decreased post-exercise in all trials but was significantly higher 1 h post-exercise in the DC trial. There were no between trial differences in the temporal responses of hypothalamic-pituitary-adrenal axis stress hormones, plasma interleukin-6, the magnitude of leukocytosis and neutrophilia and changes in neutrophil function. It was concluded that acute DC consumption may affect insulin, glucose, antioxidant status and oxidative stress responses, but has minimal effects on immunoendocrine responses, to prolonged exercise [11290].

While production of reactive oxygen and nitrogen species (RONS) is associated with some of
the beneficial adaptations to regular physical exercise, it is not established whether RONS play a role in the improved insulin-stimulated glucose uptake in skeletal muscle obtained by endurance training. To assess the effect of antioxidant supplementation during endurance training on insulin-stimulated glucose uptake, 21 young healthy (age 29 ± 1 years, BMI 25 ± 3 kg/m²) men were randomly assigned to either an antioxidant (AO) 500 mg vitamin C and 400 IU vitamin E (alpha-tocopherol) daily or a placebo (PL) group that both underwent a supervised intense endurance-training program 5 times/wk for 12 wk. A 3-h euglycemic-hyperinsulinemic clamp, a maximal oxygen consumption (VO₂max) and maximal power output (Pmax) test, and body composition measurements (fat mass, fat-free mass) were performed before and after the training. Muscle biopsies were obtained for determination of the concentration and activity of proteins regulating glucose metabolism. Although plasma levels of vitamin C and alpha-tocopherol increased markedly in the AO group, insulin-stimulated glucose uptake increased similarly in both the AO and the PL group in response to training. VO₂max and Pmax also increased similarly in both groups as well as protein content of GLUT4, hexokinase II, and total Akt. The results indicate that administration of antioxidants during strenuous endurance training has no effect on the training-induced increase in insulin sensitivity in healthy individuals [11291].

The objectives of one study were to evaluate pro-oxidant-antioxidant balance (PAB) associations with the commonly measured parameters of oxidative stress and antioxidative defence in elite female volleyball athletes and to investigate changes in the parameters of oxidative stress during a period of intense training and dietary antioxidant supplementation. Twenty-seven female volleyball players participated in this study. Blood samples were collected the day before the pre-competitive mesocycle training period began. After the first blood sample donation and during the next six weeks fourteen players (supplemented group) received a cocktail of antioxidants while thirteen of them (control group) received no dietary supplementation. The following parameters were measured: reactive oxygen metabolites (ROMs), superoxide anion (O₂⁻), malondialdehyde (MDA), advanced oxidation protein products (AOPP), lipid hydroperoxides (LOOH), biological antioxidative potential (BAP), paraoxonase activity toward paraoxon (POase) and diazoxon (DZOase), superoxide dismutase (SOD), total sulphhydryl group concentration (SH groups) and pro-oxidant-antioxidant balance. Significant associations were observed between biomarkers of oxidative damage with PAB in multiple linear regression model in the supplemented and the control groups (82 % vs 83 %) before training and in the control group (82 %) after training. Significant associations between antioxidative defence parameters and PAB values were found in the supplemented group after six-weeks of training (57 %). It was concluded that in the absence of antioxidant supplementation, PAB values were dependent on the association with biomarkers of oxidative damage before and after training. After a six-week training period and the applied antioxidant supplementation, PAB values were under the influence of non-enzymatic anti-oxidative defence [11292].

Strenuous physical activity is known to generate reactive oxygen species to a point that can exceed the antioxidant defense system and lead to oxidative stress. Dietary intake of antioxidants, plasma enzymatic (superoxide dismutase, glutathione reductase, and glutathione peroxidase, GPx, activities, nonenzymatic (total antioxidant status, TAS, uric acid, alpha-tocopherol, retinol, alpha-carotene, beta-carotene, lycopene, and lutein + zeaxanthin) antioxidants, and markers of lipid peroxidation (thiobarbituric-acid-reactive substances, TBARS) and muscle damage (creatine kinase, CK) were measured in 17 elite male kayakers and canoeists under resting conditions and in an equal number of age- and sex-matched sedentary individuals. Athletes showed significantly increased plasma values of alpha-tocopherol, alpha-carotene, beta-carotene, and superoxide dismutase activity, and a significantly lower TAS level. Antioxidant intake (alpha-tocopherol, vitamin C, and beta-carotene) and plasmatic GPx, glutathione reductase, lycopene, lutein + zeaxanthin, retinol,
and uric acid levels were similar in both groups. Nevertheless, TBARS and CK levels were found to be significantly higher in the kayakers and canoeists. This work suggests that despite the enhanced levels of antioxidants, athletes undergoing regular strenuous exercise exhibited more oxidative stress than sedentary controls [09359].

Effects of exercise training on important determinants of children's long-term health, such as redox and iron status, have not been adequately investigated. The aim of the present study was to examine changes in markers of the redox, iron and nutritional status of boy and girl swimmers during a prolonged period of training. 11 boys and 13 girls, aged 10-11 years, were members of a swimming club. They were assessed at the beginning of the training season, at 13 weeks and at 23 weeks through blood sampling and recording of the diet. Reduced glutathione increased at 13 and 23 weeks, whereas oxidised glutathione decreased at 13 weeks, resulting in an increase of the reduced/oxidised glutathione ratio at 13 and 23 weeks. Total antioxidant capacity, catalase, thiobarbituric acid-reactive substances, hemoglobin, transferrin saturation and ferritin did not change significantly. Carbohydrate intake was below 50 percent of energy and fat intake was above 40 percent of energy. Intakes of saturated fatty acids and cholesterol were excessive. Iron intake was adequate but intakes of folate, vitamin E, calcium and magnesium did not meet the recommended daily allowances. No significant differences were found between sexes in any of the parameters measured. In conclusion, child swimmers improved the redox status of glutathione during training, although the intake of antioxidant nutrients did not change. The iron status was not impaired by training. Suboptimal intake of several nutrients suggests the need for nutritional monitoring and education of children athletes [09360].

It has been difficult to determine, from the published literature, whether men or women have higher levels of exercise-induced oxidative stress. The aim of one study was to compare variations between the sexes in lipid hydroperoxide (LPO), superoxide dismutase (SOD), catalase (CAT), glutathione reductase (GR), and lactate dehydrogenase (LDH) after 3 different running exercises performed at the same speed. Eligible participants were healthy university students of both sexes. The participants performed running exercise tests at distances of 800, 1500, and 3000 m at a speed of 10 km/h. Blood samples were taken from the participants just before and immediately after the running activities to determine LPO, SOD, CAT, GR, and LDH, and these measures were compared both before and after exercise and between the sexes. A total of 17 young and healthy, but not physically trained, students (n=8 men; n=9 women) participated in this study. Height, weight, and maximum oxygen consumption values were significantly higher in men than in women. Significant gender effects were found in LPO levels at 3000 m and in SOD activity at 800 m, and 3000 m. CAT activity also significantly differed between the sexes at 800 m and 1500 m. However, no significant gender-time interaction effect was observed for any measurement at the 800-, 1500-, and 3000-m distances. Changes in LPO, SOD, and CAT activities at different running distances were not different between men and women over time because of a nonsignificant gender-time interaction. With regard to changes in oxidative stress, men and women had similar responses to exercise at the same absolute workload, despite significant differences in physical characteristics [09361].

Until recently it has been considered free oxygen radical production in the body to be a solely “negative” occurrence that might be countered by supplementation with antioxidant nutrients. The supposed benefits included improved health and mortality, and for athletes, the extra advantages of enhanced performance through a reduction in exercise-induced damage. In fact a Cochrane Review found little or no difference in the normal population between antioxidant administration and those taking a placebo. Mortality was, in fact, slightly higher in the antioxidant group. However, it is well established that physical exercise results in increased free-radical production in active skeletal muscles. Importantly, numerous reports
indicate that exercise-induced free-radical production is responsible for oxidative damage to cells and contributes to muscular fatigue during prolonged exercise. The fact that working skeletal muscles produce radicals has motivated many athletes to begin using antioxidant supplements in hopes of preventing exercise-induced free-radical damage and/or muscular fatigue. However, whether or not antioxidant supplements are helpful or harmful to the athlete remains a highly debated topic. Free radicals are molecules or any chemical species that contain one or more unpaired electrons in their outer orbital. In cells, radicals can be formed by either losing a single electron or gaining an electron. An unpaired electron results in molecular instability, and therefore radicals are highly reactive molecules that can promote oxidative damage to proteins, lipids and DNA. This radical-mediated damage is referred to as “oxidative damage,” and oxidation of cellular constituents can lead to cellular dysfunction and, in extreme cases, cell death. Also, note that reactive oxygen species (ROS) is a general term that not only refers to oxygen-centred radicals but also includes non-radical but reactive derivatives of oxygen (e.g. hydrogen peroxide). The term “oxidative stress” was introduced in 1985 and is commonly defined as a disturbance in the prooxidant-antioxidant balance in favour of oxidants with the imbalance leading to oxidative damage. Indeed, one of the hallmarks of oxidative stress in cells is the appearance of biomarkers of oxidative damage (e.g. oxidised proteins and/or lipids). Note, however, that exercise-induced oxidative stress is a transient occurrence. Indeed, the exercise-induced spike in radical production is short lived, and growing evidence suggests that this spike in oxidants after exercise is a required signalling pathway for training adaptations to occur. This brief rise in oxidants should not be confused with prolonged oxidative stress found in some pathological conditions. Given that all cells produce radicals, it is not surprising that cells contain an endogenous antioxidant system composed of both enzymatic and non-enzymatic antioxidants. Moreover, dietary antioxidants (e.g. vitamin C and vitamin E) cooperate with the endogenous antioxidant defence systems to form a united antioxidant network in muscle fibres. This cooperative interaction between endogenous antioxidants and dietary antioxidants has fuelled the argument that antioxidant supplementation will boost the muscle fibre’s ability to scavenge ROS and protect against exercise-induced oxidative damage and fatigue. Muscle fatigue is commonly defined as a reduction in the ability of a muscle to generate force. Exercise-induced muscle fatigue is a multifactorial process, and the specific causes of fatigue can vary widely. Nonetheless, growing evidence indicates that radical production in skeletal muscles contributes to fatigue during prolonged submaximal exercise (i.e. events lasting >30 min). ROS production increases in contracting skeletal muscles, and low levels of ROS play an essential role in the regulation of muscle force production. Indeed, low levels of ROS in contracting skeletal muscles are required to achieve optimum force production. However, high levels of ROS can induce oxidative damage to muscle proteins and lipids, and diminish muscle force production. Indeed, well-controlled animal studies indicate that scavenging radicals via antioxidants can protect skeletal muscle against oxidative damage and also delay fatigue during prolonged submaximal exercise. In contrast, antioxidant scavengers are not effective in delaying muscle fatigue in animals performing high intensity exercise. A growing number of studies suggest that acute administration of the antioxidant N-acetylcysteine (NAC) delays human muscle fatigue during prolonged submaximal exercise. Specifically, NAC administration has been shown to delay muscular fatigue in humans during submaximal exercise tasks. Similar NAC does not retard human muscle fatigue during exercise close to VO2max. In contrast to the findings that acute NAC administration can delay muscle fatigue during prolonged submaximal exercise, there is little evidence that other more commonly used antioxidant supplements (e.g. beta carotene, vitamin E, and vitamin C) can improve human exercise performance. Based upon current evidence, it can be concluded that NAC may be able to increase performance during prolonged exercise in humans, but there is limited evidence to indicate that vitamin C, vitamin E or beta carotene can improve performance. Regardless of whether antioxidants can delay muscular fatigue, advocates supporting antioxidant supplementation for athletes argue that rigorous exercise training
results in increased ROS production in skeletal muscles. Therefore, they suggest that antioxidant supplements are required to protect skeletal muscle fibres against oxidative damage. Although this suggestion appears reasonable, there are numerous arguments against antioxidant supplementation for athletes. First, there is no evidence that exercise-induced radical production in skeletal muscle is detrimental to human health. Secondly, regular exercise training promotes increased enzymatic and non-enzymatic antioxidants in muscle fibres resulting in improved endogenous protection against exercise-mediated oxidative damage. Therefore, this increase in endogenous antioxidants may be sufficient to protect against exercise-induced oxidative damage. Moreover, if an athlete maintains an isocaloric diet that is nutritionally well balanced, it is feasible that the athlete may not require supplementary antioxidants above those contained in the diet. There is one circumstance that may justify the use of antioxidant supplements in athletes. Specifically, some athletes may not consume well-balanced diets, and therefore these individuals could be deficient in antioxidant intake (e.g. below the recommended daily allowance (RDA) for selected antioxidant vitamins). This is a reasonable point that is supported by studies investigating the nutritional habits of athletes. Perhaps the two strongest arguments against antioxidant supplementation for athletes and other active individuals are the following. First, emerging evidence indicates that antioxidant supplementation prevents important exercise-induced adaptations in skeletal muscle. Indeed, compelling evidence indicates that exercise-induced ROS production serves as a required signal to promote the expression of numerous skeletal muscle proteins including antioxidant enzymes, mitochondrial proteins and heat-shock proteins. Secondly, two recent reports indicate that antioxidant supplementation with high levels of vitamins E and C (about 16 times higher than RDA for adults) can blunt the training adaptation to exercise. Another key argument against antioxidant supplementation in athletes is that current research does not support the notion that antioxidant supplementation is beneficial to human health. Specifically, a meta-analysis of 68 randomised antioxidant supplement trials (total of 232,606 human participants) concluded that dietary supplementation above the RDA with beta carotene, vitamin A and vitamin E does not improve health outcomes and may increase mortality. At present, there is limited scientific evidence to recommend antioxidant supplements to athletes or other physically active individuals. In fact, the current evidence suggests that athletes should use caution when considering supplementation with high doses of antioxidants [09362].

There is a considerable commercial market, especially within the sports community, claiming the need for antioxidant supplementation. One argument for antioxidant supplementation in sports is that physical exercise is associated with increased reactive oxygen and nitrogen species (RONS) production, which may cause cell damage. However, RONS production may also activate redox-sensitive signaling pathways and transcription factors, which subsequently, may promote training adaptation. The aim of one study was to investigate the effects of combined vitamin C and E supplementation to healthy individuals on different measures of exercise performance after endurance training. Using a double-blinded placebo-controlled design, moderately trained young men received either oral supplementation with vitamins C and E (n=11) or placebo (n=10) before and during 12 wk of supervised, strenuous bicycle exercise training of a frequency of 5 d per week. Muscle biopsies were obtained before and after training. After the training period, maximal oxygen consumption, maximal power output, and workload at lactate threshold increased markedly in both groups. Also, glycogen concentration, citrate synthase, and beta-hydroxyacyl-CoA dehydrogenase activity in the muscle were significantly higher in response to training in both groups. However, there were no differences between the two groups concerning any of the physiological and metabolic variables measured. The results suggest that administration of vitamins C and E to individuals with no previous vitamin deficiencies has no effect on physical adaptations to strenuous endurance training [10413].
Dietary antioxidants include vitamin C, vitamin E, carotenoids (mainly beta-carotene), polyphenols (e.g. flavonoids), selenium, glutathione and coenzyme Q10. Changes in plasma endogenous and dietary antioxidants and oxidative stress markers were studied following two 90 min elite female soccer games separated by 72 h of either active or passive recovery. The active recovery group (n 8) trained for 1 h at 22 and 46 h after the first game (low-intensity cycling and resistance training), while the passive group rested (n 8). Blood samples were taken before the games; immediately after the games; 21, 45 and 69 h after the first game; and immediately after the second game. The oxidative stress markers and antioxidants were not affected by active recovery. The oxidative stress marker GSSG increased by the same extent after both the games, while the lipid peroxidation marker diacron-reactive oxygen metabolite remained unchanged. The endogenous antioxidants total glutathione and uric acid and ferric reducing/antioxidant power increased immediately after both the games with the same amplitude, while increases in cysteine, cysteine-glycine and total thiols reached significant levels only after the second game. The changes in dietary antioxidants after the first game were either rapid and persistent (tocopherols and ascorbic acid (AA) increased; polyphenols decreased) or delayed (carotenoids). This resulted in high pre-second game levels of tocopherols, AA and carotenoids. Polyphenols returned to baseline at 69 h, and were not affected by the second game. In conclusion, the soccer-associated dietary antioxidant defence, but not the endogenous antioxidant defence, is persistent. Similar acute oxidative stress and endogenous antioxidant responses and dissimilar dietary antioxidant reactions occur during two repeated female soccer games. Finally, the complex antioxidant response to soccer is not affected by active recovery training [10530].

Antioxidant requirements have neither been defined for endurance nor been defined for ultra-endurance athletes. To verify whether an acute bout of ultra-endurance exercise modifies the need for nutritive antioxidants, it was aimed to investigate the changes of endogenous and exogenous antioxidants in response to an Ironman triathlon and to particularise the relevance of antioxidant responses to the indices of oxidatively damaged blood lipids, blood cell compounds and lymphocyte DNA, and to examine whether potential time-points of increased susceptibility to oxidative damage are associated with alterations in the antioxidant status. Blood that was collected from forty-two well-trained male athletes 2 d pre-race, immediately post-race, and 1, 5 and 19 d later was sampled. The key findings of the study were that immediately post-race, vitamin C, alpha-tocopherol, and levels of the Trolox equivalent antioxidant capacity, the ferric reducing ability of plasma and the oxygen radical absorbance capacity (ORAC) assays increased significantly. Exercise-induced changes in the plasma antioxidant capacity were associated with changes in uric acid, bilirubin and vitamin C. Also, significant inverse correlations between ORAC levels and indices of oxidatively damaged DNA immediately and 1 d post-race suggest a protective role of the acute antioxidant responses in DNA stability. Significant decreases in carotenoids and gamma-tocopherol 1 d post-race indicate that the antioxidant intake during the first 24 h of recovery following an acute ultra-endurance exercise requires specific attention. Furthermore, the present study illustrates the importance of a diversified and well-balanced diet to maintain a physiological antioxidant status in ultra-endurance athletes in reference to recommendations [10531].

Also physical exercise in general is accepted to be protective, acute and strenuous exercise has been shown to induce oxidative stress. Enhanced formation of free radicals leads to oxidation of macromolecules and to DNA damage. On the other hand ultra-endurance events which require strenuous exercise are very popular and the number of participants is continuously increasing worldwide. Since only few data exists on Ironman triathletes, who are prototypes of ultra-endurance athletes, one study was aimed at assessing the risk of oxidative stress and DNA damage after finishing a triathlon and to predict a possible health
risk. Blood samples of 42 male athletes were taken 2 days before, within 20 min after the race, 1, 5 and 19 days post-race. Oxidative stress marker increased only moderately after the race and returned to baseline after 5 days. Marker of DNA damage measured by the SCGE assay with and without restriction enzymes as well as by the sister chromatid exchange assay did either show no change or deceased within the first day after the race. Due to intake during the race and the release by the cells plasma concentrations of vitamin C and α-tocopherol increased after the event and returned to baseline 1 day after. This study indicates that despite a temporary increase in some oxidative stress markers, there is no persistent oxidative stress and no DNA damage in response to an Ironman triathlon in trained athletes, mainly due to an appropriate antioxidant intake and general protective alterations in the antioxidant defence system [10532].

The "Marathon des Sables" is a competition known to induce oxidative stress. Antioxidant vitamins prevent exercise-induced oxidative damages. The purpose of one study was to evaluate daily intake and plasma level of the main antioxidant vitamins (alpha-tocopherol, vitamin C, beta-carotene and retinol) in 19 male athletes who participated in this competition. Data collected before the beginning of the competition included daily dietary intake using a 7-day food record and plasma biochemical measurements (alpha-tocopherol, vitamin C, beta-carotene and retinol). First, total energy intake was obviously lower than the energetic intake usually observed in well-trained endurance athletes. Second, antioxidant vitamins intake was also insufficient. Indeed, the intake was lower than the French Dietary Reference Intakes (DRI) for this population in 18 subjects for vitamin E and 6 subjects for vitamin C, beta-carotene and Retinol Equivalent. As a significant relationship was found between total energy intake and the intake of vitamin E and vitamin C, the low total energy intake contributed partially to the insufficient antioxidant vitamins intake. The dietary questionnaire analysis also revealed a low intake of vegetable oils, fruits and vegetables. However, plasma concentrations of these antioxidant vitamins were similar to the literature data observed in athletes. The study evidenced obvious insufficient energy intake in ultra endurance athletes associated with a low antioxidant vitamin intake [07372].

The effects of antioxidant diet supplements on blood lactate concentration and on the aerobic and anaerobic thresholds and their adaptations to training were analysed. Fifteen amateur male athletes were randomly assigned to either a placebo group or an antioxidant-supplemented group (90 days supplementation with 500 mg/day of vitamin E and 30 mg/day of beta-carotene, and the last 15 days also with 1 g/day of vitamin C). Before and after the antioxidant supplements, the sportsmen performed a maximal exercise test on a cycle ergometer and maximal and submaximal physiological parameters were assessed together with blood lactate concentration. Maximal oxygen uptake (VO\textsubscript{2max}), maximal blood lactate concentration, and the maximal workload attained rose significantly in both groups after the 3 months of training. At the end of the study, maximal blood lactate concentration was lower in the group that took supplements than in the placebo group. The percentage of VO\textsubscript{2max} attained at the anaerobic threshold rose significantly in both groups after 3 months of training, although the final value in the supplemented group was higher than that in the placebo group. Antioxidant diet supplements induced lower increases in blood lactate concentration after a maximal exercise test and could improve the efficiency in which aerobic energy is obtained [07373].

It was examined the influence of 3 consecutive days of high-intensity cycling on blood and urinary markers of oxidative stress. Eight highly-trained male cyclists completed an interval session (9 exercise bouts lasting 30 s each, at 150 % peak power output) on day 1, followed by 2 laboratory-simulated 30 km time trials on days 2 and 3. The cyclists also completed a submaximal exercise trial matched to the interval session for oxygen consumption. Blood was collected pre- and post-exercise for the determination of malondialdehyde (MDA), total
antioxidant status (TAS), vitamin E, and the antioxidant enzyme activity of superoxide dismutase and glutathione peroxidase, while urine was collected for the determination of allantoin. There were significant increases in plasma MDA concentrations, plasma TAS, and urinary allantoin excretion following the high-intensity interval session on day 1, whereas plasma vitamin E concentration significantly decreased. Post-exercise changes in plasma MDA, TAS concentrations, and urinary allantoin excretion were all significantly attenuated over the 3 consecutive days of exercise, whereas resting plasma TAS concentration was elevated. There were no significant changes in plasma MDA, TAS, or allantoin excretion following submaximal exercise and there were no significant changes in antioxidant enzyme activity over consecutive days of exercise or following submaximal exercise. Consecutive days of high-intensity exercise enhanced resting plasma TAS concentration and reduced the post-exercise increase in plasma MDA concentrations [07374].

Cognitive performance

Antioxidant properties of some vitamins and trace elements may help to prevent cognitive decline. The aim of one study was to estimate the long-term effects of antioxidant nutrient supplementation on the cognitive performance of participants in the Supplementation in Vitamins and Mineral Antioxidants (SU.VI.MAX) study 6 y after the end of the trial. This study included 4447 French participants aged 45-60 years who were enrolled in the SU.VI.MAX study (1994-2002), which was a double-blind, placebo-controlled, randomized trial. From 1994 to 2002, participants received daily vitamin C (120 mg), beta-carotene (6 mg), vitamin E (30 mg), selenium (100 μg), and zinc (20 mg) in combination or as a placebo. In 2007-2009, the cognitive performance of participants was assessed with 4 neuropsychological tests (6 tasks). Principal components analysis (PCA) was performed to identify cognitive-function summary scores. Associations between antioxidant supplementation and cognitive functions, in the full sample and by subgroups, were estimated through ANOVA and expressed as mean differences and 95% CIs. Subgroup analyses were performed according to baseline characteristics. Subjects receiving active antioxidant supplementation had better episodic memory scores (mean difference: 0.61; 95% confidence interval 0.02 to 1.20). PCA indicated 2 factors that were interpreted as showing verbal memory and executive functioning. Verbal memory was improved by antioxidant supplementation only in subjects who were nonsmokers or who had low serum vitamin C concentrations at baseline. This study supports the role of an adequate antioxidant nutrient status in the preservation of verbal memory under certain conditions [11404].

Gender differences

The purpose of one study was to determine the influence of gender and antioxidant supplementation on exercise-induced oxidative stress. Twenty-five men and 23 women ran for 30 min at 80 percent VO_2max, once before and once after 2 weeks of supplementation, and again after a 1-week wash-out period. Subjects were randomly assigned to either placebo (P), antioxidant (A: 400 IU vitamin E+1 g vitamin C), or a fruit and vegetable powder (FV) treatment. Blood was obtained at rest and immediately after exercise. Before supplementation, women had higher resting reduced glutathione, total glutathione, and plasma vitamin E compared with men. With both A and FV supplementations, plasma vitamin E gender differences disappeared. Protein carbonyls, oxidized glutathione, and malondialdehyde all increased similarly for both genders in response to exercise. Both A and FV attenuated the reduced glutathione decrease and the oxidized glutathione and protein carbonyls increase compared with P, with no gender differences. 8-hydroxydeoxyguanosine was lower with treatment A compared with FV and P only for men. Plasma vitamin C increased 39 percent (A) and 21 percent (FV) compared with P. These data indicate that
women have higher resting antioxidant levels than men. Markers of oxidative stress increased similarly in both genders in response to exercise of similar intensity and duration. Two weeks of antioxidant supplementation can attenuate exercise-induced oxidative stress equally in both genders [07375].

*Flavonoids (including quercetin)*

Phytochemicals are chemicals produced by plants, and include tannins, lignins and flavonoids. The largest and best studied polyphenols are the flavonoids, with more than 6000 identified and classified into at least six subgroups: flavonols, flavones, flavanones, flavanols (and their oligomers, proanthocyanidins), anthocyanidins and isoflavonoids. Flavonoids are widely distributed in plants and function as plant pigments, signalling molecules and defenders against infection and injury. Dietary intake of flavonoids ranges from 50 to 800 mg/day depending on the consumption of fruits and vegetables and the intake of tea. In the USA, total flavonoid intake averages 210 mg/day, and in Spain 313 mg/day, with important sources including tea, citrus fruit and juice, beers and ales, wines, melon and berries, apples, onions and bananas. A high intake of fruits and vegetables has been linked in numerous studies to a reduced risk of cardiovascular disease and various types of cancer. The disease-reducing influence of fruits and vegetables may be partly due to high levels of flavonoids. Although cell culture and animal scientific evidence is promising in support of the role of flavonoid intake in disease prevention, human studies are mixed and inconclusive when taken as a whole. Part of the problem is that flavonoid data are available on a limited number of foods, hampering efforts to estimate total flavonoid intake in human subjects. Many flavonoids possess strong anti-inflammatory, anti-viral, antioxidant, anti-obesity and anti-carcinogenic properties when studied in vitro using large doses of the purified form. Inflammation and oxidative stress are key mechanisms in the pathogenesis of certain disease states, supporting the proposed strategy of increased flavonoid intake for the prevention of cancer, diabetes mellitus and cardiovascular disease. However, results from randomised, double-blinded studies in humans with large doses of purified flavonoids such as quercetin have been disappointing. Flavonoids vary widely in bioavailability, and most are poorly absorbed, undergo active efflux and are extensively conjugated and metabolically transformed, all of which can affect their bioactive capacities. Despite low bioavailability of the parent flavonoid, some of the in vivo metabolites may accumulate in tissues and produce bioactive influences, but conclusive human data are lacking. For example, animal data indicate that quercetin metabolites accumulate in the vascular tissue and there act as complementary antioxidants, with plasma albumin facilitating the translocation of quercetin metabolites to the vascular target. There is a growing realisation that bioactive influences of individual flavonoids are potentiated when mixed with other flavonoids (e.g. the flavonol quercetin with the flavanol epigallocatechin 3-gallate; EGCG) or are included in a cocktail or extract of other polyphenols and nutrients. Two or more flavonoids ingested together may increase bioavailability and decrease elimination by competitive inhibition of glucuronide and sulphate conjugation in both the intestine and liver, and by inhibiting efflux transporters such as P-glycoprotein, breast cancer resistance protein and multidrug resistance protein 2. The health-protective effects of plant foods are not produced by a single component but rather by complex mixtures of interacting molecules. The polyphenols and natural components provide a multifaceted defensive strategy for both plants and humans. The ‘pharma’ approach of using large doses of a single bioactive molecule is thus seldom successful in the application of nutrition to human health and performance. In addition, a metabolomics or nutrigenomics approach is needed to improve the capacity of investigators to capture the complex and subtle influences of flavonoid supplements or flavonoid-rich extracts, foods and beverages on whole-body metabolism and physiology. Various nutritional agents have been tested for their capacity to attenuate oxidative stress, inflammation and immune changes following intensive exercise, and thus lower the magnitude of physiological stress and the risk of upper
respiratory tract infection (URTI). Some question the value of using nutritional supplements as countermeasures to exercise-induced oxidative stress and inflammation because these may interfere with important signalling mechanisms for training adaptations. Another viewpoint is that nutritional supplements attenuate but do not totally block exercise-induced oxidative stress and inflammation, analogous to the beneficial use of ice packs to reduce swelling following mild injuries. Pure flavonoids such as quercetin, EGCG and isoflavones, or flavonoid-rich plant extracts, are being tested by an increasing number of investigative teams as performance aids and countermeasures to exercise-induced inflammation, DOMS (delayed onset of muscle soreness), oxidative stress, immune dysfunction and URTI. Most studies have focused on the ability of flavonoid-rich tea and fruit and vegetable extracts to counter oxidative stress and, the majority indicates an effective response. The second most common outcome measure is related to inflammation and DOMS, and again, most studies support protective effects when flavonoid mixtures or plant extracts are ingested before demanding bouts of exercise. Results are mixed for performance outcomes, and few studies have included immune and URTI measures. For any particular flavonoid or plant extract studied within an exercise context, few papers are available, and research designs vary widely with regard to the supplementation dose and regimen, the mode of exercise stress and outcome measures. The flavonoid supplementation period in studies varies from 15 min to 60 days before an exercise challenge, with most studies clustered between 7 and 21 days. Nonetheless, the data in general support that flavonoid-rich plant extracts and unique flavonoid-nutrient mixtures (e.g. quercetin with green tea extract and fish oil, or isoflavones with lycopene) help to counter exercise-induced oxidative stress and inflammation/DOMS. More exercise-related research has been conducted with quercetin than any other flavonoid. In one of the earliest studies with exercise-stressed cyclists, supplementation with pure quercetin (1000 mg/day) over a 5-week period reduced illness rates but did not counter postexercise inflammation, oxidative stress, or immune dysfunction. In a follow-up study using a similar design, quercetin supplementation combined with green tea extract, isoquercetin and fish oil did cause a sizeable reduction in exercise-induced inflammation and oxidative stress, with chronic augmentation of innate immune function. Quercetin's role as a performance aid has been tested by several research teams with mixed results. Animal studies support a role for quercetin as an exercise mimic for mitochondrial biogenesis and enhanced endurance performance. One study with untrained human subjects indicated a modest enhancement in skeletal muscle mitochondrial density and endurance performance, but far below what was reported in mice. Although data are limited and supplementation regimens vary widely, most studies have concluded that flavonoid–nutrient mixtures or flavonoid-rich tea, fruit and vegetable extracts ingested acutely or chronically before an exercise challenge attenuate postexercise oxidative stress, inflammation and DOMS. Results are mixed for performance outcomes, and few studies have included immune measures. Current evidence seems to support a higher antioxidant requirement in athletes than non-athletes to help reduce oxidative damage induced by exercise. Flavonoid-rich extracts when consumed just before or chronically for days or weeks before heavy exertion partly counter postexercise inflammation and oxidative stress. Research is needed to define better optimal dosing regimens. It is also important to determine whether unique flavonoid mixtures that include several of the most bioactive flavonoids across different subgroups amplify these influences, while also bolstering immunity and operating as exercise mimetics for mitochondrial biogenesis. Whether athletes need higher dietary antioxidants, including flavonoids, than sedentary people because of a higher turnover of oxygen radicals imposed by high intensity training and competition is still controversial and speculative. In the meantime, the most optimally effective way to increase antioxidant intake is to consume a varied diet focused on foods that are naturally good sources of antioxidants such as fruit, vegetables and whole grains. This strategy also helps minimise the risk of exceeding intake. When there is a perceived need to supplement dietary intake, it seems sensible to choose a product that provides a combination of antioxidants, including flavonoids, at moderate levels,
rather than large doses of a single nutrient [10533].

Astaxanthin

Astaxanthin, a xanthophyll carotenoid, is a nutrient with unique cell membrane actions and diverse clinical benefits. This molecule neutralizes free radicals or other oxidants by either accepting or donating electrons, and without being destroyed or becoming a pro-oxidant in the process. Its linear, polar-nonpolar-polar molecular layout equips it to precisely insert into the membrane and span its entire width. In this position, astaxanthin can intercept reactive molecular species within the membrane's hydrophobic interior and along its hydrophilic boundaries. Clinically, astaxanthin has shown diverse benefits, with excellent safety and tolerability. In double-blind, randomized controlled trials (RCTs), astaxanthin lowered oxidative stress in overweight and obese subjects and in smokers. It blocked oxidative DNA damage, lowered C-reactive protein (CRP) and other inflammation biomarkers, and boosted immunity in the tuberculin skin test. Astaxanthin lowered triglycerides and raised HDL-cholesterol in another trial and improved blood flow in an experimental microcirculation model. It improved cognition in a small clinical trial and boosted proliferation and differentiation of cultured nerve stem cells. In several Japanese RCTs, astaxanthin improved visual acuity and eye accommodation. It improved reproductive performance in men and reflux symptoms in H. pylori patients. In preliminary trials it showed promise for sports performance (soccer). In cultured cells, astaxanthin protected the mitochondria against endogenous oxygen radicals, conserved their redox (antioxidant) capacity, and enhanced their energy production efficiency. The concentrations used in these cells would be attainable in humans by modest dietary intakes. Astaxanthin's clinical success extends beyond protection against oxidative stress and inflammation, to demonstrable promise for slowing age-related functional decline [11538].

Astaxanthin is a carotenoid. It belongs to a larger class of phytochemicals known as terpenes. It was examined the effect of astaxanthin (AST) on substrate metabolism and cycling time trial (TT) performance by randomly assigning 21 competitive cyclists to 28 d of encapsulated AST (4 mg/d) or placebo (PLA) supplementation. Testing included a VO_{2max} test and on a separate day a 2 h constant intensity pre-exhaustion ride, after a 10 h fast, at 5 percent below VO_{2max} stimulated onset of 4 mmol/L lactic acid followed 5 min later by a 20 km TT. Fourteen participants successfully completed the trial. Overall, it was observed significant improvements in 20 km TT performance in the AST group (n=7), but not the PLA (n=7). The AST group was significantly different vs PLA. The AST group significantly increased power output (20 W), while the PLA group did not (1.6 W). The mechanism of action for these improvements remains unclear, as it was observed no treatment effects for carbohydrate and fat oxidation, or blood indices indicative of fuel mobilization. While AST significantly improved TT performance the mechanism of action explaining this effect remains obscure [11539].

In handball

The chronic exposure to regular exercise training seems to improve antioxidant defense systems. However, the intense physical training imposed on elite athletes may lead to overtraining associated with oxidative stress. The purpose of one study was to investigate the effect of different training loads and competition on oxidative stress, biochemical parameters and antioxidant enzymatic defense in handball athletes during 6-months of monitoring. Ten male elite handball athletes were recruited to the study. Blood samples were collected four times every six weeks throughout the season. During most intense periods of training and competitions there were significant changes in plasma indices of oxidative stress.
increased TBARS and decreased thiols). Conversely, chronic adaptations to exercise training demonstrated a significant protective effect against oxidative stress in erythrocyte (decrease in TBARs and carbonyl group levels). Erythrocyte antioxidant enzyme activities were significantly increased, suggesting a training-induced antioxidant adaptation. Biomarkers of skeletal muscle damage were significantly increased during high-intensity training period (creatine kinase, lactate dehydrogenase and aspartate aminotransferase). No significant changes were observed in plasma IL-6, TNF-alpha and uric acid, whereas a significant reduction was found in the IL-1beta concentration and gamma-glutamyl transferase activity. Oxidative stress and antioxidant biomarkers can change throughout the season in competitive athletes, reflecting the physical stress and muscle damage that occurs as the result of competitive handball training. In addition, these biochemical measurements can be applied in the physiological follow-up of athletes [13737].

alpha-Tocopherol, ascorbic acid, and beta-carotene

It was hypothesized that alpha-tocopherol, ascorbic acid, and beta-carotene, either applied individually or in combination, would modulate redox homeostasis and affect the regulation of genes involved in DNA repair under stress conditions. To test this hypothesis, it was analyzed the influence of these vitamins, either supplied individually or in combination, on the plasma lipid peroxide level and the hepatic level of 8-hydroxy-2'-deoxyguanosine in rats. It was also evaluated the expression of p53 and Mdm2 protein in the intestinal epithelium, as these proteins are involved in the cellular regulation of DNA damage repair. Male Wistar rats (n=112) were supplemented with α-tocopherol (2 mg), ascorbic acid (12 mg), and beta-carotene (1 mg), both individually and in combination, for 14 days; 32 control rats were treated with placebo. Half of the animals in each group (n=8) were subjected to 15-minute treadmill running at 20 m/min to cause exercise-induced oxidative stress. A statistically significant reduction in lipid peroxide levels was observed in the plasma of rats subjected to exercise and given 2 or 3 of the antioxidants. Exercise, as well as coadministration of the antioxidants, had no significant effect on the amount of DNA damage. Downward trends in the level of p53 protein expression were observed both in exercised and nonexercised animals, especially when the studied vitamins were administered in combination. Our findings suggest that alpha-tocopherol, ascorbic acid, and beta-carotene, when given concurrently, have primarily antioxidant effects on lipids under stress but do not significantly affect the regulation of p53 gene expression [13738].

Catechins

Catechins, abundant in green tea, exhibit many biological actions for potential clinical applications. The purpose of a study was to explore the potential benefits of catechin ingestion on recovery of physical performance after downhill running. Institute of Cancer Research mice were used to examine the effects of prior catechin ingestion (0.5 % w/w in diet for 3 weeks) on 1) wheel-running activity, 2) running endurance, 3) muscle force, and 4) muscle oxidative stress and inflammation after downhill running (16 m/min for 5 min, 18 m/min for 5 min, 20 m/min for 10 min, and 22 m/min for 130 min). Voluntary wheel-running activity and the contractile force of the isolated soleus muscle decreased after downhill running. Notably, catechin ingestion significantly alleviated the running-induced decrease in voluntary wheel-running activity by 35 percent; the catechin-treated mice maintained endurance running capacity. Furthermore, catechins alleviated the decrease in tetanic force evident in the soleus muscle after downhill running. Catechins suppressed the running-induced increases in plasma creatine phosphokinase levels by 52 percent; this was also true of the carbonylated protein content of the soleus muscle by 17 percent, malondialdehyde levels by 32 percent in the gastrocnemius muscle, and myeloperoxidase activity of the
gastrocnemius by 22 percent. The levels of tumor necrosis factor-alpha, interleukin-1beta, and monocyte chemoattractant protein-1 in the gastrocnemius muscle were significantly lower by 33, 29, and 35 percent, respectively, in treated mice; the expression levels of mRNAs encoding these fell in parallel. The results suggest that long-term intake of catechins, perhaps through their antioxidant properties, attenuates downhill running-induced muscle damage by suppressing muscle oxidative stress and inflammation, hastening recovery of physical performance in mice [13739].

*In chronic obstructive pulmonary disease*

Oxidative stress may contribute to exercise intolerance in patients with chronic obstructive pulmonary disease (COPD). One study sought to determine the effect of an acute oral antioxidant cocktail (AOC, vitamins C and E, and alpha-lipoic acid) on skeletal muscle function during dynamic quadriceps exercise in COPD. Ten patients with COPD performed knee extensor exercise to exhaustion and isotime trials after either the AOC or placebo (PL).

Pre- to postexercise changes in quadriceps maximal voluntary contractions and potentiated twitch forces (Q(tw,pot)) quantified quadriceps fatigue. Under PL conditions, the plasma electron paramagnetic resonance (EPR) spectroscopy signal was inversely correlated with the forced expiratory volume in 1 s to forced vital capacity ratio (FEV1/FVC), an index of lung dysfunction and maximal voluntary contraction force AOC consumption increased plasma ascorbate levels and attenuated the area under the curve of the EPR spectroscopy free radical signal but it did not alter the endurance time or quadriceps fatigue. The ability of the AOC to decrease the EPR spectroscopy signal, however, was prominent in those with high basal free radicals with minimal effects in those with low levels. These data document a relation between directly measured free radicals and lung dysfunction and the ability of the AOC to decrease oxidative stress in COPD. Acute amelioration of free radicals, however, does not appear to affect dynamic quadriceps exercise performance [13740].

*Experimental*

One study aimed to evaluate the effect of selenium supplementation on lipid peroxidation and lactate levels in rats subjected to acute swimming exercise. Thirty-two adult male rats of Sprague-Dawley type were divided into four groups. Group 1, control; group 2, selenium-supplemented; group 3, swimming control; group 4, selenium-supplemented swimming group. The animals in groups 2 and 4 were supplemented with (i.p.) 6 mg/kg/day sodium selenite for 4 weeks. The blood samples taken from the animals by decapitation method were analyzed in terms of erythrocyte-reduced glutathione (GSH), serum glutathione peroxidase (GPx) and superoxide dismutase (SOD), and plasma malondialdehyde (MDA) and lactate using the colorimetric method, and serum selenium values using an atomic emission device. In the study, the highest MDA and lactate values were found in group 3, while the highest GSH, GPx and SOD values were obtained in group 4. Group 2 had the highest and group 3 had the lowest selenium levels. Results of the study indicate that the increase in free radical production and lactate levels due to acute swimming exercise in rats might be offset by selenium supplementation. Selenium supplementation may be important in that it supports the antioxidant system in physical activity [10414].

*In mice*

Antioxidant supplements are widely consumed by the general public; however, their effects of on exercise performance are controversial. The aim of this study was to examine the effects of an antioxidant cocktail (alpha-lipoic acid, vitamin E and coenzyme Q10) on exercise performance, muscle function and training adaptations in mice. C57Bl/J6 mice were placed on antioxidant supplement or placebo-control.
diets (n=36/group) and divided into trained (8 weeks treadmill running) (n=12/group) and untrained groups (n=24/group). Antioxidant supplementation had no effect on the running performance of trained mice nor did it affect training adaptations; however, untrained female mice that received antioxidants performed significantly better than placebo-control mice. Furthermore, antioxidant-supplemented females (untrained) showed elevated respiratory capacity in freshly excised muscle fibers (quadriceps femoris), reduced oxidative damage to muscle proteins, and increased expression of mitochondrial proteins compared to placebo-controls. These changes were attributed to increased expression of proliferator-activated receptor gamma coactivator 1alpha (PGC-1alpha) via activation of AMP-activated protein kinase (AMPK) by antioxidant supplementation. Overall, these results indicate that this antioxidant supplement exerts gender specific effects; augmenting performance and mitochondrial function in untrained females, but does not attenuate training adaptations [13728].

**Hydroxycitrate**

Glycogen stored in skeletal muscle is the main fuel for endurance exercise. The present study examined the effects of oral hydroxycitrate (HCA) supplementation on post-meal glycogen synthesis in exercised human skeletal muscle. Eight healthy male volunteers (aged 22 years) completed a 60-min cycling exercise at 70-75 % VO2_max and received HCA or placebo in a crossover design repeated after a 7 days washout period. They consumed 500 mg HCA or placebo with a high-carbohydrate meal (2 g carbohydrate/kg body weight, 80 % carbohydrate, 8 % fat, 12 % protein) for a 3-h post-exercise recovery. Muscle biopsy samples were obtained from vastus lateralis immediately and 3 h after the exercise. We found that HCA supplementation significantly lowered post-meal insulin response with similar glucose level compared to placebo. The rate of glycogen synthesis with the HCA meal was approximately onefold higher than that with the placebo meal. In contrast, GLUT4 protein level after HCA supplementation was significantly decreased below the placebo level, whereas expression of fatty acid translocase (FAT)/CD36 mRNA was significantly increased above the placebo level. Furthermore, HCA supplementation significantly increased energy reliance on fat oxidation, estimated by the gaseous exchange method. However, no differences were found in circulating NEFA and glycerol levels with the HCA meal compared with the placebo meal. The present study reports evidence that HCA supplementation enhanced glycogen synthesis rate in exercised human skeletal muscle and improved post-meal insulin sensitivity [12457].

**Applephenon**

It was examined the effects of Applephenon and ascorbic acid administration on physical fatigue. In a double-blinded, placebo-controlled, three-way crossover design, 18 healthy volunteers were randomized to oral Applephenon (1200 mg/d), ascorbic acid (1000 mg/d), or placebo for 8 d. The fatigue-inducing physical task consisted of workload trials on a bicycle ergometer at fixed workloads for 2 h on two occasions. During the test, subjects performed non-workload trials with maximum velocity for 10 s at 30 min (30-min trial) after the start of the test and 30 min before the end of the test (210-min trial). The change in maximum velocity between the 30- and 210-min trials was higher in the group given Applephenon than in the group given placebo; ascorbic acid had no effect. These results suggest that Applephenon attenuates physical fatigue, whereas ascorbic acid does not [07376].
Creatine

Athletes, body builders, and military personnel use dietary creatine as an ergogenic aid to boost physical performance in sports involving short bursts of high-intensity muscle activity. Lesser known is the essential role creatine, a natural regulator of energy homeostasis, plays in brain function and development. Creatine supplementation has shown promise as a safe, effective, and tolerable adjunct to medication for the treatment of brain-related disorders linked with dysfunctional energy metabolism, such as Huntington's Disease and Parkinson's Disease. Impairments in creatine metabolism have also been implicated in the pathogenesis of psychiatric disorders, leaving clinicians, researchers and patients alike wondering if dietary creatine has therapeutic value for treating mental illness. One review summarized the neurobiology of the creatine-phosphocreatine circuit and its relation to psychological stress, schizophrenia, mood and anxiety disorders. While present knowledge of the role of creatine in cognitive and emotional processing is in its infancy, further research on this endogenous metabolite has the potential to advance our understanding of the biological bases of psychopathology and improve current therapeutic strategies [12414].

A broad spectrum of beneficial effects has been ascribed to creatine (Cr), phosphocreatine (PCr) and their cyclic analogues cyclo-(cCr) and phospho-cyclocreatine (PcCr). Cr is widely used as nutritional supplement in sports and increasingly also as adjuvant treatment for pathologies such as myopathies and a plethora of neurodegenerative diseases. Additionally, Cr and its cyclic analogues have been proposed for anti-cancer treatment. The mechanisms involved in these pleiotropic effects are still controversial and far from being understood. The reversible conversion of Cr and ATP into PCr and ADP by creatine kinase, generating highly diffusible PCr energy reserves, is certainly an important element. However, some protective effects of Cr and analogues cannot be satisfactorily explained solely by effects on the cellular energy state. Here it was used mainly liposome model systems to provide evidence for interaction of PCr and PcCr with different zwitterionic phospholipids by applying four independent, complementary biochemical and biophysical assays: chemical binding assay, surface plasmon resonance spectroscopy (SPR), (solid-state $^{31}$P-NMR, and (differential scanning calorimetry (DSC). SPR revealed low affinity PCr/phospholipid interaction that additionally induced changes in liposome shape as indicated by NMR and SPR. Additionally, DSC revealed evidence for membrane packing effects by PCr, as seen by altered lipid phase transition. Finally, PCr efficiently protected against membrane permeabilization in two different model systems: liposome-permeabilization by the membrane-active peptide melittin, and erythrocyte hemolysis by the oxidative drug doxorubicin, hypoosmotic stress or the mild detergent saponin. These findings suggest a new molecular basis for non-energy related functions of PCr and its cyclic analogue. PCr/phospholipid interaction and alteration of membrane structure may not only protect cellular membranes against various insults, but could have more general implications for many physiological membrane-related functions that are relevant for health and disease [12415].

Very high blood creatine kinase (CK) concentrations have been observed among recent finishers of the 161-km Western States Endurance Run (WSER), and it has been suggested that there is a link between rhabdomyolysis and hyponatremia. Therefore, the purpose of one study was to compare CK concentrations of finishers in the 2010 WSER with past values, and to determine whether there was an association between blood CK and sodium concentrations. Consenting 2010 WSER finishers provided blood samples at the finish for
determination of blood CK and sodium concentrations. Finish time, age, and gender were obtained from official race results, and running experience was determined from our database as number of prior 161-km ultramarathon finishes. From 216 (66 %) of the 328 finishers, median and mean CK concentrations were found to be 20 850 IU/L and 32 956 IU/L, respectively (range 1500-264 300 IU/L), and 13 (6%) had values greater than 100 000 IU/L. These values were statistically higher than those reported from the 1995 WSER. The CK concentration was not significantly associated with finish time, age, gender, or running experience. Blood sodium concentrations were obtained from a subgroup of 159 runners, and the relationship between blood CK and sodium concentrations did not reach statistical significance. It was concluded that creatine kinase concentrations of 2010 WSER finishers are higher than values previously reported. More research should focus on explaining this observation and on whether there is a possible link between higher CK concentrations and hyponatremia [12416].

The purpose of one study was to examine the effects of 7 days of supplementation with 20 g/day of creatine monohydrate (CM) on mean power (MP) and peak power (PP) from the Wingate anaerobic test (WAnT), body weight (BW), 1-repetition maximum (1RM) bilateral leg extension (LE) strength, and 1RM bench press (BP) strength. The study used a randomized, double-blind, placebo-controlled design. Twenty-two men (age 22 ± 2 years) were randomly assigned to either a supplement (SUPP; n=10) or placebo (PLAC; n=12) group. The SUPP group ingested 20 g/d of CM powder for 7 days, whereas the PLAC ingested 20 g/d of maltodextrin powder. Measurements for the PLAC and SUPP groups included BW, PP, and MP from two 30-second WAnTs (separated by 7 minutes), and 1RM strength for LE and BP. Testing was conducted before (PRE) and after (POST) 7 days of ingesting either the supplement or placebo. The results of this study indicated that there was a significant increase from PRE to POST testing in MP for the SUPP group (5 %) but not for the PLAC group (-0.3 %). There were no between-group differences, however, for 1RM LE and 1RM BP strength. Furthermore, there were no changes in PP or BW for either group. The findings of this study indicated that loading with 20 g/d of CM for 7 days increased MP (5.4 % increase) from the WAnT, but it had no effect on strength (1RM LE and 1RM BP), PP, or BW [12417].

It was aimed to investigate the role of betaine supplementation on muscle phosphoryl-creatine (PCr) content and strength performance in untrained subjects. Additionally, it was compared the ergogenic and physiological responses to betaine versus creatine supplementation. Finally, we also tested the possible additive effects of creatine and betaine supplementation. This was a double-blind, randomized, placebo-controlled study. Subjects were assigned to receive betaine (BET; 2 g/day), creatine (CR; 20 g/day), betaine plus creatine (BET+CR; 2+20 g/day, respectively) or placebo (PL). At baseline and after 10 days of supplementation, it was assessed muscle strength and power, muscle PCr content, and body composition. The CR and BET+CR groups presented greater increase in muscle PCr content than PL (p=0.004 and p=0.006, respectively). PCr content was comparable between BET versus PL (p=0.78) and CR versus BET+CR (p=0.99). CR and BET+CR presented greater muscle power output than PL in the squat exercise following supplementation. Similarly, bench press average power was significantly greater for the CR-supplemented groups. CR and BET+CR groups also showed significant pre- to post-test increase in 1-RM squat and bench press. No significant differences for 1-RM strength and power were observed between BET versus PL and CR versus BET+CR. Body composition did not differ between the groups. In conclusion, it was reported that betaine supplementation does not augment muscle PCr content. Furthermore, it was shown that betaine supplementation combined or not with creatine supplementation does not affect strength and power performance in untrained subjects [12418].
Creatine is one of the most popular and widely researched natural supplements. The majority of studies have focused on the effects of creatine monohydrate on performance and health; however, many other forms of creatine exist and are commercially available in the sports nutrition/supplement market. Regardless of the form, supplementation with creatine has regularly shown to increase strength, fat free mass, and muscle morphology with concurrent heavy resistance training more than resistance training alone. Creatine may be of benefit in other modes of exercise such as high-intensity sprints or endurance training. However, it appears that the effects of creatine diminish as the length of time spent exercising increases. Even though not all individuals respond similarly to creatine supplementation, it is generally accepted that its supplementation increases creatine storage and promotes a faster regeneration of adenosine triphosphate between high intensity exercises. These improved outcomes will increase performance and promote greater training adaptations. More recent research suggests that creatine supplementation in amounts of 0.1 g/kg of body weight combined with resistance training improves training adaptations at a cellular and sub-cellular level. Finally, although presently ingesting creatine as an oral supplement is considered safe and ethical, the perception of safety cannot be guaranteed, especially when administered for long period of time to different populations (athletes, sedentary, patient, active, young or elderly) [12419].

There is an extensive and still growing body of the literature supporting the efficacy of creatine (Cr) supplementation. In sports, creatine has been recognized as the most effective nutritional supplement in enhancing exercise tolerance, muscle strength and lean body mass. From a clinical perspective, the application of Cr supplementation is indeed exciting. Evidences of benefits from this supplement have been reported in a broad range of diseases, including myopathies, neurodegenerative disorders, cancer, rheumatic diseases, and type 2 diabetes. In addition, after hundreds of published studies and millions of exposures creatine supplementation maintains an excellent safety profile. Thus, it is contended that the widespread application of this supplement may benefit athletes, elderly people and various patient populations [12420].

Creatine is a nitrogen-containing substance found naturally in small amounts in animal foods. In recent years, creatine has been synthesized, mainly as creatine monohydrate, and has been marketed to athletes at all levels. Creatine supplements come in various forms (powder, pills, candy, chews, gels, serum, micronized) for both strength and endurance athletes, including products marketed specifically for males, females, and adolescents. Creatine is a very popular sports supplement. Studies of various athletic groups report usage ranging from 17-75 percent. The most cited reasons for taking creatine are enhanced performance and appearance. Indeed, creatine continues to be one of the most popular sports supplements of all time. Oral creatine supplementation, usually as creatine monohydrate, has been reported to increase muscle supplies of free creatine and creatine phosphate (phosphocreatine; PCr), a high-energy phosphagen. A typical creatine loading protocol involves the ingestion of 20 grams of creatine monohydrate over the course of a day, usually in four separate doses of 5 grams each, for 4-6 consecutive days. Once loaded, a daily dose of 2–5 grams helps maintain elevated muscle creatine levels. Consuming carbohydrate with creatine appears to increase muscle creatine stores significantly more than creatine supplementation alone. Some individuals, particularly vegetarians with initially low levels of intramuscular creatine, may respond more effectively to creatine supplementation, while individuals with higher intramuscular creatine and phosphocreatine levels and those with fewer type II muscle fibers may be less responsive to supplementation. It has been suggested that the improvements in performance associated with creatine supplementation are due to parallel improvements in ATP resynthesis during exercise as a consequence of increased PCr availability, particularly within the type II muscle fibers. Creatine is one of the most researched sports supplements, as literally hundreds of studies
have evaluated its effects on various types of sport performance. Most of the research has focused on the ability of creatine supplementation to increase muscle mass and related muscular strength and power applicable to performance in very-high-intensity sports, such as sprinting in track events. Creatine supplementation appears to increase total body and lean body mass; however, short-term gains in total body mass may be primarily water, but long-term gains associated with resistance training appear to be lean muscle mass. Most studies document increases in muscle mass when creatine is supplemented during resistance training. The increase in muscle mass may be associated with a creatine supplementation-induced ability to do more repetitions during training, which may induce favorable genetic adaptations in the muscle. It has been suggested that the increase in lean body mass often reported after creatine supplementation could be mediated by signaling pathways, such as those involving insulin-like growth factor. In a related way, it has been studied the effect of 12 weeks of creatine supplementation and resistance training on muscular strength and myosin heavy chain (MHC) mRNA and protein expression. Compared to both a control and placebo group, the creatine group significantly increased fat-free mass and strength. Additionally, it was found that in general the MHC mRNA and protein expression were significantly higher in the creatine group compared to the other groups, and suggested that the increased strength and muscle size associated with creatine supplementation may be attributed to increase MHC synthesis. Research using muscle biopsy techniques has also shown increases in muscle cell diameter associated with 12 weeks of creatine supplementation and resistance training, which may be associated with the potential for creatine supplementation to amplify the resistance training-induced increase in satellite cell number and myonuclei concentration in skeletal muscle [06239].

Critical reviews of the scientific literature, including a meta-analysis and a monograph generally indicate that creatine supplementation may increase muscular strength and endurance as documented by enhanced performance in 1-repetition maximum strength tests, increased number of repetitions in various isotonic and isokinetic resistance exercise tasks, and increased work output during maximal short term (6-30 seconds) cycle ergometer tasks. In general, activities that involve sprinting, jumping or cycling performance show improved performance following creatine supplementation, but the beneficial effects appear to be less consistent. For example, using a standard creatine loading protocol with well-trained male sprinters as subjects, it was reported significant improvements in 100-meter sprint velocity and time to complete 6 intermittent 60-meter sprints. It was also reported significant increases in peak power and total work production in 10 sets of multiple 6-second bike sprints with varying periods of recovery in an 80-minute time frame following creatine supplementation. Conversely, it was reported no significant improvement in a 70-meter shuttle run sprint power test by well-trained tennis players and no beneficial effects on repeated 10-second skating sprints in ice-hockey players. Some research findings have a direct application to sports competition, such as an increased 1-RM performance in weight lifting and faster 100-meter sprint run times. The laboratory findings for other types of exercise performance are also rather strong, and do support a possible application to actual field competitions. For example, findings of increased muscle power output during intermittent sprint exercises may be applicable to football (soccer) and other sports associated with high-intensity intermittent sprinting. In one such study, it was studied the effects of creatine supplementation on an exercise test protocol designed to simulate match play in soccer (football). The test involved 5 blocks of 11-minute exercise involving sprint running, agility runs, and a precision ball-kicking drill interspersed with recovery walks, jogs and runs. Creatine supplementation improved performance in some repeated sprint and agility tasks even though the subjects increased body mass, but the creatine had no effect on ball kicking accuracy. Thus, creatine supplementation might improve speed in repetitive sprints, important for many sports, but may not necessarily enhance sports skills. In support
of this latter point, several studies reported no significant effects of creatine loading on tennis skill performance as measured by power and precision of their serves [06239].

Creatine is one of the most popular athletic supplements with sales in the US surpassing 400 million dollars in 2004. Due to the popularity and efficacy of creatine supplementation over 200 studies have examined the effects of creatine on athletic performance. Despite the abundance of research suggesting the effectiveness and safety of creatine a fallacy appears to exist in the general public driven by media claims and anecdotal reports that creatine supplementation can result in muscle cramps and dehydration. Although, a number of published studies have refuted these claims, a recent position statement by the American College of Sports Medicine (ACSM) in 2001 advised individuals who are managing their weight and exercising intensely or in hot environments to avoid creatine supplementation. Recent reports now suggest that creatine may enhance performance in hot and or humid conditions by maintaining hematocrit, aiding thermoregulation and reducing exercising heart rate and sweat rate. Creatine may also positively influence plasma volume during the onset of dehydration. Considering these new published findings, little evidence exists that creatine supplementation in the heat presents additional risk and should be taken into consideration as position statements and other related documents are published [08408].

In 1992 a watershed paper was published by Roger Harris and co-workers on the capacity of the muscle to increase its phosphocreatine concentration following supplementation with a creatine product. This led to an explosion of interest in this unique ergogenic aid - a product of apparently genuine value to biochemists, sports scientists, athletes, coaches, clinicians and the supplement industry. Clearly, the story of creatine is a remarkable one. In the space of two decades, the annual production and use of creatine supplements has grown exponentially, and the publication of creatine supplementation trials in the peer-reviewed literature can be measured in the hundreds. Creatine supplements owe their popularity both to the internet age and the evidence base of beneficial uses. As is the case for any supplement, however, it can be expected that the knowledge to continue to evolve, while our caution about individual products will need to be maintained in view of the frailties in the regulation of supplement manufacture and marketing [10406].

Creatine, a derivative from three amino acids, is distributed at approximately 95 percent in skeletal muscle mass; the remainder is located in the brain, the testes and the kidneys. Its synthesis starts mainly in the kidneys from glycine and arginine, forming alpha-methylguanidoacetic acid, which is conducted through the blood to the liver where it reacts with S-adenosylmethionine to synthesise creatine. Approximately 1-2 g of creatine is produced over 24 h and released mainly to the skeletal muscle system. Some creatine is also added to the pool by adequate dietary intake, predominantly from meat and fish, with a typical diet supplying approximately 1-2 g of creatine daily. It may be assumed that there is a total creatine pool of approximately 120 g in a man of 70 kg body weight. In skeletal muscle, creatine is slowly degraded to creatinine (approximately 2 g/day), a reaction without any enzyme intervention, and is released to the blood and the kidney to be expelled through the urine. Creatine is involved in the regulation of cellular energy demand. Under resting conditions, ATP is mainly formed in mitochondria through oxidative phosphorylation with ADP. Transported in sarcoplasm, some ATP molecules react with creatine, via the enzyme phosphorylcreatine kinase, to form phosphorylcreatine and ADP until equilibrium is reached. When ATP is needed for cellular energy, such as for muscle contraction, the phosphorylcreatine kinase reverse reaction replenishes the ATP content. Creatine thus acts indirectly to maintain a phosphorylcreatine reservoir for energy needs, more specifically to supply the muscle system with ATP. In 1992, it was demonstrated that oral creatine supplementation could increase muscle creatine levels approximately 20 percent. Subsequently, many studies have demonstrated that oral creatine supplementation can
maximise muscle creatine levels by either: a loading dose of 20 g/day for approximately 5
days followed by a maintenance dose of 2–3 g/day; or by the maintenance dose of 2–3 g/day
for approximately 30 days. These regimes lead to improved performance of repeated high-
intensity exercise, increased strength and lean body mass and enhanced fatigue resistance
for exercise tasks lasting 30 s or less, particularly when combined with progressive
resistance training. The mechanisms through which creatine supplementation improves
exercise performance and body composition include metabolic enhancements (increased
pre-exercise phosphorylcreatine, increased pre-exercise muscle glycogen), molecular
adaptations (increased gene expression of growth factors) and reduced muscle damage.
However, creatine supplementation does not increase skeletal muscle protein synthesis.
Many sports competitors are using creatine monohydrate as an ergogenic aid to boost their
performance. Being a natural substance, synthesised by mammals, including humans,
creatine has never been included on any doping list [10406].

It is worth commenting that creatine supplements have potentially greater and more
mainstream value than as performance enhancers for athletes. Creatine supplementation
can improve muscle mass and fatigue resistance in sarcopenic older adults in whom a better
function means an enhanced ability to perform activities of daily living. The benefits of
creatine ingestion have been extended to patient populations as well, and there are many
reports of improved muscle function in patients with various muscle (e.g. muscular
dystrophy) and degenerative central nervous system disorders (e.g. Parkinson's and
Huntington's diseases). Promising new data have emerged demonstrating that creatine
supplementation can improve cognitive processing in older adults. Despite published
allegations of detrimental effects of oral creatine supplementation on liver metabolism,
studies on humans have not shown any significant increase in plasma urea, nor liver enzyme
activity, during 5 years of creatine supplementation. No reports have observed a modification
of the glomerular filtration rate, nor the presence of microalbuminuria. All values remained
within the normal range adapted for the age range. Experimentally, an excess conversion of
creatine to sarcosine may result in cytotoxic agents such as methylamine. However, in
humans taking up to 20 g creatine per day for 2 weeks urine methylamine excretion remains
largely under the upper limit for healthy individuals. Even if there are no health risks induced
by oral creatine supplementation, it is safer to remain cautious when this substance is
administered chronically. We advise that creatine supplementation should not be used by
individuals with pre-existing renal disease or those with a potential risk of renal dysfunction
(diabetes, hypertension, reduced glomerular filtration rate). Regular check-ups should be
undertaken to monitor potential dysfunction, which could appear with some individuals less
prone to compensate any homeostatic imbalance. Great care should also be taken as far as
the purity of exogenous creatine supplements is concerned. Analytical tests must prove their
unique nutraceutical composition, as safety is not assured in some preparations [10406].

The purpose of the one study was to examine player-movement patterns to determine total
distance covered during competitive Rugby League match play using global positioning
systems (GPSs) and to examine pre, during, and postmatch creatine kinase (CK) and
endocrine responses to competitive Rugby League match play. Seventeen elite rugby league
players were monitored for a single game. Player movement patterns were recorded using
portable GPS units. Saliva and blood samples were collected 24 hours prematch, 30 minutes
prematch, 30 minutes postmatch, and then at 24-hour intervals for a period of 5 days
postmatch to determine plasma CK and salivary testosterone, cortisol, and
testosterone:cortisol ratio (T:C). The change in the dependent variables at each sample
collection time was compared to 24-hour prematch measures. Backs and forwards traveled
distances $5,747 \pm 1,095$ and $4,774 \pm 1,186$ m, respectively, throughout the match. Cortisol
and CK increased significantly from 30 minutes prematch to 30 minutes postmatch. Creatine
kinase increased significantly postmatch, with peak CK concentration measured 24 hours
Cortisol displayed a clear pattern of response with significant elevations up to 24 hours postmatch, compared with 24 hours prematch. The GPS was able to successfully provide data on player-movement patterns during competitive rugby league match play. The CK and endocrine profile identified acute muscle damage and a catabolic state associated with Rugby League match play. A return to normal T:C within 48 hours postmatch indicates that a minimum period of 48 hours is required for endocrine homeostasis postcompetition. Creatine kinase remained elevated despite 120 hours of recovery postmatch identifying that a prolonged period of at least 5 days modified activity is required to achieve full recovery after muscle damage during competitive Rugby League match play [10407].

The effects of creatine supplementation on muscle metabolism and exercise performance during a simulated endurance road race were investigated. Twelve adult male endurance-trained cyclists completed a simulated road race on a cycle ergometer (Lode), consisting of a two-hour cycling bout at 60 percent of peak aerobic capacity (VO\textsubscript{2peak}) with three 10-second sprints performed at 110 percent VO\textsubscript{2peak} every 15 minutes. Cyclists completed the 2-hr cycling bout before and after dietary creatine monohydrate or placebo supplementation (3 g/day for 28 days). Muscle biopsies were taken at rest and five minutes before the end of the two-hour ride. There was a 25 percent increase in resting muscle total creatine and 38 percent increase in muscle creatine phosphate in the creatine group. Plasma glucose, blood lactate, and respiratory exchange ratio during the 2-hour ride, as well as VO\textsubscript{2peak}, were not affected by creatine supplementation. Submaximal oxygen consumption near the end of the two-hour ride was significantly decreased by approximately 10 percent by creatine supplementation. Changes in plasma volume from pre- to post-supplementation were significantly greater in the creatine group than the placebo group at 90 minutes of exercise. The time of the final sprint to exhaustion at the end of the 2-hour cycling bout was not affected by creatine supplementation. Power output for the final sprint was increased by about 33 percent in both groups (creatine vs placebo not significant). It can be concluded that although creatine supplementation may increase resting muscle total creatine, muscle creatine phosphate, and plasma volume, and may lead to a reduction in oxygen consumption during submaximal exercise, creatine supplementation does not improve sprint performance at the end of endurance cycling exercise [10408].

During high-intensity exercise, intracellular creatine phosphate (PCr) is rapidly broken down to maintain adenosine triphosphate turnover. This has lead to the widespread use of creatine monohydrate as a nutritional ergogenic aid. However, the increase in intracellular PCr and the concomitant increase in intracellular water have not been investigated with regard to their effect on active range of movement (ROM). Forty male subjects (age, 24+/−3.2 years) underwent restricted randomization into 2 equal groups, either an intervention group (CS) or a control group (C). The CS group ingested 25 g/day of creatine monohydrate for 5 days, followed by 5 g/day for a further 3 days. Before (24 h before starting supplementation (PRE) and after (on the 8th day of supplementation (POST)) this loading phase, both groups underwent goniometry measurement of the shoulder, elbow, hip, and ankle. Data indicated significant reductions in active ROM in 3 movements: shoulder extension, shoulder abduction, and ankle dorsiflexion. There was also a significant increase in body mass for the CS group. The results suggest that short-term supplementation with creatine monohydrate reduces the active ROM of shoulder extension and abduction and of ankle dorsiflexion. Although the mechanism for this is not fully understood, it may be related to the asymmetrical distribution of muscle mass around those joints [10409].

The purpose of one study was to examine the effects of 5 days of creatine loading on the electromyographic fatigue threshold (EMG FT) in college-age men. Sixteen men participated in this double-blind study and were randomly placed into either placebo (n=8) or creatine (5 g
dicreatine citrate plus 10 g of flavored fructose powder per packet; n=8) loading groups. Each participant ingested 1 packet 4 times/d, totaling 20 g/d for 5 days (loading). Before and after loading, each participant performed a discontinuous cycle-ergometer test to determine his EMG FT, using bipolar surface electrodes placed on the vastus lateralis of the right thigh. Four 60-s work bouts (ranging from 200 to 400 W) were completed. Adequate rest was given between bouts to allow for the participants' heart rate to drop within 10 beats of their resting HR. The EMG amplitude was averaged over 5-s intervals for each 60-s work bout. Resulting slopes from each successive work resulted in a nonsignificant interaction for supplement and time. In addition, a significant increase in weight was observed in the creatine group. These data suggest that there was a minimal influence of creatin loading on EMG FT for the participants in this study [08409].

It was present a case of acute cholestatic liver injury associated with the combination of whey protein and creatine supplements. The difficulty of diagnosing drug-induced liver injury is emphasized. The patient was a healthy, 27-year-old man who presented with painless jaundice. He had no occupational exposures to solvents, was not taking prescription medications, and did not use recreational drugs or alcohol. He was an enthusiastic weight-lifter and had been taking creatine for 8 to 9 months and whey protein supplements for 4 weeks prior to the development of symptoms [08410].

The purpose of this study was to determine the effect of 30 days of single-dose creatine supplementation with phosphate salts on body weight and anaerobic working capacity in men. Using a double-blind design, 32 men randomly received 1 serving of either 5 g creatin + 4 g phosphate (n=17) or 20 g of dextrose as placebo (n=15) for 30 days. Results showed no significant differences between groups for working capacity at any time point; however, body weight was significantly increased at 10 days in the creatin group (1.0 kg) versus placebo (0.0 kg), and remained elevated for the duration of the study [08411].

The daily oral ingestion of supplementary creatine monohydrate can substantially elevate the creatine content of human skeletal muscle. This chapter aims to summarize the current knowledge regarding the impact muscle creatine loading can have on exercise performance and rehabilitation. The major part of the elevation of muscle creatine content is already obtained after one week of supplementation, and the response can be further enhanced by a concomitant exercise or insulin stimulus. The elevated muscle creatine content moderately improves contractile performance in sports with repeated high-intensity exercise bouts. More chronic ergogenic effects of creatine are to be expected when combined with several weeks of training. A more pronounced muscle hypertrophy and a faster recovery from atrophy have been demonstrated in humans involved in resistance training. The mechanism behind this anabolic effect of creatine may relate to satellite cell proliferation, myogenic transcription factors and insulin-like growth factor-1 signalling. An additional effect of creatine supplementation, mostly when combined with training, is enhanced muscle glycogen accumulation and glucose transporter (GLUT4) expression. Thus, creatine may also be beneficial in sport competition and training characterized by daily glycogen depletion, as well as provide therapeutic value in the insulin-resistant state [08412].

Creatine, a derivative from three amino acids, is distributed at approximately 95 percent in skeletal muscle mass; the remainder is located in the brain, the testes and the kidneys. Its synthesis starts mainly in the kidneys from glycine and arginine, forming alpha-methylguanidoacetic acid, which is conducted through the blood to the liver where it reacts with S-adenosylmethionine to synthesise creatine. Approximately 1-2 g of creatine is produced over 24 h and released mainly to the skeletal muscle system. Some creatine is also added to the pool by adequate dietary intake, predominantly from meat and fish, with a typical diet supplying approximately 1-2 g of creatine daily. It may be assumed that there is a
total creatine pool of approximately 120 g in a man of 70 kg body weight. In skeletal muscle, creatine is slowly degraded to creatinine (approximately 2 g/day), a reaction without any enzyme intervention, and is released to the blood and the kidney to be expelled through the urine. Creatine is involved in the regulation of cellular energy demand. Under resting conditions, ATP is mainly formed in mitochondria through oxidative phosphorylation with ADP. Transported in sarcoplasm, some ATP molecules react with creatine, via the enzyme phosphorylcreatine kinase, to form phosphorylcreatine and ADP until equilibrium is reached. When ATP is needed for cellular energy, such as for muscle contraction, the phosphorylcreatine kinase reverse reaction replenishes the ATP content. Creatine thus acts indirectly to maintain a phosphorylcreatine reservoir for energy needs, more specifically to supply the muscle system with ATP. In 1992, it was first demonstrated that oral creatine supplementation could increase muscle creatine levels approximately 20 percent. Subsequently, many studies have demonstrated that oral creatine supplementation can maximise muscle creatine levels by either a “loading” dose of 20 g/day for approximately 5 days followed by a “maintenance dose” of 2-3 g/day, or by the “maintenance dose” of 2-3 g/day for approximately 30 days. These regimes lead to improved performance of repeated high-intensity exercise, increased strength and lean body mass and enhanced fatigue resistance for exercise tasks lasting 30 s or less, particularly when combined with progressive resistance training. The mechanisms through which creatine supplementation improves exercise performance and body composition include metabolic enhancements (increased pre-exercise phosphorylcreatine, increased pre-exercise muscle glycogen), molecular adaptations (increased gene expression of growth factors) and reduced muscle damage. However, creatine supplementation does not increase skeletal muscle protein synthesis. Many sports competitors are using creatine monohydrate as an ergogenic aid to boost their performance. Being a natural substance, synthesised by mammals, including humans, creatine has never been included on any doping list. Creatine supplementation can improve muscle mass and fatigue resistance in sarcopenic older adults in whom a better function means an enhanced ability to perform activities of daily living. Anecdotal reports from athletes have claimed that creatine supplementation may induce muscle cramps. However, it appears that muscle cramping might be due to the intensity of exercise rather than creatine supplementation itself. Despite published allegations of detrimental effects of oral creatine supplementation on liver metabolism, studies on humans have not shown any significant increase in plasma urea, nor liver enzyme activity, during 5 years of creatine supplementation. Even if there are no health risks induced by oral creatine supplementation, it is safer to remain cautious when this substance is administered chronically. It has been advised that creatine supplementation should not be used by individuals with pre-existing renal disease or those with a potential risk of renal dysfunction (diabetes, hypertension, reduced glomerular filtration rate). Regular check-ups should be undertaken to monitor potential dysfunction, which could appear with some individuals less prone to compensate any homeostatic imbalance. Great care should also be taken as far as the purity of exogenous creatine supplements is concerned. Analytical tests must prove their unique nutraceutical composition, as safety is not assured in some preparations [10240].

It is known from studies in young athletes that creatine supplements have beneficial effects on muscular functional capacity, so it is being widely used as a performance-enhancing substance in both professional and amateur sports men and women. They are approved and considered relatively safe, but there have been a few case reports of renal dysfunction associated with their use. It was presented a case of a patient who developed acute renal failure and lactic acidosis while using creatine and metformin simultaneously [10241].

It currently is unknown whether creatine supplementation is safe for people with or at risk of kidney disease. It was reported on the short-term effects of creatine supplementation on kidney function in a young man with a single kidney and mildly decreased glomerular
filtration rate (GFR). A 20-year-old man who had undergone unilateral nephrectomy and presented with mildly decreased GFR without kidney damage underwent a trial with 35 days of creatine supplementation (20 g/d for 5 days followed by 5 g/d for the next 30 days) and had his kidney function monitored. After the intervention, $^{51}$Cr-EDTA clearance, proteinuria, and electrolyte levels were unchanged. Albuminuria, serum urea level, and estimated creatinine clearance were decreased, whereas serum creatinine level was slightly increased, falsely suggesting kidney function impairment. This prospective report suggests that short-term creatine supplementation may not affect kidney function in an individual with a single kidney, mild decreased GFR, and ingesting a high-protein diet (i.e. 2.8 g/kg/d). This finding has great relevance considering that creatine-induced kidney disease has been a growing concern, even for healthy people [10242].

It is known from studies in young athletes that creatine supplements have beneficial effects on muscular functional capacity, so it is being widely used as a performance-enhancing substance in both professional and amateur sports men and women. They are approved and considered relatively safe, but there have been a few case reports of renal dysfunction associated with their use. It was presented a case of a patient who developed acute renal failure and lactic acidosis while using creatine and metformin simultaneously [10243].

Coingestion of D-pinitol with creatine (CR) has been reported to enhance creatine uptake. The purpose of this study was to evaluate whether adding D-pinitol to CR affects training adaptations, body composition, whole-body creatine retention, and/or blood safety markers when compared to CR ingestion alone after 4 weeks of resistance training. Twenty-four resistance trained males were randomly assigned in a double-blind manner to creatine + pinitol (CRP) or creatine monohydrate (CR) prior to beginning a supervised 4-week resistance training program. Subjects ingested a typical loading phase (i.e. 20 g/d-1 for 5 days) before ingesting 5 g/d-1 the remaining 23 days. Performance measures were assessed at baseline (T0), week 1 (T1), and week 4 (T2) and included 1 repetition maximum (1RM) bench press (BP), 1RM leg press (LP), isokinetic knee extension, and a 30-second Wingate anaerobic capacity test. Fasting blood and body composition using dual-energy x-ray absorptiometry (DEXA) were determined at T1 and T3. Data were analyzed by repeated measures analysis of variance (ANOVA). Creatine retention significantly increased in both groups as a result of supplementation but was not different between groups. Significant improvements in upper- and lower-body strength and body composition occurred in both groups. However, significantly greater increases in lean mass and fat-free mass occurred in the CR group when compared to CRP. Thus, adding D-pinitol to creatine monohydrate does not appear to facilitate further physiological adaptations while resistance training. Creatine monohydrate supplementation helps to improve strength and body composition while resistance training [09348].

The objective of this study was to determine whether creatine supplementation could improve mechanical power output, and swimming performance in highly trained junior competitive fin swimmers. Sixteen male fin swimmers (age: 16 ± 2 years) were randomly and evenly assigned to either a creatine (4x5 g/day creatine monohydrate for 5 days) or placebo group (same dose of a dextrose-ascorbic acid placebo) in a double-blind research. Before and after creatine the average power output was determined by a Bosco-test and the swimming time was measured in two maximal 100 m fin swims. After five days of creatine the average power of one minute continuous rebound jumps increased by 20 percent. The lactate concentration was significantly less after 5 minutes restitution at the second measurement in both groups. The swimming time was significantly reduced in both first and second sessions of swimming in the creatine group, but remained almost unchanged in the placebo group. The results of this study indicate that five day creatine supplementation enhances the dynamic strength and may increase anaerobic metabolism in the lower
extremity muscles, and improves performance in consecutive maximal swims in highly trained adolescent fin swimmers [09323].

The purpose of the present study was to examine player-movement patterns to determine total distance covered during competitive Rugby League match play using global positioning systems (GPSs) and (b) examine pre, during, and postmatch creatine kinase (CK) and endocrine responses to competitive Rugby League match play. Seventeen elite rugby league players were monitored for a single game. Player movement patterns were recorded using portable GPS units (SPI-Pro, GPSports, Canberra, Australia). Saliva and blood samples were collected 24 hours prematch, 30 minutes prematch, 30 minutes postmatch, and then at 24-hour intervals for a period of 5 days postmatch to determine plasma CK and salivary testosterone, cortisol, and testosterone:cortisol ratio (T:C). The change in the dependent variables at each sample collection time was compared to 24-hour prematch measures. Backs and forwards traveled distances 5,747 ± 1,095 and 4,774 ± 1,186 m, respectively, throughout the match. Cortisol and CK increased significantly from 30 minutes prematch to 30 minutes postmatch. Creatine kinase increased significantly postmatch, with peak CK concentration measured 24 hours postmatch (889 ± 238 UL). Cortisol displayed a clear pattern of response with significant elevations up to 24 hours postmatch, compared with 24 hours prematch. The GPS was able to successfully provide data on player-movement patterns during competitive rugby league match play. The CK and endocrine profile identified acute muscle damage and a catabolic state associated with Rugby League match play. A return to normal T:C within 48 hours postmatch indicates that a minimum period of 48 hours is required for endocrine homeostasis postcompetition. Creatine kinase remained elevated despite 120 hours of recovery postmatch identifying that a prolonged period of at least 5 days modified activity is required to achieve full recovery after muscle damage during competitive Rugby League match play [10495].

The classical role of creatine-phosphate (PCr) is seen as a reservoir of high-energy phosphates defending cellular ATP levels under anaerobic conditions, high rates of energy transfer or rapid fluctuations in energy requirement. Although the high concentration of PCr in glycolytic fast-twitch fibers supports the role of PCr as a buffer of ATP, the primary importance of the creatine kinase (CK) reaction may in fact be to counteract large increases in ADP, which could otherwise inhibit cellular ATPase-mediated systems. A primary role for CK in the maintenance of ADP homeostasis may explain why, in many conditions, there is an inverse relationship between PCr and muscle contractility but not between ATP and muscle contractility. The high rate of ATP hydrolysis during muscle contraction combined with restricted diffusion of ADP supports that ADP concentration increases transiently during the contraction phase (ADP spikes) and that these are synchronized with the contraction. The presence of CK, structurally bound in close vicinity to the sites of ATP utilization, will reduce the amplitude and duration of the ADP spikes through PCr-mediated phosphotransfer. When PCr is reduced, the efficiency of CK as an ATP buffer will be reduced and the changes in ADP will become more prominent. The presence of ADP spikes is supported by the finding that other processes known to be activated by ADP (i.e. AMP deamination and glycolysis) are stimulated during exercise but not during anoxia, despite the same low global energy state. Breakdown of PCr is driven by increases in ADP above that depicted by the CK equilibrium and the current method to calculate ADPfree from the CK reaction in a contracting muscle is therefore questionable [11267].

Supplemental creatine has been promoted for its positive health effects and is best known for its use by athletes to increase muscle mass. In addition to its role in physical performance, creatine supplementation has protective effects on the brain in models of neuronal damage and also alters mood state and cognitive performance. Creatine is found in high protein foods, such as fish or meat, and is also produced endogenously from the biosynthesis of
arginine, glycine, and methionine. Changes in brain creatine levels, as measured using magnetic resonance spectroscopy, are seen in individuals exposed to drugs of abuse and depressed individuals. These changes in brain creatine indicate that energy metabolism differs in these populations relative to healthy individuals. Recent work shows that creatine supplementation has the ability to function in a manner similar to antidepressant drugs and can offset negative consequences of stress. These observations are important in relation to addictive behaviors as addiction is influenced by psychological factors such as psychosocial stress and depression. The significance of altered brain levels of creatine in drug-exposed individuals and the role of creatine supplementation in models of drug abuse have yet to be explored and represent gaps in the current understanding of brain energetics and addiction [11588].

Creatine (N-(aminoiminomethyl)-N-methyl glycine) is an ingredient commonly found in food, mainly in fish and meat, and is sold as a dietary supplement in markets around the world. Creatine crystallizes from water as monoclinic prisms holding one molecule of water of crystallization per molecule of creatine. Continued drying of CM results in a loss of the water of crystallization at around 100°C, yielding anhydrous creatine. Creatine is a weak base with a pkb value of 11.02 at 25°C. As a result, creatine can only form salts with strong acids, having a pka value of less than 3.98. Creatine forms salts by the protonation of its guanidine moiety. In addition to salt formation, creatine is able to act as a complexing agent. Creatinine use as an ergogenic aid and possible treatment for certain neuromuscular disorders is well documented in scientific literature. Numerous studies have found that CM supplementation increases muscle phosphagen levels generally by 10 to 40 percent. Acute and chronic supplementation of CM has been reported to improve performance primarily during high intensity, intermittent activities. The impact on performance has been associated with the magnitude of change in baseline phosphagen levels. Numerous studies have shown that CM supplementation during training promotes greater gains in performance and/or fat-free mass. The only clinically significant side effect reported in literature has been weight gain, which is an attribute desired by many athletes who desire to increase muscle mass as well as clinical populations concerned about muscle wasting. Consequently, CM has proven to be one of the most effective, safe, and well-studied ergogenic aids. In recent years, the popularity of creatine has risen dramatically, especially among athletes. In the USA alone, creatine-containing dietary supplements make up a large portion of the estimated USD 2.7 billion in annual sales of sports nutrition supplements. The form of creatine that has been most extensively studied and commonly used in dietary supplements is creatine monohydrate (CM). Studies have consistently indicated that CM supplementation increases muscle creatine and phosphocreatine concentrations by approximately 15 to 40 percent, enhances anaerobic exercise capacity, and increases training volume leading to greater gains in strength, power, and muscle mass. A number of potential therapeutic benefits have also been suggested in various clinical populations. Studies have indicated that CM is not degraded during normal digestion and that nearly 99 percent of orally ingested CM is either taken up by muscle or excreted in urine. Further, no medically significant side effects have been reported in literature. Nevertheless, supplement manufacturers have continually introduced newer forms of creatine into the marketplace. These newer forms have been purported to have better physical and chemical properties, bioavailability, efficacy, and/or safety profiles than CM. However, there is little to no evidence that any of the newer forms of creatine are more effective and/or safer than CM whether ingested alone and/or in combination with other nutrients. In addition, whereas the safety, efficacy, and regulatory status of CM is clearly defined in almost all global markets; the safety, efficacy, and regulatory status of other forms of creatine present in today's marketplace as a dietary or food supplement is less clear. Accompanying the explosive growth in sales has been the introduction of different forms of creatine. Creatine monohydrate (CM), first marketed in the early 1990s, is the form most commonly found in dietary supplement/food products and most
frequently cited in scientific literature. The introduction into the marketplace of alternate forms of creatine, beginning in the late 1990s, was presumably an attempt to differentiate the multitude of creatine-containing products available to consumers and improve certain attributes such as solubility and efficacy. However, the legal and regulatory status of these various forms of creatine in the USA and other markets around the world is at best uncertain. To date, with the exception of Japan, CM is the only form of creatine to be officially approved or accepted in key markets such as the USA, European Union (EU), Canada and South Korea. The continued presence of other forms of creatine in the marketplace, especially in the US, may be due to a multitude of factors. These include, but may not be limited to, a lack of awareness or understanding on the part of marketers of applicable laws and regulations, intentional noncompliance with the law, and/or inadequate enforcement of the law. The public health implications of widespread distribution and use of these unauthorized forms of creatine is unknown and warrants careful monitoring. New forms of creatine are marketed with claims of improved physical, chemical, and physiological properties in comparison to CM. Claims include improved stability when combined with other ingredients or in liquids, improved solubility in water, improved bioavailability, and even an increase in performance. Creatine salts such as citrate, maleate, fumarate, tartrate, pyruvate, ascorbate, and orotate were first introduced to the marketplace as early as the late 1990s. Creatine and acids with multiple acid moieties such as citric acid can form salts as well as complexation products. In addition to creatine and its salts, derivatives of creatine such as creatine ester or even creatine alcohols are currently marketed as dietary supplements. Both ingredients do not contain creatine as such, since they have been chemically altered. While it is assumed that the human body will transfer those molecules into creatine upon intake, there are no published data available to base firm conclusions. The amount of creatine in different forms of creatine varies. Creatine monohydrate contains 88 percent of creatine, whereas the creatine content in other forms of creatine is lower with the exception of creatine anhydrous. Commercial creatine salts are formed in solution or by mechanical processes such as milling or grinding under the presence of residual water. Complexes are formed by the subsequent replacement of the solvating molecules by the new ligands. Creatine monohydrate powder is very stable showing no signs of degradation over years, even at elevated temperatures. To detect a potential degradation of creatine, one must measure the content of its degradation product, creatinine. The degradation of creatine can be reduced or even halted by either lowering the pH under 2.5 or increasing the pH. A very high pH results in the deprotonation of the amide function of the creatine molecule, thereby preventing the intramolecular cyclization. A very low pH results in the protonation of the amide function of the creatine molecule, thereby preventing the intramolecular [11268].

The uptake of creatine is simplified in a two-step approach: first, uptake into the bloodstream; second, uptake into the target tissue. The term “bioavailability” refers to both the intestinal absorption and the use of a substance by the body’s cells and tissues. First indications of a potential change of creatine bioavailability can be gathered from the amount of creatine taken up into the blood plasma after oral administration. However, a change in the total amount of creatine in the blood plasma cannot be directly extrapolated to a potential increase in desired performance. An increased amount of creatine in the plasma could be the result of decreased uptake into the target tissue resulting in an actual decrease in overall bioavailability. On the other hand, an initial rise in plasma creatine levels, followed by a reduction in plasma levels, is an indication of increased uptake into the target tissue. This has been demonstrated in vivo by combining creatine with insulin-stimulating ingredients such as high amounts of glucose or protein. Conclusive proof of an increase in relevant bioavailability can only be gained by assessing the amount of creatine reaching the target tissue, the muscle, measured by muscle biopsy and/or whole body creatine retention assessed by measuring the difference between creatine intake and urinary excretion. Dietary creatine is presumed to have high bioavailability since intestinal absorption of CM is already
close to 100 percent. However, the response to creatine supplementation is heterogeneous, due in part to some non-responders, which might be overcome by alternative forms of creatine. Over the years, there has been significant commercial interest in determining whether creatine could be delivered in a liquid form. The thought has been since CM is relatively insoluble that development of a liquid or suspended form of creatine may be more convenient to consume, be more readily absorbed into the blood stream, and promote a greater efficiency in transport of creatine to the muscle. Some companies have even claimed that minimal amounts of liquid creatine would need to be ingested because of enhanced efficiency in transport through the blood and into the muscle. A limitation with these theories is that CM is not stable for any substantial length of time in liquid. Consequently, while researchers have been working on ways to suspend creatine within gels and fluids, it has been generally considered to be impractical to develop into a product due to limitations in shelf-life. In addition, while people may prefer the taste of liquid or gel versions of creatine, there is no evidence that these delivery forms provide a superior performance benefit. In analysis of this literature, it is clear that CM supplementation promotes significant increases in muscle creatine levels in most individuals. There is some evidence that co-ingestion of CM with various nutrients (e.g. carbohydrate, protein, d-pinitol) may enhance creatine uptake to a greater degree. However, there is no evidence that effervescent creatine, liquid creatine, and/or CEE promotes greater uptake of creatine to the muscle. Rather, there is some evidence that some of these forms of creatine may be less effective and/or be of greater clinical concern in terms of safety [11268].

Explanations as to why these alternate creatine forms are prevalent in the marketplace despite not having met the legal and regulatory requirements in the various markets are likely two-fold. Legal definitions of and regulatory requirements for “dietary supplements” (USA and Korea), “food supplements” (EU), “natural health products” (Canada), and “non-drug food additives” (Japan) are complex, differ between countries/regions, and can be confusing. Lack of awareness and/or understanding of the given country’s applicable requirements may be one explanation for the lack of compliance on the part of some marketers. To the extent that the laws and regulations are known and understood, inadequate enforcement by regulators can create an environment where noncompliance is perceived to be without consequences, resulting in the forgoing of required registration or notification requirements. In the USA, the increased prevalence of these alternate forms (CEE in particular) in dietary supplement products, with no enforcement action from FDA, has helped to support this misperception. The public health implications of having unsanctioned or unapproved forms of creatine on the market remain to be fully realized. While classical animal toxicity and short- and long-term clinical safety studies have been conducted in humans, the basic safety data on new forms of creatine is lacking. At present, there do not appear to be any imminent or specific safety concerns associated with any of these alternate forms. However, this must be monitored carefully through post-market surveillance and published case reports. As far as the marketplace is concerned, the presence of these newer and typically more expensive forms of creatine in a multitude of consumer products that are often marketed with misleading and/or unsubstantiated claims of greater bioavailability, efficacy, and safety sets a negative precedent. The reality that companies need not fulfill the necessary registration or notification requirements to satisfy regulatory authorities, but still feel free to market their ingredients and products without penalty establishes an “unlevel” playing field among competitors. This undermines any incentive to invest upfront resources to establish ingredients as safe and efficacious prior to reaching consumers. Inevitably, this will result in unintended and unforeseen consequences, which will serve to erode consumer confidence [11268].

It aimed to investigate the possible role of creatine (CR) supplementation in counteracting dexamethasone-induced muscle wasting and insulin resistance in rats. Also, it was examined whether CR intake would modulate molecular pathways involved in muscle remodeling and
insulin signaling. Animals were randomly divided into four groups: (1) dexamethasone (DEX); (2) control pair-fed (CON-PF); (3) dexamethasone plus CR (DEX-CR); and (4) CR pair-fed (CR-PF). Dexamethasone (5 mg/kg/day) and CR (5 g/kg/day) were given via drinking water for 7 days. Plantaris and extensor digitorum longus (EDL) muscles were removed for analysis. Plantaris and EDL muscle mass were significantly reduced in the DEX-CR and DEX groups when compared with the CON-PF and CR-PF groups. Dexamethasone significantly decreased phospho-Ser(473)-Akt protein levels compared to the CON-PF group and CR supplementation aggravated this response. Serum glucose was significantly increased in the DEX group when compared with the CON-PF group. CR supplementation significantly exacerbated hyperglycemia in the dexamethasone-treated animals. Dexamethasone reduced GLUT-4 translocation when compared with the CON-PF and CR-PF groups and this response was aggravated by CR supplementation. In conclusion, supplementation with CR resulted in increased insulin resistance and did not attenuate muscle wasting in rats treated with dexamethasone. Given the contrast with the results of human studies that have shown benefits of CR supplementation on muscle atrophy and insulin sensitivity, it was suggested caution when extrapolating this animal data to human subjects [11269].

Nutritional supplements are very popular especially among athletes although some studies show either controversial or even negative results. However, whey protein and creatine seem to have positive effects on muscle size, strength and athletic performance without major adverse effects and high costs. Most studies have shown that supplementation of whey protein can enhance muscle growth in response to resistance training. Some studies also suggest that whey may enhance recovery from heavy exercise and possibly decrease muscle damage and soreness. Creatine supplementation increases the intracellular pool of phosphocreatine in skeletal muscle. Phosphocreatine provides a reserve of energy to rapidly regenerate ATP, which is consumed as a result of muscle contraction. Creatine has been studied in hundreds of clinical trials and has shown benefits including increased muscle strength, power and size [11270].

It was described a case in which serum creatinine is elevated due to the use of creatine ethyl ester. One week after withdrawal, the plasma creatinine had normalised. There are two types of creatine products available: creatine ethyl ester (CEE) and creatine monohydrate (CM). Plasma creatinine is not elevated in all creatine-using subjects. CEE, but not CM, is converted into creatinine in the gastrointestinal tract. As a result the use of CEE may be associated with elevated plasma creatinine levels. Since plasma creatinine is a widely used marker for renal function, the use of CEE may lead to a false assumption of renal failure [11271].

Creatine monohydrate (Cr), the most diffuse supplement in the sports industry, is receiving greater attention because of its beneficial effects in a wide number of human degenerative diseases and conditions. These effects can be barely explained on the basis of the sole ergogenic role of the Cr/CrP system. Indeed, a wide number of research articles indicate that Cr is capable of exerting multiple, non-energy related, effects on diverse and relevant cellular targets. Among these effects, the antioxidant activity of Cr emerges as an additional mechanism which is likely to play a supportive role in the Cr-cytoprotection paradigm [11272].

Doubtful allegations of adverse effects of creatine supplementation have been released through the press media and through scientific publications. In one review it was tried to separate the wheat from the chaff by looking for the experimental evidence of any such claims. Anecdotal reports from athletes have appeared on muscle cramp and gastrointestinal complaints during creatine supplementation, but the incidence of these is limited and not
necessarily linked to creatine itself. Despite several unproved allegations, liver (enzymes, urea) and kidneys (glomerular filtration urea and albumin excretion rates) show no change in functionality in healthy subjects supplemented with creatine, even during several months, in both young and older populations. The potential effects (production of heterocyclic amines) of mutagenicity and carcinogenicity induced by creatine supplementation have been claimed by a French Sanitary Agency (AFSSA), which might put consumers at risk. Even if there is a slight increase (within the normal range) of urinary methylamine and formaldehyde excretion after a heavy load of creatine (20 g/day) this is without effect on kidney function. The search for the excretion of heterocyclic amines remains a future task to definitively exclude the unproved allegation made by some national agencies. It was advised that high-dose (>3-5 g/day) creatine supplementation should not be used by individuals with pre-existing renal disease or those with a potential risk for renal dysfunction (diabetes, hypertension, reduced glomerular filtration rate). A pre-supplementation investigation of kidney function might be considered for reasons of safety, but in normal healthy subjects appears unnecessary [11273].

The daily oral ingestion of supplementary creatine monohydrate can substantially elevate the creatine content of human skeletal muscle. One chapter aimed to summarize the current knowledge regarding the impact muscle creatine loading can have on exercise performance and rehabilitation. The major part of the elevation of muscle creatine content is already obtained after one week of supplementation, and the response can be further enhanced by a concomitant exercise or insulin stimulus. The elevated muscle creatine content moderately improves contractile performance in sports with repeated high-intensity exercise bouts. More chronic ergogenic effects of creatine are to be expected when combined with several weeks of training. A more pronounced muscle hypertrophy and a faster recovery from atrophy have been demonstrated in humans involved in resistance training. The mechanism behind this anabolic effect of creatine may relate to satellite cell proliferation, myogenic transcription factors and insulin-like growth factor-1 signalling. An additional effect of creatine supplementation, mostly when combined with training, is enhanced muscle glycogen accumulation and glucose transporter (GLUT4) expression. Thus, creatine may also be beneficial in sport competition and training characterized by daily glycogen depletion, as well as provide therapeutic value in the insulin-resistant state [07346].

Studies attributing gains in strength and lean body mass (LBM) to creatine monohydrate (CrM) during resistance exercise (RE) training have not assessed these changes alongside cellular and subcellular adaptations. Additionally, CrM-treated groups have seldom been compared with a group receiving a placebo similar in nitrogen and energy. The purpose of one study was to examine the effects of a CrM-containing protein-carbohydrate (PRO-CHO) supplement in comparison with a supplement containing a similar amount of nitrogen and energy on body composition, muscle strength, fiber-specific hypertrophy, and contractile protein accrual during RE training. In a double-blind, randomized protocol, resistance-trained males were matched for strength and placed into one of three groups: protein (PRO), PRO-CHO, or the same PRO-CHO supplement (1.5 g/kg body weight and day) containing CrM (Cr-PRO-CHO) (0.1 g/kg body weight and day). Assessments were completed the week before and after a 10-wk structured, supervised RE program: strength (1RM, three exercises), body composition (DEXA), and vastus lateralis muscle biopsies for determination of muscle fiber type (I, IIA, IIX), cross-sectional area (CSA), contractile protein, and creatine content. Cr-PRO-CHO provided greater improvements in 1RM strength. At least 40% of the strength improvements could be attributed to hypertrophy of muscle involved in this exercise. Cr-PRO-CHO also resulted in greater increases in LBM, fiber CSA, and contractile protein compared with PRO and PRO-CHO. In RE-trained participants, supplementation with Cr-PRO-CHO provided greater muscle hypertrophy than an equivalent dose of PRO-CHO, and
this response was apparent at three levels of physiology (LBM, fiber CSA, and contractile protein content) [07347].

The effects of short-term oral creatine (Cr) supplementation on exercise performance and on blood pressure and renal function were assessed. Thirty-five healthy, active duty, U.S. Army volunteers (20 men and 15 women; age, 22-36 years) at Fort Sam Houston, Texas, supplemented their diet for 7 days with 20 g/day of either Cr or taurine (as placebo). There was no significant difference in 2-minute push-up counts between the Cr and taurine groups from before to after supplementation. The Cr group demonstrated a significant increase in serum creatinine levels, compared with the taurine group, and this increase could be misinterpreted as impairment of renal function. No adverse changes in blood pressure, body composition, weight, or serum Cr phosphokinase levels were observed. We conclude that short-term creatine supplementation appears to be safe but does not enhance push-up performance [07348].

Creatine supplementation (CS) has been reported to increase body weight and improve performance during high intensity, short duration, exercise tasks. However, none of the published studies has investigated the influence of CS on performance related hydrodynamic variables during swimming. To investigate the effect of oral CS on swimming velocity, body composition and hydrodynamic variables during the period of final preparation of competitive junior female swimmers. In a double blind and randomized manner, 16 female swimmers, were supplemented with 20 g/day of creatine monohydrate (CS group), or a maltodextrin placebo (PL group) for 21 days. Just pre- and post-21 days of supplementation, subjects performed 2x25 swimming bouts at maximum velocity with a 3 min recovery between bouts. The variables measured were 25 m swimming velocity (MSV(25)); active drag force (D(f)); hydrodynamic coefficient (C(x)); power output (P(o)). Body measures were also analysed: body weight (kg), fat-mass (% FAT), body water (% H_2O), and fat free mass (FFM). Significant differences were observed in hydrodynamic values: the CS group showed a significant reduction (approximately 25 %), in D(f), C(x) and P(o) values, when comparing pretest with post-test. No differences were found in variables related to body composition and performance between CS group and PL group, as well as for CS group during the experimental period. These data suggest that 21 days of CS produced significant effects on gross and/or propelling efficiency during swimming in female athletes. However, CS did not influence performance, body weight and body composition [07349].

Rugby union football requires muscular strength and endurance, as well as aerobic endurance. Creatine supplementation may enhance muscular performance, but it is unclear if it would interfere with aerobic endurance during running because of increased body mass. The purpose of one study was to determine if creatine supplementation during 8 weeks of a season of rugby union football can increase muscular performance, without negatively affecting aerobic endurance. Rugby union football players were randomized to receive 0.1 g.kg(-1).d(-1) creatine monohydrate (n=9) or placebo (n=9) during 8 weeks of the rugby season. Players practiced twice per week for approximately 2 h per session and played one 80 min game per week. Before and after the 8 weeks, players were measured for body composition (air displacement plethysmography), muscular endurance (number of repetitions at 75% of one repetition maximum (1 RM) for bench press and leg press), and aerobic endurance (Leger shuttle-run test with 1 min stages of progressively increasing speed). There were time main effects for body mass, fat mass, and a trend for an increase in lean tissue mass, with no differences between groups. The group receiving creatine supplementation had a greater increase in the number of repetitions for combined bench press and leg press tests compared with the placebo group. There were no changes in either group for aerobic endurance. Creatine supplementation during a rugby union football season is effective for increasing muscular endurance, but has no effect on body composition or
aerobic endurance [07350].

It was examined the effects of creatine supplementation on the response to repeated bouts of resistance exercise. Young men (24 ± 5 years) were divided into creatine monohydrate (CM, n=9) and placebo (PL, n=9) groups. On day (D) 1 and D15, subjects performed four sets of bicep curls at 75 percent 1-RM to concentric failure. On D8-D13, subjects consumed either 20 g/d creatine monohydrate or placebo. Muscle soreness and elbow joint range of motion (ROM) were assessed on D1-D5 and D15-D19. Serum creatine kinase activity (CK) was assessed on D1, D3, D5, D15, D17, and D19. The first exercise bout produced increases in muscle soreness and CK, and decreases in ROM in both groups. The second bout produced lesser rises in serum CK, muscle soreness, and a lesser decrease in ROM with greater attenuation of these damage markers in CM than PL. CK levels on D17 were lower muscle soreness from D15-19 was lower, and elbow ROM was decreased in PL, but not CM on D16. It was concluded that creatine supplementation provides an additive effect on blunting the rise of muscle damage markers following a repeated bout of resistance exercise. The mechanism by which creatine augments the repeated bout effect is unknown but is likely due to a combination of creatine's multifaceted functions [13681].

Creatine is an ergogenic supplement that has been used by athletes with the goal of increasing strength gains in the weight room. In the 1990s, creatine became a popular supplement used by athletes to augment resistance training. The popularity of creatine grew as studies began to show some benefits with strength training, particularly with short, high-intensity exercises. A survey of first division athletes in 1999 found that 48 percent of male athletes reported current or prior use of creatine. Creatine also was found to be the most popular supplement used by a cohort of high school athletes in a survey completed in Iowa in 2001. It was found that usage increased in high school by grade, and in the 11th and 12th grade, the usage was about 12 percent. The recent surveys have shown a decrease in popularity of creatine with whey protein being the most popular. Creatine has been one of the more extensively studied dietary supplements. There have been upward of 300 studies evaluating the effects of creatine on resistance training, with 70% reporting increases in strength. Several forms of creatine exist; however creatine monohydrate has been the most extensively studied, and its formulation has shown benefits in short-duration, high-intensity weightlifting and cycling [13682].

Creatine monohydrate is a dietary supplement that increases muscle performance in short-duration, high-intensity resistance exercises, which rely on the phosphocreatine shuttle for adenosine triphosphate. Many situations within athletics and during training for sport require fast and intense muscle contractions. Intense sport activities less than 10 s in duration are dependent on intramuscular stores of adenosine triphosphate (ATP) and phosphocreatine. Several studies have shown increases in intramuscular stores of creatine and phosphocreatine with creatine monohydrate supplementation, and the increases range from 10 to 40 percent. However there is an upper limit of creatine stores that are possible in human muscle, which has been reported as high as 160 g in the human body. Therefore athletes with full stores of creatine in their muscles will not receive benefit from supplementation. People with lower creatine stores in their muscles receive the greatest effect on intramuscular creatine stores when supplemented with oral creatine. Therefore the theory behind creatine supplementation is to increase stores in the muscle to facilitate ATP and phosphocreatine production, delaying the onset of muscle fatigue. The effective dosing for creatine supplementation includes loading with 0.3 g/kg/d for 5 to 7 days, followed by maintenance dosing at 0.03 g/kg/d most commonly for 4 to 6 weeks. However loading doses are not necessary to increase the intramuscular stores of creatine. Creatine monohydrate is the most studied; other forms such as creatine ethyl ester have not shown added benefits. Creatine is a relatively safe supplement with few adverse effects reported. The most
common adverse effect is transient water retention in the early stages of supplementation. When combined with other supplements or taken at higher than recommended doses for several months, there have been cases of liver and renal complications with creatine. Further studies are needed to evaluate the remote and potential future adverse effects from prolonged creatine supplementation [13682].

**Biochemistry**

Creatine is a nitrogenous amine that was discovered in 1832. It is found primarily in skeletal muscle, with 95 percent of the body's creatine stores found within skeletal muscle. The total amount of creatine in the body is equal to the free creatine plus the phosphocreatine, which equals approximately 120 g in a 70-kg person. The exogenous sources of creatine are animal products such as red meat and fish. The normal dietary intake of creatine in an omnivorous diet is around 1 g per day. The liver, kidney, and pancreas form endogenous stores of creatine. The endogenous production of creatine is down-regulated during exogenous creatine supplementation; however, the endogenous production returns to baseline after supplementation is discontinued. The first step in endogenous synthesis of creatine occurs in the kidney and starts with the amino acids glycine and arginine. The product is then transferred to the liver where a methyl group from methionine is added forming creatine. Circulating creatine is brought into skeletal muscle via transporters in the cell membrane. The rate of creatine uptake has been shown to be influenced by exercise, catecholamines, and insulin-like growth factor. Once within the cell, creatine can be phosphorylated to form phosphocreatine in a reversible enzymatic reaction facilitated by creatine kinase. The phosphate group comes from ATP forming adenosine diphosphate (ADP). The reverse reaction occurs when ATP is being used by the cell, and phosphocreatine can shuttle a phosphate group to ADP [13682].

During short-duration, high-intensity exercises, ATP needs are met by both anaerobic glycolysis and phosphocreatine shuttle. Anaerobic glycolysis is the dominant form of ATP production between 10 and 30 s when at maximal effort, while the phosphocreatine shuttle predominates as an ATP source during maximal effort exercises less than 10 s. By increasing stores of phosphocreatine with creatine supplementation, the belief is one can decrease muscle fatigue and increase performance by prolonging the phosphocreatine shuttle. In addition to increasing phosphocreatine stores, there are other proposed mechanisms by which creatine supplementation can improve performance during these exercises. One proposed mechanism is faster resynthesis of phosphocreatine during rest and recovery between bouts of maximal exercises; more creatine in the muscles would equate to more potential phosphocreatine. Conflicting data exist regarding creatine supplementation improving phosphocreatine resynthesis. Other mechanisms include aiding ATP production via glycolysis by increasing phosphofructokinase activity or by buffering hydrogen ions [13682].

**Creatine ethyl ester**

Creatine ethyl ester has received recent attention. In order to increase the intramuscular creatine levels, one of the latest creatine variations is creatine ethyl ester. Creatine ethyl ester is alleged to increase creatine bioavailability. Esterification of creatine decreases its hydrophilicity, and manufacturers of creatine ethyl ester claim that this allows it to bypass the creatine transporter due to enhanced sarcolemmal permeability toward creatine. Studies have shown that creatine ethyl ester is a substrate for creatine kinase. Yet recent studies show that creatine ethyl ester is converted to creatinine, not creatine. Increases in plasma creatinine were found with creatine ethyl ester. In addition, nonenzymatic cleavage of creatine ethyl ester was reported, leading them to report that creatine ethyl ester is a pronutrient for creatinine rather than creatine under all physiological conditions encountered.
during transit through the various tissues; thus no ergogenic effect is to be expected from supplementation. Other forms of creatine, such as a buffered form of creatine, to increase hydrophilic nature of the molecule is a more efficacious and/or safer form of creatine to consume than creatine monohydrate. Creatine ethyl ester has received recent attention. In order to increase the intramuscular creatine levels, one of the latest creatine variations is creatine ethyl ester. Creatine ethyl ester is alleged to increase creatine bioavailability. Esterification of creatine decreases its hydrophilicity, and manufacturers of creatine ethyl ester claim that this allows it to bypass the creatine transporter due to enhanced sarcolemmal permeability toward creatine. Studies have shown that creatine ethyl ester is a substrate for creatine kinase. Yet recent studies show that creatine ethyl ester is converted to creatinine, not creatine. Increases in plasma creatinine were found with creatine ethyl ester. In addition, nonenzymatic cleavage of creatine ethyl ester was reported, leading them to report that creatine ethyl ester is a pronutrient for creatinine rather than creatine under all physiological conditions encountered during transit through the various tissues; thus no ergogenic effect is to be expected from supplementation. Other forms of creatine, such as a buffered form of creatine, to increase hydrophilic nature of the molecule is a more efficacious and/or safer form of creatine to consume than creatine monohydrate [13682].

**Physiological aspects**

Creatine is produced endogenously at an amount of about 1 g/d. Synthesis predominately occurs in the liver, kidneys, and to a lesser extent in the pancreas. The remainder of the creatine available to the body is obtained through the diet at about 1 g/d for an omnivorous diet. Ninety-five percent of the bodies’ creatine stores are found in the skeletal muscle and the remaining 5 percent is distributed in the brain, liver, kidney, and testes. As creatine is predominately present in the diet from meats, vegetarians have lower resting creatine concentrations. The majority of creatine in the human body is in two forms, either the phosphorylated form making up 60 percent of the stores or in the free form which makes up 40 percent of the stores. The average 70 kg young male has a creatine pool of around 120-140 g which varies between individuals depending on the skeletal muscle fiber type and quantity of muscle mass. The endogenous production and dietary intake matches the rate of creatinine production from the degradation of phosphocreatine and creatine at 2.6 percent and 1.1 percent/day respectively. In general, oral creatine supplementation leads to an increase of creatine levels within the body. Creatine can be cleared from the blood by saturation into various organs and cells or by renal filtration. Three amino acids (glycine, arginine and methionine) and three enzymes (L-arginine:glycine amidinotransferase, guanidinoacetate methyltransferase and methionine adenosyltransferase) are required for creatine synthesis. The impact creatine synthesis has on glycine metabolism in adults is low, however the demand is more appreciable on the metabolism of arginine and methionine. Creatine ingested through supplementation is transported into the cells exclusively by CreaT1. However, there is another creatine transporter Crea T2, which is primarily active and present in the testes. Creatine uptake is regulated by various mechanisms, namely phosphorylation and glycosylation as well as extracellular and intracellular levels of creatine. Crea T1 has shown to be highly sensitive to the extracellular and intracellular levels being specifically activated when total creatine content inside the cell decreases. It has also been observed that in addition to cytosolic creatine, the existence of a mitochondrial isoform of Crea T1 allows creatine to be transported into the mitochondria. Indicating another intramitochondrial pool of creatine, which seems to play an essential role in the phosphate-transport system from the mitochondria to the cytosol. Myopathy patients have demonstrated reduced levels of total creatine and phosphocreatine as well as lower levels of CreaT1 protein, which is thought to be a major contributor to these decreased levels [12419].

**Effects of creatine supplementation on physical performance**
Chronic supplementation with creatine monohydrate has been shown to promote increases in total intramuscular creatine, phosphocreatine, skeletal muscle mass, lean body mass and muscle fiber size. Furthermore, there is robust evidence that muscular strength and power will also increase after supplementing with creatine. However, it is not known if the timing of creatine supplementation will affect the adaptive response to exercise. Thus, the purpose of one investigation was to determine the difference between pre versus post exercise supplementation of creatine on measures of body composition and strength. Nineteen healthy recreational male bodybuilders (mean; age 23; height 166 cm; weight: 80 kg) participated in this study. Subjects were randomly assigned to one of the following groups: PRE-SUPP or POST-SUPP workout supplementation of creatine (5 grams). The PRE-SUPP group consumed 5 grams of creatine immediately before exercise. On the other hand, the POST-SUPP group consumed 5 grams immediately after exercise. Subjects trained on average five days per week for four weeks. Subjects consumed the supplement on the two non-training days at their convenience. Body composition (Bod Pod(R)) and 1-RM bench press (BP) were determined. Diet logs were collected and analyzed (one random day per week; four total days analyzed). There was a significant time effect for fat-free mass (FFM) and BP, however, fat mass (FM) and body weight did not reach significance. While there were trends, no significant interactions were found. However, using magnitude-based inference, supplementation with creatine post workout is possibly more beneficial in comparison to pre workout supplementation with regards to FFM, FM and 1-RM BP. Qualitative inference represents the likelihood that the true value will have the observed magnitude. Furthermore, there were no differences in caloric or macronutrient intake between the groups. It was concluded that creatine supplementation plus resistance exercise increases fat-free mass and strength. Based on the magnitude inferences it appears that consuming creatine immediately post-workout is superior to pre-workout vis a vis body composition and strength [13683].

It was examined the effects of creatine supplementation on the response to repeated bouts of resistance exercise. Young men (24 year) were divided into creatine (CM, n=9) and Placebo (PL, n=9) groups. On day (D) 1 and D15, subjects performed four sets of bicep curls at 75% 1-RM to concentric failure. On D8-D13, subjects consumed either 20 g/d creatine monohydrate or placebo. Muscle soreness and elbow joint range of motion (ROM) were assessed on D1-D5 and D15-D19. Serum creatine kinase activity (CK) was assessed on D1, D3, D5, D15, D17, and D19. The first exercise bout produced increases in muscle soreness and CK, and decreases in ROM in both groups. The second bout produced lesser rises in serum CK, muscle soreness, and a lesser decrease in ROM with greater attenuation of these damage markers in CM than PL. CK levels on D17 were lower (+110 % over D15 for CM vs +343 % for PL), muscle soreness from D15-19 was lower (-75 % for CM vs -56 % for PL compared with first bout), and elbow ROM was decreased in PL, but not CM on D16. It was concluded creatine supplementation provides an additive effect on blunting the rise of muscle damage markers following a repeated bout of resistance exercise. The mechanism by which creatine augments the repeated bout effect is unknown but is likely due to a combination of creatine's multifaceted functions [13685].

It was evaluated the effect of Creatine (Cr) supplementation on muscle fatigue and physiological indices after intermittent swimming bouts in trained swimmers. Sixteen healthy non-elite swimmers (19 ± 4 years, 75 ± 12 kg) were randomly assigned into two groups of either Cr supplementation or placebo and performed six repeated sprints swimming bouts of 50-m departing every 120 seconds. The Cr group was supplemented 4 times a day for 6 days. Blood lactate, Creatine Kinase (CK), creatinine, heart rate, best repeated sprint (RSb) and mean repeated sprint (RSm) times, and percentage of speed decrement (%Dec) were measured at the various phases of swimming bouts. Repeated measure ANOVA and
independent t-student tests showed CK and blood lactate concentration increased gradually after the third and sixth swimming bouts. % Dec in Cr group was significantly lower after 3rd swimming bout, also heart rate in Cr group was associated with lower increase in HR mean compared to placebo. These results suggest that Cr supplementation may improve swimming performance and reduce increased blood lactate levels following intermittent sprint swimming bouts. In conclusion Cr supplementation in trained swimmers may improve anaerobic performance and heart rate variations independent of the effect of intensive sprint swimming bouts [13686].

The goal of one study was to evaluate the effects of creatine (Cr) supplementation on oxidative stress and inflammation markers after acute repeated-sprint exercise in humans. Twenty-five players under age 20 years were randomly assigned to two groups: Cr supplemented and placebo. Double-blind controlled supplementation was performed using Cr (0.3 g/kg) or placebo tablets for 7 d. Before and after 7 d of supplementation, the athletes performed two consecutive Running-based Anaerobic Sprint Tests (RAST). RAST consisted of six 35-m sprint runs at maximum speed with 10 sec rest between them. Blood samples were collected just prior to start of test (pre), just after the completion (0 h), and 1 h after completion. Average, maximum, and minimum power values were significantly greater in the Cr-supplemented group compared with placebo. There were significant increases in plasma tumor necrosis factor alpha (TNF-alpha) and C-reactive protein (CRP) up to 1 h after acute sprint exercise in the placebo-supplemented group. Malondialdehyde, lactate dehydrogenase (LDH), catalase, and superoxide dismutase enzymes also were increased after exercise in both groups. Red blood cell glutathione was lower after exercise in both groups. Cr supplementation reversed the increase in TNF-alpha and CRP as well as LDH induced by acute exercise. Controversially, Cr supplementation did not inhibit the rise in oxidative stress markers. Also, antioxidant enzyme activity was not different between placebo and Cr-supplemented groups. Thus, creatinin supplementation inhibited the increase of inflammation markers TNF-alpha and CRP, but not oxidative stress markers, due to acute exercise [13684].

In addition to performance measurements, evidence has supported increases in fat-free mass and type II muscle fiber area. Muscle glycogen levels may also be affected by creatine supplementation, likely as a result of increased cellular water content. Increases in body mass with creatine supplementation have been reported as far back as 1928. However current evidence suggests that the increase in body mass observed with creatine is due to the decreased urine output and water retention during the initial stages of creatine loading. There is no evidence that creatine supplementation affects protein synthesis. Sport-specific performance also has been studied quite extensively to see if the effect of creatine supplementation extended from the weight room to the field of play. Multiple studies have investigated creatine supplementation effect on sprinting, swimming, and agility training and have failed to show an effect [13682].

Creatine monohydrate’s effect on resistance training exercises has been extensively researched. There are numerous controlled studies that have reported increases in performance and muscle strength in short-duration, maximum-intensity exercises. Resistance training has been measured in many ways in the literature, including exercises such as bench press, leg press, biceps curls, leg extensions, jump squats, and bicycle ergometry. The method of measurement of strength and performance in creatine studies includes one repetition maximum, mean power, total force, and number of repetitions. The results regarding creatine supplementation’s ergogenic effect are not unanimous. However, there is a significant body of evidence that creatine increases performance in short-duration, maximum-intensity resistance training. Conflicting evidence exists regarding studies of the effect of creatine supplementation on anaerobic performance. Currently, studies consistently
have observed no effect on aerobic performance with creatine supplementation [13682].

The majority of studies focusing on creatine supplementation report an increase in the body’s creatine pool. There is a positive relationship between muscle creatine uptake and exercise performance. It has been observed a significant increase in strength performance after 12 weeks creatine supplementation with a concurrent periodized heavy resistance training protocol. The creatine supplementation protocol consisted of a week-long loading period of 25 g/d followed by a 5 g maintenance dose for the remainder of the training. These positive effects were attributed to an increased total creatine pool resulting in more rapid adenosine triphosphate (ATP) regeneration between resistance training sets allowing athletes to maintain a higher training intensity and improve the quality of the workouts along the entire training period. It is regularly reported that creatine supplementation, when combined with heavy resistance training leads to enhanced physical performance, fat free mass, and muscle morphology. A 2003 meta-analysis showed individuals ingesting creatine, combined with resistance training, obtain on average +8 and +14 percent more performance on maximum (1RM) or endurance strength (maximal repetitions at a given percent of 1RM) respectively than the placebo groups. However, contradicting studies have reported no effects of creatine supplementation on strength performance. These conflicting results can be explained by the possibility that the supplemented groups were formed by a greater amount of non-responders or even because creatine supplementation was administered on the training days only (3 times a week). This strategy has not been adequately tested as effective in middle aged and older men for maintaining post loading elevated creatine stores. A quantitative, comprehensive scientific summary and view of knowledge up to 2007 on the effects of creatine supplementation in athletes and active people was published in a 100 citation review position paper by the International Society of Sports Nutrition. More recent literature has provided greater insight into the anabolic/performance enhancing mechanisms of creatine supplementation suggesting that these effects may be due to satellite cell proliferation, myogenic transcription factors and insulin-like growth factor-1 signalling. Collectively, in spite of a few controversial results, it seems that creatine supplementation combined with resistance training would amplify performance enhancement on maximum and endurance strength as well muscle hypertrophy [12419].

Effects of creatine on anaerobic exercise

Creatine has demonstrated neuromuscular performance enhancing properties on short duration, predominantly anaerobic, intermittent exercises. It has been observed enhanced neuromuscular function of the elbow flexors in both electrically induced and voluntary contractions but not on endurance performance after 4 loading doses of 5 g creatine plus 15 g maltodextrin for 5/d in young, moderately trained men. Creatine supplementation may facilitate the reuptake of Ca$^{2+}$ into the sacroplasmic reticulum by the action of the Ca$^{2+}$ adenosine triphosphatase pump, which could enable force to be produced more rapidly through the faster detachment of the actomyosin bridges. A previous meta-analysis reported an overall creatine supplementation effect size of 0.24 ± 0.02 for activities lasting ≤30 s. (primarily using the ATP-phosphocreatine energy system). For this short high-intensity exercise, creatine supplementation resulted in a 7.5 ± 0.7 percent increase from base line which was greater than the 4.3 ± 0.6 percent improvement observed for placebo groups. When looking at the individual selected measures for anaerobic performance the greatest effect of creatine supplementation was observed on the number of repetitions which showed an ES of 0.64 ± 0.18. Furthermore, an increase from base line of 45.4 ± 7.2 percent compared to 22.9 ± 7.3 percent for the placebo group was observed. The second greatest ES was on the weight lifted at 0.51 ± 0.16 with an increase from base line of 13.4 ± 2.7 percent for the placebo group and 24.7 ± 3.9 percent for the creatine group. The possible effect of creatine supplementation on multiple high intensity short duration bouts (<30 s) have shown
an effect size not statistically significant from 0. This would indicate that creatine supplementation might be useful to attenuate fatigue symptoms over multiple bouts of high-intensity, short duration exercise. The ES of creatine on anaerobic endurance exercise (>30-150s), primarily using the anaerobic glycolysis energy system, was 0.19 ± 0.05 with an improvement from baseline of 4.9 ± 1.5 percent for creatine and -2.0 ± 0.6 percent for the placebo [12419].

Although creatine supplementation has been shown to be more effective on predominantly anaerobic intermittent exercise, there is some evidence of its positive effects on endurance activities as well. From a meta-analysis, it would appear that the ergogenic potential for creatine supplementation on predominantly aerobic endurance exercise diminishes as the duration of the activity increases over 150s. However it is suggested that creatine supplementation may cause a change in substrate utilization during aerobic activity possibly leading to an increase in steady state endurance performance. Despite that, the effects of creatine supplementation on endurance performance have been questioned by some studies. In addition, of the concern related to the dosage used in many studies, it could be possible that the potential benefits of creatine supplementation on endurance performance were more related to effects of anaerobic threshold localization [12419].

Effects of creatine supplementation on skeletal muscle hypertrophy

It has been observed greater improvements on 1RM, lean body mass, fiber cross sectional area and contractile protein in trained young males when resistance training was combined with a multi-nutrient supplement containing 0.1 g/kg/d of creatine, 1.5 g/kg/d of protein and carbohydrate compared with protein alone or a protein carbohydrate supplement without the creatine. These findings were novel because at the time no other research had noted such improvements in body composition at the cellular and sub cellular level in resistance trained participants supplementing with creatine. When creatine supplementation is combined with heavy resistance training, muscle insulin like growth factor (IGF-1) concentration has been shown to increase. Compared to placebo, creatine groups produced greater increments in IGF-1 (78 % vs 55 %) and body mass (2.2 vs 0.6 kg). Additionally, vegetarians within the supplemented group had the largest increase of lean mass compared to non vegetarian (2.4 and 1.9 kg, respectively). Changes in lean mass were positively correlated to the modifications in intramuscular total creatine stores which were also correlated with the modified levels of intramuscular IGF-1. The authors suggested that the rise in muscle IGF-1 content in the creatine group could be due to the higher metabolic demand created by a more intensely performed training session. These amplifying effects could be caused by the increased total creatine store in working muscles. Even though vegetarians had a greater increase in high energy phosphate content, the IGF-1 levels were similar to the amount observed in the non vegetarian groups. These findings do not support the observed correlation pattern by which a low essential amino acid content of a typical vegetarian diet should reduce IGF-1 production [12419].

The objective of one study was to determine if additional dietary protein improves the lean tissue deposition and carcass merit of pigs supplemented creatine monohydrate in combination with a high glycemic carbohydrate (dextrose). Forty-eight crossbred barrows and gilts (91 kg) were blocked by sex assigned to 1 of 12 pens (4 pigs/pen, 16 pigs/treatment). Treatments included: control (CON; basal diet consisting of a ground corn-soybean base), combination diet (COMBO; basal diet supplemented with 0.92 % creatine monohydrate and 2.75 % dextrose), and a combination high protein diet (COMBOHP; COMBO formulated to contain a minimum of 16 % crude protein). Barrows on the COMBOHP gained the least 10th rib fat and expressed the highest percentage fat-free carcass lean after 28 days on test. No significant treatment differences were noted in the fat
and lean tissue accretion of gilts. Treatments had no affect the meat quality parameters of barrow and gilt carcasses [11400].

**Effect on plasma levels of pro-inflammatory cytokines**

The effect of creatine supplementation upon plasma levels of pro-inflammatory cytokines: interleukin (IL) 1 beta and IL-6, tumor necrosis factor alpha (TNFalpha), and Interferon alpha (INF alpha) and prostaglandin E2 (PGE2) after a half-ironman competition were investigated.

Eleven triathletes, each with at least three years experience of participation in this sport were randomly divided between the control and experimental groups. During 5 days prior to competition, the control group (n=6) was supplemented with carbohydrate (20 g/day) whereas the experimental group (n=5) received creatine (20 g/day) in a double-blind trial. Blood samples were collected 48 h before and 24 and 48 h after competition and were used for the measurement of cytokines and PGE2. Forty-eight hours prior to competition there was no difference between groups in the plasma concentrations (pg/mL) of IL-6, TNFalpha, INF alpha, IL-1 beta, and PGE2. Twenty-four and 48 h after competition plasma levels of TNFalpha, INF alpha, IL-1 beta and PGE2 were significantly increased in both groups. However, the increases in these were markedly reduced following creatine supplementation. An increase in plasma IL-6 was observed only after 24 h and, in this case, there was no difference between the two groups. It was concluded that creatine supplementation before a long distance triathlon competition may reduce the inflammatory response induced by this form of strenuous of exercise [07351].

**Effects of creatine on glycogen stores**

It is suggested that another mechanism for the effect of creatine could be enhanced muscle glycogen accumulation and GLUT4 expression, when creatine supplementation is combined with a glycogen depleting exercise. Whereas it has been observed that creatine supplementation alone does not enhance muscle glycogen storage it was observed positive effects of creatine supplementation for enhancing initial and maintaining a higher level of muscle glycogen during 2 hours of cycling. In general, it is accepted that glycogen depleting exercises, such as high intensity or long duration exercise should combine high carbohydrate diets with creatine supplementation to achieve heightened muscle glycogen stores [12419].

**Effects on blood lactate**

To determine the effects of creatine supplementation on blood lactate during incremental cycling exercise 13 male subjects (23 ± 2 years) performed a maximal, incremental cycling test to exhaustion before (Pre) and after (Post) 6 d of creatine supplementation (4 doses/d of 5 g creatine + 15 g glucose). Blood lactate was measured at the end of each exercise stage during the protocol, and the lactate threshold was determined as the stage before achieving 4 mmol/L. Lactate concentrations during the incremental test were analyzed using a 2 (condition) × 6 (exercise stage) repeated-measures ANOVA. Differences in power at lactate threshold, power at exhaustion, and total exercise time were determined by paired t tests. Lactate concentrations were reduced during exercise after supplementation, demonstrating a significant condition effect. There was a tendency for increased power at the lactate threshold. Total time to fatigue approached significant increases as did maximal power output. The findings demonstrate that creatine supplementation decreases lactate during incremental cycling exercise and tends to raise lactate threshold. Therefore, creatine supplementation could potentially benefit endurance athletes [13687].

**Effects on kidney function**

1928
The aim of one study was to determine the effects of creatine supplementation on kidney function in resistance-trained individuals ingesting a high-protein diet. A randomized, double-blind, placebo-controlled trial was performed. The participants were randomly allocated to receive either creatine (20 g/d for 5 d followed by 5 g/d throughout the trial) or placebo for 12 weeks. All of the participants were engaged in resistance training and consumed a high-protein diet (i.e., ≥ 1.2 g/Kg/d). Subjects were assessed at baseline (Pre) and after 12 weeks (Post). Glomerular filtration rate was measured by $^{51}$Cr-EDTA clearance. Additionally, blood samples and a 24-h urine collection were obtained for other kidney function assessments. No significant differences were observed for $^{51}$Cr-EDTA clearance throughout the trial. Creatinine clearance, serum and urinary urea, electrolytes, proteinuria, and albuminuria remained virtually unchanged. It was concluded that a 12-week creatine supplementation protocol did not affect kidney function in resistance-trained healthy individuals consuming a high-protein diet; thus reinforcing the safety of this dietary supplement [13688].

**Effects on inflammatory markers**

The goal of one study was to evaluate the effects of creatine (Cr) supplementation on oxidative stress and inflammation markers after acute repeated-sprint exercise in humans. Twenty-five players under age 20 years were randomly assigned to two groups: Cr supplemented and placebo. Double-blind controlled supplementation was performed using Cr (0.3 g/kg) or placebo tablets for 7 d. Before and after 7 d of supplementation, the athletes performed two consecutive Running-based Anaerobic Sprint Tests (RAST). RAST consisted of six 35-m sprint runs at maximum speed with 10 sec rest between them. Blood samples were collected just prior to start of test (pre), just after the completion (0 h), and 1 h after completion. Average, maximum, and minimum power values were greater in the Cr-supplemented group compared with placebo. There were significant increases in plasma tumor necrosis factor alpha (TNF-alpha) and C-reactive protein (CRP) up to 1 h after acute sprint exercise in the placebo-supplemented group. Malondialdehyde, lactate dehydrogenase (LDH), catalase, and superoxide dismutase enzymes also were increased after exercise in both groups. Red blood cell glutathione was lower after exercise in both groups. Cr supplementation reversed the increase in TNF-alpha and CRP as well as LDH induced by acute exercise. Controversially, Cr supplementation did not inhibit the rise in oxidative stress markers. Also, antioxidant enzyme activity was not different between placebo and Cr-supplemented groups. It was concluded that Cr supplementation inhibited the increase of inflammation markers TNF-alpha and CRP, but not oxidative stress markers, due to acute exercise [13689].

**Side effects of creatinine**

The International Society of Sports Nutrition’s position statement on creatine monohydrate states that there is no scientific evidence of side effects or adverse effects when creatine is used appropriately. They therefore conclude that if used properly, creatine is an acceptable nutritional supplement and ergogenic aid for young athletes to use. No adverse effects were reported in a study of young healthy individuals after supplementation with creatine from 7 d to 10 weeks. Creatine is excreted by the kidney, which led to the hypothesis that creatine supplementation may be detrimental to renal function. Several studies have looked at serum creatinine levels during creatine loading but have not reported significant increases in serum creatinine in younger healthy populations. Slight increases in serum creatinine levels have been reported with larger doses of creatine during the loading phase, although not statistically significant. However increases in urinary creatinine excretion and decreases in total urine volume output have been reported during creatine loading. The decrease in
urinary output is thought to result in fluid retention and weight gain during the initial phases of creatine supplementation. Creatine has been reported to result in weight gain and water retention during short-term use. In the literature, there is a case report of a 20-year-old man with interstitial nephritis as a result of creatine supplementation. However the individual in the case was taking loading doses of creatine (20 g/d) over a 4-week period instead of the recommended and well-studied loading phase of 5 to 7 d. A longer study of creatine supplementation in nonathletes with other medical comorbidities also did not show evidence of renal problems [13682].

Although there have not been significant increases in serum creatinine with creatine supplementation, there have been other concerns about the effects of creatine loading on the kidney. Creatine can be metabolized to methylamine and subsequently formaldehyde during urinary excretion. Both methylamine and formaldehyde are known cytotoxic substances raising concerns about potential harmful effects to the kidney with long-term use. Studies have shown significant increases in both methylamine and formaldehyde after short-term creatine supplementation at loading doses. Further studies are needed to further evaluate the potential harm to the kidney related to the increases in urinary methylamine and formaldehyde levels, particularly with longer term use and high loading doses of creatine. In the literature, there are case reports of young healthy individuals developing acute liver failure when one of the dietary supplements they were ingesting was creatine. However in these cases, the individuals were taking large doses of creatine in addition to several other dietary supplements for weight training. When creatine has been studied in isolation and at acceptable doses, there have been no significant adverse effects to the liver [13682].

Since creatine does result in a decrease in urinary volume and water retention during supplementation, concerns arose that athletes could develop problems staying hydrated and regulating body temperature. Creatine supplementation increases intracellular volume with increased cellular water volume. A study evaluated lower extremity anterior compartment pressures after heat-stressed exercise, and it did find transient asymptomatic increases in compartment pressures with creatine supplementation compared to placebo. There is a case report of compartment syndrome occurring with large doses of creatine, with subsequent resolution with cessation. In 1998, the University of Tennessee football team had many of their football players develop cramping during a game, after the team instituted a creatine supplementation program. The number of athletes was disproportional to historic values of athletes cramping, which caused the linkage to creatine usage. Further studies have since shown no increase in the incidence of cramping in college football players taking creatine. Several studies also have reported no issues with heat tolerance or hydration status with creatine supplementation [13682].

*Dosing protocols applied in creatine*

A typical creatine supplementation protocol consists of a loading phase of 20 g CM/d or 0.3 g CM/kg/d split into 4 daily intakes of 5 g each, followed by a maintenance phase of 3-5 g CM/d or 0.03 g CM/kg/d for the duration of the supplementation period. Other supplementation protocols are also used such as a daily single dose of around 3-6 g or between 0.03 to 0.1 g/kg/d. However, this method takes longer (between 21 to 28 days) to produce ergogenic effects. It was also found that a moderate protocol consisting of 20 g CM taken in 1g doses (evenly ingested at 30-min intervals) for 5 days resulted in reduced urinary creatine and methylamine excretion, leading to an estimated increase in whole body retention of creatine (+13 %) when compared with a typical loading supplementation protocol of 4 x 5 g/d during 5 days (evenly ingested at 3 hour intervals). This enhancement in creatine retention would lead to a significantly higher weight gain when people follow a moderate
protocol ingestion of several doses of small amounts of CM evenly spread along the day [12419].

Studies have shown that intramuscular stores of total creatine and phosphocreatine can be increased by supplementing with oral creatine monohydrate for 5 to 7 d with a dose of 20 to 25 g/d. The greatest increase of creatine and phosphocreatine is reported to be in the first 2 d of supplementation. The typical dosing in studies that have shown increases in strength performance includes both a loading and maintenance phase. Depending on the study, the loading phase varies from 5 to 7 days at 0.3 g/kg/day. During the loading phase, the daily dose is divided into four equal doses throughout the day dissolved in a liquid. After the 5- to 7-d loading phase, the athlete continues with the maintenance phase at 0.03 g/kg/day. The length of the maintenance phase varies in studies from 28 d to 10 week. When a carbohydrate or protein is added to creatine supplementation, there may be an increase in muscle retention of creatine, particularly in the first few days, resulting in a decreased need for loading. However alternative dosing methods also have been shown to effectively increase creatine stores and have effects on strength gains. Regimens without the creatine loading phase, 3 to 6 g/day for 28 days and 6 g/day for 12 weeks, also have been shown to be effective in increasing creatine stores. The increase in creatine stores occurs more slowly and therefore may take longer to see the strength training effects [13682].

**Commercially available forms of creatine**

There are several different available forms of creatine: creatine anhydrous which is creatine with the water molecule removed in order to increase the concentration of creatine to a greater amount than that found in CM. Creatine has been manufactured in salt form: creatine pyruvate, creatine citrate, creatine malate, creatine phosphate, magnesium creatine, creatine orotate, Kre Alkalyn (creatine with baking soda). Creatine can also be manufactured in an ester form. Creatine ethyl ester (hydrochloride) is an example of this, as is creatine gluconate which is creatine bound to glucose. Another form is creatine effervescent which is creatine citrate or CM with citric acid and bicarbonate. The citric acid and bicarbonate react to produce an effervescent effect. When mixed with water the creatine separates from its carrier leaving a neutrally charged creatine, allowing it to dissolve to a higher degree in water. Manufacturers claim that creatine effervescent has a longer and more stable life in solution. When di-creatine citrate effervescent was studied for stability in solution it was found that the di-creatine citrate dissociates to citric acid and creatine in aqueous solutions which in turn forms CM and eventually crystallises out of the solution due to its low solubility. Some of the creatine may also convert to creatinine. In summary, creatine salts have been show to be less stable than CM. However the addition of carbohydrates could increase their stability. The potential advantages of creatine salts over CM include enhanced aqueous solubility and bioavailability which would reduce their possible gastrointestinal adverse effects. The possibility for new additional formulation such as tablets or capsules is interesting for its therapeutic application due to its attributed better dissolution kinetics and oral absorption compared to CM. However more complete in vivo pharmaceutical analysis of creatine salts are required to fully elucidate their potential advantages/disadvantages over the currently available supplement formulations [12419].

**Monhydrate**

Creatine monohydrate (CrM) has been consistently reported to increase muscle creatine content and improve high-intensity exercise capacity. However, a number of different forms of creatine have been purported to be more efficacious than CrM. The purpose of this study was to determine if a buffered creatine monohydrate (KA) that has been purported to promote greater creatine retention and training adaptations with fewer side effects at lower doses is more efficacious than CrM supplementation in resistance-trained individuals. In a
double-blind manner, 36 resistance-trained participants (20 years, 181 cm, 82 kg, and 15 % body fat) were randomly assigned to supplement their diet with CrM (Creapure® AlzChem AG, Trostberg, Germany) at normal loading (4 x 5 g/d for 7-days) and maintenance (5 g/d for 21-days) doses; KA (Kre-Alkaly®; All American Pharmaceutical, Billings, MT, USA) at manufacturer’s recommended doses (KA-L, 1.5 g/d for 28-days); or, KA with equivalent loading (4 x 5 g/d for 7-days) and maintenance (5 g/d) doses of CrM (KA-H). Participants were asked to maintain their current training programs and record all workouts. Muscle biopsies from the vastus lateralis, fasting blood samples, body weight, DEXA determined body composition, and Wingate Anaerobic Capacity (WAC) tests were performed at 0, 7, and 28-days while 1RM strength tests were performed at 0 and 28-days. Data were analyzed by a repeated measures multivariate analysis of variance (MANOVA) and are presented as mean ± SD changes from baseline after 7 and 28-days, respectively. Muscle free creatine content obtained in a subgroup of 25 participants increased in all groups over time after 7 and 28-days, respectively, with no significant differences among groups. However, while no overall group differences were observed, pairwise comparison between the KA-L and CrM groups revealed that changes in muscle creatine content tended to be greater in the CrM group. Although some significant time effects were observed, no significant group x time interactions were observed in changes in body mass, fat free mass, fat mass, percent body fat, or total body water; bench press and leg press 1RM strength; WAC mean power, peak power, or total work; serum blood lipids, markers of catabolism and bone status, and serum electrolyte status; or, whole blood makers of lymphocytes and red cells. Serum creatinine levels increased in all groups with higher doses of creatine promoting greater increases in serum creatinine but the increases observed (0.1-0.2 mg/dL) were well within normal values for active individuals (i.e. <1.28 ± 0.2 mg/dL). Serum LDL was decreased to a greater degree following ingesting loading doses in the CrM group but returned to baseline during the maintenance phase. No side effects were reported. It was concluded that neither manufacturers recommended doses of KA (1.5 g/d) or KA with equivalent loading (20 g/d for 7-days) and maintenance doses (5 g/d for 21-days) of CrM promoted greater changes in muscle creatine content, body composition, strength, or anaerobic capacity than CrM (20 g/d for 7-days, 5 g/d for 21-days). There was no evidence that supplementing the diet with a buffered form of creatine resulted in fewer side effects than CrM. These findings do not support claims that consuming a buffered form of creatine is a more efficacious and/or safer form of creatine to consume than creatine monohydrate [12421].

Creatine is a hydrophilic polar molecule that consists of a negatively charged carboxyl group and a positively charged functional group. The hydrophilic nature of creatine limits its bioavailability. In an attempt to increase creatines bioavailability creatine has been esterified to reduce the hydrophilicity; this product is known as creatine ethyl ester. Manufacturers of creatine ethyl ester promote their product as being able to by-pass the creatine transporter due to improved sarcolemmal permeability toward creatine. The results of at least one study showed that ethyl ester was not as effective as CM to enhance serum and muscle creatine stores. Furthermore creatine ethyl ester offered no additional benefit for improving body composition, muscle mass, strength, and power. This research did not support the claims of the creatine ethyl ester manufacturers [12419].

Polyethylene glycol is a non-toxic, water-soluble polymer that is capable of enhancing the absorption of creatine and various other substances. Polyethylene glycol can be bound with CM to form polyethylene glycosylated creatine. There are that results seem to indicate that the addition of polyethylene glycol could increase the absorption efficiency of creatine but further research is needed before a definitive recommendation can be reached [12419].

**Polyethylene glycosylated creatine**
The purpose of this study was to examine the effects of 28 days of polyethylene glycosylated
creatine (PEG-creatine) supplementation (1.25 and 2.50 g/d) on anaerobic performance measures (vertical and broad jumps, 40-yard dash, 20-yard shuttle run, 3-cone drill), upper and lower body muscular strength and endurance (bench press and leg extension), and body composition. The study used a randomized, double-blind, placebo-controlled, parallel design. Seventy-seven adult males (mean age 22 years; body mass 82 kg) volunteered to participate and were randomly assigned to a placebo (n=23), 1.25 g/d of PEG-creatine (n=27) or 2.50 g/d of PEG-creatine (n=27) group. The subjects performed anaerobic performance measures, muscular strength (1RM) and endurance (80 % 1RM) tests for bench press and leg extension, and underwater weighing for the determination of body composition at Day 0 (baseline), Day 14, and Day 28. The results indicated there were significant improvements in vertical jump, 20-yard shuttle run, 3-cone drill, muscular endurance for bench press, and body mass for at least one of the PEG-creatine groups without changes for the placebo group. Thus, the present results demonstrated that PEG-creatine supplementation at 1.25 and/or 2.50 g/d had an ergogenic effect on lower body vertical power, agility, change-of-direction ability, upper body muscular endurance, and body mass [13690].

Creatine in combination with other supplements

Although creatine can be bought commercially as a standalone product it is often found in combination with other nutrients. A prime example is the combination of creatine with carbohydrate or protein and carbohydrate for augmenting creatine muscle retention mediated through an insulin response from the pancreas. The addition of 10 g of creatine to 75 g of dextrose, 2 g of taurine, vitamins and minerals, induced a change in cellular osmolarity which in addition to the expected increase in body mass, seems to produce an up regulation of large scale gene expression (mRNA content of genes and protein content of kinases involved in osmosensing and signal transduction, cytoskeleton remodelling, protein and glycogen synthesis regulation, satellite cell proliferation and differentiation, DNA replication and repair, RNA transcription control, and cell survival). Similar findings have also been reported for creatine monohydrate supplementation alone when combined with resistance training. A commercially available pre-workout formula comprised of 2.05 g of caffeine, taurine and glucuronolactone, 7.9 g of L-leucine, L-valine, L-arginine and L-glutamine, 5 g of di-creatine citrate and 2.5 g of beta-alanine mixed with 500 ml of water taken 10 minutes prior to exercise has been shown to enhance time to exhaustion during moderate intensity endurance exercise and to increase feelings of focus, energy and reduce subjective feelings of fatigue before and during endurance exercise due to a synergistic effect of the before mentioned ingredients. The role of creatine in this formulation is to provide a neuroprotective function by enhancing the energy metabolism in the brain tissue, promoting antioxidant activities, improving cerebral vasculature and protecting the brain from hyperosmotic shock by acting as a brain cell osmolyte. Creatine can provide other neuroprotective benefits through stabilisation of mitochondrial membranes, stimulation of glutamate uptake into synaptic vesicles and balance of intracellular calcium homeostasis [12419].

Safety and side effects of creatine

There have been a few reported renal health disorders associated with creatine supplementation. These are isolated reports in which recommended dosages are not followed or there is a history of previous health complaints, such as renal disease or those taking nephrotoxic medication aggravated by creatine supplementation. Specific studies into creatine supplementation, renal function and/or safety conclude that although creatine does slightly raise creatinine levels there is no progressive effect to cause negative consequences to renal function and health in already healthy individuals when proper dosage recommendations are followed. Urinary methylamine and formaldehyde have been shown to increase due to creatine supplementation of 20 g/d; this however did not bring the production
outside of normal healthy range and did not impact on kidney function. A retrospective study, that examined the effects of long lasting (0.8 to 4 years) CM supplementation on health markers and prescribed training benefits, suggested that there is no negative health effects (including muscle cramp or injuries) caused by long term CM consumption. In addition, despite many anecdotal claims, it appears that creatine supplementation would have positive influences on muscle cramps and dehydration. Creatine was found to increase total body water possibly by decreasing the risk of dehydration, reducing sweat rate, lowering core body temperature and exercising heart rate. Furthermore, creatine supplementation does not increase symptoms nor negatively affect hydration or thermoregulation status of athletes exercising in the heat. Additionally, CM ingestion has been shown to reduce the rate of perceived exertion when training in the heat. It is prudent to note that creatine supplementation has been shown to reduce the body’s endogenous production of creatine, however levels return to normal after a brief period of time when supplementation ceases. However, long term effects are unknown, therefore safety cannot be guaranteed. Whilst the long term effects of creatine supplementation remain unclear, no definitive certainty of either a negative or a positive effect upon the body has been determined for many health professionals and national agencies [12419].

**In muscle wasting**

It was aimed to investigate the possible role of creatine (CR) supplementation in counteracting dexamethasone-induced muscle wasting and insulin resistance in rats. Also, it was examined whether CR intake would modulate molecular pathways involved in muscle remodeling and insulin signaling. Animals were randomly divided into four groups: (1) dexamethasone (DEX); (2) control pair-fed (CON-PF); (3) dexamethasone plus CR (DEX-CR); and (4) CR pair-fed (CR-PF). Dexamethasone (5 mg/kg/day) and CR (5 g/kg/day) were given via drinking water for 7 days. Plantaris and extensor digitorum longus (EDL) muscles were removed for analysis. Plantaris and EDL muscle mass were significantly reduced in the DEX-CR and DEX groups when compared with the CON-PF and CR-PF groups. Dexamethasone significantly decreased phospho-Ser473-Akt protein levels compared to the CON-PF group and CR supplementation aggravated this response. Serum glucose was significantly increased in the DEX group when compared with the CON-PF group. CR supplementation significantly exacerbated hyperglycemia in the dexamethasone-treated animals. Dexamethasone reduced GLUT-4 translocation when compared with the CON-PF and CR-PF groups and this response was aggravated by CR supplementation. In conclusion, supplementation with CR resulted in increased insulin resistance and did not attenuate muscle wasting in rats treated with dexamethasone. Given the contrast with the results of human studies that have shown benefits of CR supplementation on muscle atrophy and insulin sensitivity, it was suggested caution when extrapolating this animal data to human subjects [12422].

**Effects of statins**

It was measured the serum levels of myoglobin, total creatine kinase (CK), and the CK myocardial (CK-MB), muscle (CK-MM), and brain (CK-BB) isoenzymes in 37 subjects treated with statins and 43 nonstatin-treated controls running the 2011 Boston Marathon. Venous blood samples were obtained the day before (PRE) and within 1 hour (FINISH) and 24 hours after (POST) the race. The hematocrit and hemoglobin values were used to adjust for changes in the plasma volume. The CK distribution was normalized using log transformation before analysis. The exercise-related increase in CK 24 hours after exercise, adjusted for changes in plasma volume, was greater in the statin users than in the controls. The increase in CK-MB 24 hours after exercise was also greater in the statin users than in the controls. However, the increases in muscle myoglobin did not differ at any point between the 2 groups.
Increases in CK at both FINISH and POST race measurements were directly related to age in the statin users but not in the controls suggesting that susceptibility to exercise-induced muscle injury with statins increases with age. In conclusion, the results show that statins increase exercise-related muscle injury [12423].

**Creatine monohydrate and conjugated linoleic acid**

Aging is associated with lower muscle mass and an increase in body fat. We examined whether creatine monohydrate (CrM) and conjugated linoleic acid (CLA) could enhance strength gains and improve body composition (i.e. increase fat-free mass (FFM); decrease body fat) following resistance exercise training in older adults (>65 y). Men (n=19) and women (n=20) completed six months of resistance exercise training with CrM (5g/d)+CLA (6g/d) or placebo with randomized, double blind, allocation. Outcomes included: strength and muscular endurance, functional tasks, body composition (DEXA scan), blood tests (lipids, liver function, CK, glucose, systemic inflammation markers (IL-6, C-reactive protein)), urinary markers of compliance (creatine/creatinine), oxidative stress (8-OH-2dG, 8-isoP) and bone resorption (Nu-telopeptides). Exercise training improved all measurements of functional capacity and strength, with greater improvement for the CrM+CLA group in most measurements of muscular endurance, isokinetic knee extension strength, FFM, and lower fat mass. Plasma creatinine, but not creatinine clearance, increased for CrM+CLA, with no changes in serum CK activity or liver function tests. Together, this data confirms that supervised resistance exercise training is safe and effective for increasing strength in older adults and that a combination of CrM and CLA can enhance some of the beneficial effects of training over a six-month period [07352].

**Creatine kinase**

Total creatine kinase (CK) levels depend on age, gender, race, muscle mass, physical activity and climatic condition. High levels of serum CK in apparently healthy subjects may be correlated with physical training status, as they depend on sarcomeric damage: strenuous exercise that damages skeletal muscle cells results in increased total serum CK. The highest post-exercise serum enzyme activities are found after prolonged exercise such as ultradistance marathon running or weight-bearing exercises and downhill running, which include eccentric muscular contractions. Total serum CK activity is markedly elevated for 24 h after the exercise bout and, when patients rest, it gradually returns to basal levels. Persistently increased serum CK levels are occasionally encountered in healthy individuals and are also markedly increased in the pre-clinical stages of muscle diseases. Some authors, studying subjects with high levels of CK at rest, observed that, years later, subjects developed muscle weakness and suggested that early myopathy may be asymptomatic. Others demonstrated that, in most of these patients, hyperCKemia probably does not imply disease. In many instances, the diagnosis is not formulated following routine examination with the patients at rest, as symptoms become manifest only after exercise. Some authors think that strength training seems to be safe for patients with myopathy, even though the evidence for routine exercise prescription is still insufficient. Others believe that, in these conditions, intense prolonged exercise may produce negative effects, as it does not induce the physiological muscle adaptations to physical training given the continuous loss of muscle proteins. High CK serum levels in athletes following absolute rest and without any further predisposing factors should prompt a full diagnostic workup with special regards to signs of muscle weakness or other simple signs that, in both athletes and sedentary subjects, are not always promptly evident. These signs may indicate subclinical muscle disease, which training loads may evidence through the onset of profound fatigue. It is probably safe to counsel athletes with suspected myopathy to continue to undertake physical activity at a
lower intensity, so as to prevent muscle damage from high intensity exercise and allow ample recovery to favour adequate recovery. CK values show great variability among individuals. Some athletes are low responders to physical training, with chronically low CK serum levels. Some athletes are high responders, with higher values of enzyme: the relationship among level of training, muscle size, fibre type and CK release after exercise should be investigated further. In addition, more details about hyperCKemia could come from the evaluation of the kinetics of CK after stress in healthy athletes with high levels of CK due to exercise, comparing the results with the ones obtained from athletes with persistent hyperCKemia at rest. Finally, it would be important to quantify the type of exercise more suited to athletes with myopathy and the intensity of exercise not dangerous for the progression of the pathology [07402].

Under such conditions the catalytic concentration of CK in the serum displays a far greater increase than the serum concentration of other muscle proteins. The serum concentration of CK peaks 1-4 days after exercise and remains elevated for several days. Thus, athletes participating in daily training have higher resting values than non-athletes, although this response to training is mitigated by the so-called repeated-bout effect. The serum concentration of creatine kinase (CK) is used widely as an index of skeletal muscle fibre damage in sport and exercise. Since athletes have higher CK values than non-athletes, comparing the values of athletes to the normal values established in non-athletes is pointless. The purpose of this study was to introduce reference intervals for CK in athletes. CK was assayed in serum samples from 483 male athletes and 245 female athletes, aged 7-44. Samples had been obtained throughout the training and competition period. For comparison, CK was also assayed in a smaller number of non-athletes. The reference intervals were 82-1083 U/L (37 degrees C) in male and 47-513 U/L in female athletes. The upper reference limits were twice the limits reported for moderately active non-athletes in the literature or calculated in the non-athletes in this study. The upper limits were up to six times higher than the limits reported for inactive individuals in the literature. When reference intervals were calculated specifically in male football (soccer) players and swimmers, a threefold difference in the upper reference limit was found (1492 vs 523 U/L, respectively), probably resulting from the different training and competition demands of the two sports. It was concluded that sport training and competition have profound effects on the reference intervals for serum CK. Introducing sport-specific reference intervals may help to avoid misinterpretation of high values and to optimise training [07353].

**Influence on glucose metabolism**

Findings have indicated that creatine supplementation may affect glucose metabolism. This study aimed to examine the effects of creatine supplementation, combined with aerobic training, on glucose tolerance in sedentary healthy male. Subjects (n=22) were randomly divided in two groups and were allocated to receive treatment with either creatine (CT) (approximately 10 g/day over three months) or placebo (PT) (dextrose). Administration of treatments was double blind. Both groups underwent moderate aerobic training. An oral glucose tolerance test (OGTT) was performed and both fasting plasma insulin and the homeostasis model assessment (HOMA) index were assessed at the start, and after four, eight and twelve weeks. CT demonstrated significant decrease in OGTT area under the curve compared to PT. There were no differences between groups or over time in fasting insulin or HOMA. The results suggest that creatine supplementation, combined with aerobic training, can improve glucose tolerance but does not affect insulin sensitivity, and may warrant further investigation with diabetic subjects [07354].

**Creatine and whey protein**
Studies that have attributed gains in lean body mass to dietary supplementation during resistance exercise (RE) training have not reported these changes alongside adaptations at the cellular and subcellular levels. Therefore, the purpose of this study was to examine the effects of two popular supplements – whey protein (WP) and creatine monohydrate (CrM) (both separately and in combination) – on body composition, muscle strength, fiber-specific hypertrophy (i.e. type I, IIa, IIx), and contractile protein accrual during RE training. In a double-blind randomized protocol, resistance-trained males were matched for strength and placed into one of four groups: creatine/carbohydrate (CrCHO), creatine/whey protein (CrWP), WP only, or carbohydrate only (CHO) (1.5 g/kg body weight per day). All assessments were completed the week before and after an 11-week structured, supervised RE program. Assessments included strength (1RM, three exercises), body composition (DEXA), and vastus lateralis muscle biopsies for determination of muscle fiber type (I, IIa, IIx), cross-sectional area (CSA), contractile protein, and creatine (Cr) content. Supplementation with CrCHO, WP, and CrWP resulted in significantly greater 1RM strength improvements (three of three assessments) and muscle hypertrophy compared with CHO. Up to 76 percent of the strength improvements in the squat could be attributed to hypertrophy of muscle involved in this exercise. However, the hypertrophy responses within these groups varied at the three levels assessed (i.e. changes in lean mass, fiber-specific hypertrophy, and contractile protein content). Although WP and/or CrM seem to promote greater strength gains and muscle morphology during RE training, the hypertrophy responses within the groups varied. These differences in skeletal muscle morphology may have important implications for various populations and, therefore, warrant further investigation [07355].

Cognitive effects of creatine

The effect of creatine supplementation and sleep deprivation, with intermittent moderate-intensity exercise, on cognitive and psychomotor performance, mood state, effort and salivary concentrations of cortisol and melatonin were examined. Subjects were divided into a creatine supplementation group and a placebo group. They took 5 g of creatine monohydrate or a placebo, dependent on their group, four times a day for 7 days immediately prior to the experiment. They undertook tests examining central executive functioning, short-term memory, choice reaction time, balance, mood state and effort at baseline and following 18-, 24- and 36-h sleep deprivation, with moderate intermittent exercise. Saliva samples were taken prior to each set of tests. A group x time analysis of covariance, with baseline performance the covariate, showed that the creatine group performed significantly better than the placebo group on the central executive task but only at 36 h. The creatine group demonstrated a significant linear improvement in performance of the central executive task throughout the experiment, while the placebo group showed no significant effects. There were no significant differences between the groups for any of the other variables. A significant main effect of time was found for the balance test with a linear improvement being registered. Cortisol concentrations on Day 1 were significantly higher than on Day 2. Mood significantly deteriorated up to 24 h with no change from 24 to 36 h. Effort at baseline was significantly lower than in the other conditions. It was concluded that, during sleep deprivation with moderate-intensity exercise, creatine supplementation only affects performance of complex central executive tasks [07356].

Use in women

Creatine is an amino acid compound produced by the liver, kidneys, and pancreas. It is also found in meat and fish. Ninety-five percent of the body’s creatine stores are in muscle.
Creatine provides a fast, but short, energy burst. Energy stored in adenosine triphosphate is used in the first second of activity, while energy stored in creatine phosphate is used in the next 10 seconds. Creatine supplementation is used to increase myocyte phosphocreatine; it has been found to increase muscle phosphocreatine by 20 percent [07086].

**Prevalence**

Many surveys have found creatine to be the most commonly used supplement. Creatine use is consistently higher in men compared with women. The 2001 NCAA study of substance use habits of college student-athletes showed that 26 percent of athletes had tried creatine at least once in the past year. The same survey repeated in 2005 found an increased prevalence of 40 percent athletes who had tried creatine. The study did not differentiate between women and men. A survey given to high preadolescent and adolescent boys and girls found that 0.4 percent of girls had tried creatine in the past year, compared with 4.3 percent of boys. Further, a study evaluating high school athletes found that significantly more boys than girls had used creatine (21 % vs 3 %) [07086].

**Effects**

Creatine supplementation has been tested in athletes participating in both sprint and endurance activities. Studies have shown benefits in short, repetitive, and high-intensity activities with brief recovery periods. A meta-analysis by Branch supported claims of previous studies that creatine can improve performance during high-intensity exercise lasting shorter than 30 seconds. Smaller benefits were seen in longer durations of 30 to 150 seconds. A benefit has also been found in number of maximum repetitions in weight lifters, power output and force in cyclists, and short-burst sprints in swimming. Evidence for improvement in track and field events has been inconclusive. Several studies have been conducted to analyze creatine’s effect in women. An article compared the effect on size in men and women. Studies in women had a larger relative improvement from baseline compared with men (14 ± 3.8 % vs 5.5 ± 0.7%). A double-blind, randomized, placebo-controlled trial published in 2002 examined creatine’s effect in elite women soccer players under conditions simulating game or practice. They found a significant increase in body mass resulting from creatine supplementation for 6 days, an average increase of 0.8 kg. They also found improved performance in repeated sprint and agility tasks that they calculated might significantly impact game performance [07086].

**Side effects**

However, creatine-related adverse effects include weight gain, gastrointestinal discomfort, and muscle cramps. There have been case reports of renal compromise, but these have been unsubstantiated [07086].

**Effect on myostatin**

Myostatin is a catabolic regulator of skeletal muscle mass. The purpose of one study was to determine the effect of resistance training for 8 weeks in conjunction with creatine supplementation on muscle strength, lean body mass, and serum levels of myostatin and growth and differentiation factor-associated serum protein-1 (GASP-1). In a double-blinded design 27 healthy male subjects were assigned to control (CON), resistance training plus placebo (RT+PL) and resistance training+creatine supplementation (RT+CR) groups. The protocol consisted of 3 days per week of training for 8 weeks, each session including three sets of 8-10 repetitions at 60-70 percent of 1 RM for whole-body exercise. Blood sampling, muscular strength testing and body composition analysis (full body DEXA) were performed at 0, 4th and 8th weeks. Myostatin and GASP-1 was measured. Resistance training caused significant decrease in serum levels of myostatin and increase in that of GASP-1. Creatine supplementation in conjunction with resistance training lead to greater decreases in serum
myostatin, but had not additional effect on GASP-1. The effects of resistance training on serum levels of myostatin and GASP-1, may explain the increased muscle mass that is amplified by creatine supplementation [10244].

**Children**

The safety of creatine in the pediatric and adolescent population is lacking appropriate research. In addition, studies that have shown benefit in resistance training have not included subjects less than 18 years of age. Therefore creatine supplementation in athletes less than 18 years old needs further research before it should be recommended [13682].

**Creatine purity**

Creatine is an unregulated dietary supplement that is readily available to consumers and legal for use in athletic training. The supplement is not banned by The National Collegiate Athletic Association (NCAA) or by the International Olympic Committee (IOC). The NCAA does prohibit individual institutions from distributing creatine supplements. The IOC ruled to allow creatine given the substance is readily found in animal proteins. However creatine is a dietary supplement that falls under the Dietary Supplement Health and Education Act, and is not directly regulated by the Food and Drug Administration. In general, those who participate in athletics under the supervision of institutions such as the NCAA and IOC should use caution when using any dietary supplement due to reported contamination of creatine [13682].

**In taekwondo**

Taekwondo (TKD) is a combat sport, which has also been proposed as a fitness program, with a strong anaerobic component. Creatine (Cr) supplementation is used to improve both anaerobic exercise performance and body composition. Therefore, Cr supplementation could be beneficial in TKD. To determine the effect of Cr supplementation (50 mg/kg body wt) on body composition, anaerobic power and blood chemistry in young male TKD practitioners 10 male TKD practitioners (age 20 ± 2 years) participated in a placebo-controlled, double blind, crossover study. Body composition (DEXA), anaerobic power (Wingate Test), blood lactate and blood chemistry were measured before and after supplementation. Differences between data before and after supplementation were calculated for each treatment (Cr and Placebo) and were compared using the Wilcoxon signed-rank test. Fat mass (kg) decreased after placebo and increased following Cr intake. Serum triglyceride concentration (mg/mL) increased after Cr and decrease with placebo. No changes were found in others parameters. Thus, Cr supplementation may increase fat mass and serum triglycerides concentration in young male TKD practitioners without improvement in anaerobic power. Cr supplementation appears to be safe, but athletes should be careful when they want to loss fat [13691].

**Effect on tennis**

Creatine supplementation is popular among tennis players but it is not clear whether it actually enhances tennis performance. To examine the effects of creatine supplementation on tennis specific performance indices. In a randomised, double blind design, 36 competitive male tennis players (24 creatine, mean age 23 years; 12 placebo, 23 years) were tested at baseline, after six days of creatine loading, and after a maintenance phase of four weeks (14 creatine, 10 placebo). Serving velocity (10 serves), forehand and backhand velocity (three series of 5x8 strokes), arm and leg strength (bench press and leg press), and intermittent running speed (three series of five 20 metre sprints) were measured. Compared with
placebo, neither six days nor five weeks of creatine supplementation had a significant effect on serving velocity; forehand velocity, or backhand velocity. There was also no significant effect of creatine supplementation on repetitive sprint power after 5, 10, and 20 metres, or in the strength of the upper and lower extremities. It was concluded that creatine supplementation is not effective in improving selected factors of tennis specific performance and should not be recommended to tennis players [06270].

*Effect on ice-hockey*

Creatine monohydrate supplementation is beneficial for enhancing high-intensity exercise performance, especially activities that involve repeated sprints. Creatine monohydrate supplementation is common in ice-hockey players. The purpose of one study was to determine the effect of creatine monohydrate supplementation on sprint skating performance in Junior B and collegiate ice-hockey players. Seventeen ice-hockey players were randomly assigned to receive creatine (0.3 g/kg body mass/day for 5 days) or placebo. Before and after supplementation players performed repeated sprints to exhaustion on a skating treadmill (repeated 10-s sprints; 30-s rest between sprints) while blood lactate was simultaneously collected. The time to exhaustion on the treadmill test was calculated as total amount of time, including partial intervals, before the player reached exhaustion. Players were also tested for peak torque and average power during knee extension/flexion (3 sets of 10 reps; 60-s rest between sets) on an isokinetic dynamometer at 60 degrees/s. The change in time to exhaustion from before to after supplementation averaged 21 ± 7 s in the creatine group and 22 ± 13 s in the placebo group, with no differences between groups. Likewise, there were no differences between groups for changes in isokinetic peak torque and average power. There were no differences between groups over time for blood lactate changes during the repeated sprints on the treadmill. It was concluded that creatine was not effective for improving performance in these ice-hockey players [06271].

*Effect on sprint running*

The aim of one study was to examine the effects of short-term creatine monohydrate supplementation on multiple sprint running performance. Using a double-blind research design, 42 physically active men completed a series of 3 indoor multiple sprint running trials (15 x 30 m repeated at 35-second intervals). After the first 2 trials (familiarization and baseline), subjects were matched for fatigue score before being randomly assigned to 5 days of either creatine (4/day x 5 g creatine monohydrate + 1 g maltodextrin) or placebo (4/day x 6 g maltodextrin) supplementation. Sprint times were recorded via twin-beam photocells, and earlobe blood samples were drawn to evaluate posttest lactate concentrations. Relative to placebo, creatine supplementation resulted in a 0.7 kg increase in body mass and a 0.4 percent reduction in body fat. There were no significant between-group differences in multiple sprint measures of fastest time, mean time, fatigue, or posttest blood lactate concentration. Despite widespread use as an ergogenic aid in sport, the results of the study suggest that creatine monohydrate supplementation conveys no benefit to multiple sprint running performance [06272].

*During sleep deprivation*

The effect of creatine supplementation and sleep deprivation, with intermittent moderate-intensity exercise, on cognitive and psychomotor performance, mood state, effort and salivary concentrations of cortisol and melatonin were examined. Subjects were divided into a creatine supplementation group and a placebo group. They took 5 g of creatine monohydrate or a placebo, dependent on their group, four times a day for 7 days
immediately prior to the experiment. They undertook tests examining central executive functioning, short-term memory, choice reaction time, balance, mood state and effort at baseline and following 18-, 24- and 36-h sleep deprivation, with moderate intermittent exercise. Saliva samples were taken prior to each set of tests. A group x time analysis of covariance, with baseline performance the covariate, showed that the creatine group performed significantly better than the placebo group on the central executive task but only at 36 h. The creatine group demonstrated a significant linear improvement in performance of the central executive task throughout the experiment, while the placebo group showed no significant effects. There were no significant differences between the groups for any of the other variables. A significant main effect of time was found for the balance test with a linear improvement being registered. Cortisol concentrations on Day 1 were significantly higher than on Day 2. Mood significantly deteriorated up to 24 h with no change from 24 to 36 h. Effort at baseline was significantly lower than in the other conditions. It was concluded that, during sleep deprivation with moderate-intensity exercise, creatine supplementation only affects performance of complex central executive tasks [06273].

Side effects

Allegations about side effects of creatine supplementation by athletes have been published in the popular media and scientific publications. One of the purported effects of oral creatine supplementation is increased muscle mass. A review of the literature reveals a 1.0 to 2.3 percent increase in body mass, which is attributed to fat-free mass and, more specifically, to skeletal-muscle mass. Although it is unlikely that water retention can completely explain these changes, increase in muscle-protein synthesis has never been observed after creatine supplementation. Indirect evidence based on mRNA analyses suggests that transcription of certain genes is enhanced. Although the effect of creatine on muscle-protein synthesis seems irrefutable according to advertising, this allegation remains under debate in the scientific literature. The kidneys appear to maintain their functionality in healthy subjects who supplement with creatine, even over several months. The authors, however, thought that creatine supplementation should not be used by an individual with preexisting renal disease and that risk should be evaluated before and during any supplementation period. Even if there is a slight increase in mutagenic agents (methyamine and formaldehyde) in urine after a heavy load of creatine (20 g/day), their excretion remains within a normal range. No data are currently available regarding the potential production of heterocyclic amines with creatine supplementation. In summary, the major risk for health is probably associated with the purity of commercially available creatine [06274].

The main aim of one study was to investigate the effects of two different creatine-supplementation protocols on incidence of gastrointestinal (GI) distress in top-level athletes. Data were collected from 59 top-level male soccer players who were allocated in a double-blind design to three randomly assigned trials: ingesting creatine supplement (2 x 5-g doses or 1 x 10-g dose) or placebo for 28 days. In order to assess potential side effects of the supplementation regimen, all subjects were instructed to report any adverse effects of supplementation on their GI system. Survey questions covered perceived side effects on GI system linked with creatine supplementation. In all three treatment groups, the most frequent GI complaints were diarrhoea (39 %), stomach upset (24 %), and belching (17 %). It was not found a significant difference between incidence of GI distress symptoms between 5 gram doses and the placebo group after the survey. Yet, significant differences were found for incidence of diarrhoea between the 5 and 10 gram groups (29 % vs 56 %, respectively). Moreover, diarrhoea was significantly more frequent in the 10 gram group as compared with the placebo group (56 % vs 35 %). There is no reason to believe that short-term oral creatine supplementation for 28 days has any detrimental effect on the GI tract if taken in a recommended amount (10 g per day in two equal doses). The risk of diarrhoea may be
increased, however, following intake of 10 grams of creatine per single serving [08413].

**Safe levels**
Creatine monohydrate (creatine) has become an increasingly popular ingredient in dietary supplements, especially sports nutrition products. A large body of human and animal research suggests that creatine does have a consistent ergogenic effect, particularly with exercises or activities requiring high intensity short bursts of energy. Human data are primarily derived from three types of studies: acute studies, involving high doses (20 g/d) with short duration (<1 week), chronic studies involving lower doses (3-5 g/d) and longer duration (1 year), or a combination of both. Systematic evaluation of the research designs and data do not provide a basis for risk assessment and the usual safe Upper Level of Intake (UL) derived from it unless the newer methods described as the Observed Safe Level (OSL) or Highest Observed Intake (HOI) are utilized. The OSL risk assessment method indicates that the evidence of safety is strong at intakes up to 5 g/d for chronic supplementation, and this level is identified as the OSL. Although much higher levels have been tested under acute conditions without adverse effects and may be safe, the data for intakes above 5 g/d are not sufficient for a confident conclusion of long-term safety [06275].

**Creatine and bicarbonate**
Creatine and sodium bicarbonate supplementation independently increase exercise performance, but it remains unclear whether combining these 2 supplements is more beneficial on exercise performance. The purpose of one study was to evaluate the impact of combining creatine monohydrate and sodium bicarbonate supplementation on exercise performance. Thirteen healthy, trained men (21) completed 3 conditions in a double-blinded, crossover fashion: (a) Placebo (Pl; 20 g maltodextrin), (b) Creatine (Cr; 20 g), and (c) Creatine plus sodium bicarbonate (Cr + Sb). Each condition consisted of supplementation for 2 days followed by a 3-week washout. Peak power, mean power, relative peak power, and bicarbonate concentrations were assessed during six 10-second repeated Wingate sprint tests on a cycle ergometer with a 60-second rest period between each sprint. Compared with Pl, relative peak power was significantly higher in Cr (4 %) and Cr + Sb (7 %). Relative peak power was significantly lower in sprints 4-6, compared with that in sprint 1, in both Pl and Cr. However, in Cr + Sb, sprint 6 was the only sprint significantly lower compared with sprint 1. Pre-Wingate bicarbonate concentrations were significantly higher in Cr + Sb (10 %), compared with in Pl and Cr, and mean concentrations remained higher after sprint 6, although not significantly. Combining creatine and sodium bicarbonate supplementation increased peak and mean power and had the greatest attenuation of decline in relative peak power over the 6 repeated sprints. These data suggest that combining these 2 supplements may be advantageous for athletes participating in high-intensity, intermittent exercise [13693].

**Experimental**
Thirty-six male rats were used; divided into 6 groups (n=6): saline; creatine (Cr); eccentric exercise (EE) plus saline 24 h (saline + 24 h); eccentric exercise plus Cr 24 h (Cr + 24 h); eccentric exercise plus saline 48 h (saline + 48 h); and eccentric exercise plus Cr 48 h (Cr + 48 h). Cr supplementation was administered as a solution of 300 mg/kg body weight/day in 1 mL water, for two weeks, before the eccentric exercise. The animals were submitted to one downhill run session at 1.0 km/h until exhaustion. Twenty-four and forty-eight hours after the exercise, the animals were killed, and the quadriceps were removed. Creatine kinase levels, superoxide production, thiobarbituric acid reactive substances (TBARS) level, carbonyl content, total thiol content, superoxide dismutase, catalase, glutathione peroxidase,
interleukin-1beta (IL-1beta), nuclear factor kappa B (NF-kb), and tumour necrosis factor (TNF) were analysed. Cr supplementation neither decreases Cr kinase, superoxide production, lipoperoxidation, carbonylation, total thiol, IL-1beta, NF-kb, or TNF nor alters the enzyme activity of superoxide dismutase, catalase, and glutathione peroxides in relation to the saline group, respectively. There are positive correlations between Cr kinase and TBARS and TNF-alpha 48 hours after eccentric exercise. The present study suggests that Cr supplementation does not decrease oxidative stress and inflammation after eccentric contraction [13692].

**Carnitine**

The purpose of one study was to investigate the effects of acute L-Carnitine intake on badminton players' metabolic and blood lactate values. A total of 16 Turkish national badminton players (8 male, 8 female) were voluntarily participated. No significant differences were found between first (without L-Carnitine intake) and second (with L-Carnitine intake) measurements of female participants as regards to all measured parameters. There was a significant difference in EMHR (exercise maximum heart rate) of males between two measurements. However the differences in other parameters were not significant. Anaerobic threshold values of female subjects were not significant difference. Respiratory exchange ratio of males was significantly different at anaerobic threshold. These results show that L-carnitine intake one hour prior to the exercise has no effect on the metabolic and blood lactate values of badminton players [08414].

Ninety-five per cent of the body’s carnitine (3-hydroxy-4-N,N,N-trimethylaminobutyric acid; C7H15NO3) store (about 25 g) exists within skeletal muscle where it plays a central role in fat and carbohydrate oxidation, particularly during exercise. The recommended upper limit of L-carnitine supplementation is 2 g/day, but no adverse effects were reported following feeding up to 6 g/day for 1 year. The main food source of carnitine is meat. Non-vegetarians ingest 1 mg/kg of dietary carnitine per day, whereas strict vegetarians ingest around 0.01 mg/kg. Research has been directed towards supplementing dietary L-carnitine to improve exercise performance. However, neither oral (2-6 g/day for 1 day to 4 months) nor intravenous (up to 65 mg/kg) L-carnitine administration has been found to alter fuel metabolism during exercise or, more importantly, increase muscle carnitine content in humans. Despite this, L-carnitine feeding as a tool to promote apparent fat loss remains the foundation of a multimillion dollar dietary supplement industry in the present day. More recently, intravenous infusion of L-carnitine along with insulin (to stimulate Na+ dependent muscle carnitine transport) has been found to increase muscle total carnitine content by about 15 percent in healthy volunteers, and to have a measurable effect on muscle fuel metabolism at rest. This stimulatory effect on muscle carnitine accumulation occurred in the physiological range for serum insulin concentration (50-90 mU/l). Furthermore, feeding L-carnitine (3 g/d) together with carbohydrate (500 ml solution containing 94 g of simple sugars) for 2 weeks increased whole-body carnitine retention compared with ingestion of L-carnitine alone. However, because orally administered L-carnitine has a poor bioavailability (<15 % for a 2-6 g dose), it is likely that this supplementation regimen would take about 100 days to increase muscle carnitine content by about 10 percent. Further research is required to determine the impact that an insulin-mediated increase in muscle carnitine content has on muscle fuel metabolism and performance during exercise [09344].

Carnosine is found in high concentrations in skeletal muscles, where it is involved in several physiological functions. The muscle carnosine content measured within a population can vary by a factor 4. The aim of one study was to further characterize suggested determinants
of the muscle carnosine content (diet, gender and age) and to identify new determinants (plasma carnosinase activity and testosterone). It was investigated a group of 149 healthy subjects, which consisted of 94 men (12 vegetarians) and 55 women. Muscle carnosine was quantified in M. soleus, gastrocnemius and tibialis anterior using magnetic resonance proton spectroscopy and blood samples were collected to determine CNDP1 genotype, plasma carnosinase activity and testosterone concentration. Compared to women, men have 36, 28 and 82 percent higher carnosine concentrations in M. soleus, gastrocnemius and tibialis anterior muscle, respectively, whereas circulating testosterone concentrations were unrelated to muscle carnosine levels in healthy men. The carnosine content of the M. soleus is negatively related to the subjects’ age. Vegetarians have a lower carnosine content of 26 percent in gastrocnemius compared to omnivores. In contrast, there is no difference in muscle carnosine content between omnivores with a high or low ingestion of beta-alanine. Muscle carnosine levels are not related to the polymorphism of the CNDP1 gene or to the enzymatic activity of the plasma carnosinase. In conclusion, neither CNDP1 genotype nor the normal variation in circulating testosterone levels affects the muscular carnosine content, whereas vegetarianism, female gender and increasing age are the factors associated with reduced muscle carnosine stores [10410].

Twenty nonvegetarian active males were pair-matched and randomly assigned to receive 2 g of L-carnitine L-tartrate (LC) or placebo per day for 2 weeks. Participants exercised for 90 min at 70 percent VO₂ max after 2 days of a prescribed diet (13.6 ± 1.6 MJ, 57 % carbohydrate, 15 % protein, 26 % fat, 2 % alcohol) before and after supplementation. Results indicated no change in carbohydrate oxidation, nitrogen excretion, branched-chain amino acid oxidation, or plasma urea during exercise between the baseline and end of supplementation in either group. After 2 weeks of carnitine supplementation the plasma ammonia response to exercise tended to be suppressed, with no change in the placebo group. The data indicate that 2 weeks of carnitine supplementation does not affect fat, carbohydrate, and protein contribution to metabolism during prolonged moderate-intensity cycling exercise. The tendency toward suppressed ammonia accumulation, however, indicates that oral carnitine supplementation might have the potential to reduce the metabolic stress of exercise or alter ammonia production or removal, which warrants further investigation [09349].

Infusion of carnitine has been observed to increase non-oxidative glucose disposal in several studies, but the effect of oral carnitine on glucose disposal in non-diabetic lean versus overweight/obese humans has not been examined. This study examined the effects of 14 days of L-carnitine L-tartrate oral supplementation (LC) on blood glucose, insulin, non-esterified fatty acids (NEFA) and GLP-1 responses to an oral glucose tolerance test (OGTT). Sixteen male participants were recruited (lean, n=8, and overweight/obese, n=8). After completing a submaximal predictive exercise test, participants were asked to attend three experimental sessions. These three visits were conducted in the morning to obtain fasting blood samples and to conduct 2 h OGTTs. The first visit was a familiarisation trial and the final two visits were conducted 2 weeks apart following 14 days of ingestion of placebo (PL, 3 g glucose/day) and then LC (3 g LC/day) ingested as two capsules 3x/day with meals. On each visit, blood was drawn at rest, at intervals during the OGTT for analysis of glucose, insulin, non-esterified fatty acids (NEFA) and total glucagon-like peptide-1 (GLP-1). Data obtained were used for determination of usual insulin sensitivity indices (HOMA-IR, AUC glucose, AUC insulin, 1st phase and 2nd phase β-cell function, estimated insulin sensitivity index and estimated metabolic clearance rate). Data were analysed using RMANOVA and post hoc comparisons where appropriate. There was a significant difference between groups for body mass, percent fat and BMI with no significant difference in age and height. Mean (SEM) plasma glucose concentration at 30 min was significantly lower in the lean group on the LC trial compared with PL. Conversely, plasma glucose concentration was not different at
30 min, but was significantly higher at 90 min in the overweight/obese group on the LC trial LC; mmol/L). Estimated first phase and second phase beta-cell function both tended to be greater following LC in the lean group only. No effects of LC were observed on NEFA or total GLP-1 response to OGGT. It is concluded that LC supplementation induces changes in blood glucose handling/disposal during an OGTT, which is not influenced by GLP-1. The glucose handling/disposal response to oral LC is different between lean and overweight/obese suggesting that further investigation is required. LC effects on gastric emptying and/or direct ‘insulin-like’ actions on tissues should be examined in larger samples of overweight/obese and lean participants, respectively [11401].

 Ninety-five percent of the body carnitine pool resides in skeletal muscle where it plays a vital role in fuel metabolism. However, vegetarians obtain negligible amounts of carnitine from their diet. It was tested the hypothesis that muscle carnitine uptake is elevated in vegetarians compared with that in nonvegetarians to maintain a normal tissue carnitine content. Forty-one young (aged 22 years) vegetarian and nonvegetarian volunteers participated in 2 studies. The first study consisted of a 5-h intravenous infusion of L-carnitine while circulating insulin was maintained at a physiologically high concentration (170 mU/L; to stimulate muscle carnitine uptake) or at a fasting concentration (6 mU/L). The second study consisted of oral ingestion of 3 g L-carnitine. Basal plasma total carnitine concentration, 24-h urinary total carnitine excretion, muscle total carnitine content, and muscle carnitine transporter (organic cation transporter 2, OCTN2) messenger RNA and protein expressions were 16 percent, 58 percent, 17 percent, 33 percent and 37 percent lower, respectively, in vegetarian volunteers. However, although nonvegetarians showed a 15 percent increase in muscle TC during L-carnitine infusion with hyperinsulinemia, L-carnitine infusion in the presence or absence of hyperinsulinemia had no effect on muscle TC content in vegetarians. Nevertheless, 24-h urinary total carnitine excretion was 55 percent less in vegetarians after L-carnitine ingestion. It was concluded that vegetarians have a lower muscle total carnitine and reduced capacity to transport carnitine into muscle than do nonvegetarians, possibly because of reduced muscle OCTN2 content. Thus, the greater whole-body carnitine retention observed after a single dose of L-carnitine in vegetarians was not attributable to increased muscle carnitine storage [11402].

The effects of 15 d of supplementation with L-carnitine L-tartrate (LC) on metabolic responses to graded-intensity exercise under conditions of altered substrate availability were examined. Fifteen endurance-trained male athletes undertook exercise trials after a 2-d high-carbohydrate diet (60 % CHO, 25 % fat) at baseline (D0), on Day 14 (D14), and after a single day of high fat intake (15 % CHO, 70 % fat) on Day 15 (D15) in a double-blind, placebo-controlled, pair-matched design. Treatment consisted of 3 g LC (2 g L-carnitine/d; n=8) or placebo (P, n=7) for 15 d. Exercise trials consisted of 80 min of continuous cycling comprising 20-min periods at each of 20, 40, 60, and 80 percent of VO2peak. There was no significant difference between whole-body rates of CHO and fat oxidation at any workload between D0 and D14 trials for either the P or LC group. Both groups displayed increased fat and reduced carbohydrate oxidation between the D14 and D15 trials. During the D15 trial, heart rate and blood glucose concentration were lower during exercise in the LC group than in P. These responses suggest that LC may induce subtle changes in substrate handling in metabolically active tissues when fatty-acid availability is increased, but it does not affect whole-body substrate utilization during short-duration exercise at the intensities studied [11534].

The enhancement of fat oxidation during exercise is an aim for both recreational exercising individuals and endurance athletes. Nutritional status may explain a large part of the variation in maximal rates of fat oxidation during exercise. One review revealed novel insights into nutritional manipulation of substrate selection during exercise, explaining putative
mechanisms of action and evaluating the current evidence. Lowering the glycaemic index of the pre-exercise meal can enhance lipid utilisation by up to 100 percent through reduced insulin concentrations, although its application may be restricted to specific training sessions rather than competition. Chronic effects of dietary glycaemic index are less clear and warrant future study before firm recommendations can be made. A flurry of recent advances has overthrown the conventional view of l-carnitine supplementation, with skeletal muscle uptake possible under certain dietary conditions and providing a strategy to influence energy metabolism in an exercise intensity-dependent manner. Use of non-carbohydrate nutrients to stimulate muscle l-carnitine uptake may prove more beneficial for optimising lipid utilisation, but this requires more research. Studies investigating fish oil supplementation on fat oxidation during exercise are conflicting. In spite of some strong putative mechanisms, the only crossover trial showed no significant effect on lipid use during exercise. Carnitine may increase NEFA availability although it is not clear whether these effects occur. Carnitine and caffeine can increase NEFA availability under certain circumstances which could theoretically enhance fat oxidation, yet strong experimental evidence for this effect during exercise is lacking. Co-administration of nutrients to maximise their effectiveness needs further investigation.

The effects of 15 days of supplementation with L-carnitine L-tartrate (LC) on metabolic responses to graded-intensity exercise under conditions of altered substrate availability were examined. Fifteen endurance-trained male athletes undertook exercise trials after a 2-d high-carbohydrate diet (60 % CHO, 25 % fat) at baseline (D0), on day 14 (D14), and after a single day of high fat intake (15 % CHO, 70 % fat) on day 15 (D15) in a double-blind, placebo-controlled, pair-matched design. Treatment consisted of 3 g LC (2 g L-carnitine/d; n=8) or placebo (P, n=7) for 15 days. Exercise trials consisted of 80 min of continuous cycling comprising 20-min periods at each of 20, 40, 60, and 80 percent VO2peak. There was no significant difference between whole-body rates of CHO and fat oxidation at any workload between D0 and D14 trials for either the P or LC group. Both groups displayed increased fat and reduced carbohydrate oxidation between the D14 and D15 trials. During the D15 trial, heart rate and blood glucose concentration were lower during exercise in the LC group than in P. These responses suggest that LC may induce subtle changes in substrate handling in metabolically active tissues when fatty-acid availability is increased, but it does not affect whole-body substrate utilization during short-duration exercise at the intensities studied.

This study examined the effect of acute L-carnitine loading on the endurance performance of footballers. Measurements were performed on 26 candidate professional footballers who volunteered to take part in the study. Athletes were given a glass of fruit juice one hour before applying L-carnitine with the double blind method. Then 12 participants were given 3 gr of L-carnitine (LK-3) and the remaining 14 were given 4 gr (LK-4). Athletes began the exercise test at a running speed of 8 km/h, and then continued at 10km/h. The speed was increased 1 km/h every three minutes and the test continued until the subject chose to quit. Heart rate was registered using a portable telemetric heart rate monitor during the test. Blood samples were taken from the eardrums of the footballers both before the test and before the speed increase (during the 1-minute intervals), and the lactate (La) concentration was measured enzymatically. The test was repeated after one week as a group of placebos (P-3 and P-4). The result showed that the running speeds corresponding to specific La concentrations were increased and La and heart rate responses to the running speeds were decreased in both supplemented groups compared to placebos. A significant reduction in heart rate was found in LK-4 and P-4. When the Borg responses to the running speeds were analyzed, a significant difference was found in both supplemented groups. The results show that 3 or 4 gr L-carnitine taken before physical exercise prolonged exhaustion.
A huge range of supplements claims to enhance sports performance by affecting body composition – either by increasing muscle mass and/or reducing body fat. Supplements in the broad “weight loss” category include caffeine, l-carnitine, chromium picolinate, CLA (conjugated linoleic acid), dairy/calcium supplements, HMB (beta-hydroxy-beta-methylbutyrate), hydroxycut, leucine, phenylalanine, protein supplements and tyrosine. L-carnitine is synthesised from the amino acids lysine and methionine, and is found naturally in the human diet, particularly in red meat and dairy products. It has been suggested that L-carnitine supplementation can increase fatty acid transport into mitochondria, leading to an increase in fatty acid oxidation, and hence the proposed potential benefit for weight management [13678].

**Effect on post-resistance-exercise (RE)**

The purpose of one investigation was to determine the effects of 3 weeks of L-carnitine L-tartrate (LCLT) supplementation and post-resistance-exercise (RE) feeding on hormonal and androgen receptor (AR) responses. Ten resistance-trained men (mean age, 22) supplemented with LCLT (equivalent to 2 g of L-carnitine per day) or placebo (PL) for 21 d, provided muscle biopsies for AR determinations, then performed two RE protocols: one followed by water intake, and one followed by feeding (8 kcal.kg body mass, consisting of 56 % carbohydrate, 16 % protein, and 28 % fat). RE protocols were randomized and included serial blood draws and a 1-h post-RE biopsy. After a 7-d washout period, subjects crossed over, and all experimental procedures were repeated. LCLT supplementation upregulated preexercise AR content compared with PL. RE increased significantly AR content compared with pre-RE values in the PL trial only. Post-RE feeding significantly increased AR content compared with baseline and water trials for both LCLT and PL. Serum total testosterone concentrations were suppressed significantly during feeding trials with respect to corresponding water and pre-RE values. Luteinizing hormone demonstrated subtle, yet significant changes in response to feeding and LCLT. In summary, the data demonstrated that feeding after RE increased AR content, which may result in increased testosterone uptake, and thus enhanced luteinizing hormone secretion via feedback mechanisms; and LCLT supplementation upregulated AR content, which may promote recovery from RE [06281].

**Side effects**

Carnitine is a conditionally essential amino acid-like compound involved in the transport of long-chain fatty acids into the mitochondria during the beta-oxidation process. Carnitine has become an increasingly popular ingredient in dietary supplements, especially weight loss and some sports nutrition products. A number of clinical trials have been conducted examining the effect of carnitine supplementation on weight loss and energy balance. Regarding safety, systematic evaluation of the research designs and data do not provide a basis for risk assessment and the usual safe upper level of intake (UL) derived from it unless the newer methods described as the observed safe level (OSL) or highest observed intake (HOI) are utilized. The OSL risk assessment method indicates that the evidence of safety is strong at intakes up to 2000mg/day L-carnitine equivalents for chronic supplementation, and this level is identified as the OSL. Although much higher levels have been tested without adverse effects and may be safe, the data for intakes above 2000mg/day are not sufficient for a confident conclusion of long-term safety [06282].

Intestinal microbiota metabolism of choline and phosphatidylcholine produces trimethylamine (TMA), which is further metabolized to a proatherogenic species, trimethylamine-N-oxide (TMAO). It was demonstrated that metabolism by intestinal microbiota of dietary L-carnitine,
a trimethylamine abundant in red meat, also produces TMAO and accelerates atherosclerosis in mice. Omnivorous human subjects produced more TMAO than did vegans or vegetarians following ingestion of L-carnitine through a microbiota-dependent mechanism. The presence of specific bacterial taxa in human feces was associated with both plasma TMAO concentration and dietary status. Plasma L-carnitine levels in subjects undergoing cardiac evaluation (n=2,595) predicted increased risks for both prevalent cardiovascular disease (CVD) and incident major adverse cardiac events (myocardial infarction, stroke or death), but only among subjects with concurrently high TMAO levels. Chronic dietary L-carnitine supplementation in mice altered cecal microbial composition, markedly enhanced synthesis of TMA and TMAO, and increased atherosclerosis, but this did not occur if intestinal microbiota was concurrently suppressed. In mice with an intact intestinal microbiota, dietary supplementation with TMAO or either carnitine or choline reduced in vivo reverse cholesterol transport. Intestinal microbiota may thus contribute to the well-established link between high levels of red meat consumption and CVD risk [13679].

Methylhexaneamine (DMAA)

1,3 dimethylamylamine or methylexaneamine (DMAA) is a synthetic pharmaceutical patented in the 1940s as a nasal decongestant which can be used as a recreational stimulant. Alleged to occur in nature, DMAA has become a widely used ingredient in sports food supplements, despite its status as a doping agent and concerns over its safety. There is now some doubt as to whether it can be sourced naturally or whether it actually occurs naturally at all. The presence of DMAA was investigated by high performance liquid chromatography (HPLC) in extracts of the leaves and stems of four geranium species and of three well-known cultivars. The amounts of DMAA in commercial geranium (Pelargonium graveolens) oil and the leading sports supplement which uses the ingredient were also measured. DMAA was not found in any of the leaves or stems or in the commercial geranium oil included in this study. Approximately 30 mg per daily dose was found in the food supplement. Therefore, the amount of DMAA found in the supplement is most unlikely to have been sourced in nature, and it must be concluded that synthetic DMAA, known to be capable of causing severe adverse physiological effects, has been added [12436].

A number of supplements which are advertised for weight loss contain compounds which can be classified as stimulants or are related to known stimulants. Stimulants have been used as anorectic substances to aid in appetite suppression by the pharmaceutical industry for some time with compounds such as phentermine, sibutramine, benfluorex, diethylpropion, amphetamine, benzphetamine, and phenethylamine being available and included on the World Anti-Doping Agency (WADA) Prohibited List. Other stimulants such as benzylpiperazine, phenpromethamine, synephrine, and phenylethylamines have also been sold as ‘supplements’ or components of supplements and have caused athletes to return an adverse analytical finding with subsequent sanctions. This seems to be a trend that has recently surfaced where weak stimulants are added to supplements to allow them to be advertised as slimming agents. Recently the use of 2-amino-4-methylhexane (1,3-dimethylpentylamine, methylhexaneamine) has become widespread in such supplements resulting in a plethora of adverse findings since its detection has been published and implemented by anti-doping laboratories. Invariably the athletes have stated that they were unaware of the material's presence in the preparation and this plea has considerable weight, considering the numerous variations in the nomenclature used to describe this component. WADA's Explanatory Notes on the 2011 Prohibited List state. Many contain methylhexaneamine under one of many pseudonyms including Geranamine, geranium oil or extract, or a number of chemical names such as 1,3-dimethylpentylamine. This has resulted in many athletes returning an adverse finding and having sanctions imposed. Other stimulants such
as caffeine, phenpromethamine, synephrine, and phenethylamines are also to be found in supplements. One communication shows that geranium oils do not contain methylhexaneamine and that products labelled as containing geranium oil but which contain methylhexaneamine can only arise from the addition of synthetic material. Since the usual dose of methylhexaneamine is large, the drug is excreted at relatively high amounts for more than 29 h, the time for which the excretion was studied. One of the attempts to try to conceal the presence of this compound is to refer to its presence under the name Geranamine and imply that it comes from geranium oil. The concern that geranium oil may contain methylhexaneamine has also been raised and so any product listing geranium oil could be used as a defence. Geranium oils appear to be mainly obtained from Pelargonium graveolens which is a popular species of the geranium plant used in the production of geranium oil. Extraction of the oil can be performed by steam distillation or a cold-pressed process. A previous study of the chemical components in geranium oil by showed the presence of methylhexaneamine in geranium oil with a relative abundance of 0.66 percent. This is the only such reference and is often quoted when referring to methylhexaneamine. The aim of one paper was to determine the presence/absence of methylhexaneamine in a selection of geranium oils by GC-MS compared to authentic standard. Geranium oils from companies which had been extracted from various species by cold-pressing or steam distillation procedures were purchased. It should be noted that methylhexaneamine is a volatile substance and is likely to have been lost through a steam distillation extraction, so cold-pressed material had the best chance of retaining this compound. Methylhexaneamine was not found in any of the geranium oils described. The spectrum of methylhexaneamine itself consists mainly of one ion m/z 44. Since very many substances possess a spectrum similar to this and this ion is of poor diagnostic value, it is reasonable to assert that the assignment was incorrect. The paper also performs quantification based on the TIC integration without calibration to any standards so their quantitative values will also have a very large uncertainty. Four supplements – Adrenaline, Bang, Lipo 6 Black, and Phenadrine – were analyzed and the stimulant ingredients were identified as methylhexaneamine (in Adrenaline), caffeine (in Bang), alpha- and beta-phenethylamine (in Lipo 6 Black), and methylhexaneamine and phenpromethamine (in Phenadrine). This is interesting, considering that the labels indicated they had mixtures of all these ingredients! The excretion study for the supplement Phenadrine was undertaken to provide an excretion urine set for methylhexaneamine. Methylhexaneamine is easily detected as the parent compound in the urine. The concentration of methylhexaneamine is not corrected for specific gravity but the data shows that it remains very high for more than 29 h (>3 ug/mL) which would allow it to be detected for several days if values above 50 ng/mL are reported [11590].

1,3 dimethylamylamine or methylexaneamine (DMAA) is a synthetic pharmaceutical patented in the 1940s as a nasal decongestant which can be used as a recreational stimulant. Therefore, the amount of DMAA found in the supplement is most unlikely to have been sourced in nature, and it must be concluded that synthetic DMAA, known to be capable of causing severe adverse physiological effects, has been added [13698].

Methylhexaneamine (MHA) is a stimulant that is added to dietary supplements and its safety...
is an on-going debate, prompting the World Anti-Doping Agency to add it to the 2010 prohibited list. Gas chromatography-low resolution mass spectrometry (GC-MS) with electron ionization (EI) requires derivatization to convert MHA into a less volatile compound, and a 2-3 min solvent delay to prevent filament damage. Without derivatization, the EI mass spectrum of MHA, which exhibits an abundant immonium ion at m/z 44 and no other fragment ions with relative intensity >10 percent, is very similar to the EI mass spectra of 2-aminoheptane, 1,4-dimethylamylamine, and n-hexylmethylamine. When using derivatization with trifluoroacetic anhydride (TFAA) and GC-high resolution time-of-flight mass spectrometry with soft ionization, the derivatized MHA diastereoisomers can be distinguished from the trifluoroacetyl-derivatives of 1-aminoheptane, 2-aminoheptane, 1,4-dimethylamylamine (1,4-DMAA) and n-hexylmethylamine. Several nutritional supplements were analysed for MHA by this technique and the results of the measurements were presented [13699].

Methylhexaneamine (MHA) is a stimulant that is added to dietary supplements and its safety is an on-going debate, prompting the World Anti-Doping Agency to add it to the 2010 prohibited list. Gas chromatography-low resolution mass spectrometry (GC-MS) with electron ionization (EI) requires derivatization to convert MHA into a less volatile compound, and a 2-3 min solvent delay to prevent filament damage. Several nutritional supplements were analysed for MHA by this technique [13700].

Within the class of stimulating agents, particularly methylhexaneamine (1,3-dimethylamylamine, DMAA) has been subject of much discussion and research recently, mostly concerning the question as to its natural or non-natural origin and the more than 300 AAFs as recorded in 2012. It was hence a major goal to identify whether the substance is produced by plants and, if so, to which extent. Since health issues as well as deaths were put into context with DMAA (ab)use, studies on its pharmacokinetics and the detection of this compound in doping control as well as nutritional supplements has become a priority in different fields of analytical chemistry. While most analytical methodologies used in the aforementioned studies were conventional GC- or LC-MS/(MS) approaches, the utility of a GC-interfaced soft ionization source (referred to as microplasma photoionization, MPPI) with TOF analyzer for detecting and characterizing DMAA was presented. Employing trifluoroacetylation, the stereoisomers of DMAA were baseline separated on a commonly used HP5MS GC column (30 x 0.25 mm, film thickness 0.25 microm) and the respective Ar-MPPI spectra yielded diagnostic fragment ions with accurate masses allowing to identify the substance in five different nutritional supplements [13009].

Dimethylamylamine (DMAA) is a sympathomimetic amine found in weight-loss/workout supplements or used as an appetite suppressant. DMAA is a stimulant that is banned by the World Anti-Doping Agency (WADA). Adverse health effects as well as fatalities have been implicated with its use. Direct analysis in real time mass spectrometry (DART-MS) is an ambient ionization method that was employed to rapidly identify the presence of DMAA in various samples without any extraction or preparations whatsoever. DMAA was first identified in supplements, sampled directly in their solid forms. Furthermore, DMAA was detected directly in urine over 48 h as a means of indicating recent abuse of the substance. DART-MS analysis is instantaneous, and coupled with the high mass accuracy associated
with the time-of-flight mass analyzer, results in unequivocal identification of the presence of DMAA. These features demonstrate DART-MS as an attractive potential alternative screening method for the presence of drugs and medications or for toxicological investigations [13701].

1,3-dimethylamylamine (DMAA) has been a component of dietary supplements and is also used within "party pills," often in conjunction with alcohol and other drugs. Ingestion of higher than recommended doses results in untoward effects including cerebral hemorrhage. To our knowledge, no studies have been conducted to determine both the pharmacokinetic profile and physiologic responses of DMAA. Eight men reported to the lab in the morning following an overnight fast and received a single 25 mg oral dose of DMAA. Blood samples were collected before and through 24 hours post-DMAA ingestion and analyzed for plasma DMAA concentration using high-performance liquid chromatography-mass spectrometry. Resting heart rate, blood pressure, and body temperature was also measured. One subject was excluded from the data analysis due to abnormal DMAA levels. Analysis of the remaining seven participants showed DMAA had an oral clearance of 20 ± 5 L/hr, an oral volume of distribution of 236 ± 38 L, and terminal half-life of 8.5 ± 1.9 hr. Lag time, the delay in appearance of DMAA in the circulation following extravascular administration, varied among participants but averaged approximately 8 minutes (0.14 ± 0.13 hr). The peak DMAA concentration for all subjects was observed within 3-5 hours following ingestion and was very similar across subjects, with a mean of about 70 ng/mL. Heart rate, blood pressure, and body temperature were largely unaffected by DMAA treatment. These are the first data to characterize the oral pharmacokinetic profile of DMAA. These findings indicate a consistent pattern of increase across subjects with regards to peak DMAA concentration, with peak values approximately 15-30 times lower than those reported in case studies linking DMAA intake with adverse events. Finally, a single 25 mg dose of DMAA does not meaningfully impact resting heart rate, blood pressure, or body temperature [13702].

1,3-Dimethylamylamine (DMAA) is a substance with amphetamine-like effects found in bodybuilding and weight-loss products and recreational drugs (also marketed as methylhexanamine, dimethylpentylamine and geranium). DMAA was recently banned in Australia and other countries owing to toxicity, lack of health benefits, and concerns about long-term safety and potential for misuse [13703].

**Gluthatione**

Halogenated organic compounds, such as 1-bromopentane (1-BPT), are used as cleaning agents, synthesis agents, or extraction solvents in the workplace. In one study, glutathione (GSH) conjugation and hepatotoxicity induced by 1-BPT were investigated in female mice. S-Bromopentyl GSH, S-bromopentyl cysteine, and mono-hydroxypentyl mercapturic acid were identified in liver by liquid chromatography-electrospray ionization tandem mass spectrometry. Oral treatment of mice with 1-BPT at 1500 mg/kg produced maximum GSH conjugates at 6 h after treatment. For hepatotoxicity tests, the animals were treated orally with 1-BPT at 375, 750, or 1500 mg/kg in corn oil once for a dose response study or at 1500 mg/kg for 6, 12, 24, or 48 h for a time course study. 1-BPT dose-dependently increased serum activity of ALT and AST and decreased hepatic GSH levels, peaking at 6 and 12 h after treatment. 1-BPT (750 and 1500 mg/kg) also significantly increased the hepatic content of malondialdehyde. Thus, 1-BPT could cause hepatotoxicity and depletion of GSH content by forming GSH conjugates, presenting a toxicity mechanism and potential biomarkers for low molecular weight haloalkanes [08421].
Choline bitartrate plus acetylcholine

Choline is widely distributed in food fats, especially liver, egg yolk, peanuts, dairy products, human milk and phospholipids. The body synthesises choline, and a deficiency due to dietary inadequacy is unlikely. Choline is a precursor for the neurotransmitter, acetylcholine (which generates muscle contractions), and is a donor of methyl groups (lowering homocysteine levels, reducing heart disease risk). Lecithin is a natural source of choline. Choline is promoted to athletes to improve physical endurance by increasing fat lipolysis and acetylcholine production to increase muscle contractions and delay fatigue. Choline supplements are thought to stimulate brain function (improving memory, intelligence and mood state in rats). Cyclists taking 2.34 g of choline showed improved mood state but no improvement in performance. Evidence does not support claims that choline has a role in reducing body adipose tissue, or that high doses elevate fat metabolism in humans. It was reported decreased plasma choline concentrations (9-40 %) during prolonged exercise (>2 h) in elite and well-trained endurance athletes (marathon runners, cyclists, triathletes, military personnel) and possible links to reduced performance or early fatigue have fuelled interest in supplementation. Decreased choline levels and insufficient acetylcholine availability may contribute to fatigue; increasing exogenous choline may enhance acetylcholine availability for neuromuscular transmission. Two well-designed studies, involving exhaustive exercise protocols in well-trained cyclists and soldiers, provided 2.4-8.4 g of choline citrate and bitartrate in beverages consumed prior to exercise. Although supplementation increased plasma choline, it failed to delay fatigue or show performance benefits in these studies and one other. Free serum choline concentrations vary with dietary choline intake, peaking within hours of ingestion. Choline supplements, as capsules or powders, may cause gastrointestinal side effects including breakdown to trimethylamine, which leads to fishy body odours. While small supplemental doses are not currently considered harmful, athletes with gout should avoid choline supplementation. There is no clear evidence that decreased plasma choline is associated with acetylcholine depletion and fatigue. Despite studies showing elevated choline concentrations due to choline supplementation, there is no evidence that this translates into benefits in exercise performance or reductions in fatigue [10253].

Chondroitin/glucosamine

Glucosamine is a primary building block for proteoglycans. Glucosamine is available in an oral preparation with approximately 90 percent gastrointestinal absorption. Oral administration results in absorption by several tissues including bone and articular cartilage. Chondroitin is a large molecule that is absorbed from the gastrointestinal tract but not as readily as glucosamine. Theoretically, it enhances proteoglycan synthesis and prevents cartilage degradation, whether due to damage or disease. In athletes with degenerative joint disease, non-steroidal anti-inflammatories (NSAIDs) are commonly overused, and this may lead to an increased risk of adverse events. There is therefore interest in the use of glucosamine and chondroitin as both treatment and disease-modifying agents for cartilage damage in athletes. Much of the interest for the disease or damage-modifying aspects of glucosamine and chondroitin is derived from animal studies. Studies on rabbits suggest that there may be a role for glucosamine use in injury to articular cartilage. Both glucosamine and chondroitin have been studied to evaluate their effect on response to joint stress in animal chondrocytes. Results suggest that cartilage subjected to various stresses (i.e. enzyme-induced matrix depletion, heat stress, mechanical compression and cytokine stress) have an enhanced protective metabolic response of the chondrocyte when treated with glucosamine.
and chondroitin. These studies have led to the marketing of glucosamine sulphate and chondroitin to athletes for use in the modification of acute cartilage damage after an acute injury or cartilage damage due to repetitive load in athletics. This is based on the hypothesis that glucosamine sulphate and chondroitin may stimulate chondrocytes to repair damaged cartilage more efficiently and completely. There are no current studies in athletes of any age for either supplement to suggest that these effects occur. There is conflicting evidence for the use of glucosamine and chondroitin as a symptomatic treatment of osteoarthritis. There are studies that suggest both benefit and no benefit for the symptomatic use of both glucosamine and chondroitin in the treatment of knee pain. A recent large-scale Glucosamine/Chondroitin Arthritis Trial leaves doubt as to the effectiveness of glucosamine and chondroitin in the treatment of knee osteoarthritis. There are data to support a combination of glucosamine and chondroitin as effective in those patients with moderate to severe knee pain. However, no benefit was observed with individual use of these agents in this population with respect to knee pain. Neither the combination nor individual use showed any benefit in those patients classified with mild knee pain compared with placebo. A systematic, clinical review determined that there are inconsistent results regarding the effectiveness of glucosamine and chondroitin in improving pain and joint function in knee osteoarthritis. Both supplements have an excellent safety profile. Therefore, if an athlete plans to use these products, it may be suggested that clinicians should discuss whether or not there is potential for benefit in athletes with knee degenerative joint disease, as an alternative to chronic NSAID or analgesic use [10253].

Lecithin

Lecithin is a phospholipid that occurs naturally in foods of animal and plant origin such as egg yolk, soybeans and wheat germ. Lecithin is naturally high in phosphatidylcholine, which is required for normal cellular structure and function. It has been suggested that strenuous exercise results in decreased plasma choline concentrations, which is associated with decreased acetylcholine and delayed muscle contraction. Lecithin supplementation is purported to possess ergogenic properties due either to its phosphate or choline content. Very few studies have investigated the effects of lecithin supplementation on athletic performance. Trained triathletes were given a placebo and acute lecithin supplementation at a dose of 0.2 g/kg 1 h before exercise. The placebo condition decreased plasma choline concentrations by 17 percent; however, when lecithin supplementation was given, average plasma choline levels remained unchanged. In a similar study, 12 accomplished marathon runners were given either 2.2 g of lecithin or a placebo 1 day before running a marathon. Runners given the lecithin supplementation maintained normal plasma-free choline levels compared with the placebo condition, however, there was no effect on performance. Another study found that 14 days of soya lecithin supplementation had no ergogenic effect on grip strength. Acute lecithin supplementation at doses of 2.2 g prior to exercise has been administered without any known side effects. Although lecithin supplementation appears to prevent the decrease in choline levels after exercise, there is no clear evidence of any performance benefits [11279].
a dose of 0.2 g/kg 1 h before exercise. The placebo condition decreased plasma choline concentrations by 17 percent; however, when lecithin supplementation was given, average plasma choline levels remained unchanged. In a similar study, 12 accomplished marathon runners were given either 2.2 g of lecithin or a placebo 1 day before running a marathon. Acute lecithin supplementation at doses of 2.2 g prior to exercise has been administered without any known side effects. Although lecithin supplementation appears to prevent the decrease in choline levels after exercise, there is no clear evidence of any performance benefits [11392].

**Linoleic acid**

Linoleic acid, the simplest member of the omega-6 polyunsaturated fatty acid family, is an essential fatty acid. It has a particular role in maintaining the integrity of the skin, so preventing water loss, as a result of its presence within the structure of skin-specific lipids. Linoleic acid is different in structure from conjugated linoleic acid. Linoleic acid is the substrate for biosynthesis of arachidonic acid, the principal precursor of eicosanoids involved in a variety of physiological and pathophysiological responses. Linoleic acid is synthesised in plants. Consequently, plant tissues, seeds and nuts; their oils (e.g. corn oil, sunflower oil, soybean oil); and foodstuffs produced from these oils (e.g. margarines) have a high content of linoleic acid (often > 50 % of the fatty acids are present). Inclusion of seeds, nuts, grains, vegetable oils and margarines in a variety of foods and the presence of linoleic acid in animal-derived foods as a result of animal foraging and modern farming practices (e.g. feeding on grains) mean that linoleic acid is widespread in foods and in the diet. The human requirement for linoleic acid is estimated to be 0.5 percent of energy, which in a typical Western adult equates to an intake of about 1 g/day. The UK National Diet and Nutrition Survey indicated that the average intake of omega-6 fatty acids, most of which would be linoleic acid, among adults aged 19 to 64 years is about 5.4 percent of energy and that 98 percent of the population in this age range consume more than 2.7 percent of energy as omega-6 fatty acids (mainly linoleic acid). Average intakes in g/day were 12 in men and 9 in women, with 98 percent of men consuming more than 4.9 g/day and 98 percent of women consuming more than 4 g/day. Thus, intake of linoleic acid among adults in the UK is greatly in excess of the estimated requirement. A high intake of linoleic acid can competitively inhibit the biosynthesis of the omega-3 fatty acid eicosapentaenoic acid from its precursor α-linolenic acid. Given that linoleic acid is widespread in foods, there does not seem to be a case for its supplementation among athletes [11279].

Linoleic acid, the simplest member of the omega-6 polyunsaturated fatty acid family, is an essential fatty acid. It has a particular role in maintaining the integrity of the skin, so preventing water loss, as a result of its presence within the structure of skin-specific lipids. Linoleic acid is different in structure from conjugated linoleic acid. Linoleic acid is the substrate for biosynthesis of arachidonic acid, the principal precursor of eicosanoids involved in a variety of physiological and pathophysiological responses. Linoleic acid is synthesised in plants. Consequently, plant tissues, seeds and nuts; their oils (e.g. corn oil, sunflower oil, soybean oil); and foodstuffs produced from these oils (e.g. margarines) have a high content of linoleic acid (often > 50 % of the fatty acids are present). Inclusion of seeds, nuts, grains, vegetable oils and margarines in a variety of foods and the presence of linoleic acid in animal-derived foods as a result of animal foraging and modern farming practices (e.g. feeding on grains) mean that linoleic acid is widespread in foods and in the diet. The human requirement for linoleic acid is estimated to be 0.5 percent of energy, which in a typical
Western adult equates to an intake of about 1 g/day. The UK National Diet and Nutrition Survey indicated that the average intake of omega-6 fatty acids, most of which would be linoleic acid, among adults aged 19-64 years is about 5 percent of energy and that 98 percent of the population in this age range consume more than 3 percent of energy as omega-6 fatty acids (mainly linoleic acid). Average intakes in g/day were 12 in men and 9 in women, with 98 percent of men consuming more than 5 g/day and 98 percent of women consuming more than 4 g/day. Thus, intake of linoleic acid among adults in the UK is greatly in excess of the estimated requirement. Intake in the USA is likely to be even higher than in the UK. A high intake of linoleic acid can competitively inhibit the biosynthesis of the omega-3 fatty acid eicosapentaenoic acid from its precursor a-linolenic acid. Given that linoleic acid is widespread in foods, there does not seem to be a case for its supplementation among athletes [11392].

**gamma-Linolenic acid**

gamma-Linolenic acid (GLA) is the desaturated derivative of linoleic acid. It is a omega-6 fatty acid. GLA is found in certain unusual plant oils like evening primrose oil and borage oil (sometimes called starflower oil) and is typically rare in the diet. Experimental studies suggest an anti-inflammatory action mediated via prostaglandin E1 and analgesic effects. Low-dose GLA supplementation during exercise had a therapeutic benefit on claudication in patients undertaking standing leg exercises. In a large rehabilitation study in patients with compressive radiculopathy syndrome from disc-nerve root conflict, a daily supplement of 360 mg GLA + 600 mg alpha-lipoic acid improved neuropathic symptoms. Despite a lack of strong evidence from research, a wide range of GLA doses (15-700 mg/day) has been advocated as suitable for athletes wanting to increase performance and reduce inflammation. High doses are thought to impair performance and have an adverse effect on mood, perhaps because GLA is the precursor of arachidonic acid. There are claims that GLA supplementation will help bodybuilders to lose fat, but there does not appear to be strong evidence to support this [11279].

GLA is the desaturated derivative of linoleic acid. It is a omega-6 fatty acid. GLA is found in certain unusual plant oils like evening primrose oil and borage oil (sometimes called starflower oil) and is typically rare in the diet. Experimental studies suggest an anti-inflammatory action mediated via prostaglandin E1 and analgesic effects. Low-dose GLA supplementation during exercise had a therapeutic benefit on claudication in patients undertaking standing leg exercises. In a large rehabilitation study in patients with compressive radiculopathy syndrome from disc-nerve root conflict, a daily supplement of 360 mg GLA + 600 mg alpha-lipoic acid improved neuropathic symptoms. Despite a lack of strong evidence from research, a wide range of GLA doses (15-700 mg/day) has been advocated as suitable for athletes wanting to increase performance and reduce inflammation. High doses are thought to impair performance and have an adverse effect on mood, perhaps because GLA is the precursor of arachidonic acid. There are claims that GLA supplementation will help bodybuilders to lose fat, but there does not appear to be strong evidence to support this [11392].

**Conjugated linoleic acid**

The aim of one study was to measure the effects of 12 weeks of conjugated linoleic acid (CLA) supplementation on body composition, RER, RMR, blood lipid profiles, insulin sensitivity and appetite in exercising, normal-weight persons. In a double-blind, randomised,
controlled trial, sixty-two non-obese subjects (twenty-five men, thirty-seven women) received either 3.9 g/d CLA or 3.9 g high-oleic acid sunflower oil for 12 weeks. Prior to and after 12 weeks of supplementation, oral glucose tolerance, blood lipid concentrations, body composition (dual-energy X-ray absorptiometry and computerised tomography scans), RMR, resting and exercising RER and appetite were measured. There were no significant effects of CLA on body composition or distribution, RMR, RER or appetite. During the oral glucose tolerance tests, mean plasma insulin concentrations (0, 30, 120 min) were significantly lower in women who supplemented with CLA compared to high-oleic acid sunflower oil control. Serum NEFA levels in response to oral glucose were attenuated in both men and women in the CLA compared to control group. However, serum total cholesterol and LDL-cholesterol concentrations decreased in both groups and HDL-cholesterol concentrations decreased in women over 12 weeks. In conclusion, mixed-isomer CLA supplementation had a favourable effect on serum insulin and NEFA response to oral glucose in non-obese, regularly exercising women, but there were no CLA-specific effects on body composition, energy expenditure or appetite [07368].

Conjugated linoleic acid (CLA) is a term for a series of structural and geometric isomers of linoleic acid. The two double bonds in the acyl chain of linoleic acid are on carbons 9 and 12 (counting from the C-terminal carbon), separated by two single carbon-to-carbon bonds, and both are in the cis conformation. In CLA, the double bonds are separated by only a single bond (i.e. the double bonds are conjugated) and each may be in either the cis or trans conformation. Thus there are many possible forms of CLA. The major naturally occurring form in the human diet is cis-9, trans-11 CLA. This is produced as a result of rumen biohydrogenation and is found in ruminant milks, milk products and meats. These foods also contain several other CLA isomers. CLA in supplements is mainly produced by chemical treatment of sunflower oil and typically contains an equal mixture of cis-9, trans-11 and trans-10, cis-12 CLA and, often, smaller amounts of other CLA isomers. Biological effects of CLA have been demonstrated in many animal models and, in some studies, in healthy human volunteers: these effects appear to be isomer specific. Findings of CLA studies conducted among individuals who regularly exercise or in body-builders have been inconsistent. Some studies report decreased fat mass and increased fat-free (lean) mass with CLA supplementation (1.8–6 g/day of mixed isomers but predominantly an equal mix of cis-9, trans-11 and trans-10, cis-12) for about 3 months, although this is not seen in all studies. CLA has been combined with creatine and creatine and whey protein in other studies reporting reduced fat mass and increased fat-free mass. CLA may or may not increase muscle strength. It is likely that the level and duration of intake of specific biologically active CLA isomers is important, and differences in these factors may explain the contradictory findings in the literature. It is currently not possible to make a firm statement about the role of specific CLA isomers in athletic training and performance or to recommend a specific isomer or intake [10251].

Conjugated linoleic acid (CLA) is a term for a series of structural and geometric isomers of linoleic acid. Studies investigating the role of CLA supplements in decreasing fat mass and/or increasing lean mass have been inconsistent [13012].

Fat supplements are nutritional ergogenic aids used by elite and recreational athletes; many sport magazines advise that their intake can improve endurance capacity, increase VO2max, reduce fat body mass, increase lean body mass, reduce muscle glycogen breakdown, improve metabolism, and prevent or reduce muscle damage and inflammatory responses. These supplements include long-chain triacylglycerols, medium-chain triacylglycerols, fish oil, and conjugated linoleic acid (CLA). In the scientific community, a new role of dietary fat, particularly fat supplements, has been delineated in steroidogenesis, although the molecular mechanism has not yet been elucidated. CLA, one of the commercially available fat
supplements, refers to a group of positional and geometrical isomers of linoleic acid (cis-9, cis-12-octadecadienoic acid), an omega-6 essential fatty acid that exhibits various physiological effects including anti-adipogenic, anti-carcinogenic, and immune modulation effects. The main isomers of CLA are cis-9, trans-11, trans-10, and cis-12 octadecenoic acids (c9, t11-CLA and t10, c12-CLA). It has previously been shown that CLA treatment stimulates testosterone biosynthesis in the rat Leydig tumour cell line (R2C), although the testosterone pathway stimulated by the CLA treatment was not identified. High levels of testosterone may enhance muscle mass, which is important in sport science to increase maximal voluntary strength and in cachexia and anti-aging therapies to stop muscle wasting. Moreover, high levels of testosterone may improve endurance performance by increasing haemoglobin concentrations and haematocrit as well as by increasing lactate transport through the enhancement of monocarboxylate transporter 1 and 4 in skeletal muscle. Currently only two pathways have been shown to be responsible for the possible effect of CLA on testosterone biosynthesis. First, in adipocytes, perilipin and hormone-sensitive lipase (HSL) create a protective coat on the lipid droplet surface. Under stimulation, both proteins become hyperphosphorylated, and perilipin is displaced from the lipid droplet, allowing HSL to convert cholesteryl ester to free cholesterol. In Leydig cells, the same pathway may stimulate testosterone production under CLA treatment. Second, CLA may alter steroidogenesis by up-regulating specific genes encoding enzymes and transport proteins involved in the synthesis of testosterone, such as 17alpha-hydroxylase/17,20-lyase (CYP17A1), which converts progesterone into androstenedione. It has been demonstrated that a change in CYP17A1 expression may directly affect the level of testosterone. The aims of one study were to identify the pathway stimulated by CLA supplementation using a cell culture model and to determine whether this same pathway is also stimulated in vivo by CLA supplementation associated with exercise. In vitro, Leydig tumour rat cells (R2C) supplemented with different concentrations of CLA exhibited increasing testosterone biosynthesis accompanied by increasing levels of CYP17A1 mRNA and protein. In vivo, trained mice showed an increase in free plasma testosterone and an up-regulation of CYP17A1 mRNA and protein. The effect of training on CYP17A1 expression and testosterone biosynthesis was significantly higher in the trained mice supplemented with CLA compared to the placebo. The results of the present study demonstrated that CLA stimulates testosterone biosynthesis via CYP17A1, and endurance training led to the synthesis of testosterone in vivo by inducing the overexpression of CYP17A1 mRNA and protein in the Leydig cells of the testis. This effect was enhanced by CLA supplementation. Therefore, CLA-associated physical activity may be used for its steroidogenic property in different fields, such as alimentary industry, human reproductive medicine, sport science, and anti-muscle wasting [13708].

**Leptin**

Leptin is a hormone secreted primarily by adipocytes from the white adipose tissue in direct proportion to the amount of body fat present. Leptin plays a crucial role in the regulation of appetite, body fat mass, basal metabolic rate and gonadal function. Congenital deficiency of leptin is rare, but causes morbid obesity which is normalised following leptin treatment. Circulating leptin levels change acutely in accordance with energy balance; leptin levels increase with food ingestion and reduce with prolonged exercise and fasting. When there is a severe acute negative energy balance, serum leptin levels dramatically reduce by 60-80 percent, despite small changes in total fat mass. Preventing this reduction in leptin levels could attenuate hunger in dieting athletes, facilitating the adjustment of body mass to specific targets. Nevertheless, there is no account of leptin misuse by athletes for this purpose. Leptin receptors are densely expressed in the cerebellum, even more so than in the hypothalamus where leptin is supposed to exert its main action. Leptin-related changes
owing to physical activity levels may promote structural changes in the cerebellum, which is strongly implicated in motor control and learning. Leptin receptors are also expressed in human skeletal muscle, and more abundantly in women than men. Here, the main action of leptin is believed to be the stimulation of fatty acid oxidation via several pathways. Interestingly, these pathways are also activated 30 min after sprint exercise and, like sprint exercise, leptin induces PGC1alpha expression and mitochondrial biogenesis. It is known that exercise reduces leptin resistance in obese rodents or in rodents fed with high fat diets (which causes skeletal muscle insulin and leptin resistance). However, little is known about the influence of exercise on the regulation of leptin receptors and leptin signalling in human skeletal muscle. In obese humans, leptin receptors are reduced in the vastus lateralis, perhaps by a mechanism related to reduced physical activity. By contrast, 12 weeks’ of weightlifting combined with endurance training does not seem to induce changes in the number of leptin receptors in the vastus lateralis of healthy men. However, professional tennis players have increased expression of leptin receptors in the triceps brachii of the dominant arm compared with the non-dominant arm. This suggests that chronic loading may regulate the expression of leptin receptors in human skeletal muscle. An increased expression of leptin receptors in overloaded skeletal muscle may facilitate muscle growth by a mechanism involving leptin signalling, either by leptin itself or by insulin like growth factor 1. In fact, leptin administration in mice with a congenital leptin deficiency (ob/ob mice) promotes muscle hypertrophy. Thus, hypothetically, athletes could think of using leptin or leptin agonists to facilitate a reduction of fat mass, control hunger, promote muscle signalling similar to that induced by sprint training and stimulate mitochondrial biogenesis, as well as using it as an anabolic agent when combined with strength training. Therefore, the concerned authorities should keep track of potential misuse of leptin or leptin agonists [11393].

Inosine

Inosine is a nucleoside formed when hypoxanthine is attached to a ribose ring (also known as a ribofuranose) via a beta-N9-glycosidic bond. Inosine plays a role in several metabolic functions including increasing red blood cell concentrations of 2,3-diphosphoglycerate (2,3-DPG), which is involved in oxygen transport. It may also potentiate the action of endogenously formed adenosine and inhibit its uptake and clearance. It has been proposed to enhance exercise performance via the effects on 2,3-DPG or by an increase in ATP concentrations. Little scientific investigation has been conducted on inosine as an ergogenic aid and few peer-reviewed papers could be found. The available studies involving trained individuals investigated chronic intakes of large doses of inosine (e.g. 5-10 000 mg/day), but these protocols did not provide an ergogenic effect for endurance or sprint activities. It is suggested that high-dose inosine, a uric acid precursor, combined with high urinary excretion, could be detrimental and result in kidney stones or acute renal failure. In summary, there appears to be little support for the use of inosine as an ergogenic aid though it is still used in some over-the-counter fitness products. There are continuing clinical trials that may indicate a future therapeutic effect as an antioxidant for exercise [11241].

Glucosamine

The main aim of one study was to examine the effects of 4 weeks of glucosamine administration on the functional ability and the degree of pain intensity in competitive male athletes after acute knee injury. This study was a randomized, double-blind parallel trial of glucosamine (1500 mg per day) or a placebo for 28 days, utilising 106 patients with an acute
knee injury. Pain and functional ability were evaluated at the beginning of the study and at 7, 14, 21, and 28 days after starting treatment. Pain intensity at rest and while walking was assessed using a visual analog scale. Passive knee flexibility (flexion and extension) of the injured limb was measured using a modified goniometer, and the degree of knee swelling was measured and compared with the noninjured limb. No significant difference was found between the glucosamine, and placebo group in mean pain intensity scores for resting and walking, and degree of knee swelling at the 7-day, 14-day, 21-day, and 28-day assessment. There was no significant difference between passive knee flexibility at the 7-day, 14-day, and 21-day assessment. After 28 days of treatment the patients from the glucosamine group demonstrated significant improvement in knee flexion and extension as compared with the placebo group [07358].

Glucosamine is commonly used for the treatment of osteoarthritis. It is available as an over the counter preparation and also as a prescription pharmaceutical. There is concern from animal experiments that glucosamine may alter glucose metabolism through the hexosamine biosynthetic pathway. The objective of one systematic review was to determine if exogenous glucosamine adversely affects glucose metabolism in humans. The review does not separate out the effects on glucose metabolism of the various glucosamine preparations. An English-language literature search of MEDLINE, EMBASE and EBM Reviews (1950-February 2009) was conducted. The bibliographies of selected papers were manually searched for additional references. Two reviewers independently analyzed studies for quality and content using a standardized data extraction form. Eleven studies were included. Six studies were randomized controlled trials and the remaining five were prospective studies with or without controls. Four of the studies found decreased insulin sensitivity or increased fasting glucose in subjects taking glucosamine. Three of these were clinical studies using oral glucosamine. Studies that included subjects with baseline impaired glucose tolerance or insulin resistance were more likely to detect an effect on glucose metabolism than studies without such subjects. It was concluded that clinical studies, including three using oral glucosamine, have provided mixed evidence about the effect of exogenous glucosamine on glucose metabolism in humans. Therefore, more studies are needed, particularly including subjects at high risk for impairments in glucose homeostasis, before a definite conclusion can be made [11295].

“Fat burners”

The term “fat burner” is used to describe nutrition supplements that are claimed to acutely increase fat metabolism or energy expenditure, impair fat absorption, increase weight loss, increase fat oxidation during exercise, or somehow cause long-term adaptations that promote fat metabolism. Often, these supplements contain a number of ingredients, each with its own controlled mechanism of action and it is often claimed that the combination of these substances will have additive effects. The list of supplements that are claimed to increase or improve fat metabolism is long; the most popular supplements include caffeine, creatine, green tea, conjugated linoleic acid, forskolin, chromium, kelp and fucoxanthin. In this review the evidence for some of these supplements is briefly summarized. Based on the available literature, caffeine and green tea have data to back up its fat metabolism-enhancing properties. For many other supplements, although some show some promise, evidence is lacking. The list of supplements is industry-driven and is likely to grow at a rate that is not matched by a similar increase in scientific underpinning [11540].

L-arginine alpha-ketoglutarate (AAKG)
L-arginine alpha-ketoglutarate (AAKG) is marketed as a body building supplement. The components are intermediates in the metabolism of nitric oxides, but no reputable scientific evidence shows any benefits from taking AAKG as a dietary supplement. The substance was evaluated the pharmacokinetics, safety, and efficacy of L-arginine alpha-ketoglutarate in trained adult men. Subjects participated in two studies that employed a randomized, double-blind, controlled design. In study 1, 10 healthy men (30-50 year old) fasted for 8 h and then ingested 4 g of time-released or non-timed-released AAKG. Blood samples were taken for 8 h after AAKG ingestion to assess the pharmacokinetic profile of L-arginine. After 1 wk the alternative supplement was ingested. In study 2, which was placebo controlled, 35 resistance-trained adult men (30-50 year old) were randomly assigned to ingest 4 g of AAKG (three times a day, i.e. 12 g daily, n=20) or placebo (n=15). Participants performed 4 d of periodized resistance training per week for 8 weeks. At 0, 4, and 8 wk of supplementation the following tests were performed: clinical blood markers, one repetition maximum bench press, isokinetic quadriceps muscle endurance, anaerobic power, aerobic capacity, total body water, body composition, and psychometric parameters tests. Data were analyzed by repeated measures analysis of variance. In study 1, significant differences were observed in plasma arginine levels in subjects taking non-timed-release and timed-release AAKG. In study 2, significant differences were observed in the AAKG group for 1RM bench press, Wingate peak power, blood glucose, and plasma arginine. No significant differences were observed between groups in body composition, total body water, isokinetic quadriceps muscle endurance, or aerobic capacity. It was concluded that AAKG supplementation appeared to be safe and well tolerated, and positively influenced 1RM bench press and Wingate peak power performance. AAKG did not influence body composition or aerobic capacity [06293].

Blend supplements

The authors aimed to examine the acute hormonal and performance responses to resistance exercise with and without prior consumption of an amino acid/creatine/energy supplement. Eight men performed a resistance-exercise protocol at baseline, 20 min after consuming a supplement consisting of essential amino acids, creatine, taurine, caffeine, and glucuronolactone or a maltodextrin placebo. Venous blood samples were obtained before and immediately after, 15 min, and 30 min after each protocol. Area under the curve of resistance-exercise volume revealed that baseline was significantly less than supplement (10 %) and placebo (9 %). For fatigue rate, only supplement (18 % ± 12 %) was significantly lower than baseline (33 % ± 8 %). Total testosterone and growth hormone were significantly elevated at immediately after and 15 min after in all conditions. The growth hormone response was significantly lower, however, in supplement and placebo than in baseline. The total testosterone and growth hormone responses did not differ between supplement and placebo. These results indicated that a supplement consisting of amino acids, creatine, taurine, caffeine, and glucuronolactone can modestly improve high-intensity endurance; however, the anabolic-hormonal response was not augmented [08422].

It was hypothesized that triphasic multinutrient supplementation during acute resistance exercise would enhance muscular performance, produce a more favorable anabolic profile, and reduce biochemical markers of muscle damage in strength-trained athletes. Fifteen male strength-trained athletes completed two acute lower-body resistance exercise sessions to fatigue 7 days apart. After a 4-hour fast, participants consumed either a multinutrient supplement (Musashi 1-2-3 Step System) (SUPP) or placebo (PLA) beverage preexercise (PRE), during (DUR), and immediately postexercise (IP). Session volume loads were calculated as kilograms × repetitions. Lower-body peak power was measured using unloaded repeated countermovement jumps, and blood samples were collected to assess...
biochemistry, serum hormones, and muscle damage markers at PRE, DUR, IP, 30 minutes postexercise (P30), and 24 hours postexercise (P24h). The SUPP demonstrated increased glucose concentrations at DUR and IP compared with at PRE, whereas PLA demonstrated higher glucose at P30 compared with at PRE. Session volume load was higher for SUPP compared with PLA. Cortisol increased at DUR, IP, and P30 compared with at PRE in both treatments; however, SUPP also displayed lower cortisol at P24h compared with at PRE and PLA. The total testosterone response to exercise was higher for PLA compared with SUPP; however, total creatine kinase and C-reactive protein responses to exercise were lower for SUPP compared with PLA. These data indicate that although triphasic multinutrient supplementation did not produce a more favorable anabolic profile, it improved acute resistance exercise performance while attenuating muscle damage in strength-trained athletes [113743].

Nutritional support to maintain proper immune status during intense training

Prolonged exercise and heavy training are associated with depressed immune function which can increase the risk of picking up minor infections. To maintain robust immunity, athletes should eat a well-balanced diet sufficient to meet their energy, carbohydrate, protein, and micronutrient requirements. Dietary deficiencies of protein and specific micronutrients have long been associated with immune dysfunction and an adequate intake of iron, zinc, and vitamins A, D, E, B6 and B12 is particularly important in the maintenance of immune function. Consuming carbohydrate during prolonged strenuous exercise attenuates rises in stress hormones and appears to limit the degree of exercise-induced immune depression. Similar effects can be seen with daily ingestion of high-dose antioxidant vitamin supplements, though concerns have been expressed that excessive antioxidant intake may impair exercise training adaptations. It is safe to say with reasonable confidence that individual amino acids, colostrum, Echinacea, and zinc are unlikely to boost immunity or reduce infection risk in athletes. The ingestion of carbohydrate during exercise and daily consumption of probiotic and plant polyphenol (e.g. quercetin)-containing supplements or foodstuffs (e.g. non-alcoholic beer) currently offer the best chance of success. This approach is likely to be most effective for individuals who are particularly prone to illness [13744].

Electrolytes

Electrolytes are negatively (anions) or positively (cations) charged substances that, when in solution, conduct an electric current. Major physiological electrolytes include Na⁺, K⁺, Cl⁻ and HCO₃⁻, while other electrolytes such as Ca²⁺, Mg²⁺ and trace elements are also found in the body in significant amounts. Na⁺, K⁺, Cl⁻ and HCO₃⁻ are primarily responsible for normal water distribution and homeostasis throughout the body via their effect on osmotic pressure. These major electrolytes also play an essential role in regulating heart and muscle function, maintaining pH and a number of other important biochemical reactions. An athlete's demand for electrolytes increases with exercise and heat stress, as extensive sweating can mean both large water and electrolyte losses in addition to related changes in extra- and intracellular water distribution. Dehydration and an increase in plasma osmolality, which is primarily driven by Na⁺, will also stimulate osmoreceptors prompting an athlete to drink to maintain further or defend plasma volume. The primary electrolytes in sweat are Na⁺ (20-70 mmol/L) and Cl⁻, with comparatively much lower levels of K⁺ (about 5 mmol/L) and even less Ca²⁺ (about 1 mmol/L) and Mg²⁺ (about 0.8 mmol/L). As the sweating rate increases, the concentration of Na⁺ in sweat increases correspondingly, even with the lower sweat Na⁺ concentrations observed after heat acclimation. With Na⁺ being the major cation of extracellular fluid, copious sweating in particular can lead to a sizeable sweat-induced whole-
body exchangeable Na\(^+\) deficit. It is worth noting that such a deficit is not usually indicated by lower plasma osmolality or Na\(^+\) levels. A significant sodium deficit (e.g. 20-30 % of the exchangeable Na\(^+\) pool), combined with a loss in plasma volume prompting water to shift to the intravascular space, can lead to a contracted interstitial fluid compartment and possible widespread skeletal muscle cramping. Athletes affected with exertional muscle cramping related to a significant water or sodium deficit can be effectively treated either with an oral high-salt solution or intravenously. The major source of electrolytes comes from the diets. Although these (especially in the case of sodium) are frequently consumed well in excess of requirements, athletes often look for supplementary forms of electrolytes to replace those lost in sweat. This is sometimes justified when the timing and amount of necessary electrolyte replacement during or after an exercise session cannot be provided easily by food sources. The body normally conserves sufficient extracellular Na\(^+\) and Cl\(^-\) through reabsorption by the kidneys as is needed to maintain whole-body Na\(^+\) and water balance. However, an accumulating sodium deficit often needs to be offset with supplemental dietary NaCl intake during and after exercise or other physical activity when sweat losses are great. Being a predominantly intracellular cation, losses of K\(^+\) in sweat are generally low enough to be adequately met by a normal diet. The presence of modest amounts of sodium (and other electrolytes) in a sports drink, or the addition of electrolyte supplements to other beverages, can increase voluntary intake of fluid and enhance the retention of fluids consumed to restore hydration status more completely after exercise or other dehydrating activities. Accordingly, the value of simultaneous replacement of electrolytes with fluid intake in situations requiring restoration of moderate to large fluid deficits is well accepted. Excessive intake of water or other low sodium fluids can readily lead to water overload, a condition known as hyponatraemia. Exercise-related hyponatraemia typically indicates an excess of total body water compared with total body exchangeable Na\(^+\) and sometimes, in a much lesser contributing way, a measurable sweat-induced exchangeable Na\(^+\) deficit. Severe hyponatraemia can prompt serious consequences. This is because a significant decrease in plasma Na\(^+\) concentration and consequent osmotic gradient can cause brain swelling and altered mental status, seizure, respiratory distress, coma or even death. But less severe exercise-related hyponatraemia (when the plasma Na\(^+\) concentration is 125-130 mmol/l) resulting from overconsumption of fluid during physical activity in excess of sweat and urinary water losses can still prompt nausea, vomiting and headache. Its prevalence is increasingly recognised at endurance events in slow and inexperienced athletes who have low sweat rates and generous opportunities to consume fluid. This clinical situation often needs to be corrected by intravenous saline administration after being verified by a plasma or serum Na\(^+\) measurement [10391].

**Dimethylglycine**

Dimethylglycine (N,N-dimethylglycine, DMG) is a dimethylated derivative of the amino acid glycine. Found naturally in animal and plants cells, it is an intermediate in glycine synthesis from the degradation of choline. Indirectly, it is involved in a wide range of metabolic pathways through transmethylation. DMG is also an active ingredient in pangamic acid (also referred to as vitamin B15), which is another supplement with purported performance benefits. It is proposed that DMG may enhance metabolic variables of aerobic performance in humans and, historically, supplementation has been used by Soviet athletes and American Football players. Studies using trained subjects found no difference in running endurance, or heart rate and VO\(_{2}\max\) after a 21-day treatment period (200 mg/day), 24 or when 135 mg DMG was administered acutely before a treadmill test to exhaustion. Cardiorespiratory function and lactate production were also unaltered in exercising horses. Potential immunomodulating capacities of DMG in humans may have been masked by the study
design. Animal studies have failed to demonstrate an enhancement to specific or non-specific immunity. There is currently insufficient evidence to support DMG supplementation in athletic populations [10347].

**Dietary nitrates**

Nitric oxide (NO), synthesized from L-arginine by NO synthases, plays a role in adaptation to physical exercise by modulating blood flow, muscular contraction and glucose uptake and in the control of cellular respiration. Recent studies show that NO can be formed in vivo also from the reduction of inorganic nitrate (NO$_3^-$ and nitrite NO$_2^-$). The diet constitutes a major source of nitrate, and vegetables are particularly rich in this anion. The aim of one study was to investigate if dietary nitrate had any effect on metabolic and circulatory parameters during exercise. In a randomized double-blind placebo-controlled crossover study, we tested the effect of dietary nitrate on physiological and metabolic parameters during exercise. Nine healthy young well-trained men performed submaximal and maximal work tests on a cycle ergometer after two separate 3-day periods of dietary supplementation with sodium nitrate (0.1 mmol/kg and day) or an equal amount of sodium chloride (placebo). The oxygen cost at submaximal exercise was reduced after nitrate supplementation compared with placebo. On an average VO$_2$ decreased during NIT over the four lowest submaximal work rates. Gross efficiency increased during NIT over the four lowest work rates. There was no difference in heart rate, lactate, ventilation (VE), VE/VO$_2$ or respiratory exchange ratio between nitrate and placebo during any of the submaximal work rates. It was concluded that dietary nitrate supplementation, in an amount achievable through a diet rich in vegetables, results in a lower oxygen demand during submaximal work. This highly surprising effect occurred without an accompanying increase in lactate concentration, indicating that the energy production had become more efficient. The mechanism of action needs to be clarified but a likely first step is the in vivo reduction of dietary nitrate into bioactive nitrogen oxides including nitrite and NO [07377].

Nitric oxide (NO) is an important physiological signalling molecule that can modulate skeletal muscle function through its role in the regulation of blood flow, muscle contractility, glucose and calcium homeostasis and mitochondrial biogenesis and respiration. Until quite recently, it was considered that NO was generated solely through the oxidation of the amino acid L-arginine in a reaction catalysed by nitric oxide synthase (NOS). It is now appreciated, however, that NO may also be produced by the reduction of nitrate to nitrite and subsequently of nitrite to NO. This pathway may be particularly important in hypoxia. Nitrate and nitrite are present in the body as products of NO production through NOS and are also modulated through the diet. Nitrate in foods (particularly green leafy vegetables) can be reduced to nitrite by oral bacteria, leading to an increased plasma nitrite concentration that serves as a circulating “reservoir” for NO production. Several recent studies have addressed the extent to which dietary nitrate supplementation might affect the physiological responses to exercise. It was shown that 3 days of sodium nitrate supplementation (0.1 mmol/kg/day) reduced resting blood pressure and the O$_2$ cost of submaximal cycle exercise. Subsequently, we have reported that enhancing NO bioavailability through supplementation of the diet with a natural foodstuff (nitrate-rich beetroot juice) reduces resting blood pressure and the O$_2$ cost of exercise and improves exercise performance. In the first study, it was found that 4-6 days of dietary nitrate supplementation (0.5 litres of beetroot juice per day containing about 6 mmol nitrate) reduced the “steady-state” O$_2$ cost of submaximal cycle exercise by 5 percent and extended the time to exhaustion during high-intensity cycling by 16 percent. In a follow-up study, it was used $^{31}$P-magnetic resonance spectroscopy to investigate the mechanistic bases of this phenomenon. Dietary nitrate supplementation resulted in both a reduced
pulmonary $O_2$ uptake and reduced muscle metabolic perturbation, enabling high-intensity knee-extension exercise to be tolerated for a greater period of time. These data imply that the reduced $O_2$ cost of exercise following dietary nitrate supplementation is related to a reduced ATP cost of muscle force production, perhaps consequent to reduced cross-bridge cycling or sarcoplasmic reticulum $Ca^{2+}$-ATPase activity. It is also possible, however, that nitrate supplementation enhances mitochondrial efficiency. Larsen et al have reported that sodium nitrate reduced proton leakage and increased the mitochondrial P/O ratio. The positive effects of nitrate supplementation on the $O_2$ cost of submaximal exercise can be manifest acutely (ie, 2.5 h following a 6 mmol nitrate "bolus") and this effect can be maintained for at least 15 days if supplementation at the same daily dose is continued.

Because beetroot juice contains compounds other than nitrate that might also be bioactive, it has been developed a nitrate-depleted beetroot juice as a placebo. Nitrate-depleted beetroot juice had no physiological effects relative to a control condition, whereas nitrate-rich beetroot juice reduced the $O_2$ cost of both walking and running and extended the time to exhaustion by 15 percent. Most recently, it has been investigated the influence of acute dietary nitrate supplementation on 4 and 16.1 km time trial (TT) performance in competitive cyclists. It has been found that cyclists were able to produce a greater power output for the same rate of pulmonary $O_2$ uptake, resulting in a 2.7 percent reduction in the time to complete both the TT distances. Collectively, recent studies indicate that dietary nitrate supplementation reduces the $O_2$ cost of physical activity and might enhance exercise performance. While these early findings are clearly of considerable interest to athletes, it is possible that clinical populations and older people may also benefit if dietary nitrate intake can be shown to reduce the $O_2$ cost of the "activities of daily living" [11532].

Humans can reduce inorganic nitrate ($NO_3^-$) to nitrite ($NO_2^-$), nitric oxide (NO), and other bioactive nitrogen oxides. The purpose of this study was to test the hypothesis that a single dose of inorganic nitrate before exercise might enhance the tolerance of endurance athletes to high intensity exercise. Eleven cyclists (age = 34 ± 5 years, $VO_{2peak} = 65 ± 6 \text{ mL/kg/min}$) participated in this randomized, double-blind, crossover study. Subjects received dietary supplementation with nitrate ($NaNO_3$ 10 mg/kg of body mass) or a placebo ($NaCl$) 3 h before exercise. They then performed a cycle ergometer test that consisted of four 6-min submaximal workloads, corresponding to 2.0, 2.5, 3.0, and 3.5 W/kg of body mass, interspersed with 3 min of passive recovery. After a 5-min recovery period, subjects performed one incremental exercise test until exhaustion. Plasma nitrate and nitrite were significantly higher 3 h after supplementation than after the placebo at resting conditions. Nitrate supplementation significantly reduced $VO_{2peak}$ and the ratio between $VO_2$ and power at maximal intensity. This reduction of $VO_2$ occurred without changes in the time to exhaustion (nitrate = 416 ± 32 s, placebo = 409 ± 27 s) or in the maximal power (nitrate = 416 ± 29 W, placebo = 410 ± 28 W). It was concluded that a single oral dose of inorganic nitrate acutely reduces $VO_{2peak}$ without compromising the maximal exercise performance [11533].

Acute dietary nitrate ($NO_3^-$) supplementation has been reported to lower resting blood pressure, reduce the oxygen ($O_2$) cost of sub-maximal exercise, and improve exercise tolerance. Given the proposed effects of $NO_3^-$ on tissue oxygenation and metabolic rate, it is possible that $NO_3^-$ supplementation might enhance the duration of resting apnea. If so, this might have important applications both in medicine and sport. It was investigated the effects of acute $NO_3^-$ supplementation on pre-apnea blood pressure, apneic duration, and the heart rate (HR) and arterial $O_2$ saturation (SaO$_2$) responses to sub-maximal and maximal apneas in twelve well-trained apnea divers. Subjects were assigned in a randomized, double blind, crossover design to receive 70 ml of beetroot juice (BR; containing 5.0 mmol of nitrate) and placebo juice (PL: 0.003 mmol of nitrate) treatments. At 2.5 h post-ingestion, the subjects completed a series of two 2-min (sub-maximal) static apneas separated by 3 min of rest,
followed by a maximal effort apnea. Relative to PL, BR significantly reduced resting mean arterial pressure by 2 percent. The mean nadir for SaO₂ after the two sub-maximal apneas was 97.2 ± 1.6 percent in PL and 98.5 ± 0.9% in BR while the reduction in HR from baseline was not significantly different between PL and BR. Importantly, BR increased maximal apneic duration by 11 percent. In the longer maximal apneas in BR, the magnitude of the reductions in HR and SaO₂ were greater than in PL. The results suggest that acute dietary NO₃⁻ supplementation may increase apneic duration by reducing metabolic costs [12454].

Six days of dietary nitrate supplementation in the form of beetroot juice (0.5 L/d) has been reported to reduce pulmonary oxygen uptake (VO₂) during submaximal exercise and increase tolerance of high-intensity work rates, suggesting that nitrate can be a potent ergogenic aid. Limited data are available regarding the effect of nitrate ingestion on athletic performance, and no study has investigated the potential ergogenic effects of a small-volume, concentrated dose of beetroot juice. The authors tested the hypothesis that 6 d of nitrate ingestion would improve time-trial performance in trained cyclists. Using a double-blind, repeated-measures crossover design, 12 male cyclists (31 years, VO₂peak 58 mL/kg/min, maximal power 342 ± 10 W) ingested 140 ml/d of concentrated beetroot (8 mmol/d nitrate) juice (BEET) or a placebo (nitrate-deplete beetroot juice; PLAC) for 6 d, separated by a 14-d washout. After supplementation on day 6, subjects performed 60 min of submaximal cycling (2×30 min at 45 % and 65 % maximal power, respectively), followed by a 10-km time trial. Time-trial performance (953 ±1 8 vs 965 ± 18 s) and power output (294 ± 12 vs 288 ± 12 W) improved after BEET compared with PLAC supplementation. Submaximal VO₂ was lower after BEET (45 % maximal power1.92 ± 0.06 vs 2.02 ± 0.09 L/min, 65 % maximal power 2.94 ± 0.12 vs 3.11 ± 0.12 L/min) than with PLAC (main effect). Whole-body fuel selection and plasma lactate, glucose, and insulin concentrations did not differ between treatments. Six days of nitrate supplementation reduced VO₂ during submaximal exercise and improved time-trial performance in trained cyclists [12455].

**Dihydroxyacetone phosphate and pyruvate**

Dihydroxyacetone phosphate (DHAP) and pyruvate are three-carbon metabolites in the glycolytic pathway. In skeletal muscle, the glycolytic pathway metabolises glucose from the blood and stored glycogen. DHAP is formed at an intermediate step, and pyruvate is produced in the final step of glycolysis. During aerobic exercise, pyruvate enters the mitochondrion and is oxidised to produce ATP. It is not immediately clear how ingesting oral doses of DHAP/pyruvate could influence athletic performance, as it is unlikely that the ingested compounds could reach skeletal muscle and have a direct effect on metabolism. Pyruvate undergoes acid hydrolysis in the stomach and gut with the liberation of carbon dioxide gas, and ingestion of large amounts results in gastrointestinal distress. In addition, the pyruvate that is absorbed into the blood could be taken up and stored by the liver, as even the highest tolerable acute dose of pyruvate (about 25 g) represents a small amount of glucose (about 12.5 g). Only three studies have examined the potential for DHAP/pyruvate to improve exercise capacity. Despite no plausible ergogenic mechanism, two studies reported an improvement in exercise time to exhaustion (20 %). The authors attributed the improvement to increased skeletal muscle glucose utilisation. However, these studies used untrained subjects who were not blinded to the treatments. A later study examined the effects of pyruvate only and had well-trained subjects ingest 7 g/day pyruvate or placebo for 1 week followed by cycling to exhaustion at 75-80 percent of VO₂max. There was no difference in cycling endurance (90 min) between the trials, and the subjects were not able to identify the supplement they received. On the basis of these few reports and no apparent mechanism to alter metabolism, several reviews have concluded that oral pyruvate is not
ergogenic. In summary, there is currently no scientific basis for the use of DHAP/pyruvate as an ergogenic aid [10347].

**Methylsulphonymethane**

MSM is an organic sulphur compound. It is a metabolite of dimethyl sulphoxide (DMSO). MSM occurs naturally in certain foods including green vegetables, grains and milk. For over 30 years, MSM has been used as an oral daily nutritional supplement for various conditions including osteoarthritis, seasonal allergic rhinitis and autoimmune diseases, topically via a throat spray for the treatment of snoring, while athletes occasionally use MSM acutely for muscle soreness. High-quality randomised controlled trials (RCT) are lacking for all claims, but some evidence exists for an effect in osteoarthritic symptom relief. Two small RCT (MSM groups n=25 and 26) have identified statistically significant improvement in osteoarthritic pain scores with MSM compared with placebo. However, the clinical significance of the improved scores is unclear. These two RCTs of efficacy used between 3 and 6 g orally per day in divided doses. The treatment duration in both trials was 12 weeks. No studies on dose ranges have been conducted. It has been performed a meta-analysis of RCT using MSM or DMSO for symptomatic pain relief in osteoarthritis. Only 15 percent of DMSO is converted to MSM in the body and other metabolites are also produced. Combining the studies may, therefore, not be appropriate. There is no long-term safety data from studies in humans. One RCT found the rate of adverse event reporting with MSM to be equal to placebo in the short term (12 weeks). Reported adverse events were minor and mainly gastrointestinal. There are no published trials to support the use of MSM by athletes or the general population for delayed-onset muscle soreness (DOMS) or acute soft tissue injuries. In summary, there is a lack of high-quality evidence for many of the beneficial claims for MSM as a nutritional supplement. There is some limited evidence for the potential benefit of MSM in the symptomatic relief of osteoarthritis, but no definite recommendations can be made on current evidence [11359].

**Melamine**

Melamine (2,4,6-triamino-1,3,5-triazine; tripolycyanimide) is used in the production of plastics and adhesives. It has no documented ergogenic capacity. Given its high nitrogen content, melamine has been illegally used to elevate food protein quantity (such as protein supplements). Melamine and derivatives (e.g. cyanuric acid) are toxic to humans even at low quantities, with strong effects on the kidneys. Tolerable daily intake amounts vary by country and consumer age, but a typical adult level is 0.5 mg/kg/d. Shortly after the 2008 Beijing Olympics, it was discovered that protein products from multiple Chinese manufacturers contained melamine and derivatives, and that those products were distributed internationally. Although screening indicated that Olympic athletes were not exposed, other populations (particularly Chinese infants) were clinically affected. Athletes should be aware of possible melamine contamination in protein-rich foodstuffs [11359].

**Nootkatone**

Nootkatone in spray form has been shown as an effective repellent/insecticide against deer ticks and lone star ticks. It is also an effective repellent/insecticide against mosquitoes, and may repel bed bugs, head lice and other insects. It is environmentally friendly insecticide, because it is a volatile essential oil that does not persist in the environment. It is nontoxic to
humans, is an approved food additive, and "is commonly used in foods, cosmetics, and pharmaceuticals". Nootkatone (4,4a,5,6,7,8-hexahydro-6-isopropenyl-4,4a-dimethyl-2(3H)-naphthalenone), a kind of sesquiterpenoid, was first isolated from the heartwood of Alaska yellow cedar (Callitropsis nootkatensis). Traceable amounts of nootkatone are found in major Citrus species such as grapefruit (Citrus paradisi), and a whole grapefruit contains approximately 100 mg of nootkatone, mainly in the peel. Nootkatone is now available through technological advances such as chemical synthesis, biosynthesis and biotransformation. Nootkatone has a grapefruit-like flavour, tastes slightly bitter and has an odour threshold of about 1 mg/L water. It is used predominantly as a flavouring compound.

A recent animal study demonstrated that 0.2 percent (wt/wt) nootkatone feeding for 10 weeks improved swimming endurance (i.e. swimming time to fatigue) and that long-term intake of diets supplemented with 0.1-0.3 percent nootkatone significantly reduced high-fat and high-sucrose diet-induced body weight gain, abdominal fat accumulation and the development of hyperglycaemia, hyperinsulinaemia and hyperleptinaemia. These beneficial effects of nootkatone might be due in part to enhanced energy metabolism through the activation of AMP-activated protein kinase in the muscle and liver. These findings indicate that nootkatone is a potential candidate for being an ergogenic and antiobesity compound. A previous study indicated that consumption of a whole grapefruit or grapefruit juice for 12 weeks reduces body weight and improves insulin resistance in metabolic syndrome patients compared with placebo. On the other hand, there are no reports on the effects of grapefruit, including nootkatone, on physical performance in humans. Therefore, further studies are required to clarify the efficacy of nootkatone as an ergogenic compound, especially for athletes.

Octacosanol and policosanol

Octacosanol (CH3(CH2)26CH2O14) a high-molecular weight, primary aliphatic alcohol, is typically found in the natural wax extract of various plants and is commonly found in fruits, barks, leaves and whole seeds. Octacosanol supplementation has been purported to achieve several health benefits including lowering cholesterol, cytoprotective effects and antiaggregatory properties. The majority of the supplementation studies have used policosanol (wheat-germ oil extract), which contains a natural mixture of primary alcohols isolated from sugar cane wax, of which octacosanol is the main component. It has been suggested that policosanol reduces cholesterol by downregulating the cellular expression of hydroxymethylglutamyl coenzyme A reductase, although the exact mechanism remains to be elucidated. A meta-analysis has reviewed the efficacy of plant sterols and stanols as well as policosanol in the treatment of coronary heart disease, as measured by a reduction in low-density lipoprotein cholesterol levels (LDL). It was found that policosanol was more effective than both plant sterols and stanols in reducing level LDL levels and more favourably altered the lipid profile. In the 29 eligible studies, 12 mg/day (range 5-40 mg/day in 1528 participants) was found to reduce significantly the LDL levels and the LDL:high-density lipoprotein (HDL) ratio. Moreover, policosanol was more effective in reducing the total cholesterol, increasing the HDL cholesterol and lowering the triglyceride levels when compared with a placebo, plant sterols and stanols. Despite these positive findings, it should be noted that, after this meta-analysis was published, several other studies found that policosanol was ineffective in the treatment of hypercholesterolaemia. Fewer studies have examined the effects of octacosanol and policosanol on athletic performance. An early study found that 1000 microg of octacosanol significantly improved grip strength and reaction time in response to a visual stimulus. Another study found that octacosanol supplementation reduced body fat in athletes. However, limitations of this study included the lack of dietary control, lack of blinding of treatments and the involvement of athletes from different sporting backgrounds in the placebo and supplement groups. As a result, these findings should be
interpreted with caution. In summary, research into the effects of octacosanol and policosanol supplementation on athletic performance is lacking and remains unclear [11532].

**Superoxygenated water**

Recently, superoxygenated-water beverages have emerged as a new purported ergogenic substance. One study aimed to determine the effects of superoxygenated water on submaximal endurance performance. Eleven active male subjects completed a 45-min cycle-ergometry exercise test at 70 percent of their previously predicted maximal power output with a 10-min rest period, followed by a 15-min time trial. Thirty min before the exercise test subjects consumed 15 mL of either superoxygenated water or placebo. Subjects then completed the test again a week later for the other condition (double-blind, randomized). There were no significant differences in VO$_2$, VCO$_2$, RER, VE, lactate, PO$_2$, and heart rate during the exercise tests. Neither were there any significant improvements in the total distance covered or the average power output during the 15-min TT. Based on these results the authors concluded that consuming 15 mL of superoxygenated water does not enhance submaximal or maximal time trial cycling performance [09372].

Superoxygenated-water beverages have emerged as a purported ergogenic substance. One study aimed to determine the effects of superoxygenated water on submaximal endurance performance. Eleven active male subjects completed a 45-min cycle-ergometry exercise test at 70 percent of their previously predicted maximal power output with a 10-min rest period, followed by a 15-min time trial (TT). Thirty min before the exercise test subjects consumed 15 mL of either superoxygenated water (E) or placebo (P; water mixed with low-chlorine solution). Subjects then completed the test again a week later for the other condition (double-blind, randomized). The physiological variables measured during exercise were VO$_2$, VCO$_2$, respiratory-exchange ratio (RER), VE, PO$_2$, PCO$_2$, blood lactate (bLa-), and heart rate (HR). Mean distance covered and the average power output for the 15-min TT were also measured as performance indicators. There were no significant differences in VO$_2$, VCO$_2$, RER, VE, bLa-, PO$_2$, and HR during the exercise tests. Neither were there any significant improvements in the total distance covered or the average power output during the 15-min TT. It was concluded that based on these results the authors conclude that consuming 15 mL of superoxygenated water does not enhance submaximal or maximal TT cycling performance [07394].

**Non-pharmacological therapy**

Athletes dedicate their lives to improving their sporting skills and fitness to be better in their sport. It is acceptable (and logical) to enhance performance by physical training without adding substances to the athlete's body. The use of varied training programs and orthotic devices by athletes (e.g. fins for swimming training) during out-of-competition training is standard practice for most sports and one of the fundamentals of training paradigms. Most such performance-enhancing devices are, however, banned during competition [12015].

**Acupuncture**

Acupuncture (and the field of traditional Chinese medicine, TCM) is arguably an archetype of what is considered CAM in Westernised societies. Acupuncture is also increasingly being integrated into conventional medicine in these communities and is one of the most extensively scientifically studied forms of CAM. While there is still debate on the actual
physiological mechanism of how acupuncture works, many scientists believe that several mechanisms are possible. Because these proposed mechanisms are different from the underlying ethos and philosophy that govern acupuncture and TCM – the presence of the life energy (or “Qi”) flowing through channels (or “meridians”) in the human body – and how disease occur, direct comparisons with the scientific paradigms of biomedicine are not always possible. Also, individuals may use CAM and TCM due to their beliefs in the underlying traditional philosophies rather than any scientific motivation. There are several ways in which acupuncture may work. Local anaesthesia at needle insertion sites may block the analgesic effects of acupuncture which suggests that acupuncture is dependent upon neural innervation. Acupuncture may also cause the release of endogenous opioids in brainstem, subcortical, and limbic structures or induce the secretion of adrenocorticotropic hormone and cortisol from the pituitary gland thereby creating a systemic anti-inflammatory response. Indeed, functional MRI studies in humans show that acupuncture modulates limbic and basal forebrain areas involved in pain processing, while PET (positron-emission tomography) scans have shown that acupuncture is able to increase the opioid binding potential in the brain for several days. Other proposed mechanisms of how acupuncture works are through its ability to mechanically stimulate connective tissues, release adenosine at the site of needle stimulation, or increase local blood flow [12015].

Cryostimulation

Tournament season can provoke overreaching syndrome in professional tennis players, which may lead to deteriorated performance. Thus, appropriate recovery methods are crucial for athletes in order to sustain high-level performance and avoid injuries. It was hypothesized that whole-body cryostimulation could be applied to support the recovery process. To assess the effects of 5 days of whole-body cryostimulation combined with moderate-intensity training on immunologic, hormonal, and hematologic responses; resting metabolic rate; and tennis performance in a posttournament season and controlled laboratory study was performed. Twelve high-ranking professional tennis players followed a moderate-intensity training program. A subgroup was treated with the 5-day whole-body cryostimulation (-120°C) applied twice a day. The control subgroup participated in the training only. Pretreatment and posttreatment blood samples were collected and analyzed for tumor necrosis factor α, interleukin 6, testosterone, cortisol, and creatine kinase. Resting metabolic rate and performance of a tennis drill were also assessed. Proinflammatory cytokine (tumor necrosis factor alpha) decreased and pleiotropic cytokine (interleukin 6) and cortisol increased in the group exposed to cryostimulation. In the same group, greater stroke effectiveness during the tennis drill and faster recovery were observed. Neither the training program nor cryostimulation affected resting metabolic rate [12363].

Cooling

Cold water immersion has become a popular means of enhancing recovery from various forms of exercise. However, there is minimal scientific information on the physiological effects of this following cycling in the heat. Eleven male endurance trained cyclists completed two simulated approximately 40-min time trials at 34.3 ± 1.1 degrees C. It was fond that cold water immersion did not result in hypothermia and can be considered safe following high intensity cycling in the heat, using the above protocol. Cold water immersion significantly reduced heart rate and core temperature; however, all other metabolic and endocrine markers were not affected [09373].

Sublingual, ergogenic spray
Nutrients, chemicals, and drugs may be applied sublingually to provide faster absorption. Sublingual absorption occurs when a substance comes in contact with the buccal mucosa, where it diffuses through a membrane of the dense capillaries. The purpose of one study was to assess the effectiveness of a sublingual, ergogenic product containing vitamins, minerals, amino acids, and a coenzyme on muscle performance. National Collegiate Athletic Association Division I linemen (n=23) voluntarily participated in the study. All participants were tested on 102.1 kg (225 lb) bench press repetitions, vertical jump, and grip strength. One week later, participants were either a placebo or the experimental treatment before they were tested again. Repeated-measures analyses of variance (ANOVAs) yielded a significant gain for the bench press. A Newman-Keuls post hoc test revealed a significant change in the treatment group but not in the placebo group. While the treatment group demonstrated greater improvement over the placebo group for each of the remaining variables, none were significant: vertical jump and grip strength. The inconsistency of the results may be due to several factors. First, the spray may not be an ergogenic agent; second, the standardized dose may be too small for those weighing >290 lb and should be administered based on weight. Furthermore, the coenzyme and amino acids may not possess the molecular size, solubility, chemical stability, or hydrophilic character to be easily absorbed. Lastly, the data were generated by field tests and may not be sensitive enough to elicit subtle responses [09374].
Herbs

The use of herbs as ergogenic aids in exercise and sport is not novel. Ginseng, caffeine, ma huang (also called "Chinese ephedra"), ephedrine and a combination of both caffeine and ephedrine are the most popular herbs used in exercise and sports. It is believed that these herbs have an ergogenic effect and thus help to improve physical performance. Numerous studies have been conducted to investigate the effects of these herbs on exercise performance. Recently, researchers have also investigated the effects of Eurycoma longifolia Jack on endurance cycling and running performance. These investigators have reported no significant improvement in either cycling or running endurance after supplementation with this herb. As the number of studies in this area is still small, more studies should be conducted to evaluate and substantiate the effects of this herb on sports and exercise performance. For instance, future research on any herbs should take the following factors into consideration: dosage, supplementation period and a larger sample size [13745].

Ergogenic theory

Plants provide us with most nutrients essential for life. Other than essential nutrients, plant foods contain naturally occurring substances, referred to respectively as phytochemicals. Herbals, which are derived from leaves, bark, berries, roots, gums, seeds, stems or flowers of plants, also contain numerous phytochemicals thought to have nutritive or medicinal value. Herbs have been used as medicine throughout history. It was reported the earliest evidence of human use of plants for healing dates back to the Neanderthal period, and today various modern medicines may be classified as herbals. Thus, herbals are regulated as medicine in some countries, such as Germany, but as dietary supplements in others. Currently in the United States most herbals are regulated by the Dietary Supplement Health and Education Act (DSHEA), more like food ingredients than drugs. However, given the pharmacological effect of various herbals, some health professionals are emphasizing the need for regulations standardizing herbal therapy. Herbals are popular dietary supplements. In the most recent NHANES report, approximately 7 percent of the US population takes herbal or botanical dietary supplements. Athletes also take herbal supplements. For example, it was reported that 17 percent of female collegiate athletes used herbal/botanical supplements. Herbal dietary supplements are marketed to physically active individuals for a variety of reasons, including increasing energy, inducing weight loss, promoting muscle growth, or inducing other physiological or metabolic responses that may enhance exercise performance. For example, the product SportPharm contains multiple herbals, including Thermadrene, Ma Huang, Guarana, Caffeine, Purple Willow Bark, Cayenne pepper, and Ginger root, and is designed to increase mental alertness, stimulate fat-burning metabolism, and help enhance physical performance. Some sports drinks and sports bars contain herbals as well [06297].

Herbal weight loss supplements

Many weight loss supplements used by athletes contain herbs as active agents which can be vexing given their botanical, chemical and clinical diversity. Here, we offer a system for conceptualising herbal weight loss supplements by putative mechanisms of activity based on
each supplement's presumed bioactive compounds, which are mainly secondary metabolites (SM) and can be categorised into six main groups: alkaloids, flavonoids, polysaccharides, phenolics, terpenoids and other molecules. Most herbs contain compounds from multiple SM categories. Alkaloids are nitrogen-rich molecules derived from amino acid precursors: caffeine is a well-known example. Caffeine and similar molecules increase metabolism and consequently achieve a small increase in the body's rate of energy (calorie, kilojoule) expenditure. Although the physiological relevance of this effect is debated, such herbal weight loss aids are often described as thermogenic. Examples of caffeine-rich herbs include coffee, green tea, guarana and yerba mate. Other alkaloid-rich herbs used for weight loss include bitter orange, black pepper, cayenne pepper, ephedra, ginger, and Indian coleus. Not all plants that contain alkaloids are considered weight loss aids (e.g. chocolate, which contains theobromine and theophylline). Reviews have concluded that, of these, bitter orange, caffeine, ephedra, ginger and green tea supplements may be efficacious in weight loss, but isolated supplements of caffeine, ephedra and guarana may carry serious adverse event risks in the general population. Indeed, the sale of ephedra was banned by the FDA in 2004. Furthermore, it was included on the List of Banned Substances by the International Olympic Committee years prior to that and is currently prohibited for use in competition according to the WADA Banned List. Research reports have suggested that multicomponent green tea/black pepper/cayenne pepper and yerba mate supplements may promote weight loss, but yerba mate supplements may carry adverse effects. Terpenoids, also called isoprenoids, are lipids derived from five-carbon isoprene structures and include carotenoids, steroids and saponins. Terpenoids could conceivably work through several different mechanisms, though anorexiant and diuretic effects are most commonly reported. Weight loss herbs that presumably work through terpenoids include bearberry (kinnikinnick, uva ursi), bitter melon, dandelion, ginseng, gymnema, hoodia, Indian coleus, rhodiola, sarsaparilla, Siberian ginseng and veldt grape (Cissus quadrangularis, a frequent component of Hydroxycut). Recent reviews indicate bitter melon, ginseng, Siberian ginseng and veldt grape may be efficacious or have no effect on weight loss in the general population, but none have been flagged for adverse events. The supplement Hydroxycut, which contains multiple herbal and other products and varies in composition, is not recommended for use by athletes due to safety and efficacy concerns. Hoodia has no evidence for or against it as a weight loss agent. One study in overweight women concluded that Indian coleus supplementation does not directly promote weight loss, but may help in weight management. In obese rodents, gymnema supplements stimulated weight loss, whereas in diabetic rodents, bearberry supplementation maintained body weight, but decreased appetite and thirst, and dandelion had no effect. No studies could be located regarding sarsaparilla and weight loss. Flavonoids are derived from phenylalanine precursors and include anthocyanins and quercetin, and are found in herbs such as dandelion and elderberry. A mechanism by which they might assist weight loss is by reducing lipogenesis and/or increasing lipolysis. Elderberry, along with milk thistle, white willow, coffee and tea, also contain phenols (characterised by having both aromatic hydrocarbon and hydroxyl groups) such as tannins. From little information, reviews indicate elderberry, milk thistle and white willow have not convincingly demonstrated weight loss properties, yet none have perceived risk. Some weight loss aids presumably work through fibre (roughage). Fibre is comprised of polysaccharides that stimulate peristalsis through their laxative effects, may satiate appetite and may block fat absorption, thus contributing to weight loss. Fibre-rich weight loss herbs include guar bean, konjac and psyllium. Primary data conflict regarding their safety and efficacy. Two recent reviews concluded konjac and psyllium may be effective but all carry some risk of adverse effects. Literature regarding herbal supplements and weight loss is patchy. However, it is important to note that many of these conclusions are based on isolated studies or small samples; the majority is conducted on obese (e.g. non-athletic) populations; and mechanisms are often speculative. On the other hand, some may confer additional health benefits – for example, polyphenols found in green tea and milk thistle may have
anticancer, anti-inflammatory and antioxidant effects, while elderberry may be an immunomodulator capable of binding and incapacitating the influenza virus. Additional herbs not covered in this review, but used for weight loss, include bladder wrack (Fucus vesiculosus), blood orange (Citrus sinensis), bromeliad (Bromelia spp), celery seed (Apium graveolens), fenugreek (Trigonella foenum-graecum), horsetail (Equisetum spp), passionflower (Passiflora spp), red grape (Vitis vinifera) and xanthan gum. As is the case with phaseolamin and hydroxycitric acid, other compounds from herbal sources have been used for weight loss such as gamma-oryzanol, nootkatone and yohimbine. Thus, there is a vast array of herbs found in supplements including, but not limited to, those marketed for weight loss. The diversity of individual herbs as well as their simultaneous presence in some products, sometimes more than ten in one product, has become a minefield that both athletes and their sports medicine and science support staff find difficult to navigate. It is worrying how prolific these supplements have become, despite their tenuous, if any, link to a mechanism for weight loss and the lack of supporting evidence. The novel system devised here helps demystify and clarify the rationale, albeit frequently not supported by scientific evidence nor linked to weight loss, behind the inclusion of these herbs in many supplements. In terms of weight loss, it is advisable to make informed dietary changes prior to reaching for supplements. As always, and particularly in the case of some of the herbs discussed here where the evidence is scant, athletes are strongly recommended to seek advice from a sports nutrition professional before considering using any supplements. Furthermore, as stressed in previous reviews, it is essential to reiterate that any athlete who competes under the WADA (World Anti-Doping Agency, http://www.wada-ama.org) code needs to be extremely cautious about using supplements and always work with a qualified professional on risk minimisation of supplement use. The ethical/legal issues of sport can be contravened either by the deliberate use of over-the-counter compounds that are prohibited by such codes (e.g. pro-hormones and stimulants) or by inadvertent intake of these products due to contamination, fake or doping issues, with banned stimulants, such as ephedrine or sibutramine, being frequently found in weight loss supplements [13678].

Prebiotics

Prebiotics are non-digestible polysaccharides and other substances that selectively stimulate the growth or activities of one or more species of gut bacteria and which confer a health benefit on the host. These supplements purportedly yield beneficial health effects via the symbiotic relationship that exists between bacteria inhabiting the GI tract, known as the microbiota and their human host. Prebiotics increase the abundance of bacteria indigenous to the gut by providing nutrients as a source of fuel. Naturally occurring food sources with a prebiotic effect include barley, banana, oats, wheat, soya bean, asparagus, leek, chicory, garlic, artichoke and onion. Resistant starch, found in high amylose maize starch and formed through the heating and cooling of starch foods (rice and pasta), is also receiving growing recognition as a potential prebiotic. Various studies have shown that a prebiotic dose above 2.5 g, which is far higher than that occurring in natural foods, increases the abundance of lactic acid and butyrate-producing bacteria. However, all prebiotics are not equal, with clinical outcomes being dose-dependent. The most prevalent areas of clinical research with positive outcomes have been with galacto-oligosaccharides (GOS) and fructo-oligosaccharides (FOS). The fermentation of these starches by GI bacteria releases metabolic byproducts, including short-chain fatty acids (butyrate, propionate and acetate), vitamins and lipid metabolites. These fermentation byproducts modulate various aspects of the immune system and host metabolism. Non-digestible polysaccharides are thus an important dietary nutrient that warrants more scrutiny from clinicians and researchers. The potential benefits of supplementation with prebiotics on athletic performance are most likely indirect: they may be associated with the maintenance of gut health and perhaps a reduced risk of some illnesses
which might enhance the athlete's ability to train and compete. Research shows that athletes experiencing higher illness rates over a competition season tend to perform more poorly than their healthier peers. Preventing illness during training and competition is therefore a high priority for athletes. Without any direct clinical studies on athletes, select findings from closely related population cohorts provide a glimpse of the potential benefits of prebiotic supplementation in athletes. Prebiotic supplements have had beneficial effects in reducing GI and respiratory illness symptoms. Altering GI microbiota through the use of prebiotics may also favourably influence host metabolism, which may also have implications for athletes. Consumption of 16 g per day of FOS by 10 healthy adults in a randomised, double-blind placebo-controlled trial found that prebiotic consumption reduced appetite and increased plasma gut peptide concentration. In conclusion, prebiotic supplements may be of benefit to athletes by limiting illness impacting on competitive performance. Prebiotics such as GOS and FOS can modify the composition of the GI microbiota and appear to be associated with lower rates of GI and respiratory illness in healthy adults. Although there are no specific studies showing benefits of prebiotics on the health of athletes, there is accumulating evidence from studies of probiotics that alterations in gut microflora can lead to such valuable outcomes. Further research is required in various athlete populations on the various types of prebiotic supplements, dosage, timing (pre-exercise or postexercise) and underlying mechanisms before definitive guidelines on supplementation can be issued [12458].

Probiotics

Probiotic bacteria are defined as live food ingredients that are beneficial to the health of the host. Probiotics occur naturally in fermented food products such as yogurt, kefir, sauerkraut, cabbage kimchee, and soybean-based miso and natto. Numerous health benefits have been attributed to probiotics, including effects on gastrointestinal tract function and diseases, immune function, hyperlipidemia, hypertension, and allergic conditions. A systematic review of the medical literature failed to identify any studies that directly investigated the potential ergogenic effects of probiotics on athletic performance. Two published articles suggest that probiotics may enhance the immune responses of fatigued athletes. In summary, although scientific evidence for an ergogenic effect of probiotics is lacking, probiotics may provide athletes with secondary health benefits that could positively affect athletic performance through enhanced recovery from fatigue, improved immune function, and maintenance of healthy gastrointestinal tract function [07388].

It was studied effects of probiotics and training volume on oxidized LDL lipids (ox-LDL), serum antioxidant potential (s-TRAP) and serum antioxidants (s-alpha-tocopherol, s-gamma-tocopherol, s-retinol, s-beta-carotene and s-ubiquinone-10) in marathon runners during 3-months training period, 6-days preparation period and marathon run. Runners (n=127) were recruited for a randomized, double-blind intervention during which they received either Lactobacillus rhamnosus GG (LGG, probiotic group) or placebo drink (placebo group) during whole study. During the preparation period, subjects decreased training and increased carbohydrate intake. Blood samples were taken at baseline, before 6-days preparation, before and immediately after the marathon. Probiotics did not have any effect on ox-LDL, s-TRAP or serum antioxidants levels during the study. Interestingly, ox-LDL increased by 28 percent and 33 percent during the preparation period and decreased by 16 percent and 19 percent during the marathon run in the placebo and probiotic groups, respectively. No changes were seen in s-TRAP before marathon, but during run s-TRAP raised by 16 percent in both groups. The increase of ox-LDL level during the preparative period after several months' training suggests that aerobic training may reduce the concentration of ox-LDL and
that decrease of training together with increased energy intake, mainly carbohydrate, before marathon is capable of increasing the level of ox-LDL [12461].

Probiotics are food supplements that contain live microorganisms which when administered in adequate amounts can confer a health benefit on the host. There is now a reasonable body of evidence that regular consumption of probiotic strains that are proven to survive gut transit can modify the population of the gut-dwelling bacteria (microbiota) and influence immune function, though it should be noted that such effects are dose- and strain-dependent. Probiotics modify the intestinal microbiota such that the numbers of beneficial bacteria increase and usually numbers of species considered harmful are decreased. Such changes have been associated with a range of potential benefits to the health and functioning of the digestive system, as well as modulation of immune function. Probiotics have several mechanisms of action. By their growth and metabolism, they help inhibit the growth and reduce potentially harmful effects of other bacteria, antigens, toxins and carcinogens in the gut. In addition, probiotics are known to interact with the gut-associated lymphoid tissue, leading to positive effects on the innate and even the acquired immune system. Studies have shown that probiotic intake can improve rates of recovery from rotavirus diarrhoea, increase resistance to enteric pathogens and promote antitumour activity. Some evidence suggests that probiotics may be effective in alleviating some allergic and respiratory disorders in young children. In recent years, it has become evident that some probiotics, particularly Lactobacillus strains, when ingested on a daily basis, can reduce upper respiratory tract infection (URTI) incidence in adults [12462].

**Probiotic intervention studies in athletes**

Although there are few published studies of the effectiveness of probiotic use in athletes, there is growing interest in examining their potential to help maintain overall general health, enhance immune function or reduce URTI incidence and symptom severity/duration. A L. rhamnosus GG supplement was investigated in 141 marathon runners who were recruited for a randomised, double-blind intervention study in which they received probiotic or placebo daily for a 3-month training period and then participated in a marathon race with a 2-week follow-up of illness symptoms. Although there were no differences in the number of URTI or gastrointestinal symptom episodes, the duration of gastrointestinal symptom episodes in the probiotic group was shorter than in the placebo group during the training period (2.9 vs 4.3 days) and during the 2 weeks after the marathon (1.0 vs 2.3 days). In a double-blind, placebo-controlled, cross-over trial in which healthy elite distance runners received the probiotic L fermentum or placebo daily for 28 days with a 28-day washout period between the initial and the second treatment, athletes (n=20) had fewer days of respiratory illness and lower severity of respiratory illness symptoms when taking the daily probiotic. The probiotic treatment also elicited a twofold greater change in whole-blood culture interferon (IFN) gamma production compared with placebo, which may be one mechanism underpinning the positive clinical outcomes. In another study of athletes who presented with fatigue, impaired performance and a deficit in blood CD4 (T-helper) cell IFN-gamma production compared with healthy control athletes, this apparent T cell impairment was reversed following a 1-month course of daily probiotic (L acidophilus) ingestion. In a study on the effect of a L casei probiotic supplement on URTI and immune and hormonal changes in soldiers participating in 3 weeks of commando training followed by a 5-day combat course, no difference in infection incidence between groups receiving daily probiotic or placebo was reported. Among the immune parameters investigated, the major finding was a significant decrease in salivary immunoglobulin A (IgA) concentration after the combat course in the placebo group, with no change over time in the probiotic group. A recent randomised, placebo-controlled trial in 64 university athletes reported a lower incidence of URTI episodes during a 4-month winter training period in subjects receiving daily probiotic (L casei Shirota) compared with placebo:
this study also reported better maintenance of salivary IgA in the probiotic group. Importantly, in athlete and non-athlete populations, falls in salivary IgA have been associated with increased URTI incidence. Another recent study using L fermentum reported reduced URTI incidence among male but not among female athletes during 11 weeks of training. From the research reviewed, one cannot reach a solid conclusion of probiotic benefit for sports people [12462].

**Blueberries**

The improvement of insulin sensitivity by exercise has been shown to be inhibited by supplementation of vitamins acting as antioxidants. To examine effects of exercise with or without blueberries, containing natural antioxidants, on cardio-metabolic risk factors 15 healthy men and 17 women, 28 ± 7 years old, were recruited, and 26 completed a randomized cross-over trial with 4 weeks of exercise by running/jogging 5 km five times/week and 4 weeks of minimal physical activity. Participants were also randomized to consume 150 g of blueberries, or not, on exercise days. Laboratory variables were measured before and after a 5 km running-race at maximal speed at the beginning and end of each period, i.e. there were four maximal running-races and eight samplings in total for each participant. Insulin and triglyceride levels were reduced while HDL-cholesterol increased by exercise compared with minimal physical activity. Participants randomized to consume blueberries showed an increase in fasting glucose levels compared with controls, during the exercise period (blueberries: from 5.12 ± 0.49 mmol/L to 5.32 ± 0.29 mmol/L; controls: from 5.24 ± 0.27 mmol/L to 5.17 ± 0.23 mmol/L). Triglyceride levels fell in the control group (from 1.1 ± 0.49 mmol/L to 0.93 ± 0.31 mmol/L), while HDL-cholesterol increased in the blueberry group (from 1.51 ± 0.29 mmol/L to 1.64 ± 0.33 mmol/L). It was concluded that ingestion of blueberries induced differential effects on cardio-metabolic risk factors, including increased levels of both fasting glucose and HDL-cholesterol. However, since it is possible that indirect effects on food intake were induced, other than consumption of blueberries, further studies are needed to confirm the findings [13741].

**Wolfberry (goji berry)**

Wolfberry and goji berry are interchangeable terms for the red fruits of either of the two boxthorn plants in the potato family, *Lycium barbarum* (syn. *Lycium halimifolium*) and *Lycium chinense*. Both are important herbal components of traditional Chinese medicine, where they are often referred to as gou qi. The berries (ie, fructus barbarum, fructus lycii) are used for both food and medicine whereas root bark (cortex lycii radicis) is used solely for medicine. These plants should not be confused with *Solanum lycocarpum*, variously known as wolf's apple, wolf's fruit, or fruit-of-the-wolf and containing toxic alkaloids. Wolfberry fruits are the plant component used most often in sports supplements and contain several purported bioactive molecules including carotenoids, flavonoids, vitamins including plentiful vitamin C, sterols and polysaccharides. Bioavailability studies suggest that, when berries are extracted in milk as in traditional Chinese medicine, zeaxanthins (a subclass of carotenoids) are found in the bloodstream, peaking at 6 h postingestion. Many claims are made for the benefits of wolfberries with respect to health, including improved immune function, fertility, skin and eye health and even antiaging. However, good peer-reviewed evidence for many of these effects is hard to find. With respect to health, there do appear to be some reported benefits for preventing diabetic retinopathy and inhibiting prostate cancer progression. Reports of allergy to wolf berries suggest the risk of sensitivity in some individuals, even the risk of anaphylaxis and the potential for skin photosensitivity. In conclusion, there is some evidence that there
may be a few health benefits in using wolfberries (goji berries) but potential side effects are possible. There is, however, little scientific evidence to justify commercial claims that wolfberry (gogi berry) is a ‘super food’ and there is no evidence that it is of any benefit as an ergogenic aid to sports performance [13694].

Green tea

To evaluate the effect of acute ingestion of green tea polyphenols (GTP) on blood markers of oxidative stress and muscle damage in soccer players exposed to intense exercise a randomized, double-blinded study was conducted on 16 players during a general preparation period, when all athletes participated in a strength-training program focused on the development of strength endurance. After ingestion of a single dose of GTP (640 mg) or placebo, all athletes performed an intense muscle-endurance test consisting of 3 sets of 2 strength exercises (bench press, back squat) performed to exhaustion, with a load at 60 percent 1-repetition maximum and 1-min rests between sets. Blood samples were collected preexercise, 5 min after the muscle-endurance test, and after 24 hr of recovery. Blood plasma was analyzed for the concentrations of thiobarbituric acid-reacting substances (TBARS), uric acid (UA), total catechins, total antioxidant status (TAS), and activity of creatine kinase (CK); at the same time, erythrocytes were assayed for the activity of superoxide dismutase (SOD). In both groups, plasma TBARS, UA, and TAS increased significantly postexercise and remained elevated after a 24-hr recovery period. SOD activity in erythrocytes did not change significantly in response to the muscle-endurance test, whereas in both groups plasma CK activity increased significantly after 24 hr of recovery. Acute intake of GTP caused a slight but significant increase in total plasma catechins. However, GTP was found not to exert a significant effect on measured parameters. It was concluded that acute ingestion of GTP (640 mg) does not attenuate exercise-induced oxidative stress and muscle damage [12464].

The effect of green tea beverage and green tea extract on lipid changes is controversial. It was aimed to identify and quantify the effect of green tea and its extract on total cholesterol (TC), LDL cholesterol, and HDL cholesterol. It was performed a comprehensive literature search to identify relevant trials of green tea beverages and extracts on lipid profiles in adults. Weighted mean differences were calculated for net changes in lipid concentrations by using fixed-effects or random-effects models. Study quality was assessed by using the Jadad score, and a meta-analysis was conducted. Fourteen eligible randomized controlled trials with 1136 subjects were enrolled in our current meta-analysis. Green tea consumption significantly lowered the TC concentration by 7.20 mg/dL and significantly lowered the LDL-cholesterol concentration by 2.19 mg/dL. The mean change in blood HDL-cholesterol concentration was not significant. Subgroup and sensitivity analyses showed that these changes were not influenced by the type of intervention, treatment dose of green tea catechins, study duration, individual health status, or quality of the study. Overall, no significant heterogeneity was detected for TC, LDL cholesterol, and HDL cholesterol; and results were reported on the basis of fixed-effects models. The analysis of eligible studies showed that the administration of green tea beverages or extracts resulted in significant reductions in serum TC and LDL-cholesterol concentrations, but no effect on HDL cholesterol was observed [11406].

The aim of one study was to evaluate the systemic effects of an isotonic sports drink on the metabolic status of athletes of the Italian Olympic rowing team during recovery after strenuous and prolonged physical exercise by means of nuclear magnetic resonance (NMR)-based metabolomics analysis on plasma and urine. Forty-four male athletes of the Italian
Olympic rowing team were enrolled in a double-blind crossover study. All subjects underwent 2 evaluations at 1-week intervals. The evaluation was performed on a rowing ergometer after strenuous physical exercise to produce a state of dehydration. Afterward, the athletes were rehydrated either with a green tea-based carbohydrate-hydroelectrolyte drink or with oligomineral water. Three blood samples were drawn for each subject: at rest, after the exercise, and following rehydration, while 2 urine samples were collected: at rest and after the rehydration period. Biofluid samples were analyzed by high-resolution 1H NMR metabolic profiling combined with multilevel simultaneous data-analysis (MSCA) and partial-least squares-discriminant analysis (PLS-DA). The between-subject variations, as evaluated by MSCA, reflected the variations of lactate levels induced by the physical exercise. Analysis of the within-individual variance using multilevel PLS-DA models of plasma and urine metabolic profiles showed an effect of the green tea-based sports drink on glucose, citrate, and lactate levels in plasma and on acetone, 3-OH-butyrate, and lactate levels in urine. The increase of caffeine and hippuric acid levels in urine indicated the absorption of green tea extract components. NMR-based metabolomics allowed the complex effects of a green tea extract-based carbohydrate/hydroelectrolyte beverage on the energy metabolism of athletes during recovery by postexercise rehydration to be evaluated [09353].

Researchers have long been investigating strategies that can increase athletes' ability to oxidize fatty acids and spare carbohydrate, thus potentially improving endurance capacity. Green-tea extract (epigallocatechin-3-gallate; EGCG) has been shown to improve endurance capacity in mice. If a green-tea extract can stimulate fat oxidation and as a result spare glycogen stores, then athletes may benefit through improved endurance performance. Eight male cyclists completed a study incorporating a 3-way crossover, randomized, placebo-controlled, double-blinded, diet-controlled research design. All participants received 3 different treatments (placebo 270 mg, EGCG 270 mg, and placebo 270 mg + caffeine 3 mg/kg) over a 6-day period and 1 hr before exercise testing. Each participant completed 3 exercise trials consisting of 60 min of cycling at 60 percent maximum oxygen uptake (VO2max) immediately followed by a self-paced 40-km cycling time trial. The study found little benefit in consuming green-tea extract on fat oxidation or cycling performance, unlike caffeine, which did benefit cycling performance. The physiological responses observed during submaximal cycling after caffeine ingestion were similar to those reported previously, including an increase in heart rate, glucose at the 40-min exercise time point, and resting plasma free fatty acids and no change in the amount of carbohydrate and fat being oxidized. Therefore, it was concluded that green-tea extract offers no additional benefit to cyclists over and above those achieved by using caffeine [30954].

A subclass of flavonoids called catechins (and specifically epigallocatechin-3-gallate (EGCG)) from green tea (Camellia sinensis from eastern Asia; same source as white tea, black tea, etc) leaves have demonstrated cardiovascular benefits in non-exercise studies, and may also mitigate some deleterious effects of exercise. Most studies of green tea ergogenic properties have been performed in endurance-trained male cyclists with doses ranging from 135 to 270 mg/day EGCG or total catechins. Studies have shown no difference in time trial or endurance performance following green tea supplementation. The influence of green tea extract on metabolism is less clear, with one study showing it promotes lower respiratory exchange ratio values during exercise, thus indicating a higher percentage fat utilisation, but other studies showing no metabolic differences [11297].

The purpose of one study was to evaluate the effects of a long-term (4-week) green tea extract (GTE) supplementation in combination with strength training on selected blood markers of oxidative stress and muscular damage after a short-term exercise in previously untrained men. We hypothesized that GTE supplementation would elevate antioxidant potential and attenuate exercise-induced oxidative stress and muscular damage. Thirty-five
male students were exposed to 4 weeks of strength training and received (in a randomized, double-blind design) GTE (n=17; 640 mg polyphenols/d) or placebo (P; n=18). Before (term I) and after 4 weeks of strength training and supplementation (term II), students performed a short-term muscular endurance test. Blood samples were collected at rest, 5 minutes after the muscular endurance test, and after 24 hours of recovery. Supplementation with GTE enhanced plasma total polyphenols at rest and 5 minutes after the muscular endurance test. Supplementation also contributed to the rise of resting total antioxidant status in plasma. Throughout the experiment (terms I and II), a reduction in plasma lipid hydroxyperoxides was observed 24 hours after the muscular endurance test. Four weeks of strength training resulted in an increase in plasma lipid hydroxyperoxides at rest, but only in the P group. In term I, the muscular endurance test induced an increase in activity of creatine kinase in plasma after 24 hours of recovery in both the P and GTE groups. In term II, plasma creatine kinase activity after 24 hours of recovery was elevated only in the P group. In conclusion, in previously untrained men, dietary supplementation with GTE (in combination with strength training) enhances the antioxidant defense system in plasma at rest and, in turn, may give protection against oxidative damage induced by both short-term muscular endurance test and long-term strength training [11541].

Green tea catechins (GTCs) have been studied in randomized control trials for their lipid-lowering effects. Studies, however, have been small and demonstrated conflicting results. The objective of this study was to perform a systematic review and meta-analysis of randomized controlled trials evaluating the relationship between GTCs and serum lipid levels, including total, low-density lipoprotein (LDL), high-density lipoprotein (HDL) cholesterol, and triglycerides. A systematic literature search of MEDLINE, EMBASE, Cochrane CENTRAL, and the Natural Medicines Comprehensive Database was conducted through March 2010. Randomized controlled trials evaluating GTCs vs control in human beings and reporting efficacy data on at least one of the aforementioned serum lipid endpoints were included. Weighted mean differences for changes from baseline for lipid endpoints were calculated using random-effects models. Twenty trials (n=1,415) met all inclusion criteria. Upon meta-analysis, GTCs at doses ranging from 145 to 3,000 mg/day taken for 3 to 24 weeks reduced total and LDL cholesterol compared to control. GTCs did not significantly alter HDL cholesterol or triglyceride levels. The consumption of GTCs is associated with a statistically significant reduction in total and LDL cholesterol levels; however, there was no significant effect on HDL cholesterol or triglyceride levels [11542].

Green tea catechins have been hypothesized to increase energy expenditure and fat oxidation by inhibiting catechol-O-methyltransferase (COMT) and thus promoting more sustained adrenergic stimulation. Metabolomics may help to clarify the mechanisms underlying their putative physiological effects. The study investigated the effects of 7-day ingestion of green tea extract (GTE) on the plasma metabolite profile at rest and during exercise. In a placebo-controlled, double-blind, randomized, parallel study, 27 healthy physically active males consumed either GTE (n=13, 1200 mg catechins, 240 mg caffeine/day) or placebo (n=14, PLA) drinks for 7 days. After consuming a final drink (day 8), they rested for 2 h and then completed 60 min of moderate-intensity cycling exercise. Blood samples were collected before and during exercise. Plasma was analyzed using untargeted four-phase metabolite profiling and targeted profiling of catecholamines. Using the metabolomic approach, it was observed that GTE did not enhance adrenergic stimulation (adrenaline and noradrenaline) during rest or exercise. At rest, GTE led to changes in metabolite concentrations related to fat metabolism (3-beta-hydroxybutyrate), lipolysis (glycerol) and tricarboxylic acid cycle (TCA) cycle intermediates (citrate) when compared to PLA. GTE during exercise caused reductions in 3-beta-hydroxybutyrate concentrations as well as increases in pyruvate, lactate and alanine concentrations when compared to PLA. It was concluded that GTE supplementation resulted in marked metabolic differences during rest
and exercise. Yet these metabolic differences were not related to the adrenergic system, which questions the in vivo relevance of the COMT inhibition mechanism of action for GTE [13742].

Black tea

There is a belief that caffeinated drinks, such as tea, may adversely affect hydration. This was investigated in a randomised controlled trial. Healthy resting males (n=21) were recruited from the general population. Following 24 h of abstention from caffeine, alcohol and vigorous physical activity, including a 10 h overnight fast, all men underwent four separate test days in a counter-balanced order with a 5 d washout in between. The test beverages, provided at regular intervals, were 4 × 240 ml black (i.e. regular) tea and 6 × 240 ml black tea, providing 168 or 252 mg of caffeine. The controls were identical amounts of boiled water. The tea was prepared in a standardised way from tea bags and included 20 ml of semi-skimmed milk. All food taken during the 12 h intervention period was controlled, and subjects remained at rest. No other beverages were offered. Blood was sampled at 0, 1, 2, 4, 8 and 12 h, and a 24 h urine sample was collected. Outcome variables were whole blood cell count, Na, K, bicarbonate, total protein, urea, creatinine and osmolality for blood; and total volume, colour, Na, K, creatinine and osmolality for urine. Although data for all twenty-one participants were included in the analysis (mean age 36 years and mean BMI 26 kg/m²), nineteen men completed all conditions. Statistical analysis, using a factorial ANOVA approach within PROC MIXED, revealed no significant differences between tea and water for any of the mean blood or urine measurements. It was concluded that black tea, in the amounts studied, offered similar hydrating properties to water [11407].

To consider whether consumption of black tea has a positive or negative impact on health databases were searched for relevant epidemiological and clinical studies published between 1990 and 2004. Clear evidence was found for coronary heart disease (CHD), where an intake of 3 cups per day related to risk reduction. The mechanism could involve the antioxidant action of tea polyphenols. While experimental models have suggested that flavonoids attenuated cancer risk, epidemiological studies failed to demonstrate a clear effect for tea, although there is moderate evidence for a slightly positive or no effect of black tea consumption on colorectal cancer. Studies on cancer were limited by sample sizes and insufficient control of confounders. There is moderate evidence suggestive of a positive effect of black tea consumption on bone mineral density although studies were few. There is little evidence to support the effect of tea on dental plaque inhibition but evidence to support the contribution of tea to fluoride intakes and thus theoretical protection against caries. There was no credible evidence that black tea (in amounts typically consumed) was harmful. Normal hydration was consistent with tea consumption when the caffeine content was < 250 mg per cup. A moderate caffeine intake from tea appeared to improve mental performance, although sample sizes were small. There was no evidence that iron status could be harmed by tea drinking unless populations were already at risk from anaemia. Thus, there was sufficient evidence to show risk reduction for CHD at intakes of 3 cups per day and for improved antioxidant status at intakes of one to six cups per day. A maximum intake of eight cups per day would minimise any risk relating to excess caffeine consumption. Black tea generally had a positive effect on health [06290].

Ginseng
Ginseng is one of the most popular herbal dietary supplements worldwide. Sales in the United States have been reported to be over USD 300 million annually. Ginseng consists of several species belonging to the plant family Araliaceae. The two major forms are Chinese, Korean or Asian ginseng which belong to the genus Panax, and Siberian or Russian ginseng which belongs to the genus Eleutherococcus. The biologically active constituents in Panax ginseng are a complex mixture of triterpene saponins known as ginsenosides. Siberian, or Russian, ginseng consists of the dried roots and rhizome of Eleutherococcus senticosus, and contains phenolics, polysaccharides, and eleutherosides. In China, Eleutherococcus senticosus is known as wujiaseng or Ciwujia, and the proposed active ingredients are ciwujianosides. The ergogenic effect of ginseng is attributed to the ginsenosides, eleutherosides, and ciwujianosides. Ginseng is theorized to influence the hypothalamic-pituitary-adrenal cortex axis, possibly mitigating the catabolic effects of the stress hormone cortisol. Given these theorized anti-stress effects, one theory of ginseng supplementation is to enhance sports performance by allowing athletes to train more intensely or to induce an antifatiguing effect and increase stamina during competition. Other theories have been proposed to explain the potential ergonomic effect on aerobic endurance capacity, including favorable metabolic, hematologic, and cardiovascular functions. Given these postulates, much of the research involving the ergogenicity of ginseng supplementation has focused on cardiovascular or aerobic endurance performance, with some emphasis on psychomotor performance. Earlier research findings relative to the effect of ginseng on endurance performance are equivocal. For example, one reviewer indicated that controlled studies of Asian ginseng found improvement in exercise performance with use of standardized extracts, long duration of supplementation, large numbers of subjects, and elderly subjects. However, most earlier studies reporting positive ergonomic effects have been associated with improper research methodology, including no control or placebo group, no double-blind protocol, no randomization of order of treatment, no statistical analysis, or the use of nonstandardized commercial ginseng preparations containing other potential ergonomic substances. Several recent studies have reported ergonomic effects of Panax ginseng. Others reported that Panax ginseng supplementation (1.35 g/day for 30 days) significantly increased cycle ergometer endurance time in untrained adults. Also using untrained adults, it was found that eight weeks supplementation with Panax ginseng extract (6 g/day) enhanced performance in treadmill running time which, based on serum levels of antioxidant enzymes, was attributed to decreased oxidative stress. However, this one-group study involved a control pre-test followed by a post-test after the eight-week supplementation period; no placebo was utilized. The vast majority of well-controlled studies have reported no significant effect of either Panax ginseng, eleutherooccus senticosus Maxim L, Ciwujia, or a standardized ginseng extract on cardiovascular, metabolic, or psychologic responses to either submaximal or maximal exercise performance, or on maximal or supramaximal performance capacity. Several recent extensive reviews of well-designed studies have concluded that there is an absence of compelling research evidence regarding the efficacy of ginseng use to improve physical performance in humans with one of the reviews focusing solely on eleutherococcus senticosus. Well-controlled studies and detailed reviews indicate that ginseng in its various forms does not enhance exercise or sport performance [06297].

In athletics today, there is no shortage of participants looking for an extra edge in competition. In addition, there is no shortage of nutritional supplements for athletes to use with hopes of reaping ergogenic benefits. Ginseng is and will continue to be one of these supplements consumed by athletes despite little or no scientific data to support its ergogenicity. Multiple different types of ginseng can be consumed; the most studied and most common types are Siberian, Chinese, and American. Although related, each has different active compounds, and likely, different effects on the body. There do not appear to be significant adverse effects when used for short periods, but further studies are needed to confirm this. Similarly, more studies are needed to address the ergogenic potential of
ginseng. At this time, ginsengs cannot be recommended to improve athletic performance, but there may be some utility for athletes by preventing viral upper respiratory infection and improving cognition. One review evaluated recently published literature on ginseng use in athletes [06333].

Ginseng has been one of the most popular herbs said to improve human exercise performance. Unclear and anecdotal information is known about the effect of ginseng on lactate threshold and aerobic performance in humans. The purpose of one study was to investigate the effect of ginseng supplementation on lactate threshold in physically active young men. Sixty men from the Thai Navy, aged 17-22 years old, were randomized into either the ginseng (n=30) or placebo (n=30) group. The ginseng group took 3 grams of 100 percent ginseng orally, while the placebo group took an equal amount of lactose powder each day, for 8 weeks. Blood lactic acid levels for determination of lactate threshold (LT) were measured during an incremental cycle ergometer work. LT exercise performance, and heart rate (HR) responses to exercise were determined at baseline and after 8 weeks of ginseng and placebo consumption. Substrate oxidation rates during steady state exercise were assessed upon study completion. Selected markers for liver and kidney functions, including serum aspartate aminotransferase, alanine aminotransferase, blood urea nitrogen, and creatinine were monitored for possible side effects of ginseng. LT before and after 8 weeks of supplementation in the ginseng group, and in the placebo group were not different. Both groups had a similar pattern of exercise heart rate, total exercise time, and peak power output. After 8 weeks, the magnitude of difference between ginseng and placebo groups on oxidation rates of fat or carbohydrate was not statistically significant. There were no abnormal changes of markers of liver and renal functions after ginseng administration. It was concluded that daily administration of 3 g of ginseng for an 8-week period did not improve LT nor did it affect physical performances. Therefore, ginseng supplementation did not exert an ergogenic property on aerobic fitness enhancement in well-fit individuals [07393].

“Chinese herbs” is a broad phrase encompassing species from eastern or central Asia purportedly possessing ergogenic, as well as other, properties. Supplements from these herbs are marketed globally and used by athletes around the world. In contrast to drugs, herbs are commonly grown outdoors, where they may experience considerable environmental variation from one crop to another. Harvesting, storage and extraction methods can also differ greatly between crops, or between manufacturers. All of these factors would impact on potential ergogenic effects. Considering that only a handful of studies exist for only a smattering of herbs, and that the studies themselves differ in experimental design and measures, on top of the variation discussed previously, it is not surprising that multiple groups studying the same species report different results. Ginseng is perhaps the most widely reported Chinese herbal supplement used by athletes. The common name encompasses both American and Asian species (genus Panax) as well as “Siberian ginseng” (genus Eleutherococcus, formerly Acanthopanax). Ginseng is claimed to improve cardiorespiratory function, increase aerobic and anaerobic performance, and improve mental acuity via its ginsenosides (triterpenoid saponins, a subclass of glycosides). However, reviews of original research on ginseng have found conflicting results. The most recent comprehensive reviews concluded that ginseng has not demonstrated efficacy as an ergogenic aid in athletes and, further, that the results of studies reporting benefits may be confounded by unsound methodologies such as inappropriate subject populations (e.g. non-athletes) or inappropriate/absent control groups. Despite numerous testimonials, the ergogenic properties of ginseng have not been substantiated scientifically [10252].

Ginseng is one of the most popular herbal supplements in the world. Although it is used for the treatment and prevention of many ailments, it is also used to increase work efficiency and is purported to increase energy and physical stamina. Athletes use ginseng for its alleged
performance-enhancing attributes. However, many studies examining the pharmacological effects of ginseng on physical performance have not employed sound scientific design and methodology. The purpose of one review was to provide an update on published empirical research focusing primarily on the efficacy of ginseng with respect to physical and athletic performance. Despite attempts in recent investigations to improve on the scientific rigor used in examining the ergogenic properties of ginseng, the authors conclude that many of the same methodological shortcomings observed in earlier studies persist. Enhanced physical performance after ginseng administration in well-designed investigations remains to be demonstrated [09366].

Ginseng is found in many products, with the most common forms being tablet and drinks, and is believed to work as a stimulant to enhance performance by increasing alertness in a similar manner to caffeine. Ginseng refers to Asian and American species of genera Panax and Eleutherococcus, although Panax ginseng root material is most commonly used in ergogenic aids (tablets, extracts and energy drinks). Ginsenosides (triterpinoid saponins; also known as panaxosides) are purported to be the primary bioactive compounds responsible for ginseng ergogenic properties, but other compounds such as caffeine and other methylxanthines are present in ginseng supplements. A recent review of ginseng in athletic contexts concluded that its ergogenic efficacy has not been scientifically validated and that many studies showing benefits may contain methodological flaws. Ginseng is an increasingly frequent ingredient of energy drinks (along with caffeine, taurine and guarana). A recent review of performance-enhancing properties of energy drinks suggested glucose and caffeine, not ginseng, are most likely responsible for observed effects. However, it is difficult to pinpoint the effects of ginseng specifically, as it is often found in conjunction with numerous other ingredients. There is no clear scientific support for ginseng as an ergogenic aid at this time. The case of ginseng may be similar to that of and other supplements where extraneous variability is confounding studies [11297].

Emerging evidence indicates exercise training could mediate mitochondrial quality control through the improvement of mitochondrial dynamics. Ginsenoside Rg3 (Rg3), one of the active ingredients in Panax ginseng, is well known in herbal medicine as a tonic and restorative agent. However, the molecular mechanism underlying the beneficial effects of Rg3 has been elusive. In one study, it was compared the effects of Rg3 administration with aerobic exercise on mitochondrial adaptation in cardiac muscle tissue of Sprague-Dawley (SD) rats. Three groups of SD rats were studied: (1) sedentary control, (2) Rg3-treated and (3) aerobic exercise trained. Both aerobic exercise training and Rg3 supplementation enhanced peroxisome proliferator-activated receptor coactivator 1 alpha (PGC-1alpha) and nuclear factor-E2-related factor 2 (Nrf2) protein levels in cardiac muscle. The activation of PGC-1alpha led to increased mRNA levels of mitochondrial transcription factor A (Tfam) and nuclear related factor 1(Nrf1), these changes were accompanied by increases in mitochondrial DNA copy number and complex protein levels, while activation of Nrf2 increased levels of phase II detoxifying enzymes, including nicotinamide adenine dinucleotide phosphate:quione oxidoreductase 1(NQO1), superoxide dismutase (MnSOD) and catalase. Aerobic exercise also enhanced mitochondrial autophagy pathway activity, including increased conversion of LC3-I to LC3-II and greater expression of beclin1 and autophagy-related protein 7 (ATG7), these effects of aerobic exercise are comparable to that of Rg3. These results demonstrate that Rg3 mimics improved cardiac adaptations to exercise by regulating mitochondria dynamic remodeling and enhancing the quantity and quality of mitochondria [13747].
**Ginkgo biloba**

The Chinese Ginkgo tree is the world's most ancient extant, originating two hundred million years ago, and is the source for Ginkgo biloba leaf extract. Ginkgo biloba is believed to exert its mode of action when its active ingredients, the flavonoids and terpenoids, work in concert. One of the tissue level effects is stimulated release of endothelium-derived relaxing factor, which may enhance muscle tissue blood flow through improved microcirculation. Such an effect could improve aerobic endurance by enhancing muscle tissue oxidation. Most Ginkgo biloba supplementation research has been conducted in the elderly, primarily for its vasoregulatory and cognition-enhancing effects. A meta-analysis and several subsequent studies have shown that Ginkgo biloba improves exercise performance, as evaluated by walking distance, in patients with peripheral arterial disease (PAD). However, although Ginkgo biloba supplementation may improve exercise endurance in patients with PAD, there is no evidence that similar effects occur in healthy young or older athletes [06297].

Ginkgo, traditionally available as ginkgo leaf extracts in teas, is now more commonly found as a supplement in tablet form, with evidence suggesting some utility hemorrheologically. Maidenhair tree (Ginkgo biloba, spelled “ginkgo” but often pronounced “gingko”) is native to eastern Asia. Traditionally, ginkgo leaves were extracted in teas to aid memory or improve circulation, but today supplements are more commonly tablets containing about 25 percent glycosides and about 6.5 percent lactones, the purported bioactive constituents. As an ergogenic aid, ginkgo has been considered for claudication (peripheral artery disease) therapy in older adults; however, studies have found that treatment with ginkgo + exercise therapy is equivocal to exercise therapy alone. Ginkgo extract has been considered for mountain sickness or to offset hemorrheological problems associated with exercise at altitude, with one study suggesting it may or may not mitigate altitude sickness contingent on product-specific differences, which may also explain heterogeneity in previous studies. Effects of ginkgo supplementation on blood pressure or salivary cortisol production differed by gender, nature of stress and time of day. The combined evidence suggests ginkgo may have some utility hemorrheologically, but effects are likely to be inconsistent due to the variation in manufacturing processes [11297].

**Garlic**

Garlic (Allium sativum) is a herb that is used as a food in many countries. From the early ages, it was believed to have different pharmaceutical and physiological properties. Raw garlic contains different compounds, the main one being alliin. It can be physically or chemically processed in order to obtain dry garlic powder, distilled oil, macerated oil or aged garlic extract. The latter is the most commonly used as a phytotherapeutic agent and has also been the most studied in human and animal models. It is claimed that garlic and garlic extracts show pharmaceutical properties such as nutritional, immunomodulatory, antioxidant, microvascular and rheological properties. For these reasons, it is assumed that garlic could be a candidate for an antifatigue agent, and thus it is advertised as an ergogenic agent when consumed alone or mixed with other compounds. According to existing scientific literature, it appears that good evidence exists to conclude that regular and high intakes (6-10 g fresh garlic daily) may improve the peripheral circulation. This effect is achieved through a better vascular relaxation, a change in membrane lipids from the red cells that could increase their flexibility and deformability and a negative effect on blood clotting and platelets adhesion. Regarding immunomodulatory and antioxidative capacity, a meta-analysis has shown anticarcinogenic (colorectal and stomach tumours) effects of regular garlic intakes, approx 18 g of fresh garlic or six cloves daily. The reported beneficial effects of garlic extracts on
oxidative stress and microvascular biology suggest that this food may be a potential candidate for an ergogenic and antifatigue compound. However, although some in vivo or animal studies showed promising results in terms of physical performance or delayed fatigue, this has not been confirmed so far in human athletes. There are some human clinical studies on garlic supplementation and fatigue, but the designs are dubious, and in some of them, garlic has been used in conjunction with other molecules, making the interpretation of the results complicated [11297].

More than three thousand publications in the past have confirmed the efficacy of garlic for the prevention and treatment of a variety of diseases, acknowledging and validating its traditional uses. Garlic is also used for the treatment of fatigue, although the mechanism involved remain unclear. The anti-fatigue function of garlic may be closely related to its many favorable biological and pharmacological effects. In animal studies, garlic has been shown to promote exercise endurance. Differences in the methods of processing garlic result in differences in the intensity of its anti-fatigue effect, and the most favorable form of processing has been shown to be extraction of raw garlic followed by its natural aging for a long period in a water-ethanol mixture. In human studies, it has been confirmed that garlic produces symptomatic improvement in persons with physical fatigue, systemic fatigue due to cold, or lassitude of indefinite cause, suggesting that garlic can resolve fatigue through a variety of actions. Recently, primarily in Japan, attempts have been made to measure the intensity of fatigue objectively and quantitatively using biomarkers. Currently available data strongly suggest that garlic may be a promising anti-fatigue agent, and that further studies to elucidate its application are warranted [07389].

Macroalgae

Macroalgae have for centuries been consumed whole among the East Asian populations of China, Korea, and Japan. Due to the environment in which they grow, macroalgae produce unique and interesting biologically active compounds. Protein can account for up to 47 percent of the dry weight of macroalgae depending on species and time of cultivation and harvest. Peptides derived from macroalgae are proven to have hypotensive effects in the human circulatory system. Hypertension is one of the major, yet controllable, risk factors in cardiovascular disease (CVD). CVD is the main cause of death in Europe, accounting for over 4.3 million deaths each year. In the United States it affects one in three individuals. Hypotensive peptides derived from marine and other sources have already been incorporated into functional foods such as beverages and soups. The purpose of one review was to highlight the potential of heart health peptides from macroalgae and to discuss the feasibility of expanding the variety of foods these peptides may be used in [11411].

Spirulina (microalgae)

Spirulina constitutes microalgae belonging to the cyanobacteria class, with nutritional supplements (tablets, flakes and powders) typically being produced from the cultivation of two species Arthrospira platensis and Arthrospira maxima. It is also used as a feed supplement in the aquaculture, aquarium and poultry industries. Spirulina was primarily recognised as being rich in proteins and essential fatty acids, but recently has attracted attention due to its content of phytochemicals with antioxidant and hypolipidemic properties. Claims for general health benefits from spirulina intake are centuries old. Claimed ergogenic benefits relate to antioxidant defence and favourable changes in substrate utilisation during exercise. Indeed, moderately trained runners who received spirulina supplementation for 4
weeks (6 g/day) showed increased fat utilisation, reductions in markers of antioxidant stress and increased endurance at high intensity exercise (95 % VO\textsubscript{2max}) after 2 hours of submaximal running, compared with a similar trial of supplementation with egg protein placebo. Similarly, enhancements in basal antioxidant status and time to fatigue during an incremental exercise test were reported when untrained students consumed 7.5 g/day of spirulina for 3 weeks. Although these results are of interest, limitations of the current literature include the failure to study well-trained individuals, failure to standardise or identify active ingredients, general issues related to monitoring antioxidant status and the lack of protocols related to sports performance. Spirulina is generally considered safe for human consumption; however, concerns related to spirulina supplements include contamination with heavy metals or toxins produced by blue-green algae. Spirulina may join the list of other antioxidant-rich food sources and extracts which require further investigation of potential benefits to exercise performance, along with mechanisms to explain them [12382].

**Phosphatidylserine**

One study investigated the effects of 750 mg of soybean-derived phosphatidylserine, administered daily for 7 d prior to a bout of eccentric exercise and for 2 d following exercise, on delayed onset of muscle soreness and markers of muscle damage, inflammation, and oxidative stress that followed prolonged downhill running. Following preliminary testing and a familiarization session, eight recreationally active males repeated an individualized downhill run at -17 percent for 51 min at 9 km/h on four occasions (trials 1-4). Trials 1 and 3 were presupplementation control trials. After trials 1 and 3 the subjects received, in a double-blind and crossover fashion, either phosphatidylserine or a glucose polymer placebo. Trials 2 and 3 were separated by a 4-week washout period. Venous blood, perceived soreness ratings, and feeling states were assessed prior to exercise, after exercise, and at 24 and 48 h after exercise during each trial. Downhill running led to elevations in perceived soreness creatine kinase activities, myoglobin concentrations, interleukin-6 (IL-6) concentrations, and lipid hydroperoxide concentrations. However, supplementation did not significantly attenuate these responses. These results suggest that supplementation with 750 mg/day phosphatidylserine for 10 d does not afford additional protection against delayed onset of muscle soreness and markers of muscle damage, inflammation, and oxidative stress that follow prolonged downhill running [06294].

Phosphatidylserine (PtdSer) is a ubiquitous phospholipid species that is normally located within the inner leaflet of the cell membrane. PtdSer has been implicated in a myriad of membrane-related functions. As a cofactor for a variety of enzymes, PtdSer is thought to be important in cell excitability and communication. PtdSer has also been shown to regulate a variety of neuroendocrine responses that include the release of acetylcholine, dopamine and noradrenaline. Additionally, PtdSer has been extensively demonstrated to influence tissue responses to inflammation. Finally, PtdSer has the potential to act as an effective antioxidant, especially in response to iron-mediated oxidation. The majority of the available research that has investigated the effects of PtdSer supplementation on humans has concentrated on memory and cognitive function; patients experiencing some degree of cognitive decline have traditionally been the main focus of investigation. Although investigators have administered PtdSer through intravenous and oral routes, oral supplementation has wider appeal. Indeed, PtdSer is commercially available as an oral supplement intended to improve cognitive function, with recommended doses usually ranging from 100 to 500 mg/day. The main sources that have been used to derive PtdSer for supplements are bovine-cortex (BC-PtdSer) and soy (S-PtdSer); however, due to the possibility of transferring infection through the consumption of prion contaminated brain, S-PtdSer is the preferred supplement for use in
humans. Although the pharmacokinetics of PtdSer have not been fully elucidated, it is likely that oral supplementation leads to small but quantifiable increases in the PtdSer content within the cell membrane. A small number of peer-reviewed full articles exist that investigate the effects of PtdSer supplementation in the exercising human. Early research indicated that oral supplementation with BC-PtdSer 800 mg/day moderated exercise-induced changes to the hypothalamo-pituitary-adrenal axis in untrained participants. Subsequently, this finding was extended to suggest that S-PtdSer 800 mg/day reduced the cortisol response to overtraining during weight training while improving feeling of well-being and decreasing perceived muscle soreness. However, equivocal findings from our laboratory might suggest that the dose required to undertake this neuroendocrine action may vary between participants. Interestingly, recent findings demonstrating that short-term supplementation with S-PtdSer 750 mg/day improved exercise capacity during high-intensity cycling and tended to increase performance during intermittent running might suggest an innovative application for this supplement. With the findings from the existing body of literature in mind, one article focused on the potential effects of PtdSer supplementation in humans during and following exercise [06295].

**Pycnogenol**

Pycnogenol (also referred to commonly as picnogel or pycnogel) is a combination of active bioflavonoids produced from the bark of the Pinus maritime pine tree. Pycnogenol supplementation has been reported to have a wide array of health benefits, including improved cognitive function, endothelial function, blood pressure regulation and venous insufficiency. Pycnogenol also may act as an anti-inflammatory agent. In most instances, reference is made to pycnogenol as a powerful antioxidant due to the proportionally high levels of procyanadins within the compound. Recommended doses of pycnogenol range widely and depend upon the treatment aim. For example, to combat chronic venous insufficiency, recommended doses range from 150 to 360 mg/day, whereas others have recommended approximately 75 to 90 mg/day to prevent oxidative tissue damage. In a majority of clinical trials, the duration of supplementation is generally 2 to 3 months. Side effects of pycnogenol supplementation are minimal. There is at least one commercial sports supplement based on pycnogenol which claims to enhance performance and fatigue resistance, but preliminary evidence of such benefits requires further substantiation. One problem of such supplements, however, is the lack of information on the dosage of claimed active ingredients [12462].

**Kava kava (kava)**

Kava kava, or kava, is the peeled and dried root of Piper methysticum G. Forster, a centuries-old South Pacific herb used as a ritual beverage for its relaxing or calming properties. Kava root contains kava lactones (kava pyrones). The neuropharmacologic effects of kava include analgesia, sedation, and skeletal muscle relaxation, but not central nervous system depression. The mechanism is not clear, but blockage of the GABA or norepinephrine neuroreceptors may be involved. Kava is theorized to reduce excess anxiety and/or hand tremor that may disrupt performance in many sports, such as archery and pistol shooting. Kava has been marketed for its antidepressant or anti-anxiety effects, a possible alternative to prohibited or potentially risky ergogenic drugs in such sports, such as alcohol and beta blockers. A recent meta-analysis has suggested that kava extract may be effective for reduction of anxiety symptoms [06297].
St. John's wort

St. John's wort consists of the dried parts of Hypericum perforatum. St. John's wort contains many phytochemicals, including flavonoids, phenolic acids, sterols, tannins, two naphthodianthrones (hypericin and pseudohypericin), and a phloroglucinol derivative (hyperforin). St. John's wort is used therapeutically as an antidepressant. Hyperforin is thought to be the primary active ingredient in antidepressant activity, but hypericin and pseudohypericin may also be important. All are thought to help maintain optimal brain neurotransmitter levels including serotonin, norepinephrine and dopamine. Comparable to kava, St. John's wort may be theorized to reduce anxiety and hand tremor in some athletes. Additionally, as serotonin is involved in appetite control, St. John's wort is theorized to help induce weight loss, which could confer a mechanical advantage to some athletes. Reviews and meta-analyses of research with St. John's wort conclude its effects on treatment of depression are inconsistent and confusing, some showing benefits comparable to standard antidepressant drugs while others noting minimal beneficial effects. Unfortunately, however, no research evaluating the potential ergogenic effect of St. John's wort supplementation on exercise or sport performance has been uncovered. Moreover, no data are available supporting St. John's wort as a means of promoting leanness in athletes [06297].

Quercetin

It was investigated whether 6 wk of antioxidant supplementation (AS) would enhance 30 km time trial (TT) cycling performance. Eleven elite male cyclists completed a randomized, double-blind, cross-over study to test the effects of twice daily AS containing essential vitamins plus quercetin (FRS), and AS minus quercetin (FRS-Q) versus a baseline TT (B). MANOVA analysis showed that time to complete the 30 km TT was improved by 3 percent on FRS compared to B, and by 2 percent over the last 5 km. Absolute and relative (\%HR_{max}) heart rates and percent VO_{2max} were not different between trials, but average and relative power (\% peak power) was higher on FRS. Rates of carbohydrate and fat oxidation were not different between trials. Thus, FRS supplementation significantly improved high-intensity cycling TT performance through enhancement of power output. Further study is needed to determine the potential mechanism(s) of the antioxidant efficacy [06296].

To investigate the effects of 6 weeks of quercetin supplementation on physical performance during military physical training it was used a randomized, double-blind, repeated-measures, placebo-controlled design, and 58 healthy, moderately trained men and women were randomly assigned to quercetin (Q) or placebo (P) groups. Peak oxygen uptake (VO_{2peak}) during maximal effort uphill treadmill running and four physical performance measures (Army Physical Fitness Test, Baumgartner Modified Pull-Up Test, Wingate Anaerobic Test and a 36.6-m sprint) were evaluated before and after 42-54 days of supplementation with 1 g/d of quercetin with vitamins and other substances in a soft chew or placebo chew. It was found that pretreatment-to-posttreatment changes in VO_{2peak} and physical performance were not significantly different in the two groups [10534].

The purpose of one study was to measure the influence of quercetin on plasma cytokines, leukocyte cytokine mRNA, and related variables in ultramarathoners competing in a 160-km run. Sixty-three runners were randomized to quercetin and placebo groups and under double-blinded methods ingested 1000 mg/day quercetin for 3 weeks before the run. Thirty-nine of the 63 subjects (n=18 for quercetin, n=21 for placebo) finished the race and provided blood samples the morning before the race and 15-30 min postrace. Significant prerace to
postrace runner increases were measured for nine proinflammatory and anti-inflammatory plasma cytokines, cortisol, serum C-reactive protein (CRP), and creatine kinase with no significant group differences. Interleukin-6 (IL-6) mRNA did not change after the run, with a significant decrease measured for leukocyte IL-8 mRNA and significant increases for IL-1Ra mRNA and IL-10 mRNA, with no significant differences between groups. In conclusion, quercetin ingestion (1 g/day) by ultramarathon athletes for 3 weeks before a competitive 160-km race significantly increased plasma quercetin levels but failed to attenuate muscle damage, inflammation, increases in plasma cytokine and hormone levels, and alterations in leukocyte cytokine mRNA expression [08431].

Quercetin, a natural polyphenolic flavonoid substance present in a variety of food plants, has been shown in vitro and in animal studies to have widespread health and performance benefits resulting from a combination of biological properties, including antioxidant and anti-inflammatory activity, as well as the ability to increase mitochondrial biogenesis. Little is known about these effects in humans, however, especially with respect to exercise performance. The authors determined whether quercetin ingestion would enhance maximal aerobic capacity and delay fatigue during prolonged exercise in healthy but untrained participants. Twelve volunteers were randomly assigned to 1 of 2 treatments: (a) 500 mg of quercetin twice daily dissolved in vitamin-enriched Tang or (b) a nondistinguishable placebo (Tang). Baseline VO$_{2\text{max}}$ and bike-ride times to fatigue were established. Treatments were administered for a period of 7 days using a randomized, double-blind, placebo-controlled, crossover study design. After treatment both VO$_{2\text{max}}$ and ride time to fatigue were determined. Seven days of quercetin feedings were associated with a modest but significant increase in VO$_{2\text{max}}$ (3.9 % vs placebo) along with a substantial (13.2 %) increase in ride time to fatigue. These data suggest that as little as 7 days of quercetin supplementation can increase endurance without exercise training in untrained participants. These benefits of quercetin may have important implications for enhancement of athletic and military performance. This apparent increase in fitness without exercise training may have implications beyond that of performance enhancement to health promotion and disease prevention [10256].

There is increased interest among such diverse groups as the military, athletes, and the aged for novel plant-derived dietary supplements to enhance performance and maintain/improve health. Quercetin, a flavonoid found in fruits and vegetables, has unique biological properties that are likely to improve mental/physical performance and reduce infection risk during intense exercise. These properties include antiinflammatory, antioxidant, and psychostimulant activity, as well as the ability to stimulate mitochondrial biogenesis, and they form the basis for potential benefits to overall health and disease resistance. However, most information regarding quercetin is based upon in vitro and animal studies. Therefore, there is a pressing need for well-designed clinical trials to evaluate this novel dietary supplement further. One article examined the recent scientific literature concerning the role of quercetin in mental and physical performance and health [09367].

Previous research indicates that ultramarathon exercise can result in blood oxidative stress. The purpose of one investigation was to examine the efficacy of oral supplementation with quercetin, a naturally occurring compound with known antioxidant properties, as a potential countermeasure against blood oxidative stress during an ultramarathon competition. In double-blind fashion, 63 participants received either oral quercetin (250 mg, 4x/day; 1,000 mg/day total) or quercetin-free supplements 3 weeks before and during the 160-km Western States Endurance Run. Results show that quercetin supplementation did not affect race performance. In response to the ultramarathon challenge, aqueous-phase antioxidant capacity (ferric-reducing ability of plasma) was similarly elevated in athletes in both quercetin and quercetin-free treatments and likely reflects significant increases in plasma urate levels.
Alternatively, trolox-equivalent antioxidant capacity was not altered by exercise or quercetin. Accordingly, neither F2-isoprostances nor protein carbonyls were influenced by either exercise or quercetin supplementation. In the absence of postrace blood oxidative damage, these findings suggest that oral quercetin supplementation does not alter blood plasma lipid or aqueous-phase antioxidant capacity or oxidative damage during an ultramarathon challenge [09368].

Previous evidence suggests that quercetin supplementation increases performance in humans. It was examined the effects of 3 weeks of quercetin supplementation on fuel utilization, gross efficiency (GE), and perceived effort during 3 h of cycling over 3 successive days. Forty cyclists were randomized into quercetin and placebo groups and tested for maximal oxygen consumption. For 3 weeks following maximal oxygen consumption testing, subjects supplemented either 1000 mg/day quercetin or placebo during normal training. Following supplementation, subjects cycled at 57 percent maximum power for 3 h, on 3 successive days, using their own bicycles fitted to CompuTrainer Pro Model trainers. Metabolic measurements were taken every 30 min for each 3-h ride. Muscle biopsies obtained from the vastus lateralis immediately pre-exercise and postexercise on days 1 and 3 were analyzed for muscle glycogen content. Power output remained constant for all 3 exercise trials, but significant decreases over time were measured for GE, cadence, respiratory exchange ratio, blood glucose, and muscle glycogen. Significant increases were measured for heart rate and volume of oxygen consumption over time. No quercetin treatment effect was observed for any of the outcome measures in this study. These data indicate that GE is reduced during an exhausting 3-h bout of exercise. However, quercetin did not significantly affect any outcomes in these already well-trained subjects [09369].

The purpose of one study was to measure the influence of quercetin on plasma cytokines, leukocyte cytokine mRNA, and related variables in ultramarathoners competing in the 160-km Western States Endurance Run (WSER). Sixty-three runners were randomized to quercetin and placebo groups and under double-blinded methods ingested 1000 mg/day quercetin for 3 weeks before the WSER. Thirty-nine of the 63 subjects (n=18 for quercetin, n=21 for placebo) finished the race and provided blood samples the morning before the race and 15-30 min postrace. Significant prerace to postrace WSER increases were measured for nine proinflammatory and anti-inflammatory plasma cytokines, cortisol, serum C-reactive protein (CRP) and creatine kinase (CK) with no significant group differences. Interleukin-6 (IL-6) mRNA did not change post-WSER, with a significant decrease measured for leukocyte IL-8 mRNA and significant increases for IL-1Ra mRNA and IL-10 mRNA, with no significant differences between groups. In conclusion, quercetin ingestion (1 g/day) by ultramarathon athletes for 3 weeks before a competitive 160-km race significantly increased plasma quercetin levels but failed to attenuate muscle damage, inflammation, increases in plasma cytokine and hormone levels, and alterations in leukocyte cytokine mRNA expression [07392].

Quercetin supplementation increases muscle oxidative capacity and endurance in mice, but its ergogenic effect in humans has not been established. One study investigated the effects of short-duration chronic quercetin supplementation on muscle oxidative capacity; metabolic, perceptual, and neuromuscular determinants of performance in prolonged exercise; and cycling performance in untrained men. Using a double-blind, pretest-posttest control group design, 30 recreationally active, but not endurance-trained, young men were randomly assigned to quercetin and placebo groups. A noninvasive measure of muscle oxidative capacity (phosphocreatine recovery rate using magnetic resonance spectroscopy), peak oxygen uptake ($V\text{O}_{2\text{peak}}$), metabolic and perceptual responses to submaximal exercise, work performed on a 10-min maximal-effort cycling test following the submaximal cycling, and voluntary and electrically evoked strength loss following cycling were measured before and
after 7-16 days of supplementation with 1 g/day of quercetin in a sports hydration beverage or a placebo beverage. Pretreatment-to-posttreatment changes in phosphocreatine recovery time constant, $V_{0\text{peak}}$, substrate utilization, and perception of effort during submaximal exercise, total work done during the 10-min maximal effort cycling trial, and voluntary and electrically evoked strength loss were not significantly different in the quercetin and placebo groups. Short duration, chronic dietary quercetin supplementation in untrained men does not improve muscle oxidative capacity; metabolic, neuromuscular and perceptual determinants of performance in prolonged exercise; or cycling performance. The null findings indicate that metabolic and physical performance consequences of quercetin supplementation observed in mice should not be generalized to humans [09370].

Maintenance of repeated-sprint performance is a goal during team-sport competition such as soccer. Quercetin has been shown to be an adenosine-receptor antagonist and may reduce oxidative stress via inhibition of the enzyme xanthine oxidase (XO). The purpose of the study was to determine the effect of quercetin consumption on performance of repeated sprints and, secondarily, the XO and inflammatory-marker response induced by repeated-sprint exercise. Fifteen recreationally active, young adult men completed 2 repeated-sprint tests (RST), 12 × 30-m maximal-effort sprints (S1-S12), each after 1 week supplementation with a placebo, a 6 percent carbohydrate commercial sports drink, or that drink with 500 mg of quercetin-3-glicoside, consumed twice a day (1,000 mg/d). Blood samples were collected before supplementation (B0), at baseline before each RST (B1), immediately after RST (B2), and 1 hr after RST (B3). Mean sprint time increased progressively and was significantly higher by S9 for both treatments (6 %); however, there were no significant differences between treatments. Percent fatigue decrement (%FD) for placebo (4 %) was significantly less than with quercetin (5 %). Changes in blood XO, IL-6, and uric acid from B1 to B2 were +47, +77, and +25 percent, respectively, with no difference by treatment. In conclusion, repeated-sprint performance was not improved by quercetin supplementation and was worse than with placebo when expressed as %FD. Quercetin did not attenuate indicators of XO activity or IL-6, a marker of the inflammatory response after sprint exercise [11296].

It has been demonstrated to be effective in increasing physical endurance in mice and humans. However, the mechanisms involved are not fully understood. In one study, male Kunming mice were fed a diet containing 0.1 percent quercetin for 14 days before swimming for 60 min. The overall serum metabolic profile was investigated by a $^1$H nuclear magnetic resonance-based metabolomic approach. Serum glucose, lactate, nonesterified fatty acids (NEFA), and nonprotein nitrogen (NPN), as well as hepatic and muscular glycogen were measured biochemically. The results of metabolomic analysis showed that swimming induced a significant change in serum metabolic profile. Relative increases in the levels of lactate, alanine, low-density lipoprotein-very low-density lipoprotein, and unsaturated fatty acids, and decreases in choline, phosphocholine, and glucose were observed after swimming. With quercetin supplementation, these changes were attenuated. The results of biochemical assays were consistent with the data obtained from metabolomic analysis, in that serum NEFA was increased while lactate and NPN decreased after exposed to quercetin in swimming mice. Similar change in NEFA was also found in liver and gastrocnemius muscle tissues. The current findings suggest that quercetin alters energy metabolism in swimming mice and increased lipolysis may contribute to the actions of quercetin on physical endurance [12469].

Epidemiological studies support multiple disease prevention benefits for individuals consuming foods rich in the flavonol quercetin. In vitro and animal studies indicate that quercetin is a strong antioxidant and anti-inflammatory agent, and exerts antipathogenic and immune regulatory influences. Quercetin supplementation studies in community-dwelling humans do not reflect these positive benefits, but research is continuing in order to
determine the proper outcome measures, dosing regimen and adjuvants that may amplify any perceived bioactive effects of quercetin in vivo. Quercetin supplementation studies in athletes have focused on potential influences on post-exercise inflammation, oxidative stress and immune dysfunction, illness rates following periods of physiological stress and exercise performance. Results thus far have been negative for quercetin's countermeasure effects on postexercise physiological stress indicators, such as immune perturbations. However, when quercetin supplementation is combined with other polyphenols and food components such as green tea extract, isoquercetin and fish oil, a substantial reduction in exercise-induced inflammation and oxidative stress occurs in athletes, with augmentation of innate immune function. Quercetin exerts strong antiviral activities when cultured with a wide variety of pathogens. In mice, quercetin supplementation for 7 days before inoculation with influenza virus and a 3-day period of heavy exertion partially reduced the exercise-induced increase in morbidity and mortality. A 12-week community trial showed a modest reduction in upper respiratory tract infections (URTI) among physically active subjects between the ages of 40 and 85 years consuming 1000 mg quercetin per day, but not among younger adults. Cyclists randomised to 1000 mg/day quercetin or placebo for five weeks experienced reduced URTI incidence during the two-week period following three days of exhaustive exercise. Quercetin supplementation over 7 days induces an increase in mitochondrial biogenesis and treadmill endurance performance (37%) and running distance in wheels in mice. The quercetin-related effects on performance in untrained humans are modest and far below those reported in mice. About 10 different exercise studies have been conducted and, despite conflicting results regarding the effect of quercetin supplementation on endurance exercise capacity, a meta-analysis indicated an ergogenic effect which the authors described as being between trivial and small (about 3%) but which was significant [12470].

It was aimed to test exercise-induced adaptations on skeletal muscle when quercetin is supplemented. Four groups of rats were tested: quercetin sedentary, quercetin exercised, placebo sedentary, and placebo exercised. Treadmill exercise training took place 5 days a week for 6 weeks. Quercetin groups were supplemented with quercetin, via gavage, on alternate days throughout the experimental period. Sirtuin 1 (SIRT1), peroxisome proliferator-activated receptor gamma coactivator-1alpha mRNA levels, mitochondrial DNA (mtDNA) content, and citrate synthase (CS) activity were measured on quadriceps muscle. Redox status was also quantified by measuring muscle antioxidant enzymatic activity and oxidative damage product, such as protein carbonyl content (PCC). Quercetin supplementation increased oxidative damage in both exercised and sedentary rats by inducing higher amounts of PCC. Quercetin supplementation caused higher catalase and superoxide dismutase activity in the non-exercised animals, but not when quercetin is supplemented during exercise. Quercetin supplementation increased SIRT1 expression, but when quercetin is supplemented during exercise, this effect is abolished. The combination of exercise and quercetin supplementation caused lower mtDNA content and CS activity when compared with exercise alone. Quercetin supplementation during exercise provides a disadvantage to exercise-induced muscle adaptations [13746].

Soldiers

The purpose of one study was to assess the short-term effects of quercetin supplementation on aerobically demanding soldier performance. In a double-blind crossover study, 16 male soldiers performed 3 days of aerobically demanding exercise under 3 conditions: Baseline (B), Placebo (P), and Quercetin (Q). Day 1 was a treadmill VO₂peak test. Days 2 and 3 were identical, consisting of 75 minutes of loaded treadmill marching (LM) and a subsequent cycling time trial (TT) to complete 200 kJ of work. After B condition, the soldiers consumed 2 energy bars, each containing 0 mg (placebo) or 500 mg of quercetin (1,000 mg/days) for 8.5 days. Beginning day 6 of supplementation, the soldiers performed the 3 exercise days. There
was a significant increase in plasma Q after Q supplementation. Repeated measures analyses of variance revealed no differences after P or Q supplementation as compared with B in VO₂peak or TT time. The respiratory exchange ratio during LM did not differ across treatments. Ratings of perceived exertion were not affected by Q supplementation during the VO₂peak test, LM or TT. Supplementation of 1,000 mg/day of quercetin for 8.5 days had no positive effect on aerobically demanding soldier performance. It is possible that a different dosing regimen, a combination of antioxidants or a different form of quercetin supplementation, may be needed to produce an increase in soldier performance.

Mice

Quercetin has been demonstrated to be effective in increasing physical endurance in mice and humans. However, the mechanisms involved are not fully understood. In one study, male Kunming mice were fed a diet containing 0.1 percent quercetin for 14 days before swimming for 60 min. The overall serum metabolic profile was investigated by a ¹H nuclear magnetic resonance-based metabolomic approach. Serum glucose, lactate, nonesterified fatty acids (NEFA), and nonprotein nitrogen (NPN), as well as hepatic and muscle glycogen were measured biochemically. The results of metabolomic analysis showed that swimming induced a significant change in serum metabolic profile. Relative increases in the levels of lactate, alanine, low-density lipoprotein-very low-density lipoprotein, and unsaturated fatty acids, and decreases in choline, phosphocholine, and glucose were observed after swimming. With quercetin supplementation, these changes were attenuated. The results of biochemical assays were consistent with the data obtained from metabolomic analysis, in that serum NEFA was increased while lactate and NPN decreased after exposure to quercetin in swimming mice. Similar change in NEFA was also found in liver and gastrocnemius muscle tissues. The findings suggest that quercetin alters energy metabolism in swimming mice and increased lipolysis may contribute to the actions of quercetin on physical endurance.

Capsaicin

Performance in many team sports is partially dependent on the ability to perform repeatedly at high intensity. Previous research demonstrates that capsaicin (CAP) has physiological and metabolic effects that could influence exercise performance and inflammation. The purpose of this study was to investigate the influence of CAP on performance of and the interleukin-6 (IL-6) response to repeated sprints. Nineteen healthy male experienced athletes, age 18-30 years, participated in a placebo (PCB)-controlled, crossover study. During 1 trial, they consumed 3 g/d cayenne (26 mg/d CAP) and the other a PCB for days. Directly after the supplementation period, they completed a repeated sprint test (RST) consisting of 30 maximal effort sprints on 35-second intervals with sprint times measured via an electronic dual-beam timing system. Fasted blood draws for IL-6 were taken at baseline before supplementation, 45 minute pre-RST, and immediately post-RST. Rate of perceived exertion (RPE), muscle soreness (MS), and gastrointestinal distress (GD) for 5 symptom subscales were measured 1-minute pretest, during, posttest, and 1-minute posttest. The MS was additionally measured for 3-day posttest. Relative to the PCB, CAP significantly increased the sum of ratings of GD symptoms by 6.3-fold. There was no difference between treatments in fastest or mean sprint time, fatigue, IL-6 response, RPE, or MS. In summary, CAP did not influence repeated sprint performance or the IL-6 response but caused substantial GD. The CAP is not recommended for athletes involved in repeated sprinting.
The Capsicum species (C. annuum; C. frutescens), native to tropical America, incorporates such peppers as the cayenne, red, and chili. The medicinal properties of the capsicum species are attributable to a compound known as capsaicin. The United States Pharmacopeia has classified capsaicin as a stimulant, and based on their previous research have related its physiological action to caffeine, i.e., ingestion may induce sympathetic activation of the central nervous system, increasing catecholamine secretion and enhancing lipid oxidation, sparing the use of glycogen. Some research supports this hypothesis. For example, when fed capsaicin (2 mg/kg), males at rest and exposed to immersion in cold water had a significant decrease in carbohydrate as an energy source. However, limited research is available regarding the effect of capsaicin on carbohydrate metabolism during exercise. In a well-designed study, it was evaluated the effect of a breakfast meal containing 10 g of dried, hot red pepper on energy substrate use in male runners during rest and exercise (cycling at about 60 percent VO\(_{2\text{max}}\)). For the red pepper trial, plasma epinephrine and norepinephrine concentrations were significantly elevated after 30 min, but not at 60 and 150 min of rest. The hot pepper meal significantly elevated the respiratory quotient (RQ) and blood lactate levels at rest and during exercise, but there was no effect on oxygen consumption or energy expenditure during rest or exercise. These results suggest that contrary to the theory of glycogen sparing, hot red pepper ingestion stimulates carbohydrate oxidation at rest and during exercise. The authors suggested that hot red pepper ingestion before exercise could decrease endurance performance in athletes due to associated muscle and/or liver glycogen depletion. Currently, no scientific evidence is available to support an ergogenic effect of capsaicin supplementation. Additional research is merited [06297].

**Yucca**

Yucca encompasses about 40-50 medicinally potent plant species that generally thrive in arid parts of southwestern USA and Mexico. Although medical research into yucca is very limited, the most researched species is Yucca schidigera (Mojave yucca), which is found in a variety of food supplements. Yucca has a reputed place in folk medicine for a variety of conditions with the most mentioned anti-inflammatory and antiarthritic effects. The yucca extract is widely used as an animal feed additive to increase growth rate, improve feed conversion efficiency and to ease joint pains in horses and dogs. Yucca has also been shown to have antioxidant, anticancer, antidiabetic, antimicrobial and hypcholesterolaemic properties. Steroidal saponins, resveratrol and yuccaol have been identified as active principles. Having identified this combination of substances, although there is no scientific evidence, there has been an interest in yucca from the sports medicine community. Yucca saponins are precursors to cortisone. Yuccaols and resveratrol, which are mainly found in the yucca bark, are known to have a variety of actions, including inhibitors of the nuclear transcription factor kappaB (NFκB) and thus anti-inflammatory, antioxidant and free radical scavengers. In addition, resveratrol has been shown to have an influence on muscle fibres, strength and possible ergogenic effects. Resveratrol, on its own, or in the form of a yucca extract, has several potential indications in sport and exercise medicine, which warrant further research efforts. However, there are currently no established oral doses or recommendations, and there is no evidence of an ergogenic benefit in sports performance [13749].

**Teribulus terrestris**

Tribulus terrestris, commonly known as puncture vine, is an herbal preparation that has been used medicinally as a diuretic as well as treatment for hypertension and
hypercholesterolemia, and has been used for centuries in Europe as treatment for impotence. The purported active ingredients are saponins and protodiosin. As ergogenic aids, Tribulus terrestris is used in the belief that they may elicit anabolic effects via increased testosterone production. Although limited, the available research does not support an ergogenic effect of Tribulus terrestris supplementation in humans. It was found that consumption of either 10 or 20 mg/kg body weight of Tribulus terrestris extract daily for four weeks had no effect on serum testosterone or androstenedione. Also, in a double-blind, placebo-controlled study, Tribulus terrestris supplementation exerted no effect on body weight, body composition, maximal strength or muscular endurance in resistance-trained males during training; plasma testosterone levels were not measured [06297].

Tribulus terrestris is a nutritional supplement highly debated regarding its physiological and actual effects on the organism. The main claimed effect is an increase of testosterone anabolic and androgenic action through the activation of endogenous testosterone production. Even if this biological pathway is not entirely proven, T. terrestris is regularly used by athletes. Recently, the analysis of two female urine samples by GC/C/IRMS (gas chromatography/combustion/isotope-ratio-mass-spectrometry) conclusively revealed the administration of exogenous testosterone or its precursors, even if the testosterone glucuronide/epitestosterone glucuronide (T/E) ratio and steroid marker concentrations were below the cut-off values defined by World Anti-Doping Agency. To argue against this adverse analytical finding, the athletes recognized having used T. terrestris in their diet. In order to test this hypothesis, two female volunteers ingested 500 mg of T. terrestris, three times a day and for two consecutive days. All spot urines were collected during 48h after the first intake. The $^{13}$C/$^{12}$C ratio of ketosteroids was determined by GC/C/IRMS, the T/E ratio and DHEA concentrations were measured by GC/MS and LH concentrations by radioimmunoassay. None of these parameters revealed a significant variation or increased above the WADA cut-off limits. Hence, the short-term treatment with T. terrestris showed no impact on the endogenous testosterone metabolism of the two subjects [08430].

Tribulus terrestris (caltrop, puncturevine) grows in southern Asia and is consumed primarily by anaerobic athletes for its purported strength-enhancing capacities. Steroidal saponins (glycosides) are the purported bioactive compounds, believed to upregulate testosterone production thereby increasing muscle mass and strength. A study of young male rugby players supplemented with T terrestris for 5 weeks (60 % saponins by content) showed no effect of supplementation on strength or fat-free mass. Dosing did not influence urinary testosterone/epitestosterone levels. This study is representative of the few others on the topic [10252].

Tribulus terrestris is an herbal nutritional supplement that is promoted to produce large gains in strength and lean muscle mass in 5-28 days. Although some manufacturers claim T. terrestris will not lead to a positive drug test, others have suggested that T. terrestris may increase the urinary testosterone/epitestosterone (T/E) ratio, which may place athletes at risk of a positive drug test. The purpose of one study was to determine the effect of T. terrestris on strength, fat free mass, and the urinary T/E ratio during 5 weeks of preseason training in elite rugby league players. Twenty-two Australian elite male rugby league players were match-paired and randomly assigned in a double-blind manner to either a T. terrestris (n=11) or placebo (n=11) group. All subjects performed structured heavy resistance training as part of the club’s preseason preparations. A T. terrestris extract (450 mg/day) or placebo capsules were consumed once daily for 5 weeks. Muscular strength, body composition, and the urinary T/E ratio were monitored prior to and after supplementation. After 5 weeks of training, strength and fat free mass increased significantly without any between-group differences. No between-group differences were noted in the urinary T/E ratio. It was concluded that T. terrestris did not produce the large gains in strength or lean muscle mass
that many manufacturers claim can be experienced within 5-28 days. Furthermore, T. terrestris did not alter the urinary T/E ratio and would not place an athlete at risk of testing positive based on the World Anti-Doping Agency's urinary T/E ratio limit of 4:1 [07391].

Two oligosaccharides and a stereoisomer of di-p-coumaroylquinic acid were isolated from the aerial parts of Tribulus terrestris along with five known compounds. The structures of the compounds were established as O-beta-D-fructofuranosyl-(2→6)-alpha-D-glucopyranosyl-(1→6)-beta-D-fructofuranosyl-(2→6)-beta-D-fructofuranosyl-(2→1)-alpha-D-glucopyranosyl-(6→2)-beta-D-fructofuranoside, O-alpha-D-glucopyranosyl-(1→4)-alpha-D-glucopyranosyl-(1→4)-alpha-D-glucopyranosyl-(1→2)-beta-D-fructofuranoside, 4,5-di-p-cis-coumaroylquinic acid by different spectroscopic methods including 1D NMR (¹H, ¹³C and DEPT) and 2D NMR (COSY, TOCSY, HMQC and HMBC) experiments as well as ESI-MS analysis. This is the first report for the complete NMR spectral data of the known 4,5-di-p-trans-coumaroylquinic acid. The antioxidant activity represented as DPPH free radical scavenging activity was investigated revealing that the di-p-coumaroylquinic acid derivatives possess potent antioxidant activity so considered the major constituents contributing to the antioxidant effect of the plant [13753].

**Arnica**

Arnica montana is a herbaceous plant, native to many regions or Europe. Its flowering heads have been used for medicinal purposes for millennia. Arnica extracts contain sesquiterpene lactones, volatile oils and flavonoids. They are said to have anti-inflammatory and antimicrobial activity. The former property has rendered arnica preparations popular remedies for sports injuries. There are two fundamentally different types of arnica preparations: herbal and homeopathic. Herbal arnica cream (administered exclusively topically because, given orally, arnica can be toxic) has not been extensively tested in controlled clinical trials: therefore it is not known whether it is effective or not. Nevertheless, such creams are extensively used and are for sale everywhere. However, there is no good evidence that herbal or homeopathic arnica preparations have a role in sports medicine [09362].

The aim of one study was to determine if topical Arnica is effective in reducing pain, indicators of inflammation and muscle damage, and in turn improve performance in well-trained males experiencing delayed onset muscle soreness (DOMS). Twenty well-trained males matched by maximal oxygen uptake completed a double-blind, randomised placebo-controlled trial. Topical Arnica was applied to the skin superficial to the quadriceps and gastrocnemius muscles immediately after a downhill running protocol designed to induce DOMS. Topical Arnica was reapplied every 4 waking hours for the duration of the study. Performance measures (peak torque, countermovement and squat jump), pain assessments (visual analogue scale (VAS) and muscle tenderness) and blood analysis (interleukin-1 beta, interleukin-6, tumour necrosis factor-alpha, C-reactive protein, myoglobin and creatine kinase) were assessed at seven time points over five days (pre-, post-, 4, 24, 48, 72 and 96 hours after the downhill run). Participants in the topical Arnica group reported less pain as assessed through muscle tenderness and VAS 72 hours post-exercise. The application of topical Arnica did not affect any performance assessments or markers of muscle damage or inflammation. Topical Arnica used immediately after intense eccentric exercise and for the following 96 hours did not have an effect on performance or blood markers. It did however demonstrate the possibility of providing pain relief three days post-eccentric exercise [13750].
Rhodiola rosea

Rhodiola rosea is a herb part of the Crassulacae family and is also known as Arctic root, rose root and golden root. It grows in the mountainous and Arctic regions of North America, Europe and Asia. It is purported that R. rosea possesses several ergogenic properties such as increasing physical and mental performance, enhancing cognitive and neural function and free radical mitigation. It has been described as an adaptogen because of its cardioprotective effects. Although the majority of research investigating the effects of R. rosea has been conducted in the animal model, there have been several studies done in humans. The dosages investigated in humans have ranged from 100 to 600 mg/day. Studies investigating its effects on exercise performance have been mixed. R. rosea supplementation in doses of 100 mg/day for 20 days and one acute dose of 200 mg/day were found to improve endurance exercise capacity by 6.5 percent and 5.0 percent, respectively. However, other studies have found no positive effects on VO$_{2peak}$, peak power, lactate threshold and ventilatory threshold. Studies investigating R. rosea supplementation on neural and cognitive performance have also produced mixed results. Doses of 100–555 mg/day have found positive effects on cognition but other studies have found no effect using doses 200 mg/day either acutely or for 5 weeks. R. rosea contains phenylpropanoids, phenolic compounds and flavonoids; some studies have found that supplementation can increase antioxidant levels decrease muscle-damage markers and mitigate free radicals. Based on the available literature, it remains unclear whether R. rosea supplementation in doses of 100–600 mg/day can enhance either mental and/or exercise performance. However, there is some evidence that R. rosea does possess antioxidant properties. Further tightly controlled studies in well-trained athletes need to be conducted in order to determine any performance-enhancing effects [12470].

Rhodiola rosea has been theorized to enhance endurance performance through a stimulating effect. In a preliminary study, it was found that an acute dose (200 milligrams) of Rhodiola rosea improved time to exhaustion by 3 percent on a cycle ergometer, but there was no significant effect following four weeks of supplementation with 200 milligrams daily. There was no effect on maximal strength or various measures of reaction time or movement time. Using combinations of such herbals have also been shown to have no ergogenic effect. It was evaluated the ergogenic effects of Rhodiola rosea-based supplement and reported no significant effects on oxygen dynamics, various physiological measures, or cycling time to exhaustion [06297].

Rhodiola rosea is an herb purported to possess adaptogenic and ergogenic properties and has recently been the subject of increased interest The purpose of this article was to review and summarize recent investigations of the potential performance-enhancing properties of Rhodiola rosea. Such studies have generated equivocal results. Several investigations conducted in Eastern Europe have indicated that Rhodiola rosea ingestion may produce such positive effects as improved cognitive function and reduced mental fatigue. Other research from this region has illustrated enhanced endurance exercise performance in both humans and rats. Studies conducted in Western Europe and in North America have indicated that Rhodiola rosea may possess substantial antioxidant properties but have produced mixed results when attempting to demonstrate an ergogenic effect during exercise in humans [06298].

Supplements from Rhodiola species (arctic or rose root; most commonly Rhodiola rosea) are purported to have many of the same ergogenic outcomes attributed to ginseng. Like ginseng, the supposed source of bioactivity is a subclass of glycosides (in this case, rosavins). Similar to ginseng again, the evidence substantiating ergogenic effects of Rhodiola supplementation is tenuous. A review concluded that this herb may possess some benefit for endurance (vs
strength) athletes, possibly through antioxidant or mitochondrial actions. However, but experimental differences between studies hamper direct comparisons, and several studies have not supported ergogenic claims [10252].

Rhodiola rosea, is an adaptogen plant which has been reported to promote fatty acids utilisation, to ameliorate antioxidant function, and to improve body resistance to physical strenuous efforts. The purpose of one study was to investigate the effects on physical performance as well as on the redox status of a chronic Rhodiola Rosea supplementation in a group of competitive athletes during endurance exercise. Following a chronic supplementation with Rhodiola Rosea for 4 weeks, 14 trained male athletes underwent a cardio-pulmonary exhaustion test and blood samples to evaluate their antioxidant status and other biochemical parameters. These data were compared with those coming from the same athletes after an intake of placebo. The evaluation of physical performance parameters showed that HR Max, Borg Scale level, VO$_{2\text{max}}$ and duration of the test were essentially unaffected by Rhodiola Rosea assumption. On the contrary, Rhodiola Rosea intake reduced, in a statistically significative manner, plasma free fatty acids levels. No effect on blood glucose was found. Blood antioxidant status and inflammatory parameters resulted unaffected by Rhodiola Rosea supplementation. Blood lactate and plasma creatine kinase levels were found significantly lower in Rhodiola Rosea treated subjects when compared to the placebo treated group. It was concluded that chronic Rhodiola Rosea supplementation is able to reduce both lactate levels and parameters of skeletal muscle damage after an exhaustive exercise session. Moreover this supplementation seems to ameliorate fatty acid consumption. Taken together those observation confirm that Rhodiola Rosea may increase the adaptogen ability to physical exercise [10255].

The aim of one study was to investigate the effect of Rhodiola rosea supplementation on the balance of oxidants and antioxidants in the serum and erythrocytes of competitive rowers. This double-blinded study included 22 members of the Polish Rowing Team who were participating in a preparatory camp. Participants were randomly assigned to the supplemented group (n=11), who received 100 mg of R. rosea extract twice daily for 4 wk, or the placebo group (n=11). At the beginning and end of the study, participants performed a 2,000-m maximum test on a rowing ergometer. Blood samples were taken from the antecubital vein before each exercise test, 1 min after completing the test, and after a 24-hr restitution period. The following redox parameters were assessed in erythrocytes: superoxide dismutase activity, glutathione peroxidase activity, and thiobarbituric-acid-reactive substances concentrations. In addition, creatine kinase activity and total antioxidant capacity were measured in plasma samples, lactate levels were determined in capillary blood samples, and uric acid concentrations were measured in serum. After supplementation, the total plasma antioxidant capacity was significantly higher in the supplemented group than in the placebo group, and superoxide dismutase activity in erythrocytes directly after and 24 hr after the ergometry was significantly lower in athletes receiving R. rosea extracts than in the placebo group. In conclusion, supplementation with R. rosea increased antioxidant levels in the plasma of professional rowers but had no effect on oxidative damage induced by exhaustive exercise [09371].

Rhodiola rosea (RR) is an adaptogenic herb suggested to improve exercise and cognitive performance and reduce stress responses. Further, some evidence reports that L-carnitine (LC) can alter metabolism during exercise and improve performance. This study examined the effects of acute ingestion of a commercially available RR beverage (250 mg, 3 % Rosavin) with and without LC (500 mg) on exercise performance, cognitive function and salivary cortisol. In a double-blind, randomised, crossover-design, 18 healthy, active men and women (age, 21 ± 6 years; maximal oxygen uptake, VO$_{2\text{max}}$ 43 ± 9 ml/min/kg) consumed 250 ml of a RR-LC, RR and placebo beverage 45 min before a cycle to fatigue at 77 ± 11
percent of VO$_{2\text{max}}$. Immediately before and after exercise, computerised cognitive tasks of Rapid Visual Information Processing (RVP), Visual Recognition Memory (VRM) and Stroop Colour-Word (Stroop) were completed. Expired gas and heart rate were recorded continuously during exercise. Capillary blood samples were taken for lactate analysis 2 min after cycling and saliva samples were collected before beverage ingestion, before and immediately after cognitive tests for cortisol analysis. Data were analysed using repeated measures ANOVAs. Time to fatigue, physiological and cognitive variables did not differ between treatments. Cortisol increased after tests, but there was no effect of treatment on this response. However, exercise elicited higher RVP sustained attention, a faster response time in Stroop, but VRM was reduced. These findings suggest that acute RR-LC ingestion does not alter cognitive function, exercise performance or salivary cortisol. However, chronic supplementation or greater dosage might affect these results. These results show that exhaustive exercise reduces reaction time and increases attention, but memory outcomes become decreased [11543].

As a society we are increasingly concerned about our physical appearance. For example, as much as 24 percent of people in developed countries admittedly exercise to improve their performance. Professional sportsmen and amateurs alike are in a constant search for new means that will enable them better sport results in shorter time. Among those means, a prominent place belongs to dietary supplements. However, the producers often advertise products whose use in sports is neither scientifically founded nor safe. This brings on an irrational use of herbal supplements which sometimes leads to unwanted side effects, but is more often of little use. Thus, the aim of one review was to systematically evaluate some of the herbal supplements that are used as adaptogenic and ergogenic aids in sport. The review will include available data on Rhodiola rosea, Withania somnifera, Schisandra chinensis, Tribulus terrestris, Vitis vinifera, Citrus aurantium, and others. Their effects, active ingredients as well as possible adverse effects will be discussed with special focus on clinical studies [13751].

**Lack of effect on marathon running**

Adaptogens modulate intracellular signaling and increase expression of heat shock protein 72 (HSP72). Rhodiola rosea (RR) is a medicinal plant with demonstrated adaptogenic properties. The purpose of this study was to measure the influence of RR supplementation on exercise-induced muscle damage, delayed onset of muscle soreness (DOMS), plasma cytokines, and extracellular HSP72 (eHSP72) in experienced runners completing a marathon. Experienced marathon runners were randomized to RR (n=24, 6 female, 18 male) or placebo (n=24, 7 female, 17 male) groups and under double-blinded conditions ingested 600 mg/day RR extract or placebo for 30 days prior to, the day of, and seven days post-marathon. Blood samples were collected, and vertical jump and DOMS assessed the day before, 15 min post- and 1.5h post-marathon. DOMS was also assessed for seven days post-marathon. Marathon race performance did not differ between RR and placebo groups. Vertical jump decreased post-marathon with no difference between groups. Post-marathon DOMS increased significantly but the pattern of change did not differ between groups. Myoglobin (Mb), creatine phosphokinase (CPK), aspartate aminotransferase (AST), alanine aminotransferase (ALT), interleukin (IL)-6, IL-8, IL-10, monocyte chemotactic protein-1 (MCP-1), granulocyte-colony-stimulating factor (G-CSF), C-reactive protein (CRP), and eHSP72 all increased post-marathon, with no group differences over time. In conclusion, RR supplementation (600 mg/day) for 30 days before running a marathon did not attenuate the post-marathon decrease in muscle function, or increases in muscle damage, DOMS, eHSP72, or plasma cytokines in experienced runners [13752].
Cissus quadrangularis

Extracts and powders of Cissus quadrangularis have been used for many years to promote bone and tissues healing, as an analgesic, to treat infections, as an anabolic, and to promote weight loss and weight management. This review summarizes the studies in animals, humans and in vitro systems that have been conducted to determine the efficacy and safety of various Cissus preparations. Animal and in vitro studies provide support for the use of Cissus in promoting bone fracture healing and as an anti-osteoporotic. Several human studies support the use of Cissus extracts in weight management. No studies have been conducted demonstrating that Cissus exhibits anabolic and body building activities. Based on studies to date, Cissus extracts appear to be exceedingly safe and free of adverse effects at the doses commonly used. A wide variety of chemical constituents have been isolated and identified from Cissus extracts, including steroids, flavonoids, stilbenes, iridoids, triterpenes and gallic acid derivatives. However, in few cases have specific physiological effects been related to identifiable constituents. Better standardization of extracts and more well-controlled human studies are required [13754].

Cissus quadrangularis (CQ) is an ancient medicinal plant, found in warm regions of India, Sri Lanka, Malaysia, Java and West Africa. It has been used in traditional medicine to treat a number of ailments from healing bones to treating asthma. CQ has been reported to improve the healing time of bone fractures, potentially by increasing proliferation and differentiation of mesenchymal stem cells to osteoblasts. It has also been suggested to increase collagen synthesis through promoting alkaline phosphatase activity. These findings, along with supposed “anabolic steroidal substances” within CQ, have been used to promote its use within the body-building community for enhancing repair of damaged, connective tissue. However, there are no studies in athletic populations to support this [10253].

Extracts and powders of Cissus quadrangularis have been used for many years to promote bone and tissues healing, as an analgesic, to treat infections, as an anabolic, and to promote weight loss and weight management. This review summarizes the studies in animals, humans and in vitro systems that have been conducted to determine the efficacy and safety of various Cissus preparations. Animal and in vitro studies provide support for the use of Cissus in promoting bone fracture healing and as an anti-osteoporotic. Several human studies support the use of Cissus extracts in weight management. No studies have been conducted demonstrating that Cissus exhibits anabolic and body building activities. Based on studies to date, Cissus extracts appear to be exceedingly safe and free of adverse effects at the doses commonly used. A wide variety of chemical constituents have been isolated and identified from Cissus extracts, including steroids, flavonoids, stilbenes, iridoids, triterpenes and gallic acid derivatives. However, in few cases have specific physiological effects been related to identifiable constituents. Better standardization of extracts and more well-controlled human studies are required [12474].

Hydroxycut

Hydroxycut is a combination weight-loss supplement whose active ingredients include Cissus quadrangularis and caffeine. There are several subformulations containing various combinations of other botanical ingredients, including extracts of goji (Lycium barbarum), acerola (Malpighia glabra), wild mint (Mentha longifolia) and pomegranate (Punica granatum). As currently formulated, we could find no published studies assessing the product's safety and efficacy for weight loss in any population. The botanical ingredients lack evidence of efficacy for weight loss in high quality randomised trials in any population, and
the safety of individual ingredients in humans, and potential interactions, are largely unknown. Some of these botanical agents may have a significant polyphenol/antioxidant component, which may be beneficial during hard training and weight loss. A previous formulation of hydroxycut was withdrawn from the market after being associated with 23 cases of hepatotoxicity and one death. The suspected hepatotoxic ingredients included hydroxycitric acid (HCA) extracted from the garcinia cambogia fruit, chromium, and *Camellia sinensis* (green tea). These ingredients have been removed from the current formulation, although HCA continues to be available in other products, both alone and in combination with chromium and *Camellia sinensis*. Small, short-duration pilot studies have reported that 8 weeks of HCA supplementation resulted in statistically significant weight loss compared with placebo. In hydroxycut's current formulation, HCA has been replaced with *Cissus quadrangularis* (chromium and *Camellia sinensis* have also been removed). Small, short-duration pilot studies of *Cissus quadrangularis* have reported that 10 weeks of supplementation resulted in statistically significant weight loss compared with placebo. When taken as directed, the supplement provides 200 mg of caffeine per dose, with two doses suggested per day. In athletes, modest caffeine supplementation has been found to be an ergogenic aid that positively affects exercise capacity and performance; potential side-effects include irritability, tremor and an increase in heart rate. As is the case with many weight-loss supplements, hydroxycut contains potentially powerful pharmacoactive ingredients, but has never undergone high quality study to assess its safety and efficacy. To date the few published trials of *Cissus quadrangularis* (and HCA) effectiveness in non-athletes have methodological weaknesses including short duration and small size. For both HCA and *Cissus quadrangularis*, many published positive studies are funded by supplement manufacturers yet lack standard conflict of interest declarations. Because of the lack of good evidence of safety and efficacy, herbal weight-loss products are avoided by most performance nutrition practitioners in elite sport [11150].

**Echinacea**

The purpose of this investigation was to determine the effects of 4 weeks of oral Echinacea (ECH) supplementation on erythropoietin (EPO), red blood cell (RBC) count, running economy (RE), and VO$_{2\text{max}}$. Twenty-four men aged 25 years, height 179 cm, weight 88 kg, body fat 19 percent were grouped using a double-blind design and self-administered an 8,000 mg/day dosage of either ECH or placebo (PLA) in 5 × 400 mg × 4 times per day for 28 days. Blood samples were collected and analyzed for RBCs and EPO using automated flow cytometry and enzyme-linked immunosorbent assay. Maximal graded exercise tests (GXTs) were administered to measure VO$_{2\text{max}}$, RE, and heart-rate responses. Analysis of variance was used to determine statistically significant differences. The EPO increased significantly in ECH at 7 days, 14 days, and 21 days, and VO$_{2\text{max}}$ increased significantly after ECH. Running economy improved significantly in ECH as indicated by a decrease in submaximal VO$_{2\text{max}}$ during the first 2 stages of the GXT. These data suggest that ECH supplementation results in significant increases in EPO, VO$_{2\text{max}}$, and running economy [12473].

**Cordyceps sinensis**

Cordyceps sinensis is theorized to have favorable effects on the heart and circulation to improve oxidative capacity and endurance performance. Natural Cordyceps sinensis is rare, but a synthetic version is available; one version is CordyMax Cs-4. It was reported that 5 weeks of CordyMax Cs-4 supplementation had no effect on aerobic capacity or endurance exercise performance in endurance-trained male cyclists. It was evaluated the ergogenic
effects of a Cordyceps sinensis-based supplement and reported no significant effects on oxygen dynamics, various physiological measures, or cycling time to exhaustion [06297].

Labelled an ergogenic herb by some, Cordyceps sinensis is actually a fungus (not a plant) commonly called caterpillar fungus. Cordycepic acid and mannitol are the most frequently cited bioactive compounds; however, most studies of C sinensis in athletes have used a commercial product including other species (such as R rosea) or other isolated compounds. Thus, the ergogenic effects of C sinensis individually are difficult to ascertain. Its effects may lie in its ability to improve oxygen dynamics or upregulate ATP production. An investigation using short-term dosing showed no effect of a C sinensis supplement on muscle-associated parameters in young adult males. Similarly, earlier studies showed no effect of C sinensis on aerobic parameters [10252].

Cytoseira canariensis

Cytoseira canariensis has been marketed to increase muscle mass and decrease body fat by inhibiting myostatin, a growth and differentiation factor whose role is to inhibit (not promote) the growth of muscles. However, it was reported that 1,200 milligrams/day of C cytoseira canariensis supplementation during 12 weeks of resistance training had no effect on serum myostatin levels, not did it have any effect on muscle mass, muscle strength, or body fat [06297].

Smilax (sarsaparilla)

The plant genus Smilax includes several hundred species from the lily order that are distributed globally and commonly known as greenbriar or sarsaparilla (also spelled ‘zarzaporilla’ and often pronounced ‘sasparilla’). Belowground parts (rhizomes and roots) and bark from these plants are used in many traditional cultures to produce root beer, food or various herbal medicines. Smilax supplements are often produced from Smilax medica, Smilax officinalis and Smilax regelii belowground parts via extraction, and are rich in a category of plant sterols called saponins including sarsasapogenin (sarsapogenin), smilagenin (a derivative of sapogenin), sitosterol and stigmasterol. Bodybuilders consume Smilax supplements for their purported anabolic effects, mistakenly perceiving sarsaparilla sterols as prohormonal compounds that can be converted into testosterone by the human body and subsequently increase muscle mass, power, maximal performance and overall metabolism, though these possibilities have been disproved. Other benefits attributed to Smilax supplements include increasing endurance or energy, promoting recovery, lowering body fat and enhancing immune function. Documented side effects include stomach upset and kidney problems (including increased urination) and possible interactions with other supplements or drugs. Typical doses for Smilax supplements are 5-10 ml of extract or 1-4 g dried belowground parts daily. Sports nutrition authorities have found no evidence of ergogenic benefits from Smilax supplementation; therefore its use is discouraged [12459].

Yerba maté

Yerba maté tea (maté) is made from an infusion of the dried leaves of the Ilex paraguariensis tree, which is widely consumed in South America, but also found globally as both a herbal tea beverage and an ingredient in formulated foods and supplements. Numerous active phytochemicals have been identified in yerba maté tea: the two most prevalent compounds
are the polyphenols (chlorogenic acid) and xanthines (caffeine and obromine), followed by purine alkaloids (caffeic acid, 3,4-dicaffeoylquinic acid, 3,5-dicaffeoylquinic acid), flavonoids (quercetin, kaempferol and rutin), amino acids, minerals (phosphorus, iron and calcium) and vitamins (C, B1 and B2). However, unlike other teas, particularly white, green and oolong and, to a lesser extent black, yerba maté is a better alternative as it does not contain catechins, which have recently been linked with liver toxicity. Notably, the amount of caffeine in 150 mL of yerba maté tea is approximately 78 mg, which is similar to the amount found in a 250 mL cup of coffee. Hence, the primary association with sports performance is due to yerba maté being a natural source of caffeine and its associated ergogenic properties. Yerba maté has been shown to be hypocholesterolaemic, hepatoprotective, a central nervous system stimulant, diuretic, antioxidant, of benefit to the cardiovascular system, and associated with both the prevention and increased risk of some types of cancers. Also yerba maté, either on its own or in combination with other ingredients such as guarana and green tea, has been associated with weight loss. However, as with many herbal supplements, the specific evidence for an effect on athletic performance is limited and there is an increased risk of adverse effects [13749].

**Yohimbine**

Yohimbine, an alkaloid extracted from the bark of Corynanthe johimbe or Rauwolfia serpentina, has been used as a selective alpha-adrenergic receptor antagonist. The main aim of one study was to determine the effects of yohimbine supplementation on body composition and exercise performance in professional soccer players. The athletes (20 top-level male soccer players) were allocated to two randomly assigned trials. Subjects in the yohimbine group orally ingested tablets that contains yohimbine at a dose of 20 milligrams per day in two equal doses for 21 days. Subjects in the placebo group ingested an equal number of identical-looking pills that contained cellulose. There were no statistically significant changes in body mass and muscle mass within or between trials after the supplementation protocol. Percentage of body fat significantly decreased in the yohimbine group after the supplementation protocol. Furthermore, fat mass was significantly lower in the yohimbine versus placebo trial at post-supplementation assessment. There were no changes in exercise performance indicators (bench and leg press, vertical jump, dribble and power test results, shuttle run) within or between trials. No subject reported any side effects from yohimbine. The results of the current study indicate that supplementation with yohimbine combined with resistance training does not significantly alter the body mass, muscle mass, or performance indicators in professional soccer players. Nonetheless, yohimbine supplementation appears to be suitable as a fat loss strategy in elite athletes [06299].

Yohimbine is an alkaloid, that is, a naturally occurring secondary metabolite, derived from the bark of the West African tree, Pausinystalia yohimbe, and it can be bought over the counter as a herbal preparation. Traditionally, it has been used for erectile dysfunction and as an aphrodisiac. Yohimbine is an adrenergic alpha2 antagonist and, as yohimbine hydrochloride, is registered by the National Institutes of Health as a treatment for impotency where tolerance for sildenafil (Viagra) is poor. Evidence for this use in humans is not compelling but has been demonstrated in rats. Recent evidence suggests that yohimbine may benefit type 2 diabetes by increasing the blood flow to Islet cells, and it has been used for some time to improve saliva flow for those with xerostomia. Care should be taken over the provision of yohimbine, as it is known to cause agitation, anxiety, hypertension and tachycardia, with severity of these effects increasing with dose. In sport, yohimbine is perceived to reduce body fat and mobilise lipid, as well as to enhance endurance. Accordingly, it is often used in
bodybuilding and other aesthetic sports, and in sports where there is a significant aerobic component. However, despite these claims, research findings actually refute any ergogenic benefit for sport. In addition, as mentioned above, adverse effects have been established [13749].

**Bee pollen**

Bee pollen is a mixture collected by bees of pollen granules from the stamens of flowers and flower nectar. It is commercially available in granule, capsule or tablet preparations. These contain a wide and varying array of nutrients, including saccharides, amino acids, vitamins and minerals, as well as possible contaminants. Despite a long history in traditional medicine as a "superfood," there is little evidence to support the range of health claims for bee pollen. Interest in its ergogenic properties stems from anecdotal reports and testimonies from successful athletes. However, the few available studies from the 1970s and 1980s involving athletes and bee pollen supplementation (3-12-week protocols following manufacturers' recommended doses) have found minimal effects on: haemoglobin concentrations, strength and aerobic capacity, perceived exertion, time trial performance or repeated high-intensity exercise. One study did note fewer days lost to respiratory infections in swimmers supplementing with bee pollen. The limited empirical research suggests that bee pollen supplementation affords no additional benefit to athletic performance beyond that provided by a balanced diet [09135].

**Honey**

The purpose of this study was to examine the effects of natural honey supplementation on seminal plasma cytokines, oxidative stress biomarkers, and antioxidants during 8 weeks of intensive cycling training in male road cyclists. Thirty-nine healthy nonprofessional male road cyclists aged 18-28 years participated in this study. The participants were randomly assigned to exercise + supplement (E + S, n=20) and exercise (E, n=19) groups. All subjects participated in 8 weeks of intensive cycling training. Ninety minutes before each training session, subjects in the E + S group supplemented with 70 g of honey, whereas subjects in the E group received 70 g of an artificial sweetener. All subjects had an initial semen sampling at baseline (T(1)). The next 6 semen collections were collected immediately (T(2)) and 12 (T(3)) and 24 hours (T(4)) after the last training session in week 4, as well as immediately (T(5)) and 12 (T(6)) and 24 hours (T(7)) after the last training session in week 8, respectively. In the E group, 8 weeks of intensive cycling training significantly increased seminal interleukin (IL)-1β, IL-6, IL-8, tumor necrosis factor (TNF)-alpha, reactive oxygen species (ROS), and malondialdehyde (MDA) levels and significantly decreased the levels of seminal superoxide dismutase (SOD), catalase, and total antioxidant capacity (TAC). Significantly less elevation in seminal IL-1β, IL-6, IL-8, TNF-alpha, ROS, and MDA levels and significant increases in seminal SOD, catalase, and TAC concentrations were observed after the honey supplementation in the E + S group. It may be possible that honey supplementation following long-term intensive cycling training would be effective in attenuating the probable aggravating effects of intensive cycling training on spermatogenesis and fertility capacity in road cyclists [12466].

**Royal Jelly**

Royal jelly is secreted by worker bees to feed young larvae to produce a queen bee: it contains a source of amino acids, fatty acids, carbohydrate and B-vitamins, and has long
been used as a dietary supplement in complementary medicine. Little, however, is known about it in the context of exercise. It has been used sublingual doses of royal jelly, apparently combined with other components, on athletes undergoing rehabilitation in Irkutsk. It was not possible to deduce which components might have been responsible for the apparent improvements observed in the athletes' general well-being. Furthermore, royal jelly can cause allergic reactions [12459].

**Phlogenzym and wobenzym**

Phlogenzym and wobenzym are are traditionally paired and have been popular in the Eastern Bloc countries. The active ingredients found in phlogenzym are the hydrolase trypsin, the endopeptidase bromelain and the bioflavonoid rutin. Trypsin is a digestive enzyme produced by the pancreas and secreted into the small intestine, where it hydrolyses proteins. Bromelain is a proteolytic enzyme obtained from pineapples, and rutin is a bioflavonoid found in many plants, fruits and vegetables but the richest source is buckwheat. Similarly, wobenzym also contains trypsin, bromelain and rutin but also includes the proteolytic enzyme papain, the endopeptidase chymotrypsin and pancreatin which is an extract from the pancreas of animals that contains pancreatic enzymes. Phlogenzym and wobenzym are commonly known as hydrolytic enzymes or systemic enzymes and have been purported to possess anti-inflammatory, fibrinolytic and analgesic properties as well as having positive effects on oedema. Studies investigating the efficacy of phlogenzym and wobenzym in the athletic population are lacking but several studies have investigated their effects on recuperation following injury, disease and health. In a double-blind prospective randomised study, phlogenzym was compared with diclofenac in the treatment of activated osteoarthritis of the knee in 63 patients. Phlogenzym supplementation for 3 weeks in doses of six tablets per day (540 mg bromelain, 288 mg trypsin, 600 mg rutin) was found to be more effective than diclofenac in reducing pain over the 3-week period and phlogenzym was superior to diclofenac in reducing pain 3 weeks after supplementation had stopped. In a similar study, phlogenzym supplementation was found to be just as effective and well tolerated as diclofenac in the management of osteoarthritis over 3 weeks of treatment. Studies investigating phlogenzym supplementation for the treatment of lateral ankle ligament injury is mixed. Phlogenzym supplementation in conjunction with dietary counselling and acupuncture was more effective in treating rotator cuff tendinitis compared with an exercise group. However, these findings should be interpreted with caution as the group that received phlogenzym also received diet counselling and acupuncture; therefore, the significant improvement could have been attributed to other factors as there was no treatment group that solely received phlogenzym. Although studies in the athletic population are lacking and findings have been mixed, the research investigating the effects of phlogenzym and wobenzym suggests that they could be used as an effective anti-inflammatory and analgesic. However, future research should also investigate the potential mechanisms of action [12467].

**Cytochrome C**

Cytochrome C, a small haem protein, is found in the mitochondria where it is involved in the electron-transport chain. Endurance training and antioxidant supplementation have been shown to increase muscle cytochrome C concentrations. It has been hypothesised that supplementation with cytochrome C may also increase muscle levels, enhancing exercise performance by increasing maximum oxygen-carrying capacity, reducing blood lactate accumulation, and raising anaerobic threshold. However, the use of cytochrome C as an ergogenic aid to enhance aerobic exercise capacity cannot be supported [10347].
Glandulars

Glandulars are extracts from animal glands, which are normally dried, ground-up and sold in powder or tablet form. The most common glandular supplements include: thyroid; adrenal; thymus; testis and ovary; followed by glandulars from the pituitary, kidney, liver, pancreas, spleen, lung, heart, brain, uterus and prostate. Glandulars are claimed to enhance the function of the equivalent gland in the human body. The theory is that glandular tissues contain intrinsic cell-specific, but not species-specific, factors that are distinct from vitamins and minerals. Glandulars are popular with bodybuilders who believe that their ingestion will produce anabolic effects by boosting the body's production of hormones. However, glandular extracts are degraded during the digestive process and are inactive when absorbed. Therefore, it is not surprising that there is no scientific evidence that glandular tissue concentrates enhance organ and gland activities, or work ergogenically, other than through their vitamin, mineral and protein content [11297].

Lactobacillus casei Shirota

The purpose of this study was to examine the effects of a probiotic supplement during 4 mo of winter training in men and women engaged in endurance-based physical activities on incidence of upper respiratory tract infections (URTIs) and immune markers. Eighty-four highly active individuals were randomized to probiotic (n=42) or placebo (n=42) groups and, under double-blind procedures, received probiotic (PRO: Lactobacillus casei Shirota, LcS) or placebo (PLA) daily for 16 weeks. Resting blood and saliva samples were collected at baseline and after 8 and 16 wk. Weekly training and illness logs were kept. Fifty-eight subjects completed the study (n=32 PRO, n=26 PLA). The proportion of subjects on PLA who experienced 1 or more weeks with URTI symptoms was 36 percent higher than those on PRO. The number of URTI episodes was significantly higher in the PLA group than in the PRO group. Severity and duration of symptoms were not significantly different between treatments. Saliva IgA concentration was higher on PRO than PLA, significant treatment effect; this difference was not evident at baseline but was significant after 8 and 16 weeks of supplementation. Regular ingestion of LcS appears to be beneficial in reducing the frequency of URTI in an athletic cohort, which may be related to better maintenance of saliva IgA levels during a winter period of training and competition [11298].

Colostrum

The aim of one pilot investigation was to examine the influence of bovine colostrum protein concentrate (CPC) supplementation on salivary hormones, salivary IgA and heart rate variability over consecutive days of competitive cycling. Ten highly-trained male road cyclists were randomly assigned to a control (n=6, 10 g whey protein concentrate/day) or bovine CPC group (n=4, 10 g bovine CPC/day). Cyclists provided a baseline saliva sample before commencing eight weeks of supplementation, and competing in a five day cycle race. Cyclists provided saliva samples and measured heart rate variability (HRV) each day of the race. Saliva samples were analysed for cortisol, testosterone and IgA concentrations. Bovine CPC supplementation was associated with increased morning cortisol concentration on the first day of racing when compared to the control group and significantly prevented a decrease in testosterone concentration over the race period. Across the race period parasympathetic indices of HRV were elevated in the bovine CPC group and reduced in the control group, while there were no significant differences in salivary IgA between groups. It
was concluded that bovine CPC supplementation maintained salivary testosterone concentration and modulated autonomic activity over consecutive days of competitive cycling. One pilot study provides justification to explore the effects of bovine CPC on recovery in endurance athletes further \[13748\].

One study examined the effects of bovine colostrum on exercise-induced modulation of antioxidant parameters in the skeletal muscles in mice. Adult male BALB/c mice were randomly divided into four groups (control, colostrum alone, exercise and exercise with colostrum) and each group had three subgroups (day 0, 21 and 42). Colostrum groups of mice were given a daily oral supplement of 50 mg/kg body weight of bovine colostrum and the exercise group of mice were made to exercise on the treadmill for 30 minutes per day. Total antioxidants, lipid hydroperoxides, xanthine oxidase and super oxide dismutase level were assayed from the homogenate of hind limb skeletal muscles. Exercise-induced a significant oxidative stress in skeletal muscles as evidenced by the elevated lipid hydroperoxides and xanthine oxidase levels. There was a significant decrease in skeletal muscle total antioxidants and superoxide dismutase levels. Daily colostrum supplement significantly reduced the lipid hydroperoxides and xanthine oxidase enzyme level and increased the total antioxidant levels in the leg muscle. Thus, the findings of the study showed that daily bovine colostrum supplementation was beneficial to the skeletal muscle to reduce the oxidant-induced damage during muscular exercise [12465].

Colostrum is the milk produced by mammals 24-72 h after giving birth. It is rich in immune, growth and antimicrobial factors that support neonate development. The primary source of colostrum for supplementation by athletes is bovine, which is similar in composition to human colostrum. However, the concentration of immune and growth factors is up to 100 times greater in bovine colostrum. Supplements may be in liquid, capsule, tablet or powder form. The superiority of one form over another is yet to be established. Supplement quality is affected by the timing and methods of processing: non-heat-treated, early-collection colostrum is superior. Colostrum contains growth factors (125 ml/day, containing 8.4 µg/day of IGF-I). It has been found increased serum IGF-I after 8 days' supplementation during resistance training, but no increase in maximal strength. Importantly, the IGF-I content of bovine colostrum supplements may vary considerably (1.7–120 µg/day). Although bovine colostrum supplementation is associated with increases in lean body mass, limb cross-sectional area and circulating essential amino acids, these have not translated into significant improvements in maximal strength. Improved immunocompetence has been suggested by several studies in which bovine supplementation was associated with increased salivary IgA and, more importantly, a reduction in symptoms of upper respiratory tract illness after 8 weeks of supplementation. Given its varied constituents, bovine colostrum supplementation may have modest effects on numerous pathways combining to provide potential ergogenic effects. To date, however, there is limited literature to support any consistent benefits. The safety of long-term dosing (>12 weeks) is yet to be established. Those allergic to cow's milk proteins should avoid bovine colostrum supplements [10251].

The aim of one study was to investigate the influence of low-dose bovine colostrum protein concentrate (CPC) supplementation on selected immune variables in cyclists. Twenty-nine highly trained male road cyclists completed an initial 40-km time trial (TT(40)) and were then randomly assigned to either a supplement (n=14, 10 g bovine CPC/day) or placebo group (n=15, 10 g whey protein concentrate/day). After 5 weeks of supplementation, the cyclists completed a second TT(40). They then completed 5 consecutive days of high-intensity training (HIT) that included a TT(40), followed by a final TT(40) in the following week. Venous blood and saliva samples were collected immediately before and after each TT(40), and upper respiratory illness symptoms were recorded over the experimental period. Compared with the placebo group, bovine CPC supplementation significantly increased preexercise

2007
serum soluble TNF receptor 1 during the HIT period. Supplementation also suppressed the postexercise decrease in cytotoxic/suppressor T cells during the HIT period and during the following week. Bovine CPC supplementation prevented a postexercise decrease in serum IgG(2) concentration at the end of the HIT period. There was a trend toward reduced incidence of upper respiratory illness symptoms in the bovine CPC group. In summary, low-dose bovine CPC supplementation modulates immune parameters during normal training and after an acute period of intense exercise, which may have contributed to the trend toward reduced upper respiratory illness in the bovine CPC group [07390].

The aim of one experiment was to investigate the influence of low dose bovine colostrum supplementation on exercise performance in cyclists over a 10 week period that included 5 days of high intensity training (HIT). Over 7 days of preliminary testing, 29 highly trained male road cyclists completed a VO\textsubscript{2max} test (in which their ventilatory threshold was estimated), a time to fatigue test at 110 percent of ventilatory threshold, and a 40 km time trial (TT40). Cyclists were then assigned to either a supplement (n = 14, 10 g/day bovine colostrum protein concentrate, CPC) or a placebo group (n= 15, 10 g/day whey protein) and resumed their normal training. Following 5 weeks of supplementation, the cyclists returned to the laboratory to complete a second series of performance testing (week 7). They then underwent five consecutive days of HIT (week 8) followed by a further series of performance tests (week 9). The influence of bovine CPC on TT40 performance during normal training was unclear. However, at the end of the HIT period, bovine CPC supplementation, compared to the placebo, elicited a 1.9 ± 2.2 percent improvement from baseline in TT40 performance and a 2.3 ± 6.0 percent increase in time trial intensity (% VO\textsubscript{2max}), and maintained TT40 heart rate. In addition, bovine CPC supplementation prevented a decrease in ventilatory threshold following the HIT period. It was concluded that low dose bovine CPC supplementation elicited improvements in TT40 performance during an HIT period and maintained ventilatory threshold following five consecutive days of HIT [06300].

**Effect on salivary IgA**

Secretory IgA in saliva (s-IgA) is a potential mucosal immune correlate of upper respiratory tract infection (URTI) status. Nutritional supplements may improve mucosal immunity, and could be beneficial to athletes who are at increased risk of URTI. In this study, 35 distance runners (15 female, 20 male, age 35 to 58 years) consumed a supplement of either bovine colostrum or placebo for 12 weeks. Saliva samples were taken prior to training at baseline, monthly during supplementation, and 2 weeks post supplementation. Median levels of s-IgA increased by 79 percent in the colostrum group after 12 week intervention, and the time-dependent change from baseline value was significant. This significance was still apparent after adjusting for training volume and self-reporting of upper respiratory symptoms. The study has demonstrated increased s-IgA levels among a cohort of athletes following colostrum supplementation. While this result is statistically significant, its physiological interpretation must be viewed with caution due to the small numbers in this study and the large variability in s-IgA levels [06301].

**Fermented papaya**

Fermented papaya preparation (FPP) (a product of yeast fermentation of Carica papaya Linn) is a food supplement. Studies in chronic and degenerative disease conditions (such as thalassemia, cirrhosis, diabetes and aging) and performance sports show that FPP favorably modulates immunological, hematological, inflammatory, vascular and oxidative stress damage parameters. Neuroprotective potential evaluated in an Alzheimer’s disease cell
model showed that the toxicity of the beta-amyloid can be significantly modulated by FPP. Oxidative stress trigger apoptotic pathways such as the c-jun N-terminal kinase (JNK) and p38-mitogen activated protein kinase (MAPK) are preferentially activated by pro-inflammatory cytokines and oxidative stress resulting in cell differentiation and apoptosis. FPP modulated the H$_2$O$_2$-induced ERK, Akt and p38 activation with the reduction of p38 phosphorylation induced by H$_2$O$_2$. FPP reduces the extent of the H$_2$O$_2$-induced DNA damage, an outcome corroborated by similar effects obtained in the benzo[a]pyrene treated cells. No genotoxic effect was observed in experiments with FPP exposed to HepG2 cells nor was FPP toxic to the PC12 cells. Oxidative stress-induced cell damage and inflammation are implicated in a variety of cancers, diabetes, arthritis, cardiovascular dysfunctions, neurodegenerative disorders (such as stroke, Alzheimer's disease, and Parkinson's disease), exercise physiology (including performance sports) and aging. These conditions could potentially benefit from functional nutraceutical/food supplements (as illustrated here with fermented papaya preparation) exhibiting anti-inflammatory, antioxidant, immunostimulatory (at the level of the mucus membrane) and induction of antioxidant enzymes [10535].

**Ultrasonography-guided interventions**

Increasing histological and radiological understanding of the processes involved in soft-tissue injury is leading to novel targeted treatments. A number of reviews have recommended that these treatments should be performed with image guidance. One review described current ultrasound-guided interventions and injections, together with the level of evidence for these. Discussion of guided interventions will include; percutaneous lavage (barbotage), brisement, dry needling, electrocoagulation, and of guided injections; corticosteroids, autologous substances (blood and platelet rich plasma), sclerosants, and prolotherapy (hyperosmolar dextrose). Representative imaging illustrating some of these techniques is included for correlation with the methods described. As these procedures are often performed in sportspeople, it is essential that the radiologist is aware of prohibited substances and methods outlined in an annual publication from the World Anti-Doping Association (WADA) [11300].
GENE DOPING

Overviews

Hugh Montgomery's discovery of the first of more than 239 fitness genes together with rapid advances in human gene therapy have created a prospect of using genes, genetic elements, and cells that have the capacity to enhance athletic performance (to paraphrase the World Anti-Doping Agency's definition of gene doping). A brief overview covered the main areas of interface between genetics and sport, attempts to provide a context against which gene doping may be viewed, and predicted a futuristic legitimate use of genomic (and possibly epigenetic) information in sport [10257].

Gene doping is the misuse of gene therapy to enhance athletic performance. It has recently been recognised as a potential threat and subsequently been prohibited by the World Anti-Doping Agency. Despite concerns with safety and efficacy of gene therapy, the technology is progressing steadily. Many of the genes/proteins which are involved in determining key components of athletic performance have been identified. Naturally occurring mutations in humans as well as gene-transfer experiments in adult animals have shown that altered expression of these genes does indeed affect physical performance. For athletes, however, the gains in performance must be weighed against the health risks associated with the gene-transfer process, whereas the detection of such practices will provide new challenges for the anti-doping authorities [08432].

Some spectacular results from genetic manipulation of laboratory rodents and increasing developments in human gene therapy raise the spectre of genetic modification or "gene doping" in sports. Candidate targets include the induction of muscle hypertrophy through overexpression of specific splice variants of insulin-like growth factor-1 or blockade of the action of myostatin, increasing oxygen delivery by raising the hematocrit through the use of erythropoietin, induction of angiogenesis with vascular endothelial growth factors or related molecules and changes in muscle phenotype through expression of peroxisome-proliferator-activated receptor- delta and associated molecules. Some of these potential genetic enhancements, particularly where the genetic modification and its action are confined to the muscles, may be undetectable using current tests. This had lead to exaggerated predictions that gene doping in athletics will be common within the next few years. However, a review of the methods of gene transfer and the current state of the art in development of genetic treatments for human disease show that the prospects for gene doping remain essentially theoretical at present. Despite this conclusion, it will be important to continue to monitor improvements in the technology and to develop methods of detection, particularly those based on identifying patterns of changes in response to doping as opposed to the detection of specific agents [08433].

Sports authorities fear that a new form of doping called gene doping, based on the misuse of gene therapy, represents an emerging important problem and so far no methods are available for detecting it. The World Anti-Doping Agency (WADA) has included since 2003 for the first time gene doping methods in the "Prohibited List of Substances and Methods", thus detection of this new form of doping is challenging for analytical chemists. In this work, we apply affinity-based biosensors (ABBs), in particular DNA piezoelectric sensing, for detection of target DNA sequences selected as transgenosis markers. In this work, two sequences widely used in transgenosis experiments have been identified as markers: the enhanced green fluorescence protein (EGFP) gene and the promoter of cytomegalovirus (CMV). The biosensors are characterized in their analytical performances using synthetic
oligonucleotides and amplified DNA obtained from purified plasmid used as a template. Finally they have been applied to transgenic human cell cultures (human embryonic kidney HEK-EGFP), transformed with the same plasmid and carrying the target markers. This represents the closest human real matrix available for our transgenes [09375].

Performance enhancing polymorphisms (PEPs) are examples of natural genetic variation that affect the outcome of athletic challenges. Elite athletes, and what separates them from the average competitor, have been the subjects of discussion and debate for decades. While training, diet, and mental fitness are all clearly important contributors to achieving athletic success, the fact that individuals reaching the pinnacle of their chosen sports often share both physical and physiological attributes suggests a role for genetics. That multiple members of a family often participate in highly competitive events, such as the Olympics, further supports this argument. In one review, it was discussed what is known regarding the genes and gene families, including the mitochondrial genome, that are believed to play a role in human athletic performance. Where possible, it was described the physiological impact of the critical gene variants and consider predictions about other potentially important genes [09376].

Our ever-increasing understanding of the genetic control of cardiovascular and musculoskeletal function together with recent technical improvements in genetic manipulation generates mounting concern over the possibility of such technology being abused by athletes in their quest for improved performance. Genetic manipulation in the context of athletic performance is commonly referred to as gene doping. A review of the literature was performed to identify the genes and methodologies most likely to be used for gene doping and the technologies that might be used to identify such doping. A large number of candidate performance-enhancing genes have been identified from animal studies, many of them using transgenic mice. Only a limited number have been shown to be effective following gene transfer into adults. Those that seem most likely to be abused are genes that exert their effects locally and leave little, if any, trace in blood or urine. It was concluded that there is currently no evidence that gene doping has yet been undertaken in competitive athletes but the anti-doping authorities will need to remain vigilant in reviewing this rapidly emerging technology. The detection of gene doping involves some different challenges from other agents but a number of promising approaches are currently being explored [09377].

The disclosure of repeated cases of athletes who abuse performance-enhancing drugs is an ordinary phenomenon in the athletic community. In addition, the completion of sequencing of the human genome and the unprecedented advances in molecular biology have enabled the progression from traditional drug enhancement to hypothetical (at present) gene transfer. Scientific, sports, and antidoping authorities fear that gene doping will be the next major challenge. The misuse of gene therapy to improve athletic ability, which is commonly referred to as “gene doping,” represents a practice as dangerous and unethical as any type of conventional doping. However, gene doping appears to be more attractive than traditional forms of doping because it is still undetectable and thus much less presentable [09378].

Gene doping is the newest threat to the spirit of fair play in sports. Its concept stemmed out from legitimate gene therapy trials, but anti-doping authorities fear that they now may be facing a form of doping that is virtually undetectable and extremely appealing to athletes. One paper presented studies that generated mouse models with outstanding physical performance, by manipulating genes such as insulin-like growth factor 1 (IGF-1) or phosphoenolpyruvate carboxykinase (PEPCK), which are likely to be targeted for gene doping [09379].

Recent studies in somatic gene therapy indicate that long-term presence of transgenic DNA
(tDNA) following various gene transfer protocols can be found in DNA isolated from whole blood using conventional PCR protocols. Application of these protocols for the direct detection of gene doping would require almost complete knowledge about the sequence of the genetic information that has been transferred. Now it was developed and described the novel single-copy primer-internal intron-spanning PCR (spiPCR) procedure that overcomes this difficulty. Apart from the interesting perspectives that this spiPCR procedure offers in the fight against gene doping, this technology could also be of interest in biodistribution and biosafety studies for gene therapeutic applications [09380].

Gene doping is the term given to the potential misuse of gene therapy for the purposes of enhancing athletic performance. Insulin-like growth factor-I (IGF-I), the prime target of growth hormone action, is one candidate gene for improving performance. In recent years, a number of transgenic and somatic gene transfer studies on animals have shown that up-regulation of IGF-I stimulates muscle growth and improves function. This increase in muscle IGF-I is not reflected in measurable increases in circulating IGF-I. Whilst the responses obtained in the animal studies would appear to give clear benefits for performance, the transfer of such techniques to humans still presents many technical challenges. Further challenges will also be faced by the anti-doping authorities in detecting the endogenously produced products of enhanced gene expression [09381].

"Gene doping" is the term used to describe the potential abuse of gene therapy as a performance-enhancing agent. Gene doping would apply the techniques used in gene therapy to provide altered expression of genes that would promote physical superiority. For example, insulin-like growth factor 1 (IGF-1) is a primary target for growth hormone; overexpression of IGF-1 can lead to increased muscle mass and power. Although gene doping is still largely theoretical, its implications for sports, health, ethics, and medical genetics are significant [10258].

As clinical gene therapy has progressed toward realizing its potential, concern over misuse of the technology to enhance performance in athletes is growing. Although gene doping is banned by the World Anti-Doping Agency, its detection remains a major challenge. In one study, it was developed a methodology for direct detection of the transferred genetic material and evaluated its feasibility for gene doping detection in blood samples from athletes. Using erythropoietin (EPO) as a model gene and a simple in vitro system, it was developed real-time PCR assays that target sequences within the transgene corresponding to exon/exon junctions. As these junctions are absent in the endogenous gene due to their interruption by introns, the approach allows detection of trace amounts of a transgene in a large background of the endogenous gene. Two developed assays and one commercial gene expression assay for EPO were validated. On the basis of ability of these assays to selectively amplify transgenic DNA and analysis of literature on testing of gene transfer in preclinical and clinical gene therapy, it was concluded that the developed approach would potentially be suitable to detect gene transfer through gene transfer by analysis of small volumes of blood using regular out-of-competition testing [10259].

Genetic research is used to identify the relative contributions made by inherent abilities (nature) versus environmental effects (nurture) in human performance. The same approach allows a better understanding of how injuries or illnesses can result from sport or physical activity. Having identified the genes involved in athletic performance, there are the intriguing possibilities of using this information for talent search, developing individualized training programs and prevention of sports-related injuries. There are many interacting genes involved in athletic performance. This class of genes is often described as "complex" and the mode of inheritance is called "multifactorial". Discovery of these genes is difficult using the conventional case control (association) studies. Recent genomic-based developments
allowing high throughput SNP analysis are very promising. Potentially more exciting is the availability in the near future of cheaper and faster whole-genome sequencing technologies. Genetic research in exercise science has produced a lot of data including the ability to draw a human exercise gene map. However, progress at the genetic level has been slow because gene-based association studies are not powerful enough to detect multiple small but cumulative gene effects. In future, the more efficient genomic-based research approaches will accelerate the finding of “sports genes”. Data generated will be enormous, making it essential to have a direct link between the laboratory researcher and bioinformatics expertise. It was finally underlined that genetics research has moved to the genomics era, i.e. the simultaneous testing of multiple genes is now possible [10260].

Gene doping abuses the legitimate approach of gene therapy. While gene therapy aims to correct genetic disorders by introducing a foreign gene to replace an existing faulty one or by manipulating existing gene(s) to achieve a therapeutic benefit, gene doping employs the same concepts to bestow performance advantages on athletes over their competitors. Recent developments in genetic engineering have contributed significantly to the progress of gene therapy research and currently numerous clinical trials are underway. Some athletes and their staff are probably watching this progress closely. Any gene that plays a role in muscle development, oxygen delivery to tissues, neuromuscular coordination, or even pain control is considered a candidate for gene dopers. Researchers today are racing the clock because assuring the continued integrity of sports competition depends on their ability to develop effective detection strategies in preparation for the 2012 Olympics, which may mark the appearance of genetically modified athletes [10261].

The concept of gene doping grew out of the important development in the early 1970s of a novel approach in medicine that promised to treat human disease by attacking underlying genetic defects. Thus was born the idea of gene therapy. In early, phase I safety studies, gene therapy has produced effective treatments for a number of diseases, such as pediatric immune deficiency, a genetic form of blindness, and neurodegeneration, with more sure to come in the very near future. While the efficacy of treatments has not yet been confirmed in more extensive phase III studies, the success so far teaches us is that it is clearly possible to introduce new genetic functions into human beings in forms efficient and stable enough to modify traits that produce serious disease and thus to ameliorate life-threatening illness and ease suffering. The same methods can undoubtedly be used to enhance normal human traits, including traits that affect athletic ability. One might readily envision genetic modification of healthy young athletes to augment functions useful for athletic performance, such as muscle growth and contraction, endurance, blood production, pain perception, and oxygen delivery to exercising muscle. But how close we are to gene doping in sports is a matter of debate [10262].

Many forms of human enhancement are becoming more feasible, sought-after, and even justifiable in the quest for healthier, happier, and longer lives. Around the world, people have been exposed to the notion of human enhancement through sport, as some athletes seek a boost to success, stardom, and financial reward. In the past, doping and cheating in sport have been enabled by advances in pharmacology and physiology. The successful development of gene therapy has provided the concepts, tools, opportunity, and, for some, justification for genetic modification of functions that affect normal human traits, including athletic performance. As science progresses and sport and antidoping authorities express increasing concerns, the time is right to look at how advances in genetics are affecting sport in ways unexpected just a decade ago [10263].

Some early experimental studies illustrate the potential of gene therapy for treating diseases. Although most gene therapy approaches involve gain-of-function expression of exogenous...
transgenes, other methods for genetic modification have also emerged. A definitive approach to genetic modification for therapy would involve an emerging technology of site-specific sequence correction of disease-causing mutations, as through the use of zinc finger-associated recombinational methods. Although highly effective in some models, these gene therapy techniques are imperfect and still highly risky, as demonstrated by severe adverse events such as treatment-induced leukemia, or even deaths. Nevertheless, it is inevitable that, as the science and techniques mature, these same methods and concepts will be applied to broader nontherapeutic uses, including gene-based “enhancement” of human traits linked to sport [10263].

Genetic methods have been used, for instance, to demonstrate enhanced muscle function from the insulinlike growth factor (IGF-1) or follistatin transgenes and stably increased, regulatable, erythropoietin-enhanced blood production in primates. One of the most widely discussed transcriptional modulation approaches has involved small molecule modulators of peroxisomal proliferator-activated receptor delta (PPAR-delta), which regulates expression of genes involved in lipid metabolism, energy utilization, and insulin action and that increases the production of slow twitch oxidative energy-effi cient muscle fi bers. These effects have important implications for therapy of diabetes, obesity, and muscle disease. Furthermore, mice overexpressing a PPAR-delta transgene or treated with a PPAR-delta agonist show enhanced endurance performance [10263].

Traditional approaches to detection of doping in sport have been based on chemical or molecular detection of the doping agent or of markers reflecting the physiological or metabolic effect(s) of the agent (e.g. chemical assays for steroids and stimulants, molecular identifi cation of foreign erythropoietin, and detection of abnormally high erythrocyte production following exogenous erythropoietin exposure). Although this is the most direct approach, new assays are constantly needed to respond to chemical modifications that make some drugs more difficult to detect, and therefore more prone to doping abuse. A potentially more powerful detection method has emerged, based on the concept that chemical, biological, or genetic doping agents are likely to produce broad metabolic, genetic, and proteomic changes. These changes are now detectable by techniques such as microarray- or sequence-based transcriptional profiling and proteomic and metabolomic analyses that can defi ne molecular “signatures” of exposure to specifi c doping agents, or families of drugs, or methods. Such signatures may be used to identify perturbed physiological systems, even in the absence of knowledge of, or assays for, specifi c doping agents. This approach is similar to that commonly used in searches for molecular signatures of oncogenesis, developmental disorders, and so on. The World Anti-Doping Agency has sponsored international research teams with early results providing growing credence to the utility of molecular signatures in doping detection. For instance, exposure of murine myoblasts to IGF-1 has been shown to induce transcriptional and proteomic changes that may eventually constitute a “signature” specifi c for exogenous IGF-1 exposure. Of course, the application of these kinds of global assays would require rigorous validation of a connection with specifi c doping agents or methods [10263].

Currently there is no clear evidence that gene doping has already found its way to the sports ground; however it is defi nitely only a question of time when fi rst athletes will start a try. The World Anti-Doping Agency is taking the probability of such malpractice seriously, and, in 2003, the term gene doping was enumerated in the official list of banned substances and methods. As gene doping is based on the intuitive concept of administering genetic information, thus enabling the athlete’s cells to produce its own doping substances – which in most cases would be indistinguishable from endogenous proteins – it is commonly believed that gene doping detection strategies should aim at metabolic, transcriptomic or proteomic changes as a consequence of the delivery and/or expression of the transgene. However, it
remains an open issue if incontrovertible doping signatures can be established that are independent of any confounding variables such as age, gender, physical or ethnic background. It must be keep in mind that elite athletes are “exceptional people” with “exceptional skills” and “exceptional physical abilities” that will also be mirrored in “exceptional signature patterns”, for example, because of distinct genetic polymorphisms, methylation patterns or histone modifications [10418].

Somatic gene therapy carries immense potential as a therapeutic modality for the treatment of inherited or acquired diseases by supplying functional copies in substitution of mutated genes, and by improving the body's natural ability to cope with diseases and infections. Although apparently simple in concept, the practical realities of translating gene therapy strategies into clinical practice have proven to be tremendously challenging. However, previous experiences have shown that even drugs that are still in the experimental phases of research may rapidly find their way into the athletic world. Several gene therapy trials aimed at the treatment of anemia, muscular dystrophy and peripheral vascular diseases have been initiated or are currently on the way. Moreover, impressive results from preclinical animal trials might entice some athletes to try these drugs, especially as no detection method is yet at hand. Dramatically improved muscle mass and muscle performance has been shown by rAAV-mediated intramuscular transfer of insulin-like growth factor 1 and follistatin in mice. Growth hormone serum levels in rodents could be significantly increased by salivary gland and intraperitoneal administration of rAAV vector systems. Intramuscular transfer of rAAV-VEGF has been shown to improve muscle survival and regeneration following muscle damage in mice. Using a tetracycline-inducible rAAV-based vector system, sustained functional neovascularization could be achieved after intramuscular gene transfer of VEGF in a murine ischemia model. By exploiting a similar Tet-On system, precise regulation of blood hemoglobin levels could be demonstrated after intramuscular electro-mediated gene transfer of erythropoietin in mice [10418].

Among the various application strategies and vector constructs that have been established in gene therapy trials, attempts to transfer gene therapy into doping practice would most likely primarily focus on intramuscular gene transfer using AAV-derived vectors as gene delivery systems. As current non-viral vectors have proven to be highly inefficient in humans for in vivo applications, recombinant AAV would be most suitable to deliver the transgene of choice in a gene doping scenario. This is because of its low immunogenicity, stable support of gene expression in slowly dividing or postmitotic cells, and the possibility of improving tissue specificity by pseudotyping the transgene cassette into alternative AAV vector capsids. Production of these vectors is by now a routine task in many molecular biology labs, and custom-made viral vectors are offered by commercial suppliers as ready-to-use stocks. Considering application strategies, in vivo intramuscular gene transfer would be the most practicable and promising approach, as skeletal muscle is easily accessible for vector administration, is sufficiently vascularized and enables prolonged expression of the transgene because of its postmitotic state [10418].

Several detection strategies for gene doping are currently under investigation. As expression of the transgene cassette is uncoupled from intrinsic regulatory pathways, most detection strategies aim at deciphering biomarkers and expression profiles (transcriptomic, proteomic and metabolomic approaches) that are indicative of “unnatural” gene expression. It remains an open issue whether such indirect methods can be sufficiently validated to exclude all natural causes for aberrant signature patterns. Because in sports jurisdiction a positive doping test alone establishes comfortable satisfaction of guilt, athletes charged with doping offenses are functionally presumed guilty until proven innocent. But how can an athlete provide evidence for an exceptional genetic or epigenetic predisposition when current knowledge of the complex orchestration of genomic, epigenomic, transcriptomic and
proteomic regulatory networks is spotty at best? Undoubtedly, a direct detection method that unambiguously identifies the doping agent should always be preferable. The test laboratory must be designed and operated in a way that prevents contamination of reactions with amplified products from previous assays and cross-contamination between samples, both of which can lead to false-positive results. Unidirectional workflow, separation of workspace and appropriate control procedures are fundamentally crucial. As a matter of course, these prerequisites cannot be completely fulfilled in a small molecular biology lab that is routinely dealing with a bulk of cDNA preparations. Substitution of positive control cDNAs by recombinant controls that are distinguishable from transgenic DNA will further reduce the risk of cross-contamination, thus making our procedure amenable to high-throughput screening in accredited laboratories [10418].

The misuse of somatic gene therapy for the purpose of enhancing athletic performance is perceived as a coming threat to the world of sports and categorized as “gene doping”. As clinical gene therapy has progressed toward realizing its potential, concern over misuse of the technology to enhance performance in athletes is growing. Although “gene doping” is banned by the World Anti-Doping Agency, its detection remains a major challenge. In one study, it was developed a methodology for direct detection of the transferred genetic material and evaluated its feasibility for gene doping detection in blood samples from athletes. Using erythropoietin (EPO) as a model gene and a simple in vitro system, it was developed real-time PCR assays that target sequences within the transgene complementary DNA corresponding to exon/exon junctions. As these junctions are absent in the endogenous gene due to their interruption by introns, the approach allows detection of trace amounts of a transgene in a large background of the endogenous gene. Two developed assays and one commercial gene expression assay for EPO were validated. On the basis of ability of these assays to selectively amplify transgenic DNA and analysis of literature on testing of gene transfer in preclinical and clinical gene therapy, it is concluded that the developed approach would potentially be suitable to detect gene doping through gene transfer by analysis of small volumes of blood using regular out-of-competition testing [10419].

When the concept of gene doping first emerged a decade or so ago, some critics considered it improbable and far from imminent. One of my most respected colleagues, who had a prominent role in the gene therapy oversight process, called the potential for using genetic modification methods for gene doping “a lot of gale-force hand waving.” In contrast, others saw it to be the obvious next and inevitable step in doping and cheating technology and believed it offered potential advantages over drug-based doping – that it might be more effective and more difficult to detect. Many feared that gene doping would enter the world of competitive sports very quickly; in fact, the sports media have predicted that every Olympic Games in the last decade would probably be the first genetically doped games. Indeed, several instances have come to light that can only be interpreted as serious attempts at gene doping. An athletic coach in Germany was found to be making diligent efforts to obtain a gene vector called Repxygen that contains and expresses the erythropoietin gene and was developed to increase blood production in patients with serious diseases such as cancer and chronic kidney disease. The product of the gene, erythropoietin, is in fact one of the most widely used drugs in the world for treatment of these disorders and, of course, is known to be heavily abused in some endurance sports, such as cycling. In addition, shortly before the Beijing Games in 2008, a German investigative television team broadcast a program identifying a Chinese scientist who was reported to be offering genetic manipulation for athletes [10262].

There is no documented case of genetic techniques having been used to enhance athletic ability in people. We do know that genetic manipulations have produced mice and, in some cases, primates with enhanced traits crucial for athletic performance, including increased
muscle function, prolonged endurance, and elevated blood production. If gene therapy is becoming increasingly feasible and available and if the pressure for gene doping is so great, why has it not yet been documented in athletes? One reason may be that the procedures for safe, successful, and legitimate genetic manipulation for medical purposes are extremely complicated, lying outside the capability of most rogue operations. Even though the production of gene doping materials is achievable using standard graduate school or even undergraduate molecular biology technology, the truly difficult aspect of gene therapy is its execution: bringing about the safe and effective performance of complicated human clinical manipulations by methods consistent with international ethical standards of human clinical work. Even for legitimate gene therapy, it has taken several decades of experimental refinement and testing to learn how to express added genetic information safely in human patients. Gene therapy remains a highly experimental and potentially risky technique, and even some of the successful therapies have caused serious side effects, including leukemia and even death [10262].

We know from vast experience that, like all technology, the use of apparently sophisticated genetic doping methods will not await demonstration of safety, much less efficacy, before being applied in sports. For that reason, the World Anti-Doping Agency has included genetic doping in its list of banned methods since 2004 and has instituted major research projects to identify potential methods for gene doping and for detection. And yet, those intent on using illicit methods are likely to pay little attention to WADA lists or to comply with the multiple layers of local and national oversight and regulation required for gene therapy – review and approval of local institutional review boards, human subjects committees, and federal oversight and regulatory bodies. The financial and other rewards are too great and the sources of funding too deep in sports for those intent on gene doping to be concerned about such troublesome niceties [10262].

Sport is a deeply human activity dependent on an honest and transparent rule-based “contract” between participants. Those who love it deserve protection from those who would weaken or destroy its rules and introduce unethical, ineffective, and probably harmful materials and tools. Those who practice genetic manipulation, evading requirements for ethical and scientific review and applying genetic tools without full disclosure and informed consent, should certainly be considered guilty of scientific or medical malpractice and professional misconduct [10262].

The challenges posed to sports organizations concerned with gene doping are compounded by the ubiquity of the Internet, relatively unconstrained by geographical boundaries, which, when fueled with private commercial interests, creates a powerful marketing tool for promotion and distribution of performance-enhancing agents. An industry has emerged to cater to the desire of athletes and their coaches to find a competitive edge. Athletes are an especially vulnerable population in the marketing of performance enhancement. Reputable athletes or coaches with little knowledge of genetics are at a disadvantage in assessing “scientific” claims that appear in advertisements. Marketing is particularly worrisome when the science is still a work in progress, when a person’s health can be adversely affected, and when consumer knowledge about genetics is low. Although advertisements promoting products that promise to enhance athletic performance have pervaded the Internet for many years, recently it has become home for advertisements that promote products to “alter muscle genes...by activating your genetic machinery”, or that state “your genetic limitations are a thing of the past!” Although commercial web sites may be “biased, and unreliable by rigorous scientific standards, they are a principal source of information for many athletes and should be monitored when looking for evidence of developing trends in doping”. Some athletes and coaches will be tempted, prematurely and unwisely, to take advantage of results
packaged by some as performance enhancement "breakthroughs," even if they are untested in humans and the only "breakthrough" is faster or stronger mice [10263].

Our ever-increasing understanding of the genetic control of cardiovascular and musculoskeletal function together with recent technical improvements in genetic manipulation generates mounting concern over the possibility of such technology being abused by athletes in their quest for improved performance. A review of the literature was now performed to identify the genes and methodologies most likely to be used for gene doping and the technologies that might be used to identify such doping. A large number of candidate performance-enhancing genes have been identified from animal studies, many of them using transgenic mice. Only a limited number have been shown to be effective following gene transfer into adults. Those that seem most likely to be abused are genes that exert their effects locally and leave little, if any, trace in blood or urine. There is currently no evidence that gene doping has yet been undertaken in competitive athletes but the anti-doping authorities will need to remain vigilant in reviewing this rapidly emerging technology. The detection of gene doping involves some different challenges from other agents and a number of promising approaches are currently being explored [10264].

The misuse of somatic gene therapy for the purpose of enhancing athletic performance is perceived as a coming threat to the world of sports and categorized as "gene doping". One article describes a direct detection approach for gene doping that gives a clear yes-or-no answer based on the presence or absence of transgenic DNA in peripheral blood samples. By exploiting a priming strategy to specifically amplify intronless DNA sequences, we developed PCR protocols allowing the detection of very small amounts of transgenic DNA in genomic DNA samples to screen for six prime candidate genes. The detection strategy was verified in a mouse model, giving positive signals from minute amounts (20 mikroL) of blood samples for up to 56 days following intramuscular adeno-associated virus-mediated gene transfer, one of the most likely candidate vector systems to be misused for gene doping. To make our detection strategy amenable for routine testing, we implemented a robust sample preparation and processing protocol that allows cost-efficient analysis of small human blood volumes (200 microL) with high specificity and reproducibility. The practicability and reliability of the detection strategy was validated by a screening approach including 327 blood samples taken from professional and recreational athletes under field conditions [11301].

With the advances in gene therapy fears of an abuse in sports arise. The WADA's definition of the term strictly differentiates between gene doping and gene therapy. There are in vivo and ex vivo practices to manipulate the different phases of gene expression in the organism, with viral vectors being looked upon as the most efficient ones. IGF-1, PPAR-delta, MSTN and EPO play the most important roles in today's scientific research. Their potential was proven in various animal studies, showing a significant improvement of performances. Potential risks for human users include severe immune reactions, mutagenesis, and raised risk for cancer. Big efforts are being put into the development of ways of detection, however until now there are neither practicable methods of control nor any reported cases of manipulated humans. Still, a usage of gene doping that has already taken place cannot be ruled out and is highly likely [11302].

Legitimate uses of gene transfer technology can benefit from sensitive detection methods to determine vector biodistribution in pre-clinical studies and in human clinical trials, and similar methods can detect illegitimate gene transfer to provide sports-governing bodies with the ability to maintain fairness. Real-time PCR assays were developed to detect a performance-enhancing transgene (erythropoietin, EPO) and backbone sequences in the presence of endogenous cellular sequences. In addition to developing real-time PCR assays, the steps involved in DNA extraction, storage and transport were investigated. By real-time PCR, the
vector transgene is distinguishable from the genomic DNA sequence because of the absence of introns, and the vector backbone can be identified by heterologous gene expression control elements. After performance of the assays was optimized, cynomolgus macaques received a single dose by intramuscular (IM) injection of plasmid DNA, a recombinant adeno-associated viral vector serotype 1 (rAAV1) or a rAAV8 vector expressing cynomolgus macaque EPO. Macaques received a high plasmid dose intended to achieve a significant, but not life-threatening, increase in hematocrit. rAAV vectors were used at low doses to achieve a small increase in hematocrit and to determine the limit of sensitivity for detecting rAAV sequences by single-step PCR. DNA extracted from white blood cells (WBCs) was tested to determine whether WBCs can be collaterally transfected by plasmid or transduced by rAAV vectors in this context, and can be used as a surrogate marker for gene doping. It was demonstrated that IM injection of a conventional plasmid and rAAV vectors results in the presence of DNA that can be detected at high levels in blood before rapid elimination, and that rAAV genomes can persist for several months in WBCs [11303].

To achieve success in sports, many athletes consume doping substances, such as anabolic androgenic steroids and growth hormones, and ignore the negative influence of these drugs on their health. Apart from the unethical aspect of doping in sports, it is essential to consider the tremendous risk it represents to their physical condition. The abuse of pharmaceuticals which improve athletic performance may alter the expression of specific genes involved in muscle and bone metabolism by epigenetic mechanisms, such as DNA methylation and histone modifications. Moreover, excessive and relentless training to increase the muscle mass, may also have an influence on the health of the athletes. This stress releases neurotransmitters and growth factors, and may affect the expression of endogenous genes by DNA methylation, too. One paper focuses on the relationship between epigenetic mechanisms and sports, highlights the potential consequences of abuse of doping drugs on gene expression, and describes methods to molecularly detect epigenetic changes of gene markers reflecting the physiological or metabolic effects of doping agents [11304].

The quest for athletic excellence holds no limit for some athletes, and the advances in recombinant DNA technology have handed these athletes the ultimate doping weapons: recombinant proteins and gene doping. Some detection methods are now available for several recombinant proteins that are commercially available as pharmaceuticals and being abused by dopers. However, researchers are struggling to come up with efficient detection methods in preparation for the imminent threat of gene doping [07395].

After only a short history of three decades from concept to practice, gene therapy has recently been shown to have potential to treat serious human diseases. Despite this success, gene therapy remains in the realm of experimental medicine, and much additional preclinical and clinical study will be necessary for proving the efficacy and safety of this approach in the treatment of diseases in humans. However, a potential complicating factor is that advances in gene transfer technology could be misused to enhance athletic performance in sports, in a practice termed "gene doping". Moreover, gene doping could be a precursor to a broader controversial agenda of human "genetic enhancement" with the potential for a significant long-term impact on society. One review addressed the possible ways in which knowledge and experience gained in gene therapy in animals and humans may be abused for enhancing sporting prowess. It was provided an overview of recent progress in gene therapy, with potential application to gene doping and with the major focus on candidate performance-enhancement genes. It was also discussed the current status of preclinical studies and of clinical trials that use these genes for therapeutic purposes. Current knowledge about the association between the natural "genetic make-up" of humans and their physical characteristics and performance potential is also presented. It was addressed issues associated with the safety of gene transfer technologies in humans, especially when used...
outside a strictly controlled clinical setting, and the obstacles to translating gene transfer strategies from animal studies to humans. We also address the need for development and implementation of measures to prevent abuse of gene transfer technologies, and to pursue research on strategies for its detection in order to discourage this malpractice among athletes [07396].

Implications of novel genetic interventions fascinated not only researchers, physicians, and gene therapists, but also coaches, athletes, and trainers looking for athletic performance enhancement of biologic parameters, such as strength, power, and oxygen delivery, to create a critical edge in sporting competition. The creation of a superman or superwoman athlete could be planned by well-placed genetic physiologic tweaks. Without a single known human incident of gene doping, WADA bestowed the technique of gene doping a dishonored place on the list of prohibited substances. For an entire biomedical technique to be banned, before even acquiring regulatory approval by any government or before acceptance by any branch of organized medicine, seems to be unprecedented. Defined as “the transfer of genetic material to human cells for the treatment or prevention of a disease or disorder,” gene therapy uses genetic materials, such as DNA, RNA, or genetically altered cells. In the simplest form, gene therapy introduces a “therapeutic gene” (transgene) into an organism by way of a vector, often an inactive virus. Within the organism itself, the new “transgene” synthesizes the defective/missing protein or biologic substance to correct dysfunctional tissues and organs. Other gene therapy strategies involve manipulation of genes, turning them on or off as the desired physiologic response dictates. Initial gene therapy trials included protocols to treat an X-linked immunodeficiency disease and hemophilia variant. A trial of human vascular endothelial growth factor produced positive results in patients who had angina. More than 1000 gene therapy trials have been ongoing in various states of clinical study. No gene therapy protocols have been approved for medical practice by the US Food and Drug Administration, the regulatory agency charged with overseeing the development and clinical use of the medical procedure [07046].

Drug doping uses therapeutic advances in exercise physiology and clinical pharmacology to provide unfair advantages to athletes who covertly use anabolic drugs, thus dramatically enhancing competitive performance. Similar to drug doping, gene doping manipulates scientific advances originally developed for the treatment of disease. Rather than drug interventions, the gene-doping athletes appropriate advances in gene therapies. Gene doping, in concept, uses scientific developments that manipulate DNA in the most basic regulation of biologic processes, to dramatically improve aspects of athletic performance, such as speed, power, or endurance Molecular biology, particularly the “discovery” of DNA by Watson and Crick in 1953, revolutionized biology and medicine. The rate of genetic discovery in molecular biology rapidly accelerated throughout the last half of the twentieth century and into the twenty-first century. The new millennium was to be the dawning of practical, effective treatments for genetic diseases, such as muscular dystrophy, X-linked hemophilia, and other single-gene disorders. Further, with molecular biology advances that included insertions of new genes into organisms, cloning of organisms, and use of human stem cells, more than single-gene diseases could be treated. Any number of serious or fatal medical conditions might be altered with the introduction of genes that would produce “in vivo pharmacies” delivering biochemicals, including proteins and hormones, to injured or impaired tissue [07046].

Gene therapy also could improve a general disadvantageous condition, such as aging-related muscle atrophy, by introducing a transgene to produce the depleted factors involved in muscle repair and regeneration. Therapeutic genes could be targeted directly into cells, tissues, and organs limiting effects to a localized site, thus reducing the systemic side effects produced by a typical drug administration. With the advent of gene therapy, a more direct
way to deliver proteins and hormones to an athlete’s tissues and organs became reality. The sophistication and the power of these biologic alterations piqued the ingenuity of the drug-cheating coaches and athletes. A substance that can alter the basic genetic expression of DNA – such that muscles grow larger, contract more forcefully, and recover more quickly than non-doped muscles – and cannot be detected by anti-doping laboratories would be ideal to gain a competitive advantage while not running afoul of the regulatory officials. In the broad sense, genetic therapies include several categories of biotechniques [07046]

- use of recombinant DNA techniques to produce new peptides or drugs (rEPO)
- pharmacogenetics, or the use of knowledge of the specific genome of an athlete to tailor pharmacologic interventions
- somatic cell modification, which produces genetically modified cells (e.g. modified RBCs to increase blood-carrying capacity)
- germ-line modification, where the gametes or early embryos undergo gene modification to express more athletically expedient traits
- genetic preselection, where a gene scan would inform parents about the distribution of desired genes in a potential offspring
- genetic selection, where individuals are selected for particular traits (widely practiced in animal husbandry)

The common inheritance of approximately 20,000 genes defines each of us as human. However, substantial variation exists between individual human genomes, including ‘replication’ of gene sequences (copy number variation, tandem repeats), or changes in individual base pairs (mutations if <1% frequency and single nucleotide polymorphisms if >1% frequency). A vast array of human phenotypes (e.g. muscle strength, skeletal structure, tendon elasticity, and heart and lung size) influences sports performance, each itself the result of a complex interaction between a myriad of anatomical, biochemical and physiological systems. This article discusses the role for genetic influences in influencing sporting performance and injury, offering specific exemplars where these are known. Many of these preferable genotypes are uncommon, and their combination even rarer. In theory, the chances of an individual having a perfect sporting genotype are much lower than 1 in 20 million – as the number of associated polymorphisms increase, the odds decrease correspondingly. Many recently discovered polymorphisms that may affect sports performance have been described in animal or other human based models, and have been included in this review if they may apply to athletic populations. Muscle performance is heavily influenced by basal muscle mass and its dynamic response to training. Genetic factors account for approximately 50-80 percent of inter-individual variation in lean body mass, with impacts detected on both “training-naive” muscle mass and its growth response. Several cytokines such as interleukin-6 and -15, ciliary neurotrophic factor and insulin-like growth factor (IGF) have myoanabolic effects. Genotype-associated differences in endocrine function, necessary for normal skeletal muscle growth and function, may also be of significance, with complex interactions existing between thyroxine, growth hormone and the downstream regulators of the anabolic pathways (such as IGF-1 and IGF-2). Almost 200 polymorphisms are known to exist in the vitamin D receptor (VDR) gene. VDR genotype is associated with differences in strength in premenopausal women. VDR expression decreases with age and VDR genotype is associated with fat-free mass and strength in elderly men and women. Muscle fibre type determination is complex. Whilst initial composition is likely to be strongly influenced by genetic factors, training has significant effects on fibre shifts. Polymorphisms of the peroxisome proliferator-activated receptor alpha (PPARalpha) gene and R577x polymorphism of the ACTN3 gene are both associated with specific fibre compositions. Alterations in cardiac size have been associated with both increased performance and excess cardiovascular mortality. PPARalpha is a ligand-activated
transcription factor that regulates genes involved in fatty acid uptake and oxidation, lipid metabolism and inflammation. Psychology plays an important role in training, competition, tolerance of pain and motivation. However, the role of genetic variation in determining psychological state and responses remains poorly understood; only recently have specific genes been implicated in motivational behaviour and maintenance of exercise. Thyroid hormone receptors exist within the brain and influence both neurogenesis and behaviour. With the current state of knowledge, the field of genetic influences on sports performance remains in its infancy, despite over a decade of research [11544].

Gene therapy was first successfully applied in 1990 in the treatment of a four-year-old child suffering from a severe combined auto-immuno deficiency (SCAD). A number of further successes were followed by a heavy setback in 1999 when a young man died as a consequence of a gene therapy. Presently gene therapy is once more on its way to becoming a normal therapeutic measure where conventional therapies fail. The increasing practice of gene therapy of course also implies the risk of misuse in sport – gene doping. The World Anti-Doping Agency, founded in 1999, organized its first scientific workshop on gene doping in 2002 in New York. Further conferences in Stockholm (2005) and St Petersburg (2008) followed and various national and international meetings have been dedicated to the specific issue of misusing knowledge arising from biotechnological advances in medicinal research. In 2010, The Federal Institute of Sports Science of Germany organized its second conference on gene doping to assess the potential danger of misuse of modern methods of molecular biology. It featured three special areas of genetics with a view to elucidating both the possibilities of misuse and its detection: genome, transcriptome and epigenetics. Polymorphism at the myostatin gene locus and EPOreceptor gene locus are of particular interest when aiming at muscle growth and elevated oxygen capacity, respectively. Many other gene loci are related to performance in sport but are not as unilocular as gene loci previously enumerated. Results of family studies and other comparative investigations show various participating genes but significance is rarely given and ‘lucky punches’ of significance of relatively small samples lose their ground when the investigated population grows larger. Polymorphism of the gene locus UGT2B has been shown to influence the metabolism and elimination of testosterone and epitestosterone and their concentration in urine. Consequently, the impact of this phenomenon on modern sports drug testing, a field that considers the steroid profile as one of the most important sources of information in doping controls, was elucidated. Further, research concerning the role of mitochondrial DNA (regarding the energy cycle and mitochondrial myopathies related to defects of mtDNA) was presented in the context of gene therapy; its misuse potential in sport, however, has been implausible so far [11557].

The genome is not an isolated double strand of DNA in the nucleus but is encapsulated by histones, a group of protecting proteins surrounding the DNA forming strings of spheres. In a figurative sense, these shields are cut at distinct places as the first step of transcribing a part of DNA, for example, by so-called zincfinger proteins. Evidence or indication of misuse in sports has not (yet) been provided; methylation and demethylation of DNA, as another epigenetic regulatory mechanism of gene expression, may offer a tool of manipulation. The transcriptome is a mirror of genetic activity and is essential for transporting genetic information. The mRNA generated in the nucleus consists of exons and space-filling introns; the latter are removed immediately by enzymes in the cytoplasm so that the active mRNA is composed of exons only. This offers one option to detect the misuse of gene therapy because only RNA can be copied to cDNA in the cytoplasm for inserting this cDNA with a gene ferry (e.g. a virus). The resulting gene then consists of exons only and can be identified as xenobiotic. Introns will also be digested to different forms of RNA which act as regulators of further translational processes. Although a lot of knowledge about these effects is at hand, they are not sufficiently calculable yet. Manipulations on tissues also result in free circulating
DNA (cDNA) which might be useful for sports drug testing purposes. cDNA today is a powerful diagnostic tool for various diseases, for example, different forms of cancer. Samples for the detection of doping usually consist of urine and particularly blood. The latter is often preferred as genetic manipulation can be tissue-specific and not detectable in urine. Detection in blood might be possible but limited in respect to its specificity. One of the most likely target tissues of manipulation is the muscle. In order to determine whether muscle tissue has been the subject of gene doping, muscle biopsies are presumably the only way to obtain an adequate sample of cells for assaying. Although a micro biopsy may be a possibility to obtain a sufficient number of cells without injuring the muscle, which would imply a functional reduction, such specimens are currently not in the scope of anti-doping authorities. In summary, gene doping still seems to be an emerging problem in high-level sports as gene therapy develops to become a controllable tool in medicine and in the manipulation of livestock [11557].

Over the course of the past decade, technical progress has enabled scientists to investigate genome-wide RNA expression using microarray platforms. This transcriptomic approach represents a promising tool for the discovery of basic gene expression patterns and for identification of cellular signalling pathways under various conditions. Since doping substances have been shown to influence mRNA expression, it has been suggested that these changes can be detected by screening the blood transcriptome. In one review, it was critically discuss the potential but also the pitfalls of this application as a tool in doping research. Transcriptomic approaches were considered to potentially provide researchers with a unique gene expression signature or with a specific biomarker for various physiological and pathophysiological conditions. Since transcriptomic approaches are considerably prone to biological and technical confounding factors that act on study subjects or samples, very strict guidelines for the use of transcriptomics in human study subjects have been developed. Typical field conditions associated with doping controls limit the feasibility of following these strict guidelines as there are too many variables counteracting a standardized procedure. After almost a decade of research using transcriptomic tools, it still remains a matter of future technological progress to identify the ultimate biomarker using technologies and/or methodologies that are sufficiently robust against typical biological and technical bias and that are valid in a court of law [11545].

RNA interference represents a comparably new route of regulating and manipulating specific gene expression. Promising results were obtained in experimental therapies aim at the treatment of different kinds of diseases including cancer, diabetes mellitus or Duchenne muscular dystrophy. While studies on down-regulation efficiency are often performed by analyzing the regulated protein, the direct detection of small, interfering RNA molecules and antisense oligonucleotides is of great interest for the investigation of the metabolism and degradation and also for the detection of a putative misuse of these molecules in sports. Myostatin down-regulation was shown to result in increased performance and muscle growth and the regulation of several other proteins could be relevant for performance enhancement. One mini-review summarizes current approaches for the mass spectrometric analysis of siRNA and antisense oligonucleotides from biological matrices and the available data on biodistribution, metabolism, and half-life of relevant substances are discussed [11546].

The issue of gene doping has chaperoned scientific accomplishments in gene therapy for at least a decade, and despite considerable reservations as to what kind of benefit cheating athletes could possibly expect as well as detrimental health and legal consequences. Two major scenarios of gene doping are described with one being the abuse of “classical” gene therapy, i.e. introduction of synthetic DNA sequences via viral vehicles into the organism, and the other being based on RNA interference strategies. The latter has recently been considered the more promising approach in therapeutic settings, which however also implies
that there is a higher risk of its abuse in sports. The most common approach to directly determine synthetic exogenous DNA relies on the amplification by polymerase chain reaction (PCR), exploiting the presence of exon-exon junctions in exogenous DNA sequences. Using such strategies, the determination of incorporated exogenous DNA was traceable in white blood cells up to 57 weeks after intramuscular injection. In order to improve the method’s sensitivity and exclude false negative results, an internal threshold control (ITC) was suggested that should compensate for sample preparation and analysis issues. The approach was applied to a non-human primate EPO gene doping model providing proof-of-concept data, which should be corroborated with further analyses demonstrating that the principle can be applied to other DNA targets as well. In a different study, an attempt was conducted to determine the intramuscularly administered plasmid (cytomegalovirus-focal adhesion kinase) in rats using PCR. While tissue sampling of the transfected muscle allowed for the detection of the exogenous DNA sequence for up to seven days, essentially all serum samples returned negative test results, demonstrating the challenging aspect of sports drug testing since tissue sampling will not be an option in doping controls. As the most common route of gene transfer is through viral vehicles, a complementary indirect approach was presented, aiming at the detection of backbone sequences of the employed vector, seconded by the analysis of a so-called construct-specific marker. The latter comprises parts of the promoter and the transgene, representing a non-natural target for PCR amplification and analysis, supporting the differentiation of a coincidentally present virus in the host from a modified recombinant vector backbone. The methodology was applied to transduced laboratory mice and proof-of-concept was obtained for blood, urine, tears, and various tissues; however, detection windows were comparably small (1-6 days) [12475].

With one recently recommended gene therapy in Europe and a number of other gene therapy treatments now proving effective in clinical trials it is feasible that the same technologies will soon be adopted in the world of sport by unscrupulous athletes and their trainers in so called gene doping. In this article an overview of the successful gene therapy clinical trials is provided and the potential targets for gene doping are highlighted. Depending on whether a doping gene product is secreted from the engineered cells or is retained locally to, or inside engineered cells will, to some extent, determine the likelihood of detection. It is clear that effective gene delivery technologies now exist and it is important that detection and prevention plans are in place [12475].

It has been established that excessive training, by inducing stress and releasing neurotransmitters and cytokines, may naturally affect the expression of endogenous genes via DNA methylation. However, the abuse of certain physical performance-enhancing substances, such as AAS or GH, may also change the expression of genes via epigenetic mechanisms such as DNA methylation and histone modifications, this technique bearing the name of “gene doping”. Gene or cell doping is defined by WADA as “the non-therapeutic use of cells, genes, genetic elements, or of the modulation of gene expression, having the capacity to enhance athletic performance’.’ The main targets of gene doping are the myostatin gene, EPO and IGF-1. For example, removal or decrease of the expression of the myostatin gene is capable of elevating hypertrophy and muscle power. The discovery of “physical performance genes”, which have led to novel techniques for gene transfer for the purposes of gene doping, is a particularly highly detrimental feature of modern day doping because of the extreme difficulty in detecting it. Direct as well as indirect testing methods have been implemented by WADA to assist in the challenging task of detecting gene doping. Direct methods search for recombinant proteins or gene insertion vectors, while indirect methods, by nature more subjective, are based on the clinical examination of the athlete in an attempt to register bodily changes or structural differences between endogenous and recombinant proteins. This raises the urgent need for sophisticated molecular biology techniques, such as the use of lab-on-a-chip techniques and nanoparticles, to enable the
distinction between the “normal” and “modified” genome, while complex methodology is required to trace gene doping. A real-time PCR assay targeting sequences within the transgene complementary DNA corresponding to exon/exon junctions – which, due to their interruption by introns, are absent in the endogenous gene – may allow detection of trace amounts of a transgene against a broad background of the endogenous gene. This is an effective method to detect exogenous DNA. The incorporation of an internal threshold control (ITC) serves to avoid confounding false positive or false negative results, while simultaneously obtained fluorescence emission signals determine the cycle thresholds for amplification of the target and ITC sequences. This method, according to the authors, may enhance the detection capability of gene doping. Gene doping is a highly complex issue as there is a very fine line between legitimate medical intervention and nonlegitimate exploitation of an individual’s genetic make-up for competitive advantage [12011].

Gene therapy generally involves the delivery of genetic material encoding the expression of proteins that are either endogenous or biological for treatment of disease. Gene therapy has great potential to treat genetic diseases and holds much promise as a mode of delivering biological molecules in more widespread conditions. After initial hype and several lows the first gene therapy product has now been recommended for approval in Europe and there have been a number of recent clinical trials that have demonstrated the effectiveness of this treatment modality. The possibility of gene doping, defined as the transfer of nucleic acid sequences and/or the use of normal or genetically modified cells to enhance sport performance, is also a real concern in sports medicine. The abuse of knowledge and techniques gained in the area of gene therapy is a form of doping, and is prohibited for competitive athletes. As yet there is no conclusive evidence that that gene doping has been practiced in sport. However, given that gene therapy techniques improve continuously, the likelihood of abuse will increase. All gene therapy approaches use a vector to deliver the genetic material to cells and also utilize the transcriptional machinery of the cell for gene expression. The delivery vector can be as simple as naked plasmid DNA or as complex as replication deficient recombinant viruses that have innate ability to deliver genes. The first gene therapy successes were achieved in X-linked severe combined immunodeficiency (SCID) patients through ex vivo engineering their bone marrow stem cells (BMSC) with retrovirus encoding a correct copy of the common cytokine-receptor gamma chain prior to re-implantation. Although only a small percentage of cells are corrected these have a selective advantage and are able to populate the patient with a functioning immune system. This approach of engineering BMSC has been similarly adopted in the successful treatment of other genetic conditions including adenosine deaminase (ADA) SCID and X-linked chronic granulomatous disease [13755].

A literature search was conducted to identify the most relevant proteins based on their current gene doping potential using articles from Pubmed, Scopus and Embase published between 2006 and 2011. The final list of selected proteins were erythropoietin, insulin-like growth factor, growth hormone, myostatin, vascular endothelial growth factor, fibroblast growth factor, endorphin and enkephalin, α actinin 3, peroxisome proliferator-activated receptor-delta (PPAR-delta) and cytosolic phosphoenolpyruvate carboxykinase (PEPCK-C). We discuss these proteins with respect to their potential benefits, existing gene therapy experience in humans, potential risks, and chances of detection in current and future anti-doping controls. It was identified PPARdelta and PEPCK-C as having high potential for abuse. But we expect that for efficiency reasons, there will be a preference for inserting gene target combinations rather than single gene doping products. This will also further complicate detection [13755].

The possibility of gene doping, defined as the transfer of nucleic acid sequences and/or the use of normal or genetically modified cells to enhance sport performance, is a real concern in
sports medicine. The abuse of knowledge and techniques gained in the area of gene therapy is a form of doping, and is prohibited for competitive athletes. As yet there is no conclusive evidence that that gene doping has been practiced in sport. However, given that gene therapy techniques improve continuously, the likelihood of abuse will increase. A literature search was conducted to identify the most relevant proteins based on their current gene doping potential using articles from Pubmed, Scopus and Embase published between 2006 and 2011 [13011].

Given that gene therapy techniques have improved considerably, the likelihood of gene doping has increased. Today, most gene therapy studies examine hereditary diseases and cancer. Gendicine (recombinant Human Ad-p53 Injection) and Glybera (alipogene tiparvovec) are the first approved gene therapy products for human use in the USA and the EU, respectively. Gendicine is designed to place a p53 gene in cancer cells to inhibit cell growth and the Glybera gene therapy has been approved for treatment of life-threatening pancreatitis attacks in patients with lipoprotein lipase deficiency [13011].

The possibility of gene doping, defined as the transfer of nucleic acid sequences and/or the use of normal or genetically modified cells to enhance sport performance, is a real concern in sports medicine. The abuse of knowledge and techniques gained in the area of gene therapy is a form of doping, and is prohibited for competitive athletes. As yet there is no conclusive evidence that that gene doping has been practiced in sport. However, given that gene therapy techniques improve continuously, the likelihood of abuse will increase. The final list of selected proteins were erythropoietin, insulin-like growth factor, growth hormone, myostatin, vascular endothelial growth factor, fibroblast growth factor, endorphin and enkephalin, alpha-actinin 3, peroxisome proliferator-activated receptor-delta (PPAR-delta) and cytosolic phosphoenolpyruvate carboxykinase (PEPCK-C) [13011].

Gene therapist Ted Friedmann and multiple Olympic gold medallist Johann-Olav Koss were the first to describe the possibility of misusing the techniques and experiences of gene therapy in the athletic arena. In 2006, before the Turin Winter Olympic games, the president of the World Anti-Doping Agency (WADA), Dick Pound, called gene doping “the new threat that is now a reality.” Although Pound did not expect gene doping to pose a problem in Turin, he indicated that it could be a problem at the Summer Games, 2 years hence in Beijing. In fact, the problem did not materialise in China, in 2008, nor at the London 2012 Olympics, as far as the then available detection measures could determine. Yet again, we have to operate on the assumption that there may be athletes out there willing to test gene doping at the 2016 Rio de Janeiro Olympics. After all, an Olympic gold medal means considerable social and economic benefit. Historical doping control statistics show that somewhere between 1.1 and 2 percent of all athletes test positively for doping. The real number of doping users is expected to be higher, despite the fact that the governing bodies of sport place immense pressure on athletes by a strict liability rule that makes them responsible for everything in their bodies. Although the detection of doping is constantly improving, it generally trails actual practice [13011].

Today, most gene therapy studies examine hereditary diseases and cancer. Gendicine (Recombinant Human Ad-p53 Injection) and Glybera (alipogene tiparvovec) are the first approved gene therapy products for human use in the USA and the EU, respectively. Gendicine is designed to place a p53 gene in cancer cells to inhibit cell growth and the Glybera gene therapy has been approved for treatment of life-threatening pancreatitis attacks in patients with lipoprotein lipase deficiency. A general literature search was now conducted to identify the most relevant proteins based on their current gene doping potential.
The issue of gene doping has chaperoned scientific accomplishments in gene therapy for at least a decade, and despite considerable reservations as to what kind of benefit cheating athletes could possibly expect as well as detrimental health and legal consequences, there is an urgent need to pursue anti-doping efforts concerning the manipulation of the sportsmen's genetic material. Two major scenarios of gene doping are described with one being the abuse of “classical” gene therapy, i.e. introduction of synthetic DNA sequences via viral vehicles into the organism, and the other being based on RNA interference strategies. The latter has recently been considered the more promising approach in therapeutic settings, which however also implies that there is a higher risk of its abuse in sports [13012].

The most common approach to directly determine synthetic exogenous DNA relies on the amplification by polymerase chain reaction (PCR), exploiting the presence of exon-exon junctions in exogenous DNA sequences. Using such strategies, the determination of incorporated exogenous DNA was traceable in white blood cells up to 57 weeks after intramuscular injection. In order to improve the method's sensitivity and exclude false-negative results, an internal threshold control (ITC) was suggested that should compensate for sample preparation and analysis issues. The approach was applied to a non-human primate EPO gene doping model providing proof-of-concept data, which should be corroborated with further analyses demonstrating that the principle can be applied to other DNA targets as well. In a different study, an attempt was conducted to determine the intramuscularly administered plasmid (cytomegalovirus-focal adhesion kinase) in rats using PCR. While tissue sampling of the transfected muscle allowed for the detection of the exogenous DNA sequence for up to seven days, essentially all serum samples returned negative test results, demonstrating the challenging aspect of sports drug testing since tissue sampling will not be an option in doping controls [13012].

As the most common route of gene transfer is through viral vehicles, a complementary indirect approach was presented, aiming at the detection of backbone sequences of the employed vector, seconded by the analysis of a so-called construct-specific marker. The latter comprises parts of the promoter and the transgene, representing a non-natural target for PCR amplification and analysis, supporting the differentiation of a coincidentally present virus in the host from a modified recombinant vector backbone. The methodology was applied to transduced laboratory mice and proof-of-concept was obtained for blood, urine, tears, and various tissues; however, detection windows were comparably small (1-6 days) [13012].

The potential of gene doping was once more demonstrated in a multisite adeno-associated virus-IGF-1 gene transfer experiment with mice. Besides significant endurance performance enhancement (as assessed by exhaustive swimming tests), substantial alterations in the muscle proteome were recognized, affecting both energy expenditure pathways as well as structural and contractile proteins [13012].

During the last 2 decades, progress in deciphering the human gene map as well as the discovery of specific defective genes encoding particular proteins in some serious human diseases have resulted in attempts to treat sick patients with gene therapy. There has been considerable focus on human recombinant proteins which were gene-engineered and produced in vitro (insulin, growth hormone, insulin-like growth factor-1, erythropoietin). Unfortunately, these substances and methods also became improper tools for unscrupulous athletes. Biomedical research has focused on the possible direct insertion of gene material into the body, in order to replace some defective genes in vivo and/or to promote long-lasting
endogenous synthesis of deficient proteins. Theoretically, diabetes, anaemia, muscular
dystrophies, immune deficiency, cardiovascular diseases and numerous other illnesses could
benefit from such innovative biomedical research, though much work remains to be done.
Considering recent findings linking specific genotypes and physical performance, it is
tempting to submit the young athletic population to genetic screening or, alternatively, to
artificial gene expression modulation. Much research is already being conducted in order to
achieve a safe transfer of genetic material to humans. This is of critical importance since
uncontrolled production of the specifically coded protein, with serious secondary adverse
effects (polycythaemia, acute cardiovascular problems, cancer, etc.), could occur. Other
unpredictable reactions (immunogenicity of vectors or DNA-vector complex, autoimmune
anaemia, production of wild genetic material) also remain possible at the individual level.
Some new substances (myostatin blockers or anti-myostatin antibodies), although not gene
material, might represent a useful and well-tolerated treatment to prevent progression of
muscular dystrophies. Similarly, other molecules, in the roles of gene or metabolic activators
[5-aminoimidazole-4-carboxamide 1-beta-D-ribofuranoside (AICAR), GW1516], might
concomitantly improve endurance exercise capacity in ischaemic conditions but also in
normal conditions. Undoubtedly, some athletes will attempt to take advantage of these new
molecules to increase strength or endurance. Antidoping laboratories are improving detection
methods. These are based both on direct identification of new substances or their
metabolites and on indirect evaluation of changes in gene, protein or metabolite patterns
(genomics, proteomics or metabolomics) [13756].

The science behind gene doping

Definitions and history

When gene therapy is used to increase the performance of a healthy person, it is considered
gene doping by WADA. Gene doping presents the same advantages over regular doping as
gene therapy does for regular medicine, but detection of gene doping is more difficult. Gene
doping has been prohibited by the International Olympic Committee (IOC) since 2003. In
2004, WADA took responsibility for publishing the Olympic doping list, and they added gene
doping. The following new methods with the potential to enhance sport performance are
prohibited [13011]:

1. The transfer of nucleic acids or nucleic acid sequences
2. The use of normal or genetically modified cells

As for gene therapy, every known gene can be used for gene doping. Currently, only about
500 genes in the human genome are used in existing drugs, thus a significant number of the
remaining genes could bring new options for doping. At least 100 genes are already linked to
athletic performance and the number is increasing every year. Although not all of these
genes can be considered to be potential gene doping candidates, the increasing number of
genes used in medications raises expectations for the potential advantages of gene doping.
The fear is that athletes might not wait for gene therapy to be fully developed and tested
before misusing it [13011].

The explosion of genetic knowledge in the latter part of the twentieth century has given rise
to new ways of thinking about human biology in health and disease. These advances have
begun to deliver on their promise of new and more effective approaches to the prevention
and treatment of human disease. This genetic revolution started long ago in the middle of the
nineteenth century with the work of Gregor Mendel and the concepts of inheritance that
emanated from his studies of the properties of peas and other plants in the monastery in

2028
Brno in the Austro-Hungarian Empire. Mendel discovered that the physical properties of these living systems are inherited in predictable and reproducible ways and that there are biological factors in the plants that carry these traits from one generation to the next. Mendel’s work was forgotten by the scientific community until the beginning of the twentieth century when his studies were “rediscovered” independently by several scientists and, for the first time, applied to human disease by the English clinician Sir Archibald Garrod during the first decade of the twentieth century. In his clinical work, Garrod was treating patients suffering from a number of familial conditions. The rules that Mendel had worked out in plants were found to be equally important to human beings in determining human disease. Garrod coined the term “inborn errors of metabolism” to describe the underlying processes that led to the appearance of these and other inherited human conditions. The structure or composition of the factors discovered by Mendel, and first applied to human disease, was not known for many years. The discovery of the true chemical nature of the gene was made in 1944 through the work of Oswald Avery and his group at the Rockefeller Institute in New York. Avery and his team found that they could permanently and heritably change the infectivity properties of a strain of the bacterium pneumococcus by introducing deoxyribonucleic acid (DNA) from a different strain. With the discovery of the precise three-dimensional structure of DNA by James Watson and Francis Crick in Cambridge in 1953 and the elucidation of the genetic code by several groups of molecular biologists came the first real functional understanding of DNA. The “golden age” of molecular biology from 1953 through the 1970s and through the subsequent decades of one startling advance after another, have now culminated in the total sequence characterization of the human genome. Through all of these advances we know that:

- the genetic information of living systems, from microbes to humans, is contained in the sequence of four simple basic purine and pyrimidine chemical-building blocks
- many naturally occurring differences in that sequence account for normal variations among individuals of a species
- some differences in the sequence of genes, naturally occurring or induced by environmental influences, cause severe disruption of normal metabolic, cellular functions to cause disease.

**Gene transfer approach to therapy**

In the late 1960s and early 1970s, during the explosion of knowledge of molecular genetics, techniques emerged that began to promise precisely the new kind of approach to therapy. The genetic components of human disease were recognized, detailed mechanisms of gene expression were obtained, animal models of more and more human diseases were available for study in the laboratory, and early techniques for transferring foreign genes into human and other mammalian cells appeared. Inevitably, the connection of these advances in basic genetics with the need for definitive new methods of disease therapy was made, and the concept of “gene therapy” was born. From this conception more than three decades ago, it was clear that there were many difficult scientific, ethical, and policy obstacles to overcome before such techniques could be applied to humans for treatment of disease. Because of several ill-conceived and inappropriate applications of highly immature gene transfer technologies to human patients, an extensive set of oversight and regulation mechanisms have been put into place over the years. Gene transfer vectors have been constructed from many viruses (e.g. herpes viruses, pox viruses, flu viruses, even HIV). In such cases, the genes of the viruses themselves are removed or otherwise inactivated, leaving the virus with the only function of acting as a moving van, or in more surreptitious terms, a Trojan horse, to sneak foreign genes into the cells in a way that will be completely harmless to the cell.
**Therapeutic gene transfer vectors introduced into human beings**

Two principal methods have been developed to introduce gene transfer vectors into research subjects and patients. These methods are now called the “ex vivo” and “in vivo” methods and differ by whether the gene transfer vector is introduced directly into the tissues of the patient or research subject (“in vivo”) or alternatively into cells of the patients in the laboratory followed by the reintroduction of the genetically corrected cells into the patient (“ex vivo”). For instance, cells can be obtained from the bone marrow of a patient suffering from a disease that prevents normal production of blood cells. These cells can then be modified genetically by exposure to a gene transfer vector in the laboratory and the corrected cells can then be transfused back into the patient. Under these conditions, the corrected cells make their way into the defective bone marrow again, set up residence there, and replace the abnormal cells. In another ex vivo approach, skin cells can be obtained from a patient through a very small skin biopsy, grown in culture dishes in the laboratory, genetically modified as discussed earlier, and then put back into the patient in a number of tissues, including the brain where they can produce a product to correct a genetic deficiency in that organ. The use of a patient’s own cells for this ex vivo approach to transfer has the great advantage of avoiding the immune rejection of cells derived from other donors, whether they be closely related donors, unrelated donors, or possibly even nonhuman cells. In the latter cases, cells could be first put into microcapsules that prevent contact of the “foreign” cells with the host immune system that would cause an immune rejection response by the host and elimination of the therapeutic cells. In the case of the in vivo approach to gene transfer, a vector or even a “naked” piece of DNA can be introduced by injection directly into a tissue to transfer a foreign gene into the cells of that tissue [06305].

**Muscle cells**

One of the early surprises of the in vivo approach of gene transfer was that injection of DNA directly into skeletal muscle was a relatively effective way of causing a genetic modification of muscle cells and of providing prolonged expression of a foreign gene to alter muscle function. Most of these early studies involved genes that are needed specifically in the muscle cells themselves and that are involved in diseases such as muscular dystrophy. But muscle is also an excellent platform from which one can deliver many kinds of gene products into the blood stream for delivery to the entire body, and many foreign genes other than those producing muscle-specific functions have also been introduced into and expressed by muscle, including genes encoding growth factors, erythropoietin, and others. To achieve more efficient levels of gene transfer than those possible with naked DNA alone, virus vectors have also been injected directly into many tissues and organs in vivo, including many kinds of cancer, skeletal and even heart muscles, the brain, joints, the skin, the liver, the lungs and other parts of the airway, and many other sites [06305].

**Reversing the effects of transplanted genes**

We know now that our tools are still too immature to prevent serious harm to some people taking part in gene transfer experiments. It seems clear that the more effective we become with today’s tools and methods, the greater are the chances of serious and harmful side effects. Therefore, it is prudent to incorporate some procedures to remove the foreign gene or even to kill the cells carrying the transferred gene. In some cases, it might be possible to remove the cells surgically, especially if the gene transfer is performed into skin, an accessible muscle, or other tissue that can be accessed readily and can be removed with impunity. In those cases in which the foreign gene is placed into the body in the form of a small capsule from which the therapeutic gene product can be secreted into a local tissue or
into the blood stream, the capsule can be removed. One such method of selective cell removal involves the incorporation into the gene transfer vector of a “suicide” gene, i.e. a second gene in addition to the therapeutic gene that selectively acts only on cells that have been genetically modified and produces a toxin that kills them while not affecting the neighboring unmodified cells. Such an approach has been used in a number of human gene transfer studies aimed at the elimination of certain kinds of cancer cells, but until now the results of these studies have generally been imprecise. Nevertheless, these kinds of selective killing, or removal methods, in the event that the genetically modified cells grow out of control, or otherwise produce harm, hold promise [06305].

**Medical uses of gene therapy**

Gene therapy can be used to treat a variety of illnesses. It may be applied to weaken or kill cancer cells by triggering apoptosis, to enable target cells to produce a protein that otherwise has to be administered or to upregulate the production of a specific protein. Though a couple of gene therapy products have been marketed outside China to date, at least 1843 gene therapy trials have been conducted worldwide with thousands of patients suffering from cancer diseases, cardiovascular and neurological diseases and a range of other diseases. Early clinical trials in Europe and the USA had limited results and even fatalities were reported from gene therapy; however, examples of successful gene therapy include treatment of SCID-X1 and Leber’s congenital amaurosis. The proof of concept of various transfer strategies in gene therapy shows that we are at least at the beginning of a gene therapy revolution for patients with monogenic diseases [13011].

**Animal use of gene doping**

Since gene doping can increase performance, it is likely to be used in animal competitions as well. If money can be earned by betting or trading with superior animals, gene doping would be lucrative. If the achievements of horses, dogs, camels or pigeons could be improved, then it is quite possible that gene doping will be tried on these animals before human applications [13011].

**Genes versus environmental influence**

Physical traits, such as our hair color and height, as well as our personalities, intelligence, talents, and emotional properties, are the result of the potential provided by our genes and the nurturing and shaping of that potential by the environment in which we develop and grow. Furthermore, the presumed mix of the effects of “nature” and “nurture” – genetics and our environment – applies not only to what makes us normal but also to the “abnormal” traits that cause so many human diseases and suffering. In many cases, such as sickle-cell anemia and cystic fibrosis, the genetic factors are predominant. These diseases result from defects – “mutations” – in single genes, and chances are high that people who have inherited abnormal genes will develop the clinical disease, no matter how the environment is manipulated. “Nature” is enough to cause the disease. For other diseases, such as, various forms of diabetes, most heart diseases and cancer, psychiatric diseases, and so on, there may be a number of genetic factors that have to interact with each other and that also are expressed in many different ways depending on the environmental influences. “Nature”
interacts with “nurture” to bring about the clinical disease. In such cases, making changes in “nurture” may have a very significant effect on how that disease trait is expressed – hence, the reasonably effective treatments for many diseases with drugs, surgery, vaccines, and so on. It is not only disease characteristics that are affected by the influence of genes and environment but athletic performance that is affected by many of these, mixed “nature” and “nurture” factors. Of course, to be successful in sports, one must have the physical talents and capabilities – the appropriate body build, keen eyesight, and rapid hand-eye coordination to satisfy the physical demands of the sports. But it is just as important for the underlying athletic talent and physical capability to emerge in an environment that fosters participation and training – an encouraging family with sufficient resources to support purchase of equipment and the expenses of trainers and a school environment that provides athletic opportunities. It is hard to imagine becoming a successful athlete without having both the physical characteristics as well as the milieu for those traits to develop [06006].

The parts of this formula for success in sports can be, and often are, manipulated to enhance the likelihood for successful athletic performance. Only by ensuring the best possible training facilities and opportunities for athletes and providing the best medical support and care for them can we ensure that a sport maintains its important role in one’s society in fostering a healthy sense of striving for and achieving lofty goals, building a rewarding sense of physical accomplishment in the young, and providing our society with the inspiration and entertainment of sports achievement. Enlightened programs exist in many parts of the world to encourage participation in sports, provide sports facilities in schools and communities for recreational participation in sports, as well as for training selected athletes in sports academies and other sports facilities for more professional and elite levels of sports. Unfortunately, the society can manipulate other aspects of the sports environment in sly, duplicitous, surreptitious, dangerous, and venal ways, as indicated by the pervasive problem of drug abuse, doping, in sports. This is not a new phenomenon in sports, since it is recognized that athletes for centuries, as far back as ancient Greece and probably even earlier, have pursued victory by using any available means, including specialized ointments, lotions and salves, diets, and so on, openly or secretly, to achieve athletic success. In the past, many of these kinds of tools and tricks were more or less ineffective and of little use, other than for psychological support of the athlete or intimidation of competitors. However, the problems associated with doping in sports today are different from the mere psychological effects in the past because the potency of drugs in common use today give them the potential not only for having powerful and real effects on athletic performance effect but also for equally powerful but harmful physiological effects. Today’s drugs are not yesterday’s placebos. Physical traits, such as muscle size and strength, blood circulatory properties, the efficiency of our energy utilization, and others, seem to be the most common targets of genetic manipulation just as these have been vulnerable to manipulation by “traditional” drug-based doping [06006].

**Gene therapy versus gene doping**

One of the most difficult steps in gene therapy is delivering the gene into host cells. Three major techniques used for delivering genes are injecting naked DNA, viruses or modified cells 130011].

Gene doping is defined by the World Anti-Doping Agency (WADA) as “the non-therapeutic use of genes, genetic elements and/or cells that have the capacity to enhance athletic performance”. Gene therapy approaches deliver genetic material to the body's own cells which then produce the encoded protein. In this way the expressed protein can potentially be
indistinguishable from the endogenous version of the same protein encoded from chromosomal genes. This similarity is important for treatment of disease to ensure that the expressed protein is not targeted by the immune system so that long term production of the gene therapy protein is achieved. This ability to produce biologically active molecules that are potentially identical to endogenous proteins is also appealing for unscrupulous athletes as a way to deliver undetectable performance enhancing molecules [13011].

When gene therapy is used to increase the performance of a healthy person, it is considered gene doping by WADA. Gene doping presents the same advantages over regular doping as gene therapy does for regular medicine, but detection of gene doping is more difficult. Since gene doping is a powerful tool to boost performances, it may have a significant impact on the professional sports world. Gene doping has been prohibited by the International Olympic Committee (IOC) since 2003. In 2004, WADA took responsibility for publishing the Olympic doping list, and they added gene doping. The following new methods with the potential to enhance sport performance, are prohibited:

- the transfer of nucleic acids or nucleic acid sequences
- the use of normal or genetically modified cells

As for gene therapy, every known gene can be used for gene doping. Currently, only about 500 genes in the human genome are used in existing drugs, thus a significant number of the remaining genes could bring new options for doping. At least 100 genes are already linked to athletic performance and the number is increasing every year. Although not all of these genes can be considered to be potential gene doping candidates, the increasing number of genes used in medications raises expectations for the potential advantages of gene doping. The great benefits expected from gene doping make it likely that actual misuse is close at hand. As illustrated by the BALCO-affair, among other incidents, athletes are known to take more risks than average people. BALCO was an American-based company that officially advised numerous world-class athletes on nutrition, but secretly instigated cooperation between chemists, trainers and athletes to purposely evade doping controls with new and undetectable doping substances [13011].

As the London 2012 Olympics are approached, sport finds itself facing a highly specific threat to its ethos of fair play. Defined by the World Anti-Doping Agency (WADA) as "the non-therapeutic use of genes, genetic elements and/or cells that have the capacity to enhance athletic performance" gene doping presents a range of challenges to those involved in sport and exercise medicine and an urgent need for an understanding of its potential impact to healthcare. Gene doping has a molecular basis similar to gene therapy, whereby selected genes are intentionally introduced into targeted human somatic cells to facilitate the production of the "normal" physiological variant of a protein. Therapy is therefore not intended to be curative nor prevent transmission of the genetic mutation to any future children (since any modification to the human germline is universally illegal). Although several variations in the technology exist, it is essentially dependent upon a therapeutic gene coupled with a regulatory element to ensure its appropriate expression; and a vector’ (viral or synthetic) to enable its delivery to cells. Early researchers came to see two basic principles emerging that could be applied when considering the probable efficacy of gene therapy in various conditions; with the highest probable efficacy occurring if:

1. The disease process is solely due to a lack of normal protein production by its associated target cells
2. The associated target somatic cells are readily accessible

Furthermore, in order for a suitable therapeutic gene for a condition to be developed, the
genetic basis of the disorder must be well understood in order to not only ensure the desired therapeutic outcome but also that the therapy itself does not cause unforeseen harm to the recipient. However, despite early optimism, by 2011 only a handful of conditions had been successfully treated by gene therapy. Moreover, profound concerns have been voiced surrounding the safety of gene therapy following reports of severe adverse effects having occurred in trial subjects; including the development of leukaemias in a few children treated for SCID-X1 deficiency, and the unexplained death of a participant in a gene therapy trial involving rheumatoid arthritis patients. Accordingly, it is widely held that with advancing methods, the use of gene therapy will become safer, more efficient and, as such, increasingly widespread [11547]

**Epigenetics**

To achieve success in sports, many athletes consume doping substances, such as anabolic androgenic steroids and growth hormones, and ignore the negative influence of these drugs on their health. Apart from the unethical aspect of doping in sports, it is essential to consider the tremendous risk it represents to their physical condition. The abuse of pharmaceuticals which improve athletic performance may alter the expression of specific genes involved in muscle and bone metabolism by epigenetic mechanisms, such as DNA methylation and histone modifications. Moreover, excessive and relentless training to increase the muscle mass, may also have an influence on the health of the athletes. This stress releases neurotransmitters and growth factors, and may affect the expression of endogenous genes by DNA methylation, too. One paper focused on the relationship between epigenetic mechanisms and sports, highlights the potential consequences of abuse of doping drugs on gene expression, and describes methods to molecularly detect epigenetic changes of gene markers reflecting the physiological or metabolic effects of doping agents. Rapid growth and development of muscles by high physical activity is based on an integrated mechanism linking exercise with a variety of anabolic responses. The physical adaptation to environmental conditions, such as strongly developed muscles and tendons and a more resilient blood circulation, might influence epigenetic mechanisms. The so-called eustress in sports releases neurotransmitter and growth factors which may cause a change in gene expression by epigenetic mechanisms. The effects of environmental exposures can even be transmitted for several generations, suggesting transgenerational inheritance of induced epigenetic variation. The illegal intake of anabolic substances can affect the body-own gene activity in the form of an activation or repression of gene expression. The most frequently used doping agents are growth hormones and anabolic steroids that are readily detectable in urine using gas chromatography and mass spectrometry. It is estimated that every fourth sportsman takes combinations of anabolic steroids and IGF-1 (insulin-like growth factor 1). Although it is little known about the long-term effects on gene expression, these substances could influence the epigenetic pattern of the genome. Epigenetics covers three molecular mechanisms: DNA methylation, histone modifications, and remodulation of the chromatin. These processes control the transcription of genes responsible for the variability of the phenotypes. DNA methylation affects directly or indirectly the gene expression. In general, DNA methylation inhibits the access of factors to their target sequences on promoters and introns (e.g. enhances, silencer), and thus, leading to the inactivation of transcriptional expression. Moreover, the degree of chromatin condensation has a regulatory role on gene expression. In this regard, switching on and off distinct sets of genes to achieve lineage-specific activation or repression could, hence, improve the physical activity. It may be speculated, that drug-induced long-lasting changes of gene expression can increase the risk of cancer. Therefore, increasing attention should be paid to the role of DNA methylation and histone modifications in doping. To date, a main challenge of World Anti-Doping Agency
(WADA) and International Olympic Committee (IOC) is to prevent serious health risks and reduce unfair competitive advantage among athletes. Hence, specific, sensitive, and validated methods are needed or should be adapted to the sport setting, in order to document the modulated gene expression profile underlying the epigenetic influences of doping. Physical alterations caused by sports, for example, increased muscle fibres by training or drug abuse, may induce a changed epigenetic profile leading to a changed gene expression. Doping control laboratories have begun to develop methods for detection of peptide hormones using electrophoretic, chromatographic, and mass spectrometric approaches. However, sensitive and specific techniques which reveal the molecular and epigenetic outcome of doping agents are lacking. Thus, the effect of these substances on the genomic methylation pattern remains to be addressed. Therefore, efforts to translate currently available information on the molecular mechanisms of doping agents should be made [114075].

To achieve success in sports, many athletes consume doping substances, such as anabolic androgenic steroids and growth hormones, and ignore the negative influence of these drugs on their health. Apart from the unethical aspect of doping in sports, it is essential to consider the tremendous risk it represents to their physical condition. The abuse of pharmaceuticals which improve athletic performance may alter the expression of specific genes involved in muscle and bone metabolism by epigenetic mechanisms, such as DNA methylation and histone modifications. Moreover, excessive and relentless training to increase the muscle mass, may also have an influence on the health of the athletes. This stress releases neurotransmitters and growth factors, and may affect the expression of endogenous genes by DNA methylation, too. One paper focused on the relationship between epigenetic mechanisms and sports, highlights the potential consequences of abuse of doping drugs on gene expression, and describes methods to molecularly detect epigenetic changes of gene markers reflecting the physiological or metabolic effects of doping agents [11548].

**Evolving definitions**

The genotype of the athlete influences his or her performance in sport as well as the daily training. By genetic screening and by gene therapy it may be possible to assist the sportsmen in nonacceptable manner to the success. As possible health risks, immunological reactions caused by the transfer of inactivated viruses, autoimmunological reactions, negative influence on the growth of the myocardium or leukaemia are described. In the meantime, beside sports-juridical sanctions (lex sportiva), numerous countries have sanctions for doping in sport in their state norms (lex extra sportiva). The sanctions can refer to the use of prohibited substances or prohibited methods, like gene doping. One paper first describes the development of the definitions of gene doping by the World Anti-Doping Agency (WADA). Knowledge of genetic influences provides an opportunity for medical diagnostic and therapeutic attempts. Beside risks and therapeutic aspects, however, the possibilities of abuse for gene doping purposes in sports also exist. Genetic screening or gene therapy may have an advantage for athletes who use these methods. In juridical comments, it is pointed out that gene doping so far plays no role in sports, but that the legislator must consider a development in this area. Preventing abuse requires legal regulations. These regulations can include sanctions. This paper deals with the gene doping prohibition of the World Anti-Doping Agency (WADA) as confirmed and accepted by the monitoring group according to Articles 10 and 11 of the European Anti-Doping Convention by the Council of Europe, the prohibition of (gene) doping in sports of the German Medicinal Products Act (Arzneimittelgesetz) and the German Doping Agents Amounts Ordinance (Dopingmittel-Mengen-Verordnung) of the German Federal Ministry of Health. The
comprehensibility of the doping ban on the norm addressee was tested with a questionnaire. In connection with legal regulations of the German constitution, gene doping is discussed and problems which may arise by a state doping prohibition are pointed out. Criteria for including substances or methods on WADA’s prohibited list are according to Article 4.3.1 of the WADA Code 2009 that a substance or a method like gene doping fulfils any two of three criteria:

- Medical or other scientific evidence, pharmacological effect or experience that the substance or method, alone or in combination with other substances or methods, has the potential to enhance or enhances sport performance
- Medical or other scientific evidence, pharmacological effect or experience that the use of the substance or method represents an actual or potential health risk to the athlete
- WADA’s determination that the use of the substance or method violates the spirit of sport described in the introduction to the code

In addition, a substance or method also shall be included in the prohibited list according to Article 4.3.2 of the WADA Code 2009, if there are effects and/or experience of a potential to mask, for instance, prohibited substances. Since 2003, gene doping is specifically mentioned in WADA’s prohibited lists. Several changes of the gene doping definition have taken place since the first definition in 2003 [11514].

- **2003**: Gene or cell doping is defined as the non-therapeutic use of genes, genetic elements and/or cells that have the capacity to enhance athletic performance
- **2004**: Gene or cell doping is defined as the non-therapeutic use of genes, genetic elements and/or cells that have the capacity to enhance athletic performance
- **2005**: The non-therapeutic use of cells, genes, genetic elements, or of the modulation of gene expression, having the capacity to enhance athletic performance, is prohibited
- **2006**: The non-therapeutic use of cells, genes, genetic elements, or of the modulation of gene expression, having the capacity to enhance athletic performance, is prohibited
- **2007**: The non-therapeutic use of cells, genes, genetic elements, or of the modulation of gene expression, having the capacity to enhance athletic performance, is prohibited
- **2008**: The non-therapeutic use of cells, genes, genetic elements, or of the modulation of gene expression, having the capacity to enhance athletic performance, is prohibited
- **2009**: The transfer of cells or genetic elements or the use of cells, genetic elements or pharmacological agents to modulating expression of endogenous genes having the capacity to enhance athletic performance, is prohibited. Peroxisome Proliferator Activated Receptor (PPAR) agonists (e.g. GW 1516) and PPAR-AMP-activated protein kinase (AMPK) axis agonists (e.g. AICAR) are prohibited
- **2010**: The following, with the potential to enhance athletic performance, are prohibited:
  - The transfer of cells or genetic elements (e.g. DNA, RNA)
  - The use of pharmacological or biological agents that alter gene expression. Peroxisome Proliferator Activated Receptor (PPAR) agonists (e.g. GW 1516) and PPAR-AMP-activated protein kinase (AMPK) axis agonists (e.g. AICAR) are prohibited
- **2011**: The following, with the potential to enhance sport performance, are prohibited:
  - The transfer of nucleic acids or nucleic acid sequences
  - The use of normal or genetically modified cells;
The use of agents that directly or indirectly affect functions known to influence performance by altering gene expression. For example, Peroxisome Proliferator Activated Receptor (PPAR) agonists (e.g. GW 1516) and PPAR-AMP-activated protein kinase (AMPK) axis agonists (e.g. AICAR) are prohibited.

**RNA interference**

RNA interference represents a comparably new route of regulating and manipulating specific gene expression. Promising results were obtained in experimental therapies aim at the treatment of different kinds of diseases including cancer, diabetes mellitus or Duchenne muscular dystrophy. While studies on down-regulation efficiency are often performed by analyzing the regulated protein, the direct detection of small, interfering RNA molecules and antisense oligonucleotides is of great interest for the investigation of the metabolism and degradation and also for the detection of a putative misuse of these molecules in sports. Myostatin down-regulation was shown to result in increased performance and muscle growth and the regulation of several other proteins could be relevant for performance enhancement. One mini-review summarized current approaches for the mass spectrometric analysis of siRNA and antisense oligonucleotides from biological matrices and the available data on biodistribution, metabolism, and half-life of relevant substances are discussed [11549].

**Genetic enhancement**

Gene doping also could use the technique of genetic enhancement/engineering. In practice in agricultural settings, genetic enhancement places advantageous genes into organisms, not to cure disease, but to confer advantages to the organism that would improve the organism's survival or the organism's “product”: hardiness, better insect resistance, or greater yield. Genetic enhancement exploits the same techniques as gene therapy; however, it can be applied outside of medicine. Using basic principles of gene therapy (and genetic enhancement), gene doping injects genes directly into the athlete's body by one of two methods: in vitro delivery and ex vitro delivery. In gene therapy, the clinician introduces a gene that covers for a deficient gene or modulates the activity of an existent gene to correct a disease state. The goals of gene doping include the injection of novel genes or the modulation of existing genes too; however, the gene doper introduces the gene products for the enhancement of physiologic parameters expedient to the athlete's competitive tasks, rather than the treatment of a medical illness [07046].

**In vivo gene doping**

The delivery of the new gene into the athlete can be through biologic, physical, or chemical methods. Viruses can be modified to biologically insert the artificial gene into cells in a specific organ or target tissue or into cells throughout the competitor's body. Virus lines modified to transfer genes to mammalian cells include retroviruses, adenoviruses, and lentiviruses. Physical methods to deliver genes into cells use microsyringes, or gene guns. Biochemical injection vehicles use plasmids or liposomes [07046].

**Ex vivo gene doping**

The technique of exogenous gene doping involves gene transfer to cells in culture first, then implantation of the tissue into the recipient. Once implanted into the athlete's cells, the new
genes express hormones or biochemicals that again enhance tasks of the athlete in competition [07046].

**Possibilities for gene doping**

Human gene therapy involves the insertion of DNA (or RNA) into somatic cells to produce a therapeutic effect. Gene therapy was first envisaged as an approach to treating genetic disorders. In this scenario, missing or mutant genes could be replaced or repaired. Today, gene therapy has broader applications, with trials covering many clinical problems including genetic diseases, cancer, infections such as HIV, and degenerative diseases. The transfer of genetic material into cells can be undertaken in many ways, most commonly using a viral vector. For this, viruses are genetically engineered to remove infectious potential while retaining the capacity to carry a therapeutic gene(s) into selected target cells. The inserted sequences can encode a missing or mutant product as might occur in the case of cancer, or alternatively could be used to inhibit a foreign protein as would be found in HIV infection. Viral vectors have been derived from a number of different viruses. Some, such as the adenovirus, are associated with relatively mild human infections, whereas others are associated with more serious disease, for example HIV. Certain viral properties are particularly useful for gene therapy, such as the capacity to permanently integrate introduced genetic sequences into the host cell genome [06306].

Apart from viruses, there are numerous physicochemical methods for introducing DNA (or RNA) into somatic cells. The most relevant in the context of sport involves direct injection of DNA that has been formulated with a chemical carrier for more efficient uptake by cells. None of the physicochemical approaches has been successful in human trials, as the levels of gene transfer achieved are insufficient for therapeutic benefit. The results in gene therapy have generally been disappointing despite over 1000 clinical trials since 1990. Only two diseases have been successfully treated by gene therapy. Both are forms of severe combined immunodeficiency, SCID-X1 and ADA-deficiency. Unfortunately, success has come at a cost, with three of 18 infants with SCID-X1 treated developing leukaemia. This has now been shown to have been caused by insertional mutagenesis, which had previously been considered a remote theoretical risk associated with the integrating gene transfer technology used. At present, there are three limitations to gene therapy:

- gene transfer technologies are not efficient enough for most applications
- therapeutically useful integrating gene transfer technologies carry unresolved risks
- there remains an inadequate understanding of the biology of therapeutically relevant target cell populations.

Sports men and women and sporting administrators faced with the prospect of drug cheating and blood doping now need to consider gene doping. Although therapeutic benefit from gene therapy is difficult to achieve, gene doping is paradoxically more feasible because a very large output from the introduced gene may not be required, and the desired effect need only be short term. Regular injections at the time of sporting events may suffice. Gene doping is further simplified as it would not be necessary to have the transferred gene regulated so that its output corresponds to specific cellular requirements as might be the case for treating disease [06306].

Depending on the desired effect and the type of sport and athlete, gene doping might enhance performance. Athletes who compete in endurance sports, like marathons and long-distance swimming, may look to gene therapy to boost their oxygen supply or delay the
sense of fatigue. Sprinters and weight lifters, who mainly need power, may consider gene therapy to increase muscle mass or improve their injury recovery time. Boxers would appear to be most interested in improved pain tolerance from gene doping [13011].

The variables that control oxygen delivery include erythrocyte number in the blood, degree of tissue vascularization and rate of blood flow. Oxygen is delivered to the body through breathing and so improving lung function is a potential target for gene doping. Gene delivery to the lungs has primarily been developed for the treatment of cystic fibrosis, a genetic condition caused by a mutation in the gene for the protein cystic fibrosis transmembrane conductance regulator (CFTR) which regulates the movement of chloride and sodium ions across epithelial membranes, such as the alveolar epithelia located in the lungs. Gene therapy for the condition requires delivery of the correct CFTR gene to the lungs of patients for expression in the epithelium. Expressing genes that improve oxygen delivery could be achieved in lower airways if gaseous exchange could be improved. Alternatively targeting pulmonary muscle could facilitate improved lung function [13011].

**Gene-based doping for muscle function**

An obvious first approach to gene-based athletic enhancement might involve “improvement” of muscle function. Most competitive sport requires optimum muscle function – maximal and controlled force of contraction, optimal delivery of nutrients and optimized energy utilization in exercising muscle, and efficient removal of metabolic wastes. These properties of muscle and of blood circulation can be modified in many ways; certainly through the classic route of intensive training. Scientists are coming to learn a great deal about the genes that regulate muscle function in health and in disease and even the ways in which muscle function is affected by normal kinds of training. It has been proven that the injection into skeletal muscle of a muscle growth factor, insulin-like growth factor-1 (IGF-1), or of the gene that encodes this growth factor causes skeletal muscle to become hypertrophic. This causes the muscle to contract with greater force, recover from work more efficiently, and repair from injury more quickly. These studies were undertaken as part of efforts to develop therapies for muscular dystrophy and other degenerative diseases, and these have been extended to the degenerative muscle changes in normal aging and even to normal rats to determine the effects of this and other growth factors on muscle in normal, young animals. Such a gene therapy approach would be useful but certainly not ideal for correction of the muscular dystrophies since many muscles not accessible to direct injection, such as the diaphragm and heart muscle, would not be easily corrected by this approach. However, many investigators are developing methods for delivering genes and gene transfer virus vectors through the circulatory system to large tissues and even to entire limbs, and it seems that such methods would be feasible in humans in carefully monitored settings [06307].

Another approach to muscle function is through the potential manipulation of a different gene that has a powerful “braking” effect on muscle growth. All genes in the body are subject to complex regulatory processes, some of which, like IGF-1, promote cell and tissue growth, while others act as brakes to dampen the positive stimulatory factors in order to achieve a balanced state of growth – neither too much nor too little. Myostatin is one such braking gene in muscle. It acts to counter the growth-stimulatory properties of IGF-1 and similar muscle growth factors. In an effort to improve meat production, cattle breeders managed more than 100 years ago to create two breeds of cattle, the Belgian Blue and the Piedmontese, which were markedly more muscular than normal cattle. Both breeds of cattle were found to have defects in the expression of the myostatin gene, resulting in a reduced inhibition of muscle growth and thereby an increased amount of muscle growth. Mouse geneticists then engineered a breed of mice in which the myostatin gene was inactivated and the resulting
mice also had bigger, stronger muscles, similar to those of the IGF-1 “Schwarzenegger” mice of Sweeney and colleagues [06307].

**Gene-based doping for oxygen delivery to exercising tissues**

Erythropoietin is a normal hormone of humans and other mammals, and it is vital in the process of normal blood production. Erythropoietin is turned on under conditions in which an animal is exposed to lowered amount of oxygen in the environment, and it acts to increase the production of the oxygen-carrying red blood cells in the bone marrow. It is one of the world’s most important and widely prescribed therapeutic drugs, producing enormous benefits to patients in whom blood production is suppressed by diseases such as many kinds of cancer and chronic or end-stage kidney disease. It is a life-saving medicine. Unfortunately, athletes taking part in endurance sports, such as bicycling, realized that an EPO-induced rise in the level of their red blood cells also resulted in a marked improvement in their performance. The result was an uncontrolled and uninformed epidemic of EPO doping in the 1990s during which the allure of possible benefits of EPO doping was not balanced by a corresponding awareness or concern with the hazards of excessive and poorly regulated red blood cell production. In order to improve the treatment of humans with life-threatening disease, clinical scientists have been examining gene-based methods for delivering the EPO gene so that one might have a stable source of EPO production in the body without the need of repeated injections of the EPO hormone itself. In studies reported in 2003 by scientists at Stanford University in California, the normal mouse EPO gene was introduced into a virus vector in a way that allowed this gene to be expressed only in the presence of a cortisone-like steroid. In the presence of the steroid, EPO could be produced by the vector, but in the absence of the drug, no EPO could be produced. This is the sort of arrangement that one would want for genes expressed in off–on ways. The vector was used to infect human skin cells that were being grown in the laboratory, and the genetically modified cells were then transplanted back to the mice. In the absence of the inducing steroid, mice containing grafts of the genetically modified cells had perfectly normal levels of EPO and normal levels of red blood cells in their circulation. However, when the glucocorticosteroid was applied to the grafted cells in the form of a simple topical cream, the genetically modified cells responded with an increased production of EPO that was, in turn, taken up by the blood circulation to the grafts and transported to the mouse bone marrow, where production of red blood cells was turned on. The level of red blood cells rose dramatically and could be maintained in the presence of the inducing glucocorticosteroid. In its absence, the level of red blood cells eventually fell slowly back to normal as the newly produced cells went through their usual lifetime of several months [06307].

All muscle and tissue functions require carefully regulated production and utilization of metabolic energy. Muscle is a complex tissue containing a number of different kinds of muscle cells that burn energy at different rates and therefore affect muscle function and athletic performance. The slow-twitch muscle fibers are particularly fatigue-resistant, probably because of their high content of mitochondria, the power-producing elements in all cells that enable them to convert fat to energy more efficiently in contrast to the fast-twitch muscle fibers that contain fewer mitochondria and that rely completely on energy production from glucose. It was reported that mice expressing an excessive amount of a foreign gene, peroxisome proliferator-activated receptor (PPAR delta), developed an increased number of the slow-twitch fibers. The genetically altered mice showed lower levels of intramuscular triglycerides, which are associated with insulin resistance and diabetes in obese humans. Furthermore, the mice demonstrated a reduced amount of body fat and surprisingly also became more efficient energy utilizers during endurance exercising. They were known as “marathon” mice. Because the mechanism of this effect is related to the burning of calories from fat, the genetic model is becoming important for the control and treatment of obesity,
but the effects of this and probably other related genes on athletic performance are not lost on the athletic community [06307].

The variables that control oxygen delivery include erythrocyte number in the blood, degree of tissue vascularization and rate of blood flow. Oxygen is delivered to the body through breathing and so improving lung function is a potential target for gene doping. Gene delivery to the lungs has primarily been developed for the treatment of cystic fibrosis, a genetic condition caused by a mutation in the gene for the protein cystic fibrosis transmembrane conductance regulator (CFTR) which regulates the movement of chloride and sodium ions across epithelial membranes, such as the alveolar epithelia located in the lungs. Gene therapy for the condition requires delivery of the correct CFTR gene to the lungs of patients for expression in the epithelium. Expressing genes that improve oxygen delivery could be achieved in lower airways if gaseous exchange could be improved. Alternatively targeting pulmonary muscle could facilitate improved lung function [13011].

Further possibilities of detecting gene doping

It can be used methods where light emit signals in proportion to the extent to which the gene is expressed. In just several days, one can determine how the entire collection of human genes responds to exposure to any agent – a drug, an environmental toxin, etc. This is precisely the approach that is also being taken so effectively to determine the differences, for instance, between normal and cancer cells. In addition, it has become possible through an approach called “proteomic analysis” to examine simultaneously all of the thousands of proteins that are expressed by genes and that are found in blood, urine, other body fluids and in all cells. If one imagines how these and other immensely powerful new detection methods can be useful in sport doping, envision the great difficulty posed by new, “designer steroids” that are created by rogue chemists precisely to avoid detection because they are "invisible" to existing chemical tests. It is safe to presume that most or even all anabolic steroids will all use common pathways to achieve their effect, and those effects will be reflected in changes in gene expression and in the distribution of proteins (the "proteome") of affected tissues. If this approach proves effective, it would go a long way toward the goal of developing relatively noninvasive testing and monitoring procedures for drug testing and monitoring in sport doping. It is of great interest to the gene therapy community to keep track of genes that are introduced into subjects and patients, to determine how well, how long and at what levels foreign genes are expressed [06308].

Doping targets

Approximately 200 “fitness genes” are now known. Certain target genes have begun to emerge as “front runners” in the development of doping agents, particularly within fields in which a competitive advantage has been demonstrated through the use of synthetic substances and the physiological basis of this advantage is well understood [11547].

Glucose metabolism

Genetic delivery would also offer new doping approaches such as the local expression of proteins within a target organ. The liver plays an essential role in both glucose storage (glycogenesis) and in the generation of glucose (gluconeogenesis) from non-carbohydrate carbon substrates including lactate which is converted into pyruvate by lactate dehydrogenase through the Cori cycle. Through local gene delivery to the liver it may be possible to enhance either storage or liberation of glucose in the liver. There have been no
gene therapy studies that have aimed to alter glucose metabolism directly in healthy subjects but clearly treatment of diabetic patients is a potential application of gene therapy. One study in diabetic obese mice has shown that continuous expression of glucagon-like peptide (GLP)-1 from an adenoviral vector administered by intravenous injection resulted in long term remission of diabetes by improving insulin sensitivity through restoration of insulin signalling and reduction of hepatic gluconeogenesis [13011].

Red blood cell activity/delivery

Since its introduction as a therapeutic agent in the 1980s, synthetic erythropoietin (EPO) has been a drug of relevance across a number of sports, particularly those, such as cycling, in which the aerobic threshold of an athlete is known to be a major source of performance limitation. In 1997, it was reported the results of their trial in which the administration of a genetic-based EPO agent to mice and primate subjects with EPO-responsive anaemias caused a substantial increase in the subjects' haematocrit levels from 49 to 81 percent and 40 to 70 percent, respectively. Moreover, the rise was then sustained for over one year in the mice and 12 weeks in the primates; and, upon assessment of its safety profile (among the primate subjects), no adverse effects were found to have occurred in any of the monkeys to whom it was administered. One of the most significant recent advances in genetic EPO agents has been the development of “Repoxygen” by Oxford Biomedica in 2002. Comprised of a viral-vector with a human EPO gene, intra-muscular injection of the product has been trialled in the treatment of anaemia associated with renal diseases and chemotherapy. In addition, the EPO gene is under the control of a hypoxia response element and is, therefore, self-regulated, only being induced (when required) under hypoxic conditions. However, while promising results from pre-clinical trials on mice subjects were widely publicized, Oxford Biomedica ultimately chose not to develop the product any further, as it was thought that it would not be financially viable in a market where exogenous EPO agents are already widely available. Of associated interest has been the potential for the use of vascular endothelial growth factor (VEGF) and/or other angiogenic factors in order to increase tissue blood supply, thus improving tissue oxygenation and nutrition as well as the efficient removal of local waste products. It has also been raised the possibility that the use of transcription factors such as hypoxia-inducible factor 1 alpha (HIF1 alpha) may facilitate therapeutic progress. Known to activate the production of angiogenic factors and, crucially, itself be activated by muscle hypoxia and endurance training, HIF1 alpha has been shown to increase the levels of VEGF and EPO mRNA after exercise [11547].

Erythropoietin

EPO is a hormone with 165 amino acids produced mainly in the renal cortex and its production is quickly induced by hypoxia. After being released, EPO binds to the EPO receptor stimulating erythropoiesis (the production of new erythrocytes), which increases the number of haemoglobin carrying erythrocytes in the blood. Haemoglobin binds to oxygen with high affinity; although this affinity is reduced by heat or high carbon dioxide concentrations; conditions found in active muscle tissue. Thus, EPO increases the oxygen supply for muscle tissue and muscles can work longer before they build up lactic acid. The result is that maximal oxygen uptake in muscles is increased, which increases endurance. Recombinant human erythropoietin (rHuEPO) was introduced in 1988 as the protein drug epoetin-alpha in Europe (and in 1989 in the USA). It is used to treat anaemia caused by kidney disease, cancer or HIV, or for blood loss following surgery or trauma. Instead of giving a patient–donor blood to increase erythrocytes, the patient is injected with EPO to stimulate erythropoiesis. Although studies have shown the stimulation of steroidogenesis in Leydig cells by EPO leads to infertility over time, EPO has also been found to have neuroprotective properties. The first documented illicit use of rHuEPO was in the 1989 Tour de France, and
more cases have since been documented. Since EPO stimulates erythropoiesis, it increases the viscosity of the blood, thus raising the risk of microcirculation blockage, heart failure and strokes, which makes overdosing and overexpression a risk. EPO has been prohibited by the IOC since 1990 and is currently on the WADA prohibited list [13011].

Gene therapy with EPO was first tested in macaques in the late 1990s and was shown to double the number of red blood cells in 10 weeks, which increased aerobic capacity and performance. Unfortunately, EPO also made the macaques’ blood rather viscous, although the macaques did not go into cardiac arrest and survived. The macaques also had autoimmune reactions against EPO causing anaemia. In a follow-up study, regulated gene expression allowed safe production of EPO for at least 6 years. Furthermore, ex vivo gene therapy has been performed in mice causing expression of functional EPO. It has already been shown that EPO-screening of urine samples, as currently used in WADA doping controls, can identify EPO genetic therapy. Since muscle tissue produces EPO with posttranslational modifications that differ from EPO produced by the kidneys, illegal use could be detected using isoelectric focusing (a technique using differences in pH-dependent electric charges). On the basis of the promising animal studies, Repoxygen is a viral vector containing the EPO-gene and a hypoxia-response element used to treat anaemia. However, due to safety problems in in vivo testing – erythrocytosis, thrombosis and ischaemia and immune reactions – Repoxygen has not been clinically tested to date. Despite the rather problematic safety profile of Repoxygen, a 2006 incident raised fear of abuse when a German track coach was accused of supplying Repoxygen to his athletes. However, the only evidence was email correspondence with a Dutch general practitioner about the issue. Although in its infancy, given the availability of an EPO gene-therapy product, it is the most likely protein to be used for gene doping. However, the availability of a broad range of conventional EPO-products and the likelihood that the current urine EPO-detection test would identify this type of gene doping rather easily speak against the use of EPO gene doping in the sport's arena [13011].

Erythropoietin (EPO) is a glycoprotein produced predominantly by the kidney, which acts on erythroid progenitor cells in the bone marrow to regulate red blood cell production by the process of erythropoiesis which increases haemoglobin and haematocrit and therefore increases oxygen delivery. This type of systemic delivery of a protein can potentially be achieved by gene therapy. Gene delivery of EPO has been demonstrated in several experimental studies and using a variety of vectors including intramuscular injection of EPO encoding AAV in non-human primates [13011].

Because gene therapy can also be used to have local effects at the site of gene delivery it is also possible to produce proteins locally whose effects are restricted to the injection site for example the induction of the growth of new blood vessels by the process of angiogenesis. Increased blood supply will enhance oxygen delivery which could be significant in many clinical settings such as peripheral vascular disease (PVD), coronary artery disease (CAD) and wound healing. There has been progress in the development of gene therapy for the induction of angiogenesis for the treatment of CAD and PVD. Several clinical trials have examined expression of angiogenic factors such as vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF) from vectors including plasmid DNA and adenovirus. Whist there are reports of safety with these approaches there are no clear cut demonstrations of therapeutic effect in well controlled clinical trials [13011].

Erythropoietin (EPO) increases oxygen supply to muscles, thereby increasing an athlete’s endurance and performance. EPO is a hormone with 165 amino acids produced mainly in the renal cortex and its production is quickly induced by hypoxia. After being released, EPO
binds to the EPO receptor stimulating erythropoiesis (the production of new erythrocytes), which increases the number of haemoglobin carrying erythrocytes in the blood. Haemoglobin binds to oxygen with high affinity; although this affinity is reduced by heat or high carbon dioxide concentrations – conditions found in active muscle tissue. Thus, EPO increases the oxygen supply for muscle tissue and muscles can work longer before they build up lactic acid. The result is that maximal oxygen uptake in muscles is increased, which increases endurance. Recombinant human erythropoietin (rHuEPO) was introduced in 1988 as the protein drug epoetin-a in Europe (and in 1989 in the USA). It is used to treat anaemia caused by kidney disease, cancer or HIV, or for blood loss following surgery or trauma. Instead of giving a patient–donor blood to increase erythrocytes, the patient is injected with EPO to stimulate erythropoiesis. Although studies have shown the stimulation of steroidogenesis in Leydig cells by EPO leads to infertility over time, EPO has also been found to have neuroprotective properties [13011].

The first documented illicit use of rHuEPO was in the 1989 Tour de France, and more cases have since been documented. Since EPO stimulates erythropoiesis, it increases the viscosity of the blood, thus raising the risk of microcirculation blockage, heart failure and strokes, which makes overdosing and overexpression a risk. EPO has been prohibited by the IOC since 1990 and is currently on the WADA prohibited list. Gene therapy with EPO was first tested in macaques in the late 1990s and was shown to double the number of red blood cells in 10 weeks, which increased aerobic capacity and performance. Unfortunately, EPO also made the macaques' blood rather viscous, although the macaques did not go into cardiac arrest and survived. The macaques also had autoimmune reactions against EPO causing anaemia. In a follow-up study, regulated gene expression allowed safe production of EPO for at least 6 years. Furthermore, ex vivo gene therapy has been performed in mice causing expression of functional EPO. It has already been shown that EPO-screening of urine samples, as currently used in WADA doping controls, can identify EPO genetic therapy.

Since muscle tissue produces EPO with posttranslational modifications that differ from EPO produced by the kidneys, illegal use could be detected using isoelectric focusing (a technique using differences in pH-dependent electric charges) [13011].

On the basis of the promising animal studies, Biomedica, a British company in Oxford, developed Repoxygen® to be used in the treatment of cancer, diabetic neuropathy and Parkinson’s disease. Repoxygen is a viral vector containing the EPO-gene and a hypoxia response element used to treat anaemia. However, due to safety problems in in vivo testing – erythrocytosis, thrombosis and ischaemia and immune reactions – Repoxygen has not been clinically tested to date. Despite the rather problematic safety profile of Repoxygen, a 2006 incident raised fear of abuse when a German track coach was accused of supplying Repoxygen to his athletes. However, the only evidence was email correspondence with a Dutch general practitioner about the issue. In conclusion, the potential benefits and experience with EPO gene doping are quite reasonable relative to other gene-doping candidates discussed below. Although in its infancy, given the availability of an EPO gene-therapy product, it is the most likely protein to be used for gene doping. However, the availability of a broad range of conventional EPO-products and the likelihood that the current urine EPO-detection test would identify this type of gene doping rather easily speak against the use of EPO gene doping in the sport’s arena [13011].

**Skeletal muscle size, strength and endurance**

Anabolic factors known to improve muscle mass such as human growth hormone (hGHD) and insulin-like growth factor-1 (IGF-1) have already been cloned. IGF-1 is known to be important in the regulation of skeletal muscle mass through stimulating hypertrophy and enabling repair
after injury. In a study, mice that had been injected as embryos with a transgene encoding an isoform of IGF-1 demonstrated a 15 percent increase in muscle bulk even in the absence of any exercise programme. Moreover, a separate study involving the injection of an IGF-1 isoform (via an adenovirus vector) to rat subjects, has indicated that such effects may be further amplified when combined with subsequent resistance training. In the study, while all injected rats demonstrated an increase in muscle mass, the effect was considerably amplified when combined with resistance training; with a 32 percent increase in muscle mass noted among exercised rats vs. the 15 percent increase in mass in non-exercised subjects. It is also important to highlight that, in contrast to the aforementioned EPO study involving anaemic mice, subjects in both of the IGF-1 trials were essentially normal/healthy animals. As such, it seems hard to ignore the potential connotations of such trials in relation to the possible use of IGF-1 isoforms as performance-enhancing agents. Perhaps of more concern is the potential development of mechano-growth factor (MGF) gene therapy. MGF is an isoform of IGF-1 that is released locally from skeletal muscle in response to mechanical factors, such as exercise, rendering it virtually undetectable in blood or urine samples. Originally studied with regards to its possible therapeutic application in conditions relating to skeletal muscle atrophy such as Duchenne muscular dystrophy, it has been suggested that MGF may be particularly beneficial as a doping agent in light of its involvement in skeletal muscle repair following injury. It has also been demonstrated that an adenovirus-mediated shRNA expression system could be used to down regulate myostatin expression via inhibition of the enzyme “muscle atrophy F-box” (MAFbx); resulting in an increase in the muscle mass of injected mice subjects [11547].

**Insulin-like growth factor**

Although increased endurance offers major benefits for athletes like long-distance runners, EPO offers limited benefits for athletes for whom power is essential (e.g., weight lifters). For this class of athletes, IGF may be more useful since it enhances muscle growth and performance. Medical researchers currently focus on developing methods to stimulate the endogenous production of IGF to prevent muscle loss due to a range of conditions such as degenerative muscle conditions, cancer, HIV or ageing. IGF-I is a polypeptide of 7.5 kDa, structurally related to insulin and produced as a result of hypothalamus-pituitary-liver axis activation. The hypothalamus produces growth-hormone-releasing hormone (GHRH), which stimulates the pituitary to release GH thus stimulating the liver to produce IGF-I. IGF stimulates muscle repair and muscle mass hypertrophy after damage, for example, from overload or stress. Increased expression of IGF leads to increased muscle power and mass making IGF a potential target for doping. The effects of IGF-I on muscle growth have not been tested on humans, but in IGF-I-deficient patients, insulin resistance, growth disorders and cardiovascular illnesses have all been documented. Transgenic mice have been used to test the effects of IGF-I. They showed 20-50 percent larger muscle mass than regular mice and no age-induced muscle degradation. The lifespan of these mice was decreased by 50 percent, possibly due to lower levels of antioxidative molecules, or cardiac hypertrophy. Although IGF-I is on the WADA prohibited list, it is available on the internet and anecdotal evidence proves IGF-I abuse. The clear benefits of IGF – muscle growth and endurance – are desirable in many sports. The local effect of IGF allows for selective muscle growth; however, it is not expected to be one of the first targets for gene doping. The health risks of IGF gene doping, in particular, the possible clinical consequences of IGF-overexpression such as cancer and cardiac hypertrophy, are significant [13011].

The liver is also the organ that secretes most insulin-like growth factor-1 (IGF-1) which is stimulated by growth hormone. It has several effects on skeletal tissues including skeletal muscle hypertrophy and blocking muscle atrophy and it is also protective for cartilage cells. Interestingly, when the IGF-1 gene was combined with regions from the avian skeletal α-actin gene, expression of IGF-1 in a transgenic mouse resulted in muscle hypertrophy and
increase in expressed IGF only occurred within the muscle and with no increase in systemic concentrations of IGF-1. The potential for increasing muscle mass and strength with IGF-1 and the knock on influence of training has been examined. In one study IGF-1 over-expression following AAV vector delivery increased muscle size in untrained rats and a further increase in muscle mass was observed when rats were also resistance trained (ladder climbing). Furthermore when rats were detrained there was slower loss of muscle mass in rats that were treated with the IGF-1 vector [13011].

For athletes for whom power is essential (e.g. weight lifters) IGF may be useful since it enhances muscle growth and performance. Medical researchers currently focus on developing methods to stimulate the endogenous production of IGF to prevent muscle loss due to a range of conditions such as degenerative muscle conditions, cancer, HIV or ageing. IGF-I is a polypeptide of 7.5 kDa, structurally related to insulin and produced as a result of hypothalamus-pituitary-liver axis activation. The hypothalamus produces growth-hormone-releasing hormone (GHRH), which stimulates the pituitary to release GH thus stimulating the liver to produce IGF-I. IGF stimulates muscle repair and muscle mass hypertrophy after damage, for example, from overload or stress. Increased expression of IGF leads to increased muscle power and mass making IGF a potential target for doping. The effects of IGF-I on muscle growth have not been tested on humans, but in IGF-I-deficient patients, insulin resistance, growth disorders and cardiovascular illnesses have all been documented. Transgenic mice have been used to test the effects of IGF-I. They showed 20-50 percent larger muscle mass than regular mice and no age-induced muscle degradation. The lifespan of these mice was decreased by 50 percent, possibly due to lower levels of antioxidative molecules, or cardiac hypertrophy. Although IGF-I is on the WADA prohibited list, it is available on the internet and anecdotal evidence proves IGF-I abuse. The clear benefits of IGF for muscle growth and endurance are desirable in many sports. The local effect of IGF allows for selective muscle growth; however, it is not expected to be one of the first targets for gene doping. The health risks of IGF gene doping, in particular, the possible clinical consequences of IGF-overexpression such as cancer and cardiac hypertrophy, are significant [13011].

**Growth hormone (GH)**

Instead of applying IGF-based gene doping directly, it is possible to increase the production of IGF indirectly by aiming gene doping at the endogenous production of GH, that is, significantly more accessible. GH is mainly produced by the anterior pituitary gland. The pulsatile regulation of the various GH isoforms differs in men and women and is controlled by the GHRH, which fluctuates with sleep, exercise, hypoglycaemia, age, gender, amino acid availability and low levels of IGF-I. The effects of GH are regulated by GH-binding proteins. Since GH increases muscle strength, it could be used to increase athletic performances in sports where strength is important. In endurance sports when energy is scarce, GH promotes the use of lipids as fuel to conserve protein storage. Despite a 1989 ban by the IOC on GH, there is evidence of GH being used as doping. A recent survey of 10th-grade boys in the USA showed that 5 percent had taken GH and 1.2 percent of college athletes admitted to have used GH in the last year. GH-gene therapy tests in mice, rabbits, sheep and pigs have been performed with varying results. In GH-deficient mice, a 48 percent growth in the injected quadriceps was found after 60 days. The main concerns for GH use are the lack of control in expression and disruption of functional genes. No results of gene therapy with GH in humans have been published to date. Since the results of animal studies are far from convincing and the effects of GH are less targeted than IGF and other proteins, GH is not likely to be used as a target for gene doping [13011].

Instead of applying IGF-based gene doping directly, it is possible to increase the production of IGF indirectly by aiming gene doping at the endogenous production of GH, that is,
significantly more accessible. GH is mainly produced by the anterior pituitary gland. The pulsatile regulation of the various GH isoforms differs in men and women and is controlled by the GHRH, which fluctuates with sleep, exercise, hypoglycaemia, age, gender, amino acid availability and low levels of IGF-I. The effects of GH are regulated by GH-binding proteins. Since GH increases muscle strength, it could be used to increase athletic performances in sports where strength is important. In endurance sports where energy is scarce, GH promotes the use of lipids as fuel to conserve protein storage. Despite a 1989 ban by the IOC on GH, there is evidence of GH being used as doping. The main concerns for GH use are the lack of control in expression and disruption of functional genes. No results of gene therapy with GH in humans have been published to date. Since the results of animal studies are far from convincing and the effects of GH are less targeted than IGF and other proteins, GH is not likely to be used as a target for gene doping [13011].

Myostatin
Myostatin is an interesting protein as it is an inhibitor of muscle growth. In a published case a boy with inactive myostatin displayed hypertrophic limb muscle development, and at 4.5 years was able to hold two 3 kg dumbbells in horizontal suspension with extended arms. Recent work in racehorses has also linked different polymorphisms of the gene to suitability to sprint or stamina races. By preventing the action of myostatin it may be possible to increase muscle growth and one way to achieve this could be with another endogenous protein called follistatin. Myostatin binds to activin type II receptors (Act RII), particularly Act RIIA, and this interaction can be inhibited by follistatin, an activin-binding protein. When follistatin was expressed in quadriceps of non-human primates following delivery with an AAV1 encoding vector an increase in muscle size of 15 percent was observed while strength, measured in twitch force was increased by 26 percent and these changes persisted for the 6 month period of the experiment [13011].

In 2004, a German boy born with muscular thighs and strong upper arms was diagnosed with a myostatin gene deficiency. As a result, the antidoping community’s attention was then directed towards the effects of myostatin blocking. In cows, a myostatin mutation leads to downregulation of myostatin, which increases muscle growth. “Double muscled cattle” or “Belgian Blue cattle” present with significantly more muscle mass than ordinary cattle. These two examples made it clear that myostatin inhibition is yet another way to increase muscle mass, but it is more specific than the use of IGF or GH. As such, myostatin inhibitors are of interest to athletes who need muscles rather than speed; however, myostatin inhibitors are on the WADA-prohibited list. Despite the risks of inhibiting myostatin, which include reduced cardiac and respiratory functioning, the inhibitors can be purchased on the internet. It is thought that myostatin is involved in sarcopenia (age-related muscle loss), although how this occurs exactly is unclear. Some tests have found increased myostatin protein and mRNA expression in aged human and rats; others find no difference. Myostatin is overexpressed in muscle atrophy when there is immobilisation, HIV infection, sepsis, burn or glucocorticoid excess, or specific skeletal muscle degeneration diseases. These findings may lead to a new treatment for muscle atrophy using gene therapy to inhibit myostatin. Myostatin is underexpressed in Duchenne and Becker muscular dystrophy, probably as an adaptive response to increased muscle growth. Myostatin overexpression can induce cachexia and increased levels are associated with obesity and diabetes. Since the actions of myostatin inhibit muscle growth, blocking myostatin is a potential doping target. Various in vivo methods of inhibiting myostatin are available, such as [13011]:
using the myostatin propeptide, which binds to myostatin to prevent it from having an effect. Although wildtype myostatin propeptide is unstable in vivo, it can be altered to extend stability.

- using neutralising antibodies. Research in mice showed less sarcopenia-related muscle loss when antibodies were injected.

- applying follistatin in animal gene therapy studies to inhibit myostatin. Follistatin is a glycoprotein that binds to myostatin preventing myostatin from binding to its receptor.

- stimulating overexpression of a gene coding for a myostatin protein without its cleavage site to inhibit the production of myostatin.

Gene therapy to inhibit myostatin is usually based on the adeno-associated virus (AAV) vector technology, since muscle cells are one of the natural hosts for AAVs. There is long experience with all above-presented forms of myostatin gene therapy (except for antibodies) in animals; no clinical tests have been performed on humans. Athletes might be tempted to use a myostatin-inhibiting form of gene doping. The effects of myostatin are significant, but the lack of experience and the poor controllability of the various methods of myostatin blocking make it hard to say whether it is already being misused [13011].

**Vascular endothelial growth factor**

Increasing blood flow through a muscle postpones fatigue. One protein regulating muscle blood flow is VEGF or VEGF-A, also known as the vascular permeability factor. Autocrine VEGF released by endothelial cells, regulates vessel homeostasis by acting as a survival factor for endothelial cells. Paracrine VEGF produced by any hypoxic cell stimulates vessel branching. New capillary branches need additional hormones to become fully grown stable vessels. When VEGF reaches high levels in blood vessels, the blood vessel responds with increased permeability and vasodilation. Since VEGF increases neovascularisation of ischaemic tissue, it might help patients with heart diseases. On the other hand, high dosages of VEGF can cause vessel leakage and abnormalities as well as tumour tissue growth. Gene therapy targeting VEGF-mediated angiogenesis has been tested in mice, rats, rabbits and dogs with generally positive results. In a 10-year follow-up study on humans, VEGF gene therapy was found to be safe; therefore, VEGF might be of interest to athletes combating exhaustion. Since VEGF increases blood perfusion in muscles, heart, liver and lungs, it is likely to increase endurance. However, the risks of VEGF use mentioned above remain unmeasured and uncontrolled. Controlling gene expression by adding a hypoxia-response element, for example, EPO, might make VEGF safer. VEGF is a likely candidate for gene doping; however, an immune response against VEGF has been detected using affinity-based biosensors and this is likely to make detection possible soon. VEGF is on the WADA prohibited list [13011].

**Fibroblast growth factor**

VEGF production is also modulated by a specific fibroblast growth factor-2 (FGF2). FGF2 works partially in a synergistic manner with VEGF, producing some of the same intracellular effects. VEGF induces FGF2, which vice versa can induce VEGF expression. Inhibition of either VEGF or FGF2 shuts down angiogenesis. FGFs have multiple functions, some of which could be used in doping. The family of FGFs includes 22 growth factors, produced by a variety of cell types. The angiogenic effects of FGFs play an important role in muscle repair following exercise through the revascularization process during muscle regeneration. The modern clinical application of the principle of angiogenesis can be divided into two main areas: antiangiogenic therapies and proangiogenic therapies. Whereas antiangiogenic therapies are being employed to fight cancer and malignancies, which require an abundance
of oxygen and nutrients to proliferate, proangiogenic therapies are being explored as options to treat cardiovascular diseases. One of the first applications of proangiogenic methods in humans was the use of FGF-1 for the treatment of coronary artery disease. Clinical research in therapeutic angiogenesis is ongoing for a variety of atherosclerotic diseases, like coronary heart disease, peripheral arterial disease or wound healing disorders. The risks of exogenous FGF include the possibility of increasing blood supply for tumours, or stimulating pathogenic heart remodeling [13011].

Adenovirus vectors and plasmids containing genes for FGF2 and FGF6 have been tested in human skeletal muscles and significantly increased muscle repair. Phase II studies showed proteinuria as an effect of abnormal capillary network formation. Most studies combine FGF gene therapy with IGF, PDGF or VEGF. The synergistic effects of FGF with those proteins have been shown, but FGF alone has not been proven to be clinically effective. Most interesting for athletes is that FGFs increase muscle regeneration and neovascularisation. A combination of FGFs is most promising, especially for athletes recovering from injury and exercise. It is most likely that the first use of FGF-based gene doping will be in combination with another protein. All FGFs and FGF-based gene doping are prohibited by WADA [13011].

Preventing pain (endorphin and enkephalin)

Conquering pain is essential to push your body to new levels of performance. The potential to reduce the perception of pain, during exertion may allow athletes to push for longer and perform better. Gene therapy for the treatment of pain is currently being examined. Research has utilized replication deficient herpes simplex virus (HSV) encoding preproenkephalin delivered into the paws of mice. The HSV is neurotropic, able to enter nerve endings at the injection site and travel retrogradely to neuronal cell bodies in the dorsal root ganglia where transgene is expressed into preproenkephalin which reduces the response to noxious stimuli. The preproenkephalin is a precursor for enkephalin production which acts on opioid receptors as a naturally occurring analgesic. A phase 1 trial, using this method, in patients with intractable pain caused by cancer has shown safety of the approach but further study is necessary to determine its effectiveness. Although gene therapy holds promise for those suffering with chronic pain, the pain experienced by athletes is often more intermittent and is confined to periods of exertion. If pain relief is to become a target for gene doping, the therapy would have to desensitize the patient to pain during these times of high intensity, not just at a constant baseline level [13011].

A completely disparate approach for improving athletic achievements is diminishing the sensation of pain. This would specifically allow combat-sport competitors to achieve higher goals. For athletes in general, numbing the sensation of extreme exhaustion is beneficial; thus, analgesics are the most frequently used therapeutic class of drugs. Most analgesics are permitted by WADA, but opiates are prohibited as they have addictive properties that can lead to abuse. Chronic pain affects a large part of the general population and gene therapy with an endorphin or enkephalin may present a promising new approach for treatment. Endorphins and enkephalins delay fatigue and increase endurance. During exercise they diminish lactic acid-related pain and pain caused by earlier injuries. Multiple gene therapy studies aimed at combating pain have been conducted, generally with positive results. Gene therapy allows for local and specific treatment of pain, with few side effects and a low risk for abuse. Since herpes simplex virus (HSV) targets neurons specifically, this is the virus generally used for gene therapy for pain. Clinical trials using endorphin and enkephalin in HSV vectors are being performed in humans, but so far are restricted to cancer-induced pain. The pain-reducing effects of both endorphin and enkephalin seem useful for athletes and early tests in humans are in progress. Given the fact that the brain is targeted, it may be
difficult to detect endorphin or enkephalin gene doping in only blood or urine. It should be clear though, even for those without a biomedical education, that experimental medicines acting only on a partially understood brain system, pose a serious risk. Given the ambiguous doping qualities of endorphins and enkephalins it is rather unlikely that they are being used today for this purpose [13011].

alpha-Actinin 3

In 2003, the association between athletic performance and alpha-actinin 3 (ACTN3) genotype (instead of ACTN2) was demonstrated. ACTN3 is mainly produced by skeletal muscle, while actin and myosin are responsible for muscle contraction. ACTN3 binds sarcomeres at the Z-lines. Although it was long thought that ACNT3 was only important for muscle structure, it is now clear that it is also important for muscle metabolism. ACTN3 deficiency does not cause muscle disease, but rather it impairs power performance by shifting the characteristics of fast-type muscles to slow-type muscles. When there is a deficiency of ACTN3, part of the action of ACTN3 is taken over by ACTN2. ACTN3 expression increases strength (although androgens have a stronger effect than ACTN3113), while ACTN2 expression increases endurance. No exogenous forms of ACTN3 or substances that influence ACTN3 transcription are known. Sixteen percent of humans worldwide have a polymorphism in both their ACTN3 genes that causes a deficiency, and in European and Asian populations this can be up to 50 percent. It has been shown that female sprinters have a higher frequency of a functioning ACTN3 gene than the average population. Since lacking the gene does not cause disease, it is not a lucrative topic of research. No trial with an ACTN3 gene therapy product has been published, although there are a few animal studies on knock-out mice. Mice missing the ACTN3 gene weigh less than wild-type mice and have smaller muscles and less strength. On the other hand, they were able to run 33 percent longer than wild-type mice and recovered faster from fatigue. If translated to the sports arena, this indicates that increasing ACTN3 copies may be used in order to dope sprinters and diminishing ACTN3 copies as a means to stimulate endurance in marathon runners. Although both the risk of abuse and the chance of being caught would be small, no gene therapy products for ACTN3 have been tested, not even in animals. This means that currently ACTN3 is an unlikely candidate for gene doping purposes [13011].

Peroxisome proliferator-activated receptor-delta

Another genetic predisposition for achievement in the elite sporting world is the gene coding for peroxisome proliferator-activated receptor-delta (PPAR-delta). PPAR-delta – also known as PPAR-beta or NR1C2 – is a protein for regulating the oxidation of fatty acids. PPAR-delta also increases mitochondrial activity and muscular glucose uptake. Overexpression of PPAR-delta decreases the accumulation of triglycerides in muscle cells and increases the oxidative capacity in muscle fibres. This results in increased endurance and an enhanced response to endurance exercise. Both endurance and power training strongly increase the production of PPAR-delta. Elite athletes have more PPARd mRNA and protein than the general population. PPAR-ddelta agonists could be used for doping purposes and products claiming to boost performance with PPAR-delta are already for sale on the internet. MBX-8025, GW742 and GW1516 (also known as GW501516) are ligands for PPAR-delta. They are being used in studies with patients who are obese or have diabetes mellitus type II or atherosclerosis. GW1516 reduced the low-density lipoprotein and triglyceride plasma concentration, and increased fatty acid oxidation. GW1516 has passed phases II and IV clinical trials for dyslipidaemia and is detectable with mass spectrometry up to 4 days after intake. Although GW1516 may be abused, the abuse might not go unpunished. Anticipating possible abuse, the WADA put PPAR-delta agonist GW1516 and PPAR-delta-AMP-activated
protein kinase on the doping list in 2009. PPAR-delta could also be targeted with gene therapy. PPAR-delta has been delivered to various cell types using an adenoviral vector; however, effectiveness differed according to cell type. Gene doping using PPAR-delta is unlikely to be used soon, since it has only been tested in cells and not in vivo [13011].

**Cytosolic phosphoenolpyruvate carboxykinase**

An even stronger effect on endurance than PPAR-delta is found with cytosolic phosphoenolpyruvate carboxykinase PEPCK-C. In one particular study, wild-type mice were exhausted after running 0.2 km and the transgenic mice overexpressing PPAR-delta after 1.5 km; but the transgenic mice overexpressing PEPCK-C ran for more than 4.9 km. PEPCK-C regulates gluconeogenesis in the liver and kidney, and glycerooneogenesis in the liver and adipose tissue. Overexpression of PEPCK-C leads to hyperglycaemia. On a normal diet, PEPCK-C overexpression induces insulin sensitivity; on a fat-rich diet it causes insulin resistance. Despite all the evidence of PEPCK-C’s importance in gluconeogenesis, (and, thus, diabetes), no gene therapy product targeting this protein has been investigated. However, silencing vectors and decreasing PEPCK-C levels did prove to be effective in diabetic animals. Its role in skeletal muscles is not clear yet, but it is hypothesised that an increase in triglycerides leads to improved athletic performance. There are two forms of PEPCK-C: one functions in the mitochondria and one in cytosol. The PEPCK-C in cytosol is the most relevant for athletes, since the effects in trials with mice demonstrated convincing benefits for endurance. No specific PEPCK-C stimulating agent is yet known. Thiazolidinediones and glucocorticosteroids stimulate PEPCK-C production, but not specifically. Glucocorticosteroids are on the WADA-prohibited list; however, to date, no gene therapy product aimed at PEPCK-C specifically is known. Since the expression of the PEPCK-C gene would be tissue-specific, detection would be nearly impossible; thus, in addition to the significant effect of PEPCK-C, despite the lack of experience, PEPCK-C is a likely doping target [13011].

**Gene doping with intracellular molecules**

Gene therapy requires genetic material to be delivered to the cell nucleus for the therapeutically encoded genes to be expressed by the transcriptional machinery of the cell. Depending on the encoded gene product it will either be secreted from the cell or remain intracellular. It is this potential to deliver a gene whose products remain inside the engineered cells that provides opportunities for gene doping that will be extremely difficult to detect and is not feasible with delivery of recombinant proteins which act outside the cell. Candidate genes that could encode intracellular proteins include transcription factors and activators, enzymes or RNA molecules [13011].

**Transcription factors**

Type 1 muscle fibres have many mitochondria and are richly supplied by blood capillaries which allow large amounts of ATP to be produced under oxidative metabolism which means that these fibres are fatigue resistant. Type II fibres have lower levels of mitochondria and use glycolytic metabolism to produce ATP and are therefore more susceptible to fatigue. The fast manner in which the ATP is produced in type II fibres results in quick, more powerful contractions which are more important in sports such as sprinting. It is well known that endurance exercise induces phenotypic changes in skeletal muscles that lead to enhanced exercise capacity and improved metabolic homeostasis. More recently peroxisome proliferator-activated receptors (PPARs), which are nuclear receptor proteins that function as transcription factors, have been shown to have a role in regulating the fibre type within a muscle. Generation of transgenic mice in which an activated form of peroxisome proliferator-activated receptor delta (PPAR-delta) was expressed in skeletal muscle, induced an
increased number of type I muscle fibres. It was noted that these mice had an increased numbers of type I fibres compared with controls, both in normal type I rich muscle, such as soleus, and mixed type II muscle, such as gastrocnemius. These mice could also run further and for longer compared with controls, suggesting that the type I fibres generated from PPAR-delta gene expression produced a beneficial effect on the mice by increasing physical performance. Similarly, peroxisome proliferator-activated receptor gamma co-activator 1-alpha (PGC-1delta) is a transcriptional co-activator which, when over expressed in muscle, promotes a fibre switch towards oxidative type I slow fibres. Recently is has been shown that this effect is mediated via the transcription factor hypoxia-inducible factor (HIF) 2alpha. The lack of oxygen in muscle during vigorous exercise causing hypoxia is also known to induce HIF-1alpha, a transcription factor that induces expression of target genes including the angiogenic factor VEGF and EPO. These HIF transcription factors are degraded by prolyl hydroxylase enzymes under normoxic conditions but these enzymes are inactive in hypoxia permitting HIF activity. It is however possible to engineer a stable version of HIF-1alpha by point mutation of the proline residues that are subject to prolyl hydroxylation. In the mutated form HIF-1alpha is constitutively active and can be delivered to muscle genetically to enhance vascularization and potentially promote erythropoiesis. In theory, synthetic transcription factors could also be generated that have similar effects using zinc finger domains targeted to the VEGF locus which when expressed in vivo in mice induced angiogenesis [13011].

**Enzymes**

An example of an intracellular enzyme that could be used in gene doping to reduce pain is GAD which controls production of the inhibitory neurotransmitter GABA from glutamate, which has an analgesic effect. Expression of GAD from an HSV vector into the dorsal root ganglia of rats with T13 hemisections showed a reduction in pain perception below the level of the lesion [13011].

**Small inhibitory RNA (siRNA)**

Endogenous gene expression can be regulated at the level of micro RNA (miRNA) molecules which target messenger RNA (mRNA) molecules. Synthetic siRNA molecules utilize the endogenous machinery of the cell to inhibit protein translation in a similar manner to miRNA. In addition siRNA molecules can also be produced long-term inside cells as short hairpin RNA molecules that are processed inside the cell into siRNA. Both these types of RNA molecule could be utilized in gene doping strategies where inhibition of a protein's synthesis could enhance performance. An obvious target is myostatin and studies using either siRNA or shRNA targeting myostatin mRNA have demonstrated an increase in muscle size and mass [13011].

**Options for gene doping**

Along with enormous research efforts regarding gene-based therapies, the options to misuse the acquired knowledge for illicit performance enhancement increased at an almost equal level. Despite the fact that most of the therapeutic strategies employing, for example, RNA interference- or in vivo gene transfer-based approaches are still undergoing clinical trials, the potential for misuse has long been identified and various countermeasures were initiated. Particularly the detection of transgenic DNA, characterized by intronless DNA sequences from conventional blood samples have been studied using mouse or macaque models. Proof-of-concept was obtained by sampling blood of mice that underwent intramuscular adeno-associated virus (AAV)-mediated gene transfer with human VEGF-A in which the transgene was detected for 28 days in all tested animals (n=6) and up to 56 days in four out
of six rodents. Focusing on the EPO transgene, a similar real-time PCR-based methodology was presented which in contrast to the described approach above aims primarily for the analysis of white blood cells of non-human primates. Following the injection of the recombinant AAV (rAAV) vector expressing cynomolgus macaque EPO leucocytes were collected and tested for collateral transfection. Viral vector backbone as well as transgene DNA was identified for up to several months (varying with animal and serotype of the rAAV). In addition, it was shown that serum and urine represent viable matrices offering detection windows between few days and weeks. In continuation of earlier approaches suggesting the use of affinity-based biosensors targeting specific non-human plasmid regions (e.g. the enhanced green fluorescent protein (EGFP) reporter gene and the Cytomegalovirus (CMV) promoter sequence) as indicators for transgenesis events, the use of surface plasmon resonance imaging (SPRi) was described. Under the definition of gene doping of WADA's Prohibited List of 2011, the use of substances influencing the gene expression are banned (paragraph M3.3). Among these the peroxisome proliferator-activated receptor (PPAR)delta agonists such as GW1516 as well as the adenosine monophosphate (AMP)-activated protein kinase (AMPK) axis agonists (e.g. AICAR) are listed. Clinical trials of these experimental drugs are not completed, however, Internet-based suppliers offer these substances as “research chemicals” which were acquired and analyzed to ascertain authenticity, purity, quantity, and formulation using high resolution/high accuracy mass spectrometry. In both cases of GW1516 and AICAR, the ordered compounds were delivered under the disguise label of “amino acids” as an orange suspension (GW1516) and a colourless powder (AICAR). The quantity/concentration of the substances was much lower than indicated but both drug candidates were identified with correct structure and composition, thus outlining the ease of availability of these banned drug candidates to cheating athletes [12016].

**Gene doping targets**

Depending on the desired effect and the type of sport and athlete, gene doping might enhance performance. Athletes who compete in endurance sports, like marathons and long-distance swimming, may look to gene therapy to boost their oxygen supply or delay the sense of fatigue. Sprinters and weight lifters, who mainly need power, may consider gene therapy to increase muscle mass or improve their injury recovery time. Boxers would appear to be most interested in improved pain tolerance from gene doping [13011].

One of the most difficult steps in gene therapy is delivering the gene into host cells. Three major techniques used for delivering genes are injecting naked DNA, viruses or modified cells. Initially, a desired gene can be produced in bacterial plasmids and then purified. Next, the gene can be directly injected into the target tissue. Unfortunately, direct injection of DNA is not very effective due to limited uptake and nuclear translocation (although electroporation of the target tissue increases the uptake) However, it is safer than using viral vectors, since there are generally fewer immune responses, and considerably cheaper than other gene-transfer options. Genetic material can be delivered to a target tissue by using a viral vector. Viruses have evolved to efficiently transfecct cells with their genetic information and multiply, which makes them ideal for use in gene therapy. To prevent the virus from replicating, the viruses are tamed (all DNA or RNA coding for proteins allowing the virus to multiply and escape infected cells are removed) and therapeutic genes are inserted. Because of this inhibited replication, the viruses are less immunogenic. The modified virus may be injected intravascularly or directly into a target tissue, or inhaled. Injection into the target tissue limits gene expression to the injection site, whereas intravascular injection usually results in systemic expression. Inhalation is used if the lungs are the target tissue. The viral vector contains a promoter that allows the inserted gene to be transcribed and translated, thus
yielding the desired protein. For ex vivo gene therapy, stem cells are removed as in the case of patients with severe combined immune deficiency (SCID) and a therapeutic gene is introduced in vitro. The genetically modified stem cells are then injected back into the patient’s bone marrow. This can be done using plain DNA (with or without liposomes), a viral vector with electroporation or with a gene gun. The technique allows for limited screening and sorting of the cells before reinjection, which increases efficacy and safety. Disadvantages are low efficiency and increased cost. Depending on the target tissue, the gene and the desired duration of transgene expression, multiple vectors can be used [13011].

Of the three gene therapy delivery methods described, in vivo viral gene transfer is the most successful method for now. In general, the benefits are efficacy and low cost; downsides are immune responses and poor controllability of integration and expression. Ex vivo viral gene transfer can be used to insert a gene to produce a desired protein, or increase or inhibit the transcription of an already present gene by influencing promoters. On the other hand, gene expression can also be prevented using antisense RNA sequences. RNA sequences bind to the original gene, prevent translation and cause destruction by the RNase H or the siRNA pathway. Even splicing patterns can be altered by blocking splicing recognition sequences, thus allowing for the inclusion or exclusion of specific exons [13011].

**Direct injection of DNA into the target tissue**
Initially, a desired gene can be produced in bacterial plasmids and then purified. Next, the gene can be directly injected into the target tissue. Unfortunately, direct injection of DNA is not very effective due to limited uptake and nuclear translocation (although electroporation of the target tissue increases the uptake). However, it is safer than using viral vectors, since there are generally fewer immune responses, and considerably cheaper than other gene-transfer options [13011].

**Introducing genetic material using a virus**
Genetic material can be delivered to a target tissue by using a viral vector. Viruses have evolved to efficiently transfecct cells with their genetic information and multiply, which makes them ideal for use in gene therapy. To prevent the virus from replicating, the viruses are tamed (all DNA or RNA coding for proteins allowing the virus to multiply and escape infected cells are removed) and therapeutic genes are inserted. Because of this inhibited replication, the viruses are less immunogenic. The modified virus may be injected intravascularly or directly into a target tissue, or inhaled. Injection into the target tissue limits gene expression to the injection site, whereas intravascular injection usually results in systemic expression. Inhalation is used if the lungs are the target tissue. The viral vector contains a promoter that allows the inserted gene to be transcribed and translated, thus yielding the desired protein [13011].

**Ex vivo gene therapy**
For ex vivo gene therapy, stem cells are removed as in the case of patients with severe combined immune deficiency (SCID) and a therapeutic gene is introduced in vitro. The genetically modified stem cells are then injected back into the patient’s bone marrow. This can be done using plain DNA (with or without liposomes), a viral vector with electroporation or with a gene gun. The technique allows for limited screening and sorting of the cells before reinjection, which increases efficacy and safety. Disadvantages are low efficiency and increased cost. Depending on the target tissue, the gene and the desired duration of transgene expression, multiple vectors can be used. Of the three gene therapy delivery methods described earlier, in vivo viral gene transfer is the most successful method for now. In general, the benefits are efficacy and low cost; downsides are immune responses and
poor controllability of integration and expression. Ex vivo viral gene transfer can be used to insert a gene to produce a desired protein, or increase or inhibit the transcription of an already present gene by influencing promoters. On the other hand, gene expression can also be prevented using antisense RNA sequences. RNA sequences bind to the original gene, prevent translation and cause destruction by the RNAse H or the siRNA pathway. Even splicing patterns can be altered by blocking splicing recognition sequences, thus allowing for the inclusion or exclusion of specific exons [13011].

**Candidate genes for athletic gene doping**

Any physiologic process involved in producing a motor action or assisting in the implementation of a motor movement could be a candidate for gene doping. The physiologic processes of pulmonary respiration, cardiovascular circulation, oxygen delivery, striated muscle growth/efficiency/repair, and even neuromuscular coordination could be altered to give an athlete an edge over his or her competition. Although more esoteric, neurophysiologic processes, such as mental alertness, motivation, and central nervous system recovery, also might be amenable to gene doping, the list of physiologic processes related to athletic competition is long and likely only limited by current understanding of exercise physiology and exercise psychology. Even now, in the exploratory phase of gene therapy/gene doping, there are obvious candidates for the aspiring gene cheat. These primary gene candidates exist as targets of biomedical researchers looking for legitimate disease treatments [07046].

**Hematopoietic/vascular systems**

The classic example of a genetic alteration to enhance athletic performance occurred naturally in 1964. A Finnish skier, Eero Mantyranta, dominated Olympic Nordic skiing. Studies later demonstrated that Mantyranta benefited from a natural mutation in the EPO gene that produced a greater number of RBCs, with a concomitant increased oxygen-carrying capacity. This skier possessed what every blood doper in history tried to achieve – a physiologic advantage in delivering more oxygen to various tissues, including muscles. rEPO (epoetin and darbopoetin) is a much-abused injected recombinant protein that increases RBC production, leading to increased oxygen-carrying capacity and oxygen delivery to tissues. The abuse of rEPO is epidemic in cycling, leading to frequent controversy, tedious forensic investigations, and serious side effects, including death. Using gene doping, an additional EPO gene could be delivered to the athlete by way of a viral vector. Once in the athlete, the gene would express much more EPO than normally produced, even with training. The desired result would be an increase in the oxygen-carrying capacity of the blood, thus bestowing a clear competitive advantage in endurance sports. Laboratory experiments have been successful in injecting the gene into monkeys and mice. Although the procedures successfully raised hematocrit, severe side effects, including a paradoxical anemia, resulted [07046].

**Hypoxia inducible factors**

The hypoxia inducible factor (HIF) family of proteins modulates the activity of genes in low-oxygen environments. Various HIFs increase production of RBC, as well as increase cellular energy use. Enhancement of these proteins clearly would benefit the aerobic athlete [07046].

**Vascular endothelial growth factor**
Clinical studies are currently ongoing for vascular endothelial growth factor (VEGF), a gene product that encourages development of new blood vessels. This genetic manipulation would be advantageous to patients suffering from coronary artery disease. The gene-doping athlete would benefit from a putative increase in vasculature and more delivery of oxygen and nutrients to the peripheral tissues [07046].

**Actin-binding peptides**

The proteins actin and myosin form the machinery of muscle contraction. The family of actin-binding proteins in humans includes alpha-actinin alleles ACTN2 and ACTN3. Alpha-actinins maintain the structure of the myofibrillar array and regulate myofiber contraction. A defect of ACTN3 regulation occurs when the ACTN3 gene codes for a premature stop codon; ACTN2 seems to compensate in these persons. Correlation studies found evidence that the ACTN2 endows muscular endurance traits upon athletes. Conversely, elite sprinters benefit from more copies of ACTN3. Depending on the event of the competitor, gene doping with the appropriate ACTN allele could enhance endurance capacity or sprint effectiveness [07046].

**Angiotensin-converting enzyme**

Physicians are well aware of angiotensin-converting enzyme (ACE) inhibitors used for the treatment of hypertension; however, the ACE gene, like the ACTN gene, codes for proteins that seem to endow different exercise capacities. Research suggests that the ACE-I allele endows advantages in endurance, which would be useful for distance runners. The ACE-D allele seems to be associated with elite sprinting performance. Again, a gene-doping athlete could inject the appropriate gene to influence better performance in his or her event, be it a sport featuring short bursts of speed and power or a sport in which endurance is the key to success [07046].

**Insulin-like growth factor**

Several sophisticated studies, most notably at the University of Pennsylvania, targeted IGF-1, a peptide, in conjunction with HGH, intimately involved with muscle growth, repair, and power. These studies demonstrated eloquent ways in which IGF-1 controlled mammalian muscle development and demonstrated that targeted gene therapy could successfully produce hypertrophied and powerful muscles in laboratory mice. The primary investigator, Lee Sweeney, designed the procedure carefully so that the virus and the gene were not expressed systemically; by avoiding systemic distribution of the peptide, the researchers hoped to avoid the serious side effects of IGF-1, including myocardial hypertrophy and carcinogenesis. Thus, for therapeutic reasons, the researchers designed the gene therapy to be effective locally, in injected muscles. That particular feature also would benefit a doping athlete, because the transgene IGF-1 would not enter the systemic circulation where it might be detected by laboratory testing. In this University of Pennsylvania protocol, “fingerprints” of the gene therapy did occur; however, the theoretic aim of the study itself would present problems for antidoping agencies [07046].

**Myostatin**

Myostatin, known to be a negative regulator of muscle development, presents another candidate gene. This regulator protein seems to turn-off muscle growth. Substances that block myostatin or genes that produce ineffective myostatin proteins would allow superphysiologic muscle growth in terms of number and thickness of cells (as seen in certain breeds of cattle through a natural mutation). Not only do striated muscles hypertrophy
without myostatin regulation, but less fat is gained on the body of the animal. The manipulation of this regulatory protein has obvious advantages for the athlete [07046].

*Peroxisome proliferator-activated receptor delta*

The peroxisome proliferator-activated receptor delta (PPAR-delta) gene seems to be a prime candidate for gene doping. This gene codes for an increase in mitochondrial biogenesis and promotes an adapted muscle fiber transformation. The gene promotes an increase in type 1 muscle fibers (slow twitch). Elite athletes show an increase in PPAR-delta gene levels. A PPAR-delta gene was inserted into mice; it dramatically improved the animal's endurance capacity. It was concluded that “…these genetically generated fibers confer resistance to obesity with improved metabolic profiles, even in the absence of exercise. These results demonstrate that complex physiologic properties such as fatigue, endurance, and running capacity can be molecularly analyzed and manipulated” [07046].

*Endorphins*

In injuries, as well as in competition, pain limits athletic achievement. Athletes sustain countless painful injuries for which they consume an abundance of anti-inflammatory drugs and pain-relieving medicines. Likewise, the buildup of lactic acid during competition induces pain. Clearly, increasing the pain threshold – and alleviating the discomfort of nagging injuries – would improve performance. The introduction of genes producing analgesic endorphins and enkephalins would increase the pain threshold in an athlete, for pain experienced in competition as a result of lactic acid buildup and pain due to acute and chronic injury. Clinical trials are testing the efficacy of genes encoding these natural narcotic peptides for pain relief in humans [07046].

*Erythropoietin gene transfer*

Aviral gene delivery vector carrying the human Epo gene under the control of an O2-dependent hypoxia response element (Repoxygen; Oxford BioMedica) was earlier developed that might have been misused for Epo gene doping. Reportedly, however, the technique never proceeded beyond animal experiments. In addition, in vivo Epo gene transfer could probably be detected if applied by athletes, as an IEF study revealed unusual Epo glycosylation forms on allogeneic Epo transfer into skeletal muscle of cynomolgus macaques via adeno-associated virus. In the initial studies of adeno-associated virus-mediated allogeneic Epo cDNA transfer to macaques, severe anemia developed in many animals after a few months, which was probably the result of an immune reaction. Regarding the possibility of Epo gene doping in humans, strategies are under development to specifically amplify intron-less DNA sequences and PCR protocols allowing the detection of small amounts of transgenic DNA in blood. The tests take into consideration that transgenes are usually derived from the cDNA for the gene to be transferred and cDNA does not contain introns. In conclusion, Epo gene transfer is possible but medically little explored with respect to efficacy, safety, and immunogenicity. It seems less likely that any of the techniques has entered the sports scene [11116].

Aviral gene delivery vector carrying the human erythropoietin gene under the control of an O2-dependent hypoxia response element (Repoxygen®; Oxford BioMedica) was earlier developed that might have been misused for Epo gene doping. Reportedly, however, the technique never proceeded beyond animal experiments. In addition, in vivo Epo gene transfer could probably be detected if applied by athletes, as an IEF study revealed unusual Epo glycosylation forms on allogeneic Epo transfer into skeletal muscle of cynomolgus...
macaques via adeno-associated virus. In the initial studies of adeno-associated virus-mediated allogeneic Epo cDNA transfer to macaques, severe anemia developed in many animals after a few months, which was probably the result of an immune reaction. However, in using a rapamycin dimerizer-regulated gene expression system, it was achieved controlled, long-term production (up to 6 years) of Epo in rhesus monkeys, with no apparent immune response. Regarding the possibility of Epo gene doping in humans, strategies are under development to specifically amplify intron-less DNA sequences and PCR protocols allowing the detection of small amounts of transgenic DNA in blood. The tests take into consideration that transgenes are usually derived from the cDNA for the gene to be transferred and cDNA does not contain introns. In conclusion, Epo gene transfer is possible but medically little explored with respect to efficacy, safety, and immunogenicity. It seems less likely that any of the techniques has entered the sports scene [11428].

Polymorphism

Performance enhancing polymorphisms (PEPs) are examples of natural genetic variation that affect the outcome of athletic challenges. Elite athletes, and what separates them from the average competitor, have been the subjects of discussion and debate for decades. While training, diet, and mental fitness are all clearly important contributors to achieving athletic success, the fact that individuals reaching the pinnacle of their chosen sports often share both physical and physiological attributes suggests a role for genetics. That multiple members of a family often participate in highly competitive events, such as the Olympics, further supports this argument. In a review, it was discussed what is known regarding the genes and gene families, including the mitochondrial genome, that are believed to play a role in human athletic performance [10265].

Sport as case study

One of the more volatile debates that surrounds enhancement in sport has been the application of gene transfer and genetic technology more generally. In 2003, the World Anti-Doping Agency instituted a policy prohibiting the use of “gene doping” and yet there is still considerable lack of clarity over whether it will ever be possible to detect all kinds of genetic enhancement. These debates have engaged the mainstream of bioethicists where controversies relating to human enhancement abound. Sport, it would seem, has become an exemplar case study for investigations into the ends of technology in society. One of the pivotal questions surrounding sports is whether the approach to doping needs radical transformation, as the age of enlightenment gives way to an age of enhancement [06168].

Risks and complications of gene doping

Genes of relevance to doping such as growth hormone, insulin-like growth factor I, and erythropoietin have been cloned, and so are readily available. They could be used as an alternative way to produce a range of performance enhancing agents. The risks of taking these substances in the form of traditional chemicals are known, and so decisions about risk versus benefit are straightforward. The same cannot be said for gene doping, as there continue to be many unknowns in this form of cellular intervention. Effects cannot be predicted, and so the sportsperson taking this route for cheating does not have control of the product. Random integration of vector sequences, for example, could produce complications such as acute leukaemia or other forms of cancer. Finally, unlike taking a drug, gene transfer
is not easy to reverse, and so any untoward effects may be long term. There is also a small risk of inadvertent gene transfer to germ cells with the potential for harm to be passed on to an athlete's children [06306].

Groups studying EPO gene transfer have demonstrated that a high percentage of monkeys, who were genetically modified to produce a foreign EPO gene from a virus vector, has developed lifethreatening anemias, probably as a result of an immune response to vector itself. Therefore, no matter how impressive the results may be in animal testing, the gene transfer technology is not yet characterized well enough to apply in human settings in which the goal is the enhancement of normal human traits rather than the correction of a human disease [06307].

Today, the risks for gene doping are much greater than the taking of traditional chemical products. Those involved in sport should be sufficiently informed of the risks, as well as likely future benefits of gene therapy. As the technology improves, many of the complications may be avoided, and so ongoing assessment of the potential for gene doping will be necessary. Detecting gene doping cheats will be possible using the standard assays as well as through the identification of gene vectors or their products. The bypassing of various metabolic pathways through the insertion of genes may lead to changes in gene expression profiles, and this may open up another approach to detecting gene doping [06306].

Examining the history of clinical pharmacology reveals that side effects of novel treatments can be unexpected and occasionally fatal. From thalidomide to valdecoxib, newly introduced medications, even with exhaustive preclinical trials, produce unanticipated untoward side effects. Consider the potential side effects of introducing a foreign gene, by way of a viral vector, into an organism's chromosomes. Gene therapy trials made headlines several times with unexpected and fatal side effects. Then 18, Jesse Gelsinger died in 1999 as the victim of an immune response to the virus used in a well-publicized gene therapy trial. That death shocked the biomedical world and resulted in regulation as well as multiple legal actions. Several patients who were treated for an X-linked hemophilia with a gene therapy protocol developed leukemia, an obviously unexpected side effect. A gene therapy trial of EPO in macaque monkeys produced such stimulation of RBC production that the monkeys' blood thrombosed. Moreover, many of the monkeys suffered anemia, the result of an immune response to the gene therapy. The overactive immune response attacked endogenous EPO as well as gene-stimulated EPO. A similar experiment using gene-therapy EPO revealed that the gene-induced EPO was slightly different from natural monkey EPO. Likewise, the use of transgene EPO in human gene doping might induce erythrocytosis to a dangerous level, with potentially lethal consequences. Although not generally considered a risk from gene therapy, the virus vector could infect other humans. Clinical trials monitor subjects for viral shedding. It would be unlikely that gene cheats would monitor their secretions for viral contamination. Furthermore, rogue gene-doping laboratories (like their steroid-synthesizing counterparts) would not implement proper preclinical trials. Thus, there may be a possibility of a modified infectious virus passing from a gene cheat to other persons. If the experience with anabolic steroids is any indicator, athletes generally ignore common dosing recommendations [07046].

**Experimental**

One paper presents studies that generated mouse models with outstanding physical performance, by manipulating genes such as insulin-like growth factor 1 (IGF-1) or phosphoenolpyruvate carboxykinase (PEPCK), which are likely to be targeted for gene
doping. The potential transition from super mice to super athletes was also discussed, in addition to possible strategies for detection of gene doping [10266].

**Risks and complications of gene doping**

Although there is as yet no definitive evidence of genetic manipulation in athletes, gene doping is a serious health concern as gene therapy is not safe from side effects, most of which are not predictable and are potentially deleterious. The onset of severe complications of gene transfection, such as insertional oncogenesis following inactivation of tumor suppressor genes or activation of proto-oncogenes, propagation and recombination of retrovirus or adenovirus vectors, and potential humoral and cellular immune responses against transgenic proteins, could be ethically justified for the treatment of patients with serious, life-threatening disorders, but it is an unacceptable risk for healthy individuals who seek to enhance athletic performance. Such treatment is virtually impossible to reverse; early benefits in terms of improved athletic performance could later turn into serious complications, from thrombosis to cancer. In the specific case of Epo gene therapy, the administration of recombinant adeno-associated virus serotype 2 vector containing feline Epo cDNA resulted in pure RBC aplasia or pathologic erythrocytosis, which could not be abolished by injection site removal. Finally, besides health concerns, “gene cheating,” as does doping in general, contravenes the ethics of sports and influences outcomes of competitions that frequently result in considerable economical benefit [10353].

Like all new medicines, gene therapy presents unsolved problems. Until they are solved, large-scale use of gene therapy in the clinic is ruled out. Contrary to gene therapy and by implication of its illegal character, gene doping is not bound to safety regulations [0011].

The risks associated with gene doping are substantial. Gene doping is unlikely to be performed under close medical supervision/monitoring and short term gain may well be achieved at the expense of longer term health problems for athletes. It is of paramount importance that athletes and coaches are educated about the potential risks of gene doping before we read tragic headlines involving sporting heroes [13011].

**Gene silencing**

One limit to the effectiveness of gene therapy is gene silencing; thus, even when the target tissue is infected, it might not express the inserted gene [13011].

**Immune reaction**

Both the virus used and the protein itself can cause an immune reaction. How to handle this reaction appropriately is not completely clear. The immune reaction against the protein can also induce a response against the endogenous protein, as happened with EPO in macaques resulting in anaemia [13011].

**Integration**

Though not all viruses integrate, those that do can present problems. Splitting up a tumour suppressor gene, or worse, increasing production of a proto-oncogene, can lead to cancer. It is estimated that about one in every 10,000 retroviral insertions might be dangerous, and one in every 10^9 could induce cancer [13011].
**Infection of germ cells**

The danger of the infection of germ cells with gene therapy also exists. This would transfer exogenous genes to future generations. Though it is explicitly prohibited to target cells that reproduce, and it is not likely gene therapy (which is not aimed at germ cells) would cause an infection of germ cells, this risk should be strictly monitored [13011].

**Expression**

Expression of gene therapy is hard to control, and overexpression could be dangerous. In addition to the effects of the protein itself, toxicity by accumulation is also dangerous. Also, if a cell producing the desired product is infected by another virus, this could lead to overexpression of the protein. Expression is controllable by an inducer drug (e.g. doxycycline, which is approved for human use), but since this is detectable, it is less likely to be used for gene doping [13011].

**Storage and usage**

Gene therapy would require good storage and it is questionable whether those wishing to abuse it are knowledgeable about proper handling procedures. Since professionals face difficulties with the non-linear dosage-expression relationship, it is likely those who have not been thoroughly educated could do worse. Even more dangerous would be an attempt to produce gene doping in rogue laboratories, leading to unsafe products [13011].

**Long term**

Gene therapy is a new technology. Only short-term studies have been conducted, which means that the long-term effects are not yet clear. There may still be problems with gene therapy products that simply have not been identified yet. It should be emphasised that the above-listed risks are only the foreseeable risks, as all the information was obtained in regulated and controlled settings. The unknown risks present a much larger problem, because they are far more difficult to anticipate [13011].

**Uses of gene therapy**

Gene therapy can be used to treat a variety of illnesses. It may be applied to weaken or kill cancer cells by triggering apoptosis, to enable target cells to produce a protein that otherwise has to be administered or to upregulate the production of a specific protein. Though a couple of gene therapy products have been marketed outside China to date, at least 1843 gene therapy trials have been conducted worldwide with thousands of patients suffering from cancer diseases, cardiovascular and neurological diseases and a range of other diseases. Early clinical trials in Europe and the USA had limited results and even fatalities were reported from gene therapy; however, examples of successful gene therapy include treatment of SCID-X1 and Leber's congenital amaurosis. The proof of concept of various transfer strategies in gene therapy shows that we are at least at the beginning of a gene therapy revolution for patients with monogenic diseases [13011].

**Potential strategies for detection of gene doping**

*Detection of erythropoietin gene doping*
Gene doping – or the abuse of gene therapy – will continue to threaten the sports world. History has shown that progress in medical research is likely to be abused in order to enhance human performance. In one review, it was critically discussed the progress and the risks associated with the field of erythropoietin (EPO) gene therapy and its applicability to EPO gene doping. It was presented typical vector systems that are employed in ex vivo and in vivo gene therapy trials. Due to associated risks, gene doping is not a feasible alternative to conventional EPO or blood doping at this time. Nevertheless, it is well described that about half of the elite athlete population is in principle willing to risk its health to gain a competitive advantage. This includes the use of technologies that lack safety approval. Sophisticated detection approaches are a prerequisite for prevention of unapproved and uncontrolled use of gene therapy technology. In this review, we present current detection approaches for EPO gene doping, with a focus on blood-based direct and indirect approaches. Gene doping is detectable in principle, and recent DNA-based detection strategies enable long-term detection of transgenic DNA (tDNA) following in vivo gene transfer [12478].

The practice of doping threatens fair competition in sports. With the very recent reports on successful gene therapies for several diseases, the likelihood for abuse of gene transfer techniques in elite sports is rapidly increasing. It is therefore very important to develop valid detection techniques for transgenic DNA (tDNA) with ultimate sensitivity and specificity. To date, three slightly different procedures have been reported to reliably detect tDNA with sufficiently high sensitivity. Two utilize a real-time PCR-based approach and one uses a primer-internal, intron-spanning PCR approach (spiPCR). The specificity and sensitivity of these techniques, however, is still a matter of debate. Based on spiPCR, here we present a novel one-tube nested PCR approach that minimizes the chances for cross-contamination and shows increased sensitivity compared to non-nested PCR techniques. To further reduce the occurrence of false-positives based on cross-contamination, a multi-functional 19bp extended erythropoietin standard (EPO) was cloned which can be easily differentiated from transgenic EPO DNA (tEPO) and can be used as an internal or external positive control in PCR-based applications. We found that one-tube nested PCR is superior in terms of sensitivity and specificity compared to conventional PCR, and shows similar sensitivity compared to real-time based PCR assays. Although it did not reach sensitivity of spiPCR, the one-tube nested PCR technique described here is less laborious, less expensive and much faster than spiPCR. This technique might therefore be useful as a pre-screening tool for gene doping in the future [12479].

Gene doping – or the abuse of gene therapy – will continue to threaten the sports world. History has shown that progress in medical research is likely to be abused in order to enhance human performance. In one review, it was critically discussed the progress and the risks associated with the field of erythropoietin (EPO) gene therapy and its applicability to EPO gene doping. It was presented typical vector systems that are employed in ex vivo and in vivo gene therapy trials. Due to associated risks, gene doping is not a feasible alternative to conventional EPO or blood doping at this time. Nevertheless, it is well described that about half of the elite athlete population is in principle willing to risk its health to gain a competitive advantage. This includes the use of technologies that lack safety approval. Sophisticated detection approaches are a prerequisite for prevention of unapproved and uncontrolled use of gene therapy technology. In the review, it is presented current detection approaches for EPO gene doping, with a focus on blood-based direct and indirect approaches. Gene doping is detectable in principle, and recent DNA-based detection strategies enable long-term detection of transgenic DNA (tDNA) following in vivo gene transfer [12480].

There are several theoretical ways of detect gene doping. At present, human applications with gene doping have not yet materialized. However, there is a potential of misuse of this technology in the future [12242].

2062
Direct methods
- since glycosylation of EPO differs in the skeletal muscle and endogenous EPO, Lasne’s method would be able to detect the same
detection of the gene delivery system in the body in case of gene doping: plasmids, viral vectors, liposomes, and protein-DNA conjugates
- labeling all EPO gene transfer products with genetic “barcodes”

Indirect methods
- “Hematological passport”: in this concept, hematological parameters are monitored sequentially in all the athletes and subject-specific references are generated. This would be useful in finding the genetic polymorphisms/mutations leading to increased endurance in a particular person (e.g. Finnish cross-country skier Eero Mantyranta who won two gold medals in the 1964 Winter Olympics was later identified to have a mutation in the EPO-R gene that caused sustained activation of EPO signaling. Mantyranta’s oxygen carrying capacity was increased by 25-50 percent)
- “Molecular passport”: Sequential determinations of the expression levels of certain EPO target genes by DNA microarray analysis could define athlete-specific reference ranges for the level of expression of these genes. Athletes with gene expression levels above or below their personal range would be considered suspicious for doping

With novel EPO molecules around the block, misuse of them in sports would be increasing and the challenge would be to provide easy and reliable detection strategies which can be used for mass screening [12242].

Some have suggested that adaptation of the aforementioned detection methods will also be suitable for the detection of genetic doping, for example, via the detection of changes in gene expression profiles that may occur secondary to the bypassing of metabolic pathways. However, others have highlighted several difficulties when attempting to apply pre-existing detection systems to genetic doping. First, for a transgenic protein (a protein produced from a transferred gene) to be detected, it must be distinguishable from its physiological counterpart. As we have already seen, one of the fundamental aims of gene therapy is to enhance 'normal' physiological production of various proteins, thus meaning that any detection on this basis would be very challenging. Substances such as erythropoietin are known to have very short half-lives, therefore this would thus further reduce the probability of their detection via a random blood or urine sample. The only present method that may enable site specific detection would be that of a muscle biopsy to test for injected viral particles. However, while deemed safe, any biopsy method is likely to be highly unpopular with professional athletes due to its invasive nature. As has been highlighted, even if such sampling were to be enforced, engineered viral products may be indistinguishable from their endogenous counterparts and it is unclear how long such particles would persist following their injection. Recent advances have suggested that a fine needle aspiration biopsy in combination with real-time polymerase chain reaction (PCR) techniques may offer a solution to this barrier, and is one of the areas to have received both encouragement and funding from WADA. Utilizing a nested PCR assay, the authors were able to detect the presence of transgenic DNA (VEGF-A cDNA) in blood samples taken from all six of the mice subjects to whom it was administered via intramuscular adeno-associated virus (AAV)-mediated gene transfer. Furthermore, the VEGF-A transgene remained detectable at 4 weeks in all six subjects; and, remarkably, was still detected in 4/6 of the mice at day 56 post administration. This method would avoid the difficulties of ascertaining possible gene doping via muscle biopsy; and it only required minute amounts of blood (20 microL). While the authors highlight that transgenic efficiency is considerably greater in mice, they remain confident that the technique can be successfully used to detect gene doping in humans and have thus far
developed target specific identification PCRs for several other key doping targets including EPO and IGF-1. A final means of detecting gene doping may come from the immunological detection of antibodies produced in response to injected viral particles. If this were to be initiated as a detection method, repeated testing of athletes’ immune responses to various viral agents would be necessary. Moreover, since viral gene delivery requires the injection of a bolus dose of relatively high concentration (several million particles) of recombinant virus, it has been predicted that some very aggressive immune responses would be witnessed; and that these would be accompanied by significantly higher titres of antibodies than those witnessed as a result of typical viral infections. Looking to the future, application of this detection method could be limited by the development of increasingly efficient vector systems that will not induce such immunological reactions. Finally, it has been suggested that the detection of gene doping may be possible through the barcode-like labelling of agents. While proven to be successful in agricultural industries and stated to be a prerequisite for the development of any new therapeutic agent designed to induce genetic alteration, it is questionable whether a commitment to such labelling would withstand the considerable financial gains likely to be rewarded to those willing to make a gene doping product available [11547].

Administration of prohibited substances to enhance athletic performance represents an emerging medical, social, ethical and legal issue. Traditional controls are based on direct detection of substances or their catabolites. However out-of-competition doping may not be easily revealed by standard analytical methods. Alternative indirect control strategies are based on the evaluation of mid- and long-term effects of doping in tissues. Drug-induced long-lasting changes of gene expression may be taken as effective indicators of doping exposure. To validate this approach, it was used real-time PCR to monitor the expression pattern of selected genes in human hematopoietic cells exposed to nandrolone, insulin-like growth factor I (IGF-I) or growth hormone (GH). Some candidate genes were found significantly and consistently modulated by treatments. Nandrolone up-regulated AR, ESR2 and PGR in K562 cells, and SRD5A1, PPARA and JAK2 in Jurkat cells; IGF-I up-regulated EPOR and PGR in HL60 cells, and SRD5A1 in Jurkat; GH up-regulated SRD5A1 and GHR in K562. GATA1 expression was down-regulated in IGF-I-treated HL60, ESR2 was down-regulated in nandrolone-treated Jurkat, and AR and PGR were down-regulated in GH-treated Jurkat. This pilot study shows the potential of molecular biology-based strategies in antidoping controls [07397].

The WADA initiated research to prepare for the world of gene doping. Research scientists suggest several biologic/laboratory tests that could operate to expose gene-doping cheats. The usual parameters of laboratory tests – sensitivity, specificity, validity, and reliability – would need documentation to allow such innovative tests to withstand the certain legal scrutiny when elite athletes test positive for gene cheating [07046].

**Muscle biopsy**

A biopsy of suspected muscle tissue could reveal viral vehicles or evidence of altered genes; however, that possibility presents a invasive and low-yield antidoping measure [07046].

**Blood monitoring**

Proteins and hormones produced by doped genes could be exactly like endogenous proteins. Thus, it may be extremely difficult to detect the difference between the endogenous gene product and the doped-gene product; however, serial monitoring of blood parameters may reveal suspicious elevations of key biologic substances that indicate gene doping. For instance, the dramatic increase in hematocrit, in conjunction with several other hematological
parameters, could tip off a regulatory agency that an athlete used a gene-doping technique to improve oxygen delivery to muscles [07046].

**Genetic activity tests**

Interesting developments could use patterns of gene activity or gene products to detect abnormal gene activity. Detection of these patterns uses cutting-edge microchip gene array technology or nanotechnology breakthroughs. The monitoring or visualization of gene activity or gene products through the expression of DNA and RNA by a sophisticated microchip array could monitor thousands of genes, enabling the laboratory to use a sophisticated detective tool for gene doping [07046].

**Protein fingerprints**

In this process, similar to gene microarray testing, hundreds of biologic proteins could produce a "protein fingerprint" or a "genetic map" of the biochemistry of individual athletes. Suspicious alterations of such an individualized fingerprint or map would alert sporting authorities to possible gene doping [07046].

**Genetic barcodes**

It may be possible to label the transgene products with a genetic "bar code"; however, this tactic would require the cooperation of a broad array of professionals from the research scientists to the pharmaceutical houses to the administering physicians [07046].

**Laboratory techniques for detection of gene doping**

With a feasibility study a first step towards a new monitoring system for hormonal treatments was done. Screening of regulation and function of anabolic sex steroids via modified gene expression of mRNA in various tissues could be a new approach to trace treatments with unknown drugs or newly combined cocktails. In the study, uterus, liver and muscle tissue from 24 cycling heifers were taken after the animals were treated either with Melengestrol Acetate (MGA), Finaplix-H (200 mg Trenbolone Acetate) or Ralgro (36 mg Zeranol) for 56 days. In every treatment group always two heifers were given 1-fold, 3-fold and 10-fold doses of the standard preparation, the control group without any treatment consisted of two animals. The different tissue gene expression profiles were investigated via the candidate gene approach. Totally 57 candidate genes were selected according to their functionality by screening the actual literature and composed to functional groups: angiogenesis, apoptosis, cell cycle, endocrine factors, energy metabolism, inflammatory factors, muscle function, oncogenes, protein metabolism and transcription factors. Gene expression was measured using quantitative real-time RT-PCR (qRT-PCR) technology. From 24 tested candidate genes in the liver, 17 showed a significant regulation. Eight genes were influenced by MGA, 9 by Finaplix-H, and 4 by Ralgro. For the muscle tissue 19 genes were tested with the result that in the neck muscle 11 genes were regulated and in the hind limb muscle 8 genes. In the neck 5 genes were affected by MGA, 6 by Finaplix-H and 3 by Ralgro. Only 2 genes were influenced by MGA in the hind limb muscle. Finaplix-H affected 6 and Ralgro 4 genes. In the uterus 29 target genes were tested and 13 were significantly influenced by the anabolic sex steroids. Under Finaplix-H treatment eight target genes were regulated and Ralgro and MGA showed a significant regulation in four target genes. The highest gene expression changes under anabolic treatment were observed in the uterus. The analyzed genes showed significant regulations but further studies, testing different animal husbandry conditions will
be needed to identify meaningful expression patterns for the different tissues. With the investigation of the regulation and possible function of anabolic sex steroids via gene expression, a preparatory work for the development of an expression pattern for drug screening was made [06311].

It was described a direct detection approach for gene doping that gives a clear yes-or-no answer based on the presence or absence of transgenic DNA in peripheral blood samples. The procedure is based on the specific detection of intronless DNA by using a single-copy PCR protocol using a priming strategy that is specific for DNA sequences that could be abused for gene doping purposes. The priming strategy is targeting the transgene itself, as this sequence part is the minimal prerequisite to achieve a doping effect. In contrast to this, other non-human sequence parts delivered by gene transfer, such as viral sequences or promoter sequences, may vary depending on the technique used. In one study, it was provided experimental evidence that transgenic DNA can be detected for several weeks in the peripheral circulation of mice that received intramuscular adeno-associated virus (AAV)-mediated gene transfer, representing one of the most likely candidate vector systems to be used in gene doping practice. Transgenic DNA could be detected in minute amounts of blood samples, thus allowing minimally invasive sample retrieval, a fundamental prerequisite to legitimate doping testing. To make our detection strategy amenable for routine testing, it was implemented a robust sample preparation and processing protocol that allows specific and reproducible analysis of human blood samples to screen for six prime gene doping candidate genes: erythropoietin (EPO), insulin-like growth factor 1 (IGF-1), vascular endothelial growth factors A and D (VEGF-A, -D), human growth hormone 1 (GH-1) and follistatin (FST). The detection strategy was verified in a mouse model, giving positive signals from minute amounts (20 microL) of blood samples for up to 56 days following intramuscular adeno-associated virus-mediated gene transfer, one of the most likely candidate vector systems to be misused for gene doping. To make our detection strategy amenable for routine testing, it was implemented a robust sample preparation and processing protocol that allows cost-efficient analysis of small human blood volumes (200 microL) with high specificity and reproducibility. The practicability and reliability of the detection strategy was validated by a screening approach including 327 blood samples taken from professional and recreational athletes under field conditions [10360].

The non-therapeutic use of genes to enhance athletic performance (gene doping) is a novel threat to the world of sports. Skeletal muscle is a prime target of gene therapy and we asked whether we can develop a test system to produce and detect gene doping. Towards this end, it was introduced a plasmid (pCMV-FAK, 3.8 kb, 50 microg) for constitutive expression of the chicken homologue for the regulator of muscle growth, focal adhesion kinase (FAK), via gene electro transfer in the anti-gravitational muscle, m. soleus, or gastrocnemius medialis of rats. Activation of hypertrophy signalling was monitored by assessing the ribosomal kinase p70S6K and muscle fibre cross section. Detectability of the introduced plasmid was monitored with polymerase chain reaction in deoxyribonucleic acids (DNA) from transfected muscle and serum. Muscle transfection with pCMV-FAK elevated FAK expression 7- and 73-fold, respectively, and increased mean cross section by 52 and 16 percent in targeted muscle fibres of soleus and gastrocnemius muscle 7 days after gene electro transfer. Concomitantly p70S6K content was increased in transfected soleus muscle (+110 %). Detection of the exogenous plasmid sequence was possible in DNA and cDNA of muscle until 7 days after transfection, but not in serum except close to the site of plasmid deposition, 1 h after injection and surgery. The findings suggest that the reliable detection of gene doping in the immoral athlete is not possible unless a change in the current practice of tissue sampling is applied involving the collection of muscle biopsy close to the site of gene injection [12481].
With the continued development of gene therapy the potential for gene doping increases. Detection of gene doping is difficult because expressed proteins can be identical to endogenous versions of the same protein. Where gene encoded proteins are secreted from cells it may be possible to at least detect them in biological samples and in some cases it may be possible to differentiate between the endogenous molecule and ‘doping’ protein by differences in glycosylation as previously demonstrated with recombinant and endogenous EPO. If doping genes express proteins or RNA molecules that remain inside the engineered cell or are retained at their site of production, then detection will only be possible by directly sampling tissue from the doping site. Without knowledge of a precise gene doping site then multiple samples (biopsies) will be required for detection which will not be tolerated by athletes and authorities. There are other possibilities for detection of gene doping such as an immune response to the delivery vector or monitoring the metabolic profile in biological samples but these will only provide an indirect indication of gene doping and not conclusive proof. Detection of gene doping could be further complicated if the doping gene is expressed from a regulated expression system which could mean that expression can be switched “on” and “off”. The way in which the switch is controlled could be through use of another chemical such as an antibiotic, a combination of chemical regulation and endogenous demand or in response to the demands of training and performance alone. An example of this is Repoxygen™ developed by Oxford Biomedica in 2002 which comprises of a viral-vector with a human EPO gene expressed from a promoter that is activated by HIF transcription factors and therefore production of EPO is self-regulated, only being induced (when required) under hypoxic conditions. This product delivered by intramuscular (i.m.) injection has been assessed in experimental models for the treatment of anaemia. Gene doping with self-regulated genes of this sort will be even more difficult to detect [13011].

The development of gene therapy has not been a smooth journey to date. There have been some major setbacks along the way which have usually been a consequence of the vector used to deliver the therapeutic gene. Pre-existing immunogenicity in patients is caused by prior exposure to infectious forms of the virus and this can be a fundamental problem which limits effectiveness of gene delivery and results in immune killing of transduced cells. High doses of adenovirus delivered to one individual caused a massive inflammatory response with an “immune revolt” where the immune system targeted vital organs leading to his death. An area that has scarcely been explored in gene therapy trials is the re-administration of vectors which may well be attractive in gene doping but is likely to pose additional danger. Retroviruses deliver genes permanently into the genome and this can also have severe consequences. The treatment of X-linked SCID patients through ex vivo modification of BMSCs was initially effective but a number of children later developed T cell leukemia as a consequence of gene insertion activating the expression of oncogenes including LMO2 [13011].

Detection of gene doping is significantly more difficult than detection of doping with pharmaceuticals. This might make gene doping more attractive for athletes considering cheating. Currently, no specific test to detect gene doping has been approved by the WADA or used by a WADA-accredited laboratory. Any detection method would have to comply with at least the following requirements. First, the doping detection method must be adequately selective to detect cheating athletes. Second, it should be accessible and easy to use on a large scale, while remaining reliable. Finally, it should be fast, as convicting an athlete years after the crime is not desirable (although legally possible up to 8 years after a doping violation has occurred). As stated earlier, athletes who engage in doping generally use pharmaceuticals to improve their performances, so the first gene dopers are likely to have had early access to gene therapy products. Detection efforts to identify gene doping by athletes should initially explore the current uses of known gene therapy for disease treatment. Some detection methods might also help to determine the efficacy of gene
therapy for disease while in development. Generally, detection methods can be divided into two groups: direct and indirect. Direct methods test for an illegal substance, or the genetic material or virus that delivered it. Indirect methods use the effect, immune response, differences in expression or metabolic changes for detection. The direct detection of an illegal substance is preferred over indirect testing for legal reasons, but unfortunately, illegal substances are metabolized or cleared too quickly to be detected, in general [13011].

Vector biodistribution and clearance studies are essential in the development of gene transfer medicine. To provide reliable and accurate data, protocols for vector analysis must be optimized and validated. It was addressed several parameters affecting the detection of gene therapy vectors in blood. Using an in vitro system based on plasmid DNA incorporating, as a transgene, complementary DNA for human erythropoietin gene, we developed and validated a suite of real-time PCR assays for the transgene splicing sites. The most sensitive assays detected the transgene present at 0.011 percent of the copy number of the endogenous erythropoietin gene in human genomic DNA at 100 percent specificity. Plasmid linearization incorporated with PCR resulted in an increase in assay sensitivity up to 4.5-fold without compromising analysis workflow. This allowed detection of five copies of transgene in a background of 0.4 microg of genomic DNA (or 0.0035 % detectable transgene copies relevant to copies of the endogenous gene). Finally, desktop assessment of 18 DNA extraction protocols was undertaken and 5 kits were evaluated experimentally for extraction of nonviral vectors from blood. Three kits reliably detected 80 copies of the transgene in a milliliter of blood. Adoption of the described protocols will enable more reliable vector analysis in gene therapy and will assist in accurate interlaboratory comparison. The methodology will also facilitate detection of gene doping in sport, a potential new form of misuse of gene transfer technology [13757].

Athletes who illicitly use drugs to enhance their athletic performance are at risk of being banned from sports competitions. Consequently, some athletes may seek new doping methods that they expect to be capable of circumventing detection. With advances in gene transfer vector design and therapeutic gene transfer, and demonstrations of safety and therapeutic benefit in humans, there is an increased probability of the pursuit of gene doping by athletes. In anticipation of the potential for gene doping, assays have been established to directly detect complementary DNA of genes that are top candidates for use in doping, as well as vector control elements. The development of molecular assays that are capable of exposing gene doping in sports can serve as a deterrent and may also identify athletes who have illicitly used gene transfer for performance enhancement. PCR-based methods to detect foreign DNA with high reliability, sensitivity, and specificity include TaqMan real-time PCR, nested PCR, and internal threshold control PCR [13758].

**Direct methods**

Measuring the *plasma levels* of a protein would not be an accurate method for detecting gene doping. Some endogenous mechanisms to control expression prevent high plasma levels and the plasma levels of some proteins are too low to detect. Also fluctuation in physiological levels of a protein complicates this method. Measuring various isoforms of a protein would be helpful. When an exogenous protein inhibits production of the endogenous variant, a difference in the isoform ratio would be detected; thus, detection would be possible for gene doping strategies targeting EPO and GH [13011].

A *biopsy* of an infected area would provide a sample in which the virus or the exogenous gene might be detectable in an athlete. Gene transfer has been shown to be detectable in a biopsy for up to a decade. Since knowledge about the injection site is required, and biopsies are generally considered to be too invasive, methods using only blood, urine, serum, hair,
The presence of a virus might be detectable in the bloodstream, so blood samples could be tested with PCR to detect DNA or RNA or with other methods to test for viral proteins. The difficulty with this technique is timing; the persistence of viruses varies from hours to months. Testing for a virus in urine (persistence over several weeks) or saliva (persistence over several days) might be better. The downside of this approach is a possible false positive, for example, an athlete who is infected with a normal virus.

The genetic material commonly used in gene doping is complementary DNA (cDNA), which lacks introns; therefore, it can be discriminated from genomic DNA with PCR. In mice injected intramuscularly with AAV-mediated gene therapy, PCR allowed detection in the blood for several weeks, though in another test it was undetectable in blood after half an hour. However, PCR is less useful for detecting doping using genes with introns because it presents problems with alternative splicing and efficacy. In addition, it is conceivable that once a PCR detection method is introduced, gene-doping products based on genomic DNA will become available quite soon.

Since each cell type differs in post-translational modification, endogenous proteins would be distinguishable from the ones produced by gene doping. This is what caused the autoimmune reaction against EPO in macaques, resulting in anaemia. Detection would be possible with isoelectric focussing. The method is useful until viruses target cells more specifically, or specific promoter regions are developed. However, it is possible that these target cells or promoter regions might also be detectable in the future.

Genetically modified agricultural products have a genetic barcode, to help with identification. This could be done for gene therapy too, which would make the gene therapy products detectable with PCR. This approach requires global coordination in the pharmaceutical industry, which in the past has been proven to be difficult to achieve, and is likely to become practically irrelevant once gene-doping products are produced without barcodes. Creating barcodes for identification could stimulate rogue laboratory production practices that eliminate barcodes.

**Indirect methods**

Every virus induces a specific immune response in the host. Plasmid vectors or the produced proteins can induce immune responses that can be detected and distinguished from common immune responses. However, distinguishing common virus reactions from immune reactions remains a problematic issue.

Use of gene doping will probably change the transcription of other proteins as well. By tracking selected protein levels (proteomics) and gene transcription rates in a biomedical passport, dopers can be caught. One risk of this method is the chance of a false positive or false negative, since changes in training or injuries can also induce changes in metabolism. Most research on possible detection methods of gene doping uses this approach, also because this approach is potentially quite useful to determine the efficacy of gene therapy trials; but the validity is as yet unproven.

**Transgene and nonviral vectors in blood**

Vector biodistribution and clearance studies are essential in the development of gene transfer medicine. To provide reliable and accurate data, protocols for vector analysis must
be optimized and validated. It was addressed several parameters affecting the detection of gene therapy vectors in blood. Using an in vitro system based on plasmid DNA incorporating, as a transgene, complementary DNA for human erythropoietin gene, we developed and validated a suite of real-time PCR assays for the transgene splicing sites. The most sensitive assays detected the transgene present at 0.011 percent of the copy number of the endogenous erythropoietin gene in human genomic DNA at 100 percent specificity. Plasmid linearization incorporated with PCR resulted in an increase in assay sensitivity up to 4.5-fold without compromising analysis workflow. This allowed detection of five copies of transgene in a background of 0.4 microg of genomic DNA (or 0.0035 % detectable transgene copies relevant to copies of the endogenous gene). Finally, desktop assessment of 18 DNA extraction protocols was undertaken and 5 kits were evaluated experimentally for extraction of nonviral vectors from blood. Three kits reliably detected 80 copies of the transgene in a milliliter of blood. Adoption of the described protocols will enable more reliable vector analysis in gene therapy and will assist in accurate interlaboratory comparison. The methodology will also facilitate detection of gene doping in sport, a potential new form of misuse of gene transfer technology [13759].

**PCR-based detection of gene transfer vectors**

Athletes who illicitly use drugs to enhance their athletic performance are at risk of being banned from sports competitions. Consequently, some athletes may seek new doping methods that they expect to be capable of circumventing detection. With advances in gene transfer vector design and therapeutic gene transfer, and demonstrations of safety and therapeutic benefit in humans, there is an increased probability of the pursuit of gene doping by athletes. In anticipation of the potential for gene doping, assays have been established to directly detect complementary DNA of genes that are top candidates for use in doping, as well as vector control elements. The development of molecular assays that are capable of exposing gene doping in sports can serve as a deterrent and may also identify athletes who have illicitly used gene transfer for performance enhancement. PCR-based methods to detect foreign DNA with high reliability, sensitivity, and specificity include TaqMan real-time PCR, nested PCR, and internal threshold control PCR [13760].

**Regulation of gene doping**

Regulatory oversight is stricter for gene therapy trials than for most clinical trials due to the potential risks. Since the first documentation of fatalities during gene therapy, regulations have been tightened, primarily in Europe and the USA. In the USA and Europe gene therapy is only allowed in cells that do not reproduce, preventing gene therapy from affecting following generations [13011].

The ethical criteria for a drug or medical technique to be included on the WADA prohibited list are "scientific evidence, proven pharmacological effect or experience that substances or methods included have the potential to enhance or enhances sport performance." Two arguments are used for inclusion on the list: the substance or method may be harmful or cause a health risk to the athlete and the use of doping violates the spirit of sport, as defined by WADA criteria. Essentially, the substance or technique is outside "fair play," which could be construed as "cheating." The WADA tenets have been criticized as ambiguous. Clearly, any medical intervention can be a health risk; athletic competition itself is a health risk. The key factor in determining the ethical use of a drug in athletic competitions rests on the point of fair play. When is a drug not given or taken for a therapeutic purpose, but for a purpose of obtaining an unfair competitive advantage? That ethical battle continues every day in many
sporting venues. With the advent of gene therapy, the focus of the debate will turn from drugs to transgene products; however, the key element of therapeutic versus manipulative will remain unchanged [07046].

The ethics of gene doping

Is it ethical to test people, particularly children, for athletic potential? Perhaps such tests could be useful to elite athletes looking to tailor their training to their bodies. Even a tiny advantage at that level can be significant. But for almost all amateur athletes, even very good ones, there appears to be little to gain from possessing genetic information about their metabolisms or muscle fibres. However, several biotech companies, however, would beg to differ. One of them is Colorado-based Atlas Sports Genetics, which in 2008 began selling a test based on the ACTN3 gene that it claimed could determine if you were better suited for sports requiring speed/power or for those requiring endurance. In June 2010, Richmond, Virginia-based AIBioTech launched a set of genetic tests that not only look for athletic potential, but also for possible health risks that are exacerbated by strenuous physical activity. Shortly after these types of tests came to market, concerns were raised about the possible negative effects on children. Some critics worry that favourable genetic data will only lend support to the irrational dreams of any parent who believes the three-year-old across the dinner table will someday become a scholarship-snagging, endorsement-earning superstar with a million-dollar contract to shoot, kick or throw a ball. If anything, steering a child toward a particular sport or activity based on genetic data will actually limit their future opportunities, not enhance them. In a paper exploring genetic testing and sports medicine ethics, it was raised several other ethical issues associated with using genetic markers to predict athletic ability [Sports Med 2009; 39: 339-44]. There are confidentiality issues, for instance. What if a test for athletic ability also indicated a predisposition to a particular illness, such as Alzheimer disease? Who has a right to that information? Potential problems could also arise if professional athletes were compelled to undergo genetic testing. Perhaps, however, such problems are unfounded speculation. Many of the ethical concerns swirling around genetic testing in sports have no basis in reality, says the vice president of science and technology for AIBioTech, which offers a basic set of genetic tests under the Sports X Factor banner to help athletes “perform better and safer” for USD 200 [12485].

Gene transfer technology in sport is prohibited largely for its being a form of experimental science. The most likely applications of gene transfer to sports involve manipulation to enhance endurance capacity or muscle mass. Currently, research implicated for gene doping includes modifications to growth factors, such as IGF-1, recombinant EPO, and the so-called ACE gene. Ethically, its application to sport is considered by officialdom as unacceptable since there is no protocol for such use, nor standards of efficacy or safety. To this extent, any attempt to genetically modify athletes would currently be seen as medical malpractice. As such, any argument in favor of gene doping will need to address the broader question about the limits of medicine, which will involve tackling fundamental matters of medical ethics. Specifically, an argument will be required to justify treating healthy humans (athletes) with medical technology. The emergence of gene doping should mark a new paradigm for antidoping policy makers, because it presents a new landscape of ethical issues, political views on enhancement and concerns. This position does not suggest genetic exceptionalism, but speaks specifically to the moral opinions surrounding genetics, which are rather more unresolved than one might say for doping generally. The moral tension arising from the application of genetic engineering to sport reflects the crisis of authenticity in contemporary society, specifically, the demise of the natural human and the widespread ambivalence or anthropic bias over this. Fair play and health are secondary matters in this debate and, yet, they dominate, in part because they lend themselves to an artificial, but sincere moral...
intuitionism and paternalism that remains part of elite sporting culture [06168].

Considerable clarification is needed on what constitutes the genetically modified athlete. Currently, sports authorities are interested only in the somatic cell doper, who themselves consent to using gene transfer to gain an edge over a competitor. Yet it is unclear what would happen if an individual is made to be "better than well" through the same kind of use in a therapeutic context. Alternatively, are we interested in the athlete who has been born from parents that have, themselves, been modified? Last, does the ethical debate take into account the child born from parents who select a form of enhancement for their child, or perhaps select their preferred embryo on the basis of its propensity for elite sports competition? In 2004, the first genetic test for performance was made commercially available. One year later, the WADA (World Anti-Doping Agency 2005) announces in its Stockholm Declaration on gene doping that such tests are to be discouraged [06168].

It seems unlikely that the world of sports will remain untouched by the potential for gene-based enhancement to ensure victory in competition. In fact, sport represents one of the early and most obvious areas of human activity in which serious attempts at genetic enhancement are likely to be made, and made fairly soon. Because the tools of gene transfer are now slowly but surely being applied successfully to the treatment of life-threatening disease, there will increasingly be temptations to apply the same methods to many other human traits that represent less severe disease and are not disease-related at all but rather constitute normal human functions that some will wish to augment or “improve.” For instance, one such study involved the sustained expression of a gene coding for the production of the hormone erythropoietin (EPO) for delivery through the circulation to blood-forming tissues for treatment of the anemia associated with chronic kidney disease. Another study proposed the introduction of a gene encoding the insulin-like growth factor-1 (IGF-1) into muscle undergoing degenerative changes as a result of a nerve entrapment disorder. Still another proposal involved gene transfer for the correction of erectile dysfunction. The move from clear therapy to more and more clearly “enhancing” gene transfer applications should come as no surprise in a society that already accepts and even seeks improvement or enhancement of many human traits through drugs and cosmetic surgery [06307].

A gene transfer approach aimed at enhancing athletic capability, to be carried out safely and ethically, would have to conform, like all gene transfer manipulations in human subjects or patients, to the standards of ethical performance of experimental clinical research in humans. Any gene transfer in sports would also have to submit to the oversight and regulatory function of a variety of local and federal bodies that oversee all human gene transfer clinical trials and that have the responsibility of evaluating the important technical, policy, and ethical issues inherent in all human clinical research. All established codes of human medical experimentation require that the known risks and possible adverse consequences of gene transfer studies should be fully and honestly presented to patients and research subjects, and it is only after full disclosure and informed consent that a decision can be made to proceed with the study. It is also required that the anticipated benefit outweighs the known or likely harm that can be caused to the participants. Given our understanding of the science of gene transfer in humans, such studies would at best be very difficult and hazardous to the subject and therefore, unlikely for the foreseeable future to receive approval from the oversight bodies. For all of these reasons, it is impossible at the present time to perform such illicit applications ethically, safely, and honestly in ways consistent with all of the relevant tenets of human research [06307].

Only a handful of the more than 700 clinical gene therapy studies that have already taken place under truly rigorous scientific conditions have achieved a clear therapeutic result while several have caused death and other harm to participants. It is not too complicated merely to
imagine approaches to gene transfer, but carrying out an effective and safe study has proven to be excruciatingly difficult and filled with unknowns. Therefore, effective but also safe application to nontherapeutic settings such as sports might seem straightforward but is guaranteed to be frustratingly difficult. Nevertheless, the successes already achieved with immune deficiencies and imminent likely successes with other diseases establish the principle that one can alter human disease traits by genetic means and open the door widely to modification of a variety of normal human nondisease traits [06307].

Bioethical concerns

One paper provides an overview of the ethical issues pertaining to the use of genetic insights and techniques in sport. Initially, it considers a range of scientific findings that have stimulated debate about the ethical issues associated with genetics applied to sport. It also outlines some of the early policy responses to these discoveries from world leading sports organizations, along with knowledge about actual use of gene technologies in sport. Subsequently, it considers the challenges with distinguishing between therapeutic use and human enhancement within genetic science, which is a particularly important issue for the world of sport. Next, particular attention is given to the use of genetic information, which raises questions about the legitimacy and reliability of genetic tests, along with the potential public value of having DNA databanks to economize in health care. Finally, the ethics of gene transfer are considered, inviting questions into the values of sport and humanity. It argues that, while gene modification may seem conceptually similar to other forms of doping, the requirements upon athletes are such that new forms of enhancement become increasingly necessary to discover. Insofar as genetic science is able to create safer, more effective techniques of human modification, then it may be an appealing route through which to modify athletes to safeguard the future of elite sports as enterprises of human excellence [12476].

Definition of enhancement

Patented genetic technologies such as the ACTN3 genetic test are adding a new dimension to the types of performance enhancement available to elite athletes. Organized sports organizations and governments are seeking to prevent athletes’ use of biomedical enhancements. One paper discusses how these interdiction efforts will affect the use and availability of genetic technologies that can enhance athletic performance. One paper provided a working definition of enhancement, and in light of that definition and the concerns of the sports community, reviews genetic enhancement as a result of varied technologies, including, genetic testing to identify innate athletic ability, performance-enhancing drugs developed with genetic science and technology, pharmacogenetics, enhancement through reproductive technologies, somatic gene transfer, and germ line gene transfer [12477].

Genetic enhancement

These kinds of studies would obviously represent a departure from gene therapy as it has come to be recognized as an approach to preventing or correcting disease. In all countries in which gene therapy is being pursued under the all the required review and regulation, all gene transfer studies carried out until now have been aimed at conditions that would be universally seen as diseases. However, the loss of muscle mass and function as a part of human aging can be considered to be a completely normal phenomenon and therefore accepted with no need for “treatment.” On the other hand, some could maintain with good reason that genetic methods to improve muscle function, as developed in studies of terrible muscle diseases such as muscular dystrophy, would increase quality of life for millions of
people in the same way that treatment of other aspect of human aging are all acceptable parts of modern medicine. It would not be a great conceptual or technical leap then to apply the same technologies to completely normal human traits such as muscle function or blood production in normal young athletes for the specific purpose of improving athletic prowess. In that way, the world of sports may be one of the provinces of human activity to become an early target for the application of existing and future advances in the field of human gene therapy for the enhancement of nondisease human traits. Most of the more thoughtful discussions have concluded that there are severe moral objections to such efforts, even if and when the technical limitations that we now face are overcome and such changes might be produced safely without harm to the subject or, for that matter, to future generations. These have also forced a new look at the role of a sport in a society, the very concept of a sport, and its apparent evolution from a rule-based noble and romantic striving for individual achievement to potentially grotesque uncontrolled biotechnology.

Athletes need and deserve access to the best medical procedures and methods to repair their injured muscle, tendons, bones and all other tissues just as all injured patients need and deserve the best in medical repair technology. Athletes must not be deprived of the best medicine available to all others. However, it seems very likely that some methods for treatment of injuries or illness in athletes result inadvertently not only in restoration of the original normal function but that produce an enhanced physical function: stronger muscles, ligaments, and tendons less vulnerable to further injury, and so on. That is probably just as true of currently available methods of injury repair, but enhancing physical function is usually not a significant goal in treatment of injuries and illness by existing methods. Well-treated athletes are not excluded from competition because previous therapy for an injury or an illness has left them with possibly enhanced athletic capability. However, it is now becoming possible that enhanced function might not be merely an unintended consequence of treatment but in fact may become a part of the goal of the "treatment." For instance, it has been demonstrated in animal studies that treatment of some joint and musculoskeletal injuries and illness with growth factors such as IGF-1 markedly increases the degree and speed of tissue repair. If similar gene-based techniques were also to be proven to be effective in humans, it would seem to be of great benefit to offer such therapies to all injured people, including injured athletes. Could athletes ethically be deprived of such essential medical procedures? Of course not. But such an athlete's competitors might be placed in a position of unfair disadvantage. Even more troublesome, of course, is the possibility that prophylactic treatment of an injury-prone muscle in an athlete with such a factor for the direct purpose of providing such the benefit of improved athletic capability could readily become feasible. Such an application could certainly be consistent with the best principles of preventive medicine but would certainly cause discomfort in the sports context. And by sport we should not restrict ourselves only to human athletes. Race horses and other animal athletes could just as easily become the subjects for such therapy-enhancement applications.

The thin line between therapy and enhancement

One of the areas in which troublesome scientific, policy, and ethical issues related to gene transfer applications in humans is the indistinct border between therapy and enhancement. What trait is being modified? Is it a disease or the cause of a severely compromised quality of life? Is the modification justified? There are certainly human conditions that most of us – with the exception of adherents to some religious principles – would agree are "diseases" and require intervention. There are other physical traits that are not so clearly "diseases" but that many in our society nonetheless might wish to modify for the purpose of improving "quality of life" or even for cosmetic reasons. Most human characteristics span a broad range from obviously "defective" to more-or-less "normal," and most of our modern societies have

2074
already accepted the notion that the edges of this normal distribution that border on the “abnormal” or “defective” are targets for modification. For instance, there is a very wide variation in the height of human beings; some are very tall, some are very short. In some cases, such extremes result from demonstrable defects in growth factors, such as growth hormone, leading to pathological shortness. These children are often treated with growth hormone to add valuable inches to their eventual height. In many other instances, people are short in the absence of any demonstrable abnormalities in these or other growth factors. They are short because their parents are short, through whatever mechanisms that may reflect. Such a trait is just as clearly inherited as is an inborn genetic deficiency of growth hormone, but the resulting short stature might not be seen by most of us to be abnormal or require therapy. Humans also often show a loss of memory and intellectual acuity during “normal” aging. In the extreme forms of these problems found Alzheimer’s disease, we have taken the extreme nature of the changes to represent pathology and real disease, and a great deal of research is being aimed at treatment for this disorder [06309].

Influence on mood and behavior
Even complex social behaviors are now slowly coming to be understood as reflections of mixed genetic and environmental influences. For instance, mice having a deficiency in the gene known as MECP2 have been developed as a model for the human autism-like disorder called Rett’s syndrome. Mice with this genetic deficiency show deficiencies in a variety of behavioral traits important to mice-nesting behavior and reduced decisiveness in interacting with other mice. A study in mice demonstrated that defects in the gene making the protein stathmin seemed to make timid mice much more daring and less intimidated by novel situations, possibly by interfering with nerve cell connections in the part of the brain called the amygdala, a center thought to be important in fear responses. And so it seems likely that, as this kind of research gathers speed, more genes will be found with powerful effects on complex social behaviors and thereby make those genes susceptible to manipulation and possibly make these and many other normal human behaviors available for drug- and possibly genetic intervention [06309].

We also nowadays have medicine cabinets full of drugs designed to improve our moods and memory, enhance our sexual performance, and modify aspects of our personality and temperament. If drugs are acceptable for these purposes, why not genetic approaches to exactly the same conditions? It might be difficult to develop convincing and logically consistent arguments against such applications of gene transfer [06309].

Repair of injury
The effective management of injury and the repair of damaged tissues are central to athletic training and competition. A great deal of research is being carried out to develop methods to speed and improve tissue repair by introducing genes into injured muscles, tendons, joints, etc that stimulate growth and repair. In fact, studies in animal models have shown that the gene transfer into such damaged tissues can speed repair and regrowth of some injured tissues: muscle, tendon, and cartilage. Certainly, if these kinds of treatments are found to be effective in human injuries, athletes should not be deprived of the therapeutic benefits of gene-base repair of legitimate athletic injuries. However, one can also imagine a temptation to perform preventive treatment of vulnerable or repeatedly injured tissues not to treat but to prevent future injury [06309].

Misuse of genetic science: the reemergence of eugenics
Through the genetics revolution that we have been witnessing during the past several decades, we have come to realize not only that most human disease is determined at least partly by genetic components but also that most normal human traits are similarly affected to a greater or lesser degree by genetic influences. These include our most complex and
mysterious traits – our personalities and cognitive and intellectual capacities. Of course, most of the genes involved in these functions have not yet been identified but we know that they are there. We do not yet know what they are or what they do, but in time we will find them and increasingly understand them. To the extent that enhancement in sports might easily represent one of the earliest opening scenarios in the broad problem of gene-based enhancement, what occurs in the world of sports is likely to define the ways in which our society approaches and solves the problems arising from the deliberate genetic modification of human traits in general [06309].

**Specific ethical questions**

Sports medicine ethics is neither a well established branch of sports medicine nor of medical ethics. It is therefore important to raise to more general awareness some of the significant ethical implications of sports medicine practices. The field of genetics in sports is likewise in its infancy and raises significant ethical concerns. It is not yet clear how genetics will alter our understanding of human potential and performance in sports. While a number of professional medical bodies accept genetic interventions of a therapeutic nature, we argue that the use of genetic technologies to predict sports potential may well breach both the European bioethics convention and North American anti-discrimination legislation, which are designed to support important ethical ideals and the ongoing commitment of the physician to the welfare of their patient. We highlight further ethical problems associated with confidentiality and consent that may arise in genetic testing as opposed to more conventional methods of testing in sports medicine. It was concluded that genetic testing in sport that is not strictly limited to the protection of the athlete against harm, should be viewed in a very sceptical light by sports medicine professionals [09382].

In genetic preselection, the genome would be scanned, allowing parents to choose the most genetically athletically gifted offspring to survive. This process is a sophisticated twenty-first century variant of the ancient Spartan child-selection process. Although no reports exist of parents scanning the genome of their prospective children, there are reports of a sporting organization using a limited genome scan to select prospective athletes or to genetically tailor training [07046].

Although gene doping sounds like a science fiction plot, the physician should not underestimate the capacity of humans to find an edge in competition—legal or illegal. As athletes, professionals, parents, and coaches, the authors have experienced numerous examples of cheating in sports. From the simple falsification of player records to the importation of foreign athletes to the use of anabolic steroids and PEDs, athletes, coaches, boosters, parents, and physicians will bend the rules of fair play. The greater the stakes, the higher the rewards; the temptation to cheat becomes more alluring. If gene therapy becomes reality in humans – and the technique is poised to become clinically useful – those participants who hold no moral compunctions against cheating fellow competitors will use the technique. At some point in time, performance-enhancing genetics will be a reality; as professionals, be forewarned and be prepared [07046].

Without a doubt, tinkering with an athlete’s genes has enormous potential to increase performance – initial results from basic research in this area are impressive. Transgenic mice created in an effort to understand muscle growth and muscle disease were soon baptized “Schwarzenegger mice” owing to their enormously increased strength and muscle mass. Genes such as insulin-like growth factor 1 (IGF1) and myostatin, which regulate muscle mass, are obvious targets to increase performance in sporting disciplines in which sheer strength is required. Similarly, genes that stimulate blood production or increase the oxygen-carrying capacity of blood, as well as those that regulate mitochondrial energy production
and energy use, are of interest to endurance athletes. And manipulating pain perception by genetically modifying the release of endorphins in athletes' brains might be the ultimate winning combination. Irrespective of the gene of interest, the advantages over conventional doping are obvious: as the gene product is the same as the endogenously produced protein, it is much harder to detect by current methods than any injected or ingested substance. Scientists are becoming aware of this potential for abuse. Indeed, gene doping carries considerable health risks. A certain problem is that genetic enhancements would not be as tightly regulated as other endogenous processes. Once the gene is introduced to the body, in general it is turned on and so far it has not been detected a good regulatory system to turn it on and off. The highest risk for the athlete is therefore "overdosing". It is the same for EPO, IGF1 or other target genes. However, it is nearly impossible to stop people who really want to cheat. All students with some training in molecular biology can isolate these genes and produce them in bacteria as DNA. If someone really wants starting material for gene doping then it is easy to get. WADA reacted proactively by banning all forms of gene doping after scientists warned them about the possibility. The challenge, however, is to develop effective ways to prove gene doping. Conventional methods would fail to detect an inserted gene that was isolated from the athlete's own body because its product is indistinguishable from the naturally produced form. WADA has therefore established vigorous research programs to develop new detection methods. It is a global approach to characterize doping from the point of view of disturbance of the homeostasis of the system [07001].

Regardless of whether and how athletes use gene doping, genetic and genomic research has already changed the nature of sport. For example, DNA and protein profiling could be used to identify specific gene variants to predict and select athletes for certain sports. It is known for sure that there are at least 50 alleles that you don't find in the general population. If gene therapy becomes sufficiently safe to be used not only as a medical treatment but also for normal enhancement purposes, it will raise the question of whether gene doping should remain forbidden. There is already a grey zone of performance enhancements that are legally used in sports because they are accepted as standard medical treatments. Professional golfers, for example, have subjected themselves to laser eye surgery to enhance their vision. Sport is cutting edge, because technological advancements will get experimented with there first. Ethicists have already envisaged future scenarios in which genetic enhancement would be common. Gene transfer methods were developed for therapeutic use, but there are further uses now. The examples of LASIK (laser-assisted in situ keratomileusis) or therapeutic muscle treatment show how grey zones might eventually become slippery slopes that question values of fair play and joy in sport. The risk is that the athletes will be treated like pieces of meat. They are created for port activity and only for that. If commercialism pushes this so strongly, the core values about celebrating human effort and the joy of the effort and the love of the game will be lost [07001].

Many genetic researchers and academics have raised questions about the scientific validity of these genetic tests aiming at performance evaluation, claiming they have little predictive value. Some critics have also raised another concern: Is it ethical to test people, particularly children, for athletic potential? Perhaps such tests could be useful to elite athletes looking to tailor their training to their bodies. Even a tiny advantage at that level can be significant. But for almost all amateur athletes, even very good ones, there appears to be little to gain from possessing genetic information about their metabolisms or muscle fibres. Some people worry that fanatical parents will push their children too hard to excel in a particular sport based on the results of genetic tests for athleticism. Several biotech companies, however, would beg to differ. One of them is Colorado-based Atlas Sports Genetics, which in 2008 began selling a test based on the ACTN3 gene that it claimed could determine if you were better suited for sports requiring speed/power or for those requiring endurance. In June 2010, Richmond, Virginia-based AlBioTech launched a set of genetic tests that not only look for athletic
potential, but also for possible health risks that are exacerbated by strenuous physical activity. Shortly after these types of tests came to market, concerns were raised about the possible negative effects on children. Some critics worry that favourable genetic data will only lend support to the irrational dreams of any parent who believes the three-year-old across the dinner table will someday become a scholarship-snagging, endorsement-earning superstar with a million-dollar contract to shoot, kick or throw a ball. If anything, steering a child toward a particular sport or activity based on genetic data will actually limit their future opportunities, not enhance them. Early specialization may foreclose opportunities. If you give a child access to a general sports program, you are laying the foundation for them to gain abilities that could translate into a whole range of skills. In a paper exploring genetic testing and sports medicine ethics, it was raised several other ethical issues associated with using genetic markers to predict athletic ability [Sports Med 2009; 39: 339-44]. There are confidentiality issues, for instance. What if a test for athletic ability also indicated a predisposition to a particular illness, such as Alzheimer disease? Who has a right to that information? Potential problems could also arise if professional athletes were compelled to undergo genetic testing [11587].
ETHIC ISSUES IN DOPING AND ANTI-DOPING

Since ancient times, competitive athletes have been familiar with the use of ergogenic aids and they will probably continue to use unfair and harmful substances in future, because their inclination to victory, along with the mirage of glory and money, will probably overcome health and legal risks. It was now searched PubMed using the term doping over the period 1990 to the present day. By literature searching, it emerges that the phenomenon of doping is complex and multifaceted. It involves a number of causes and factors that do not originate solely in the athletic field, making universality its main feature. It is in fact observed in all ages and levels of competition, and it concerns all sports, even the most unpredictable. The high number of athletes testing positive for anti-doping controls attests that the current strategy might be analytically adequate to unmask most (but not all) doping practices, but it is probably ineffective to prevent athletes to dope and modify this upsetting trend. As doping parallels the use of medications, food supplements, alcohol and social drugs, a reinforced preventive policy is advisable. The authors concluded that current anti-doping policy should be replaced with a more efficient and practical strategy to identify and monitor abnormal and harmful deviations of the biochemical and haematological profiles [08443].

Assisting sports performance by allowable means is an acceptable behaviour to most athletes who are involved in competitive sport. Physiological, biomechanical, medical, psychological and nutritional supports are routinely provided to high performing athletes and during the natural course of the athlete development, athletes are accustomed to technologies and methods for human performance enhancement. According to the life-cycle model of performance enhancement doping practices likely to grow out of habitual engagement in a range of acceptable performance enhancement practices [08444].

Healthcare professionals working in and outside of sports medicine are bound by a range of codes of professional conduct that inter alia outline their professional obligations. Central to healthcare professionals' obligations is their duty of care of which patient confidentiality is a part. It was presented a range of Codes that direct the healthcare professional to the protection and promotion of patient welfare including the maintaining of confidentiality, which is at the heart of trustworthy relations. In apparent contravention of this duty, the 2009 version of the World Anti Doping Code appears to oblige all healthcare professionals not to assist athletes if they are known to be engaged in doping behaviours under fear of removal from working with athletes from the respective sport. It was shown that, under certain conditions, serving the best interests of their athlete patients may oblige healthcare professionals to give advice and guidance in terms of harm-minimisation. In so far as the professional conduct of a healthcare professional is guided both by professional code and WADC, they are obliged to fall foul of one or the other. It was called for urgent and pressing inter-professional dialogue with WADA to clarify this situation [09383].

Unique among allied health care professions, athletic training is predominately practiced amid competitive intercollegiate sports. Competitive sporting environments have been suggested to adversely impact morality, ethical decision-making, and behavior. The purposes of one study were to (1) investigate the effect of institutional National Collegiate Athletic Association (NCAA) participation level on preferred ethical ideologies and ethical decision-making, (2) determine the relationship between professional status (athletic training student or certified athletic trainer and ethical ideology preferences and ethical decision-making, and (3) examine whether preferred ethical ideology is related to differences in ethical decision-making. A nationally representative sample of 610 athletic training students and certified athletic trainers from 30 athletic training education programs, stratified by NCAA division level, participated in the study. All participants completed a demographic survey, the
Ethics Position Questionnaire, and the Dilemmas in Athletic Training Questionnaire. No significant relationships were noted between NCAA participation level and respondents' ethical ideology preferences. However, athletic training students and certified athletic trainers demonstrated significant preferences for specific ethical ideologies, with students adopting the subjectivist ideology more than expected and the exceptionist ideology less than expected and certified athletic trainers adopting the exceptionist ideology more than expected and the situationist ideology less than expected. In contrast to some previous research, our results suggest that competitive sporting environments do not affect athletic training students' and certified athletic trainers' ethical ideology and ethical decision-making abilities at the collegiate level. These findings serve as a baseline for future research examining the ethical ideologies and ethical decision-making levels of athletic training practitioners and other allied health professionals across clinical settings [09384].

Today's collegiate student athlete is a highly diverse individual and as such is at higher risk for many health problems both on and off the field. To determine if a preparticipation evaluation can be optimized to help the collegiate team physician and athletic trainer assess both current and past health issues of student athletes. Utilizing MEDLINE and other medical literature database search engines, the authors conducted detailed literature searches on this subject. Key words used in these searches included preparticipation physical evaluation, collegiate, athlete, cardiovascular, preventive healthcare, high risk, alcohol, tobacco, sexually transmitted disease, motor vehicle accident, adolescent, and female. Approximately 35 articles were selected for review for this report. Authors reviewed articles within their particular area of content responsibility. Personal communications with several sports medicine experts were also conducted. Twenty-three articles were selected for inclusion, in addition to information obtained from the American College of Sports Medicine and National Collegiate Athletic Association (NCAA) Web sites. Utilizing these sources, as well as guidance and suggestions from other sports medicine physicians, the authors determined that the NCAA-mandated preparticipation physical evaluation should deliver an overview of the athlete's entire health status. As detailed in this report, it is recommended that the NCAA preparticipation physical evaluation serve as a tool in tracking and assessing both current and past health issues of student athletes. These health issues would include (1) on-field health concerns such as cardiac and musculoskeletal conditions, (2) off-field health concerns (that may adversely impact on-field performance) such as sexual activity and substance abuse, and (3) health issues unique to the female student athlete, such as eating habits, nutritional record, and menstrual history. Primary care physicians should be involved in all preparticipation physical evaluations as they have the necessary expertise to recognize potential problems in these areas [09385].

It has been argued that the risk to athletes' welfare provides the only legitimate ground for restricting the use of performance enhancing drugs in sport. In one paper, it was argued that the idea of "sport", properly understood, provides further reason to impose such restrictions. A balance of excellences' argument is proposed whereby doping is considered objectionable on account of its disrupting the relation between the excellences around which sporting competition is organised. There are reason to restrict the use of performance enhancing drugs in sport not only because of the threat they pose to athletes' health but also because of the threat they pose to athletes' displaying the relevant types of sporting excellence [10267].

It has recently been attacked several arguments generally adduced to support anti-doping in sports, which are widely supported by the sports medicine fraternity, international sports federations, and international governments. It was now shown that his attack does not succeed for a variety of reasons. First, it uses an overly inclusive definition of doping at odds with the WADA definition, which has global, if somewhat contentious, currency. Second, it seriously misconstrues the position it attacks, rendering the attack without force against a
more balanced construal of an anti-doping position. Third, it makes unwarranted appeals to matters that is considered morally “clear”, while simultaneously attacking a position many others take to be equally morally “clear”, namely that of anti-doping. Such an inconsistency, attacking and appealing to the moral status quo as befits one’s argument, is not acceptable without further qualification. Fourth, his position suffers from a general methodological flaw of over-reliance upon argumentation by analogy. Moreover, it is argued that the analogies, being poorly selected and developed, fail to justify his conclusion that the anti-doping lobby lacks philosophical and moral authority for its stance. These issues are symptomatic of a more fundamental problem: any attempt at providing a blanket solution to the question of whether doping is morally acceptable or not is bound to run up against problems when applied to highly specific contexts. Thus, rather than reaching any particular conclusion for or against doping products or processes in this article, we conclude that an increased context-sensitivity will result in a more evenhanded appraisal of arguments on the matter [10420].

There is currently much concern over the use of pharmaceuticals and other biomedical techniques to enhance athletic performance – a practice we might refer to as doping. Many justifications of anti-doping efforts claim that doping involves a serious moral transgression. In one article, it was reviewed a number of arguments in support of that claim, but show that they are not conclusive, suggesting that we do not have good reasons for thinking that doping is wrong [10536].

It was thus recently attacked several arguments generally adduced to support anti-doping in sports, which are widely supported by the sports medicine fraternity, international sports federations, and international governments. It was shown that his attack did not succeed for a variety of reasons. First, it uses an overly inclusive definition of doping at odds with the WADA definition, which has global, if somewhat contentious, currency. Second, it seriously misconstrues the position it attacks, rendering the attack without force against a more balanced construal of an anti-doping position. Third, it makes unwarranted appeals to matters Kious considers morally "clear", while simultaneously attacking a position many others take to be equally morally "clear" namely that of anti-doping. Such an inconsistency, attacking and appealing to the moral status quo as befits one’s argument, is not acceptable without further qualification. Fourth, his position suffers from a general methodological flaw of over-reliance upon argumentation by analogy. Moreover, it is argued that the analogies, being poorly selected and developed, fail to justify his conclusion that the anti-doping lobby lacks philosophical and moral authority for its stance. These issues are symptomatic of a more fundamental problem: any attempt at providing a blanket solution to the question of whether doping is morally acceptable or not is bound to run up against problems when applied to highly specific contexts. Thus, rather than reaching any particular conclusion for or against doping products or processes in this article, we conclude that an increased context-sensitivity will result in a more evenhanded appraisal of arguments on the matter [10536].

It is in the nature of medical practice that it is always likely to yield ethical problems because of the role that health, illness and injury play in the lives of patients. Sports physicians can find themselves in particularly difficult (though not unique) contexts because of the role of the body in athletic performance, especially at elite and professional levels. Such difficulties as arise in sports medicine merely reflect the kinds of challenges and dilemmas (e.g. confidentiality, conflicts of interest, consent, disclosure, working with vulnerable populations) as are found in other branches of medicine, though not necessarily in precisely in the same configurations. One common professional response to the recognition of ethical demands and professional ambiguity is to establish codes of conduct such as those published by the American College of Sports Medicine (ACSM), the Australasian College of Sports Physicians (ACSP), the International Federation of Sports Medicine (FIMS) and the Faculty of Sport and Exercise Medicine (FASEM). Within the literature of applied ethics, sports ethics and sports
medicine ethics, the limitations of these codes as instruments of education, guidance and punishment have long been noted. One of the merits of the ACSP code that the article draws attention to is the articulation of standards of expectation, differentiating among other things between those actions that are, on the one hand, compulsory from exhortations to best practice on the other. One of the standard criticisms of any code of professional ethics, which has often been overlooked in discussions of sports medicine ethics, arises from the notion of scope of application. To whom do the rules apply? Sports medicine is not unique in being professionally fractured along disciplinary and geographical lines. The idea of a universal code, an Esperanto of sports medicine ethics, is almost certainly a pipe dream. Nevertheless, what the sport physician can and should do is to achieve the greatest clarity possible about the precise boundaries of their roles before engaging their services in order, first, to identify potential conflict and, second, to agree upon a clear set of priorities with the relevant parties concerned: athlete patient, Club/Team/Federation/ event organiser and so forth. It is now proposed a model of the nature of professional relations between sports physicians, athlete patients and other institutions for whom they offer paid and unpaid services (such as Clubs, Teams and National Governing Bodies) [11550].

Deterring those who in sports would be tempted to cheat and catching those who do are essential components of the current anti-doping strategy. But one should never lose sight of the ultimate goal – to protect honest athletes from losing to less talented and less dedicated competitors who use surreptitious biomedical shortcuts such as testosterone, synthetic anabolic steroids, growth hormone, EPO, stimulants or other means to gain an unfair advantage. The ethical case against drugs in sport is strong and straightforward. As long as drugs are prohibited, athletes who choose to rely on them are seeking an unfair edge over their honorable competitors. If some athletes are using drugs, all those lining up against them either have to accept the disadvantage, drop out of the competition or give in and use whatever they believe their competitors are using. Antidoping is intended to create a superior option – compete drug-free with reasonable confidence that the athletes you face are doing the same. Whenever that goal is reached, athletes are free to develop and display the particular forms of human excellence their sport embodies. Talent and dedication then have their proper place in determining who succeeds on the field of play. Perhaps this is an unconventional way to think about drug testing, but the athlete may rejoice every time an honest athlete receives an “all-clear” from the laboratory. In the end, these are the people whose integrity it is wanted to publicly affirm: the competitors whose natural gifts and hard work we believe should decide who wins and who loses [12482].

Present day elite sport culture is now less about health, courage, community and solidarity, or even character and education, fun or joy. The majority of athletes presumably believes and strive for ethics, fair play, honesty, and most are mindful of respecting themselves, the other participants, and showing teamwork, and will not knowingly break the rules and the law. While few would disagree that elite athletes epitomise the virtues of dedication and commitment, their ultimate and fundamental motivation is ultimately excellence in sporting performance [12015].

With one recently recommended gene therapy in Europe and a number of other gene therapy treatments now proving effective in clinical trials it is feasible that the same technologies will soon be adopted in the world of sport by unscrupulous athletes and their trainers in so called ‘gene doping’. In this article an overview of the successful gene therapy clinical trials is provided and the potential targets for gene doping are highlighted. Depending on whether a doping gene product is secreted from the engineered cells or is retained locally to, or inside engineered cells will, to some extent, determine the likelihood of detection. It is clear that effective gene delivery technologies now exist and it is important that detection and prevention plans are in place [13761].
The use of performance enhancing drugs among elite athletes has been in the headlines recently, particularly with Lance Armstrong’s fall from grace and his admission about widespread doping. Many argue that the use of drugs confers an unfair advantage and is ultimately dangerous to the health of the athletes. Others argue that the use of drugs is no different from other techniques employed by athletes to boost their performance: swimmers shaving their body hair; skiers wearing sleek body armour; archers and shooters having laser eye surgery to improve their accuracy. It has been put forward the provocative argument that since “there is no acceptable proof (that) drugs improve competitive performance and their use is no different from accepted sports practice, banning them is wrong and immoral”. Others argue the other side, that the use of performance enhancing drugs poses a significant risk to the health of athletes and perhaps more importantly, “threatens to undermine the very purpose of sport” by disrupting the “balance of excellences” [13762].

The history of anti-doping ethics

Sport physicians may become invested heavily in the success of their athletes, and even when there is no direct or indirect financial gain, the sport physician may push the boundaries of good medical practice. The ethical dilemmas of the sport physician with regard to return to play and conflicts of interest have been described elsewhere and this commentary will focus on the issue of doping. Over the years, physicians who were involved in the doping of athletes claimed that they were monitoring properly the athletes and simply assisting the body’s efforts at homeostasis. The argument was that if testosterone levels were low from overtraining or heavy competition, it could be boosted back up to “normal” levels. Fatigue in the setting of multiday endurance events could be cured with a small blood transfusion or the judicious use of erythropoiesis stimulating agents. These doctors emphasized that their athletes were monitored strictly, and thus, any medical risks were minimal. “Only with adequate safe controls can anabolic steroids be viewed in the same light as antibiotics, anti-asthmatic and other medications used in daily life,” stated US physician Robert Kerr in 1982, 8 years after androgenic anabolic steroids were banned. He eventually reversed his position upon the realization that athletes often pushed drug use to the extremes. This conclusion should not have come as a surprise as illustrated by the British cyclist Tommy Simpson who died on Mont Ventoux during the 1967 Tour de France while under the influence of amphetamines and alcohol. “If ten pills will kill you, I will take nine,” he reportedly said, not calculating for conditions of extreme heat and dehydration [13763].

The contested opinion of the relative harms of doping substances continued to be expressed. In 1994, Italian physician Dr Michele Ferrari was quoted in L’Equipe, “EPO is not dangerous, it is the abuse that is. It is as dangerous to drink ten litres of orange juice’. Some physicians believed that they were operating in a gray zone of acceptable medical practice and in some historical contexts that may have been an argument. For example, in the early days of blood transfusions, there was little concern over the ethical implications as it was seen to be an extension of a training method rather than ingestion of a substance. At that time, the concept of a prohibited method had not been described in antidoping. Although the first study on blood transfusions was in 1945, this method became more investigated widely in the 1970s at which time athletes began to see the performance-enhancing benefits. A steadying clamor arose to ban this practice for the same reasons as other substances are banned for the health of the athletes and the fairness of the competition. This debate was summarized nicely in 1982 by Dr. N. Gledhill, who stated that although in athletes with low hemoglobin levels the use of blood boosting could be rationalized as being therapeutic, it was nevertheless analogous to the use of physiological substances to gain an artificial and unfair
increase of performance. Therefore he recommended that the IOC prohibit it. Following the use of blood transfusions in the 1984 Los Angeles Olympics, which was publicly acknowledged by the US Cycling team, the IOC Medical Commission made this the first-ever prohibited method. An increasing understanding of this and related prohibited methods developed over the years and is now defined in the World Anti-Doping Agency (WADA) Prohibited List under Section M1; Manipulation of Blood and Blood Components [13763].

**War on doping versus war on drug**

The current anti-doping policy (“war on doping”) resembles the “war on drugs” in several aspects, including a zero-tolerance approach, ideology encroaching on human rights and public health principles, high cost using public money for repression and control, and attempts to shape internationally harmonized legal frameworks to attain its aim. Furthermore, even if for different reasons, both wars seem not to be able to attain their objectives, and possibly lead to more harm to society than they can prevent [12012].

*Doping is here to stay*

There has been a distinct trend of doping in sport for more than the last 50 years, a trend that has culminated in the current status quo that exists between the antidoping authorities and athletes that choose to cheat in this way. Some have described this status quo as a “cat-and-mouse” scenario in which the doping authorities are always one step behind the dopers. No sooner is a detection method proven to be successful than the doping athlete moves on to ever-more sophisticated substances and methods. This may be a rather simplified way of looking at the problem, but it is not wholly inaccurate. What is also clear is that there are no signs of this doping trend coming to an end. Indeed, we are probably now well beyond the stage where we should be referring to doping as a “trend” we now need to completely accept it as another of society’s ills, just as we accept that there will always be those who cheat the system in other aspects of our society [12034].

*“Everybody take doping drugs”*

Indeed, some have argued that we should stop trying to catch the cheaters of doping, and allow athletes to use whatever substances they like. According to their position, the athletes are only harming themselves. However, this view reflects a common misconception that steroid use is restricted to elite athletes. Instead, steroid use has infiltrated high school sports and neighborhood fitness centers. Thus, before it is accepted unregulated steroid use, it is important to acknowledge how widespread the problem is. The argument that “everyone's doing it”, does not take into account who “everyone” is [12100].

**Arguments for doping and their ethical anti-arguments**

The claim that carefully monitoring and modifying an athlete’s physiology with prohibited substances or methods are acceptable professional behavior is a specious one. Although the risk to particular athletes may be low with some doping substances or methods, their use distorts the notion of a level playing field and sense of fairness that reverberates through all ranks of sport. Moreover, developing athletes may come to believe it is acceptable to engage in risky (and often unmonitored) behaviors to emulate the stars and/or attempt to reach the elite level of their sport. The argument that elite sport itself is risky and in some cases far more dangerous than the practice of doping also is found wanting. Danger may be an
inherent element in some sports, and although sport federations often wrestle with the rules to improve safety, there are not many who believe that allowing doping is desirable. Although there are no large-scale social science studies, most athletes accept and encourage the application of antidoping rules. There is certainly a need to continue academic debates on what should or should not be prohibited and how best to apply antidoping rules. There are elaborate processes for stakeholders, as well as individuals, to suggest changes to the WADA Prohibited List as well as periodic revisions of the World Anti-Doping Code and Standards. Nevertheless the point remains; once a substance or method is prohibited, there can be no justification for a physician to assist or administer this to an athlete [13763].

Sport physicians will always be challenged by difficult ethical/medical decisions beyond those related to doping, and not all issues can be resolved by verifying whether the substance is on the Prohibited List. For example, the use of local anesthetics (not prohibited) in different clinical/sporting situations as well as other return-to-play issues may be quite complex. “Do no harm” is still the ultimate maxim to guide physicians, but this principle must apply to the collective health of the athletes as well as to the individual. Physicians and other responsible leaders need to promote respect for the spirit of sport and the integrity of the rules, which exist to promote fair play and the health of the athletes [13763].

The zero tolerance ban on doping has failed. The second fastest runner ever, the American Tyson Gay, tested positive for a banned substance, along with Jamaican sprinters Asafa Powell and Sherone Simpson. There is evidence of widespread doping across many sports including athletics, tennis, and cycling. Evidence from Germany suggests doping is rife in football. Despite apparent advances in the “war on doping,” the success in detecting drug misuse is limited. In 2000, the first tests for erythropoietin were introduced [13764].

Human nature

It appears it was reached the limits of human performance in sprinting about 15 years ago. Starting with Ben Johnson in 1988, only 10 men have ever run under 9.8 sec. Only two (including Usain Bolt) are currently untainted by doping. To keep improving, to keep beating records, to continue to train at the peak of fitness, to recover from the injury that modern training inevitably inflicts, athletes need enhanced physiology. We have exhausted human potential. But, to be human is to be better, and doping is not going to go away [13764].

Regulation could improve safety

The strongest argument against doping is safety. Since there have been no scientific tests of the effects of doping in healthy athletes, there are few good data available. Some have pointed to deaths of athletes as proof, but there is little evidence to attribute many of these to doping. In fact, a recent study shows French Tour de France competitors (1947-2012) had 41 percent lower mortality than the French male population as a whole. Modern doping with anabolic steroids, growth hormone, erythropoietin, and blood can be tightly monitored and, as we put together the evidence, safe limits set. An indication of their likely safety is that most current doping agents are routinely used for patient care under medical supervision. For example, growth hormone is given to children who have normal levels but who are a certain amount below the height expected for their age [13764].

Pushing humans way beyond what is physiological can have ill effects, as the East German experiments with steroids in the 70s showed. On the other hand, extreme exercise itself depletes natural levels of red blood cells, testosterone, and other hormones. But testosterone and growth hormone can all be increased within physiological endpoints (which still
constitute doping) safely under medical supervision with clear, well understood risk-benefit profiles. Anything is dangerous if taken to excess. Caffeine, a legal and popular performance enhancing substance, has been linked to deaths and dangerous overdoses. Yet it is consumed by both athletes and the general population, including children, as a performance enhancer, usually safely. Moreover, there is no such thing as risk-free sport, or life. We need a balance between the values of safety, human contribution and participation, enforceability, and spectacle. Elite sport is itself risky. Around 20 percent of professional riders starting the Tour de France do not complete, many because of crash injuries. Since 1980, at least 21 cyclists have died during competition. We should assess each substance on an individual basis. We should set enforceable, fair, and safe physiological limits. For example, blood doping and the use of erythropoietin could be dealt with at a stroke by allowing doping up to a blood cell count of 50 percent [13764].

*Spirit of sport*

A second objection lies in the nature of the intervention. If a substance came to dominate or corrupt performance, there would be good reason to ban it. For example, if drugs cause boxers to feel no fear or beta-blockers cause archers and pistol shooters to have steady hands, they should be banned because overcoming fear and tremor are integral to these sports. But if a substance allows safer, faster recovery from training or injury then it does not corrupt sport or remove essential human contribution. Indeed, analgesics and anti-inflammatory drugs are already widely used to enhance performance after injury, in competition and out. That is more unnatural and probably more dangerous than physiological doping. Athletes are using many doping products to optimise their physiology, just as they do with diet, fluid, and glucose management. Cyclist Tyler Hamilton claims in *The Secret Race* that he lost a race because he did not take a 100 calorie energy gel at the correct time (despite the fact he was also doping). Will allowing elite athletes to take drugs under medical supervision encourage children and amateurs to imitate their heroes? Again, the current ban fails this test. Amateur doping is already happening in an unsupervised manner. There is doping at college, and it is estimated that 3-5 percent of school athletes use doping. It is better to send the message that you can safely enhance physiology with a doctor when you are an adult. Many practices that have risks if taken to excess, or carried out recklessly, like driving a car or drinking alcohol, are banned for children. Over time the rules of the sport have evolved. They must evolve as humans and their technology evolve and the rules begin to create more problems than they solve. It is time to rethink the absolute ban and instead to pick limits that are safe and enforceable [13764].

*Argument against doping in sports*

The argument against doping in sport is moral, not medical. If performance enhancing drugs were no longer prohibited in sport, then being a talented sportsperson would rapidly become a dangerous occupation. Within weeks of the decision, it would no longer be a choice of whether to take performance enhancing drugs or not. You would either take them and stay competitive, or refuse and retire. Athletes who wanted to live a healthy existence would be pushed out altogether. Soon, the only competition that would matter would be the one to develop the most powerful drugs, and athletic opponents would enter into an exchange of ever escalating doses to stay ahead of each other. In a supposed attempt to level the playing field the exact opposite problem would be created. Only rich and powerful nations would have access to the best technologies, meaning the gap between the privileged and poor would actually widen [13015].

*Escalating problems*
In some nations we might see a return of the state sponsored doping programmes of the 70s and 80s. We still have many countries with totalitarian governments and dictators who show scant compassion for their citizens. Such governments would exploit and abuse their best talent from childhood to create centrally coordinated doping programmes. Politicians would bask in the reflected glory of their gladiator champions, who would later die young. Some from the pro-doping camp argue that the cheats are always one step ahead and therefore the anti-doping programme serves only to give the smartest cheaters an advantage. However the anti-doping programme also serves as a useful lid on the pressure cooker. Without it, the use of performance enhancing drugs would expand exponentially and filter deeper into our society. Some cheats are never caught, but they may still pay a heavy price for their doping. Anabolic androgenic steroids create a deleterious lipid profile (reduced high density lipoprotein cholesterol, raised low density lipoprotein cholesterol), leading to premature atherosclerosis and the risk of premature cardiac death. Much media suspicion surrounded the death of Flo-Jo, sprint queen of the Seoul 1988 Olympics. Provisional reports of a “heart seizure” became epileptic seizure in the final autopsy. Erythropoietin is not risk-free either, with many anecdotal accounts of high blood cell counts leading to sudden cardiac death. Our health systems are already creaking under the pressure of alcohol, smoking, heroin, and cocaine related illnesses. Do we really want to add to this the problems that performance enhancing drugs could create? [13764].

Engineered athletes

Legitimising performance enhancing drugs in elite and professional sport would change the message sport sends to society. A meritocratic society is one in which success is proportional to effort and ability. Sporting success is generally achieved through positive attributes such as diligence in training, effort, and self denial. Athletes inspire us because we appreciate that they got where they are through hard work. Would a bioengineered athlete be able to inspire in the same way? Like the case for a Formula 1 champion (where it is impossible to tell whether success is due to the car or the driver), it would be impossible to separate the effects of the drugs and gene doping from the human element [13764].

Bans can work

Some have argued that because we will never be able to catch every cheat, we should give up trying. The answer to futility is not to give up, however, but to make the anti-doping system more effective. In the words of the Irish political philosopher Edmund Burke, “All that is needed for evil to triumph is that good men do nothing.” So how do we make the system less futile and the deterrent respectable? Recently an area of mathematical study known as game theory has been proposed to have some of the answers. Game theory is the study of how players choose strategies to maximise their own return, in anticipation of what their opponents will do. Currently drug testing covers only a random and incomplete sample of competitors. Therefore inevitably some will elude detection through chance alone. Game theory dictates that the only rational logic is to match your rival’s anticipated strategy – to cheat yourself. However, if testing was ubiquitous, it would be virtually impossible to evade detection, and the equilibrium would be reset in favour of not cheating. Another application lies in relation to the duration of drug bans. Currently a first offence generally only leads to a two year ban, and it is very hard for sponsors and promoters to reclaim their prize money. Many athletes are prepared to take the risk of getting caught, followed by serving a soft sentence. Evidence from a retrospective cohort trial suggests that anabolic steroids continue to enhance performance for years (8 ± 3) after a washout period, so an athlete is able to return to his or her sport legally yet still gain a competitive advantage. In such circumstances, lenient sanctions are not an effective deterrent to doping. Game theory suggests that increasing the risks associated with cheating would greatly reduce its prevalence. To dope is
What justifies anti-doping?

Because of the problems of current anti-doping policy the question arises as to what the reasons for the anti-doping endeavour are. The main justification for anti-doping is formulated as follows in the 'Code', the central document published by WADA outlining anti-doping: “Anti-doping programs seek to preserve what is intrinsically valuable about sport. This intrinsic value is often referred to as “the spirit of sport”, it is the essence of Olympism; it is how we play true. The spirit of sport is the celebration of the human spirit, body and mind, and is characterized by the following values:

- ethics
- fair play and honesty
- health
- excellence in performance
- character and education
- fun and joy
- teamwork
- dedication and commitment
- respect for rules and laws
- respect for self and other participants
- courage
- community and solidarity.

Doping is fundamentally contrary to the spirit of sport.” According to WADA the spirit of sport is thus the celebration of the human spirit, body and mind. The reasons advanced against doping are that it skews a level playing field, can threaten the health of the athlete, is against the spirit of sport, and incompatible with the concept of the athlete as a role model. All these arguments are problematic. Elite sport is by definition a non-level playing field since it is about the celebration of differences. The protection of the health of the athlete argument is paternalistic and neglects the health hazards of sport itself while the distinction of avoidable and unavoidable risk is flawed. Moreover, the spirit of sport argument is fuzzy and fraught with problems, and the role-model argument is out of perspective as compared with any other role model in society. Anti-doping policies in sports have created an image of an idealized 'perfect' human. Obliging athletes to correspond to this ideal appears unfair compared to what is asked of other citizens [12012].

Given the fact that in spite of the increasingly repressive means employed to combat doping, athletes are regularly caught – while others probably get away with it – the question arises: why do athletes continue taking the risk? The underlying question is whether current anti-doping policy in sports, striving for a world free of doping in elite sports, is commensurate with how human (doping-) behaviour is determined. Using a point of view from a sociocultural perspective, but interpreting behaviour as partly determined by our evolutionary past, it may be suggested that doping in athletes is perfectly natural human behaviour. Given what modern sport is today, i.e. an important entertainment enterprise in which large amounts of money go round, strongly biased towards the celebration of winners and applying the general concept of ‘winner takes all’, it is not surprising that athletes can be drawn to whatever
promises an edge in competition. The official credo of the Olympic movement is “Citius, Altius, Fortius”, or faster, higher, stronger. It is often completed by the phrase “The most important thing is not to win but to take part.”. But the latter is not reflected by reality. Today an important tenet of elite sport is the celebration of the winner. This puts a lot of pressure on athletes, who are perpetually seeking the competitive advantage. As Petroczi states: “using doping agents may be more of a rational, outcome optimizing behaviour than deviance”. The ingredients to be a champion are a combination of talent, hard work and some luck. Talent is a licit, albeit unmerited gift and results from the genetic lottery. Hard work is essentially training and using any other means that are allowed to improve performance. Performance enhancement is a logical and essential ingredient of competitive sport. Athletes look for ways to get better, by changing their training paradigm, by eating differently, by taking vitamins, by taking licit medication, by taking supplements. A huge sports supplements industry exists and it is very common for athletes to consume a lot of substances that are not on the list of forbidden substances. Many of the supplements do nothing, a few have an effect, but quite many may pose doping problems because of adulteration, leading to accusation of doping because of positive blood or urine samples or health problems because of excess intake of some compound, erroneously seen as innocuous. Modern sport puts athletes under enormous pressure to win and the use of licit substances and methods to improve performance is explicitly encouraged. The line between licit and illicit fluctuates and has dimensions that can be perceived as arbitrary. Transgression of doping rules is not necessarily accompanied by a fundamentally different mindset as when keeping to the rules. In athletes’ minds, doping may align with illicit behaviour or with functional licit use of chemical or natural preparations [12012].

Alternatives to current anti-doping strategy

Some suggestions for possible strategies have been given. To begin with, the concept of performance enhancement by means of methods or substances, including pharmacology, should be seen as a logical consequence of elite sports endeavour and not be negated by a utopic ideological “spirit of sport” concept. Second, the health of elite athletes should still be protected, but taking into account the specificities of this risky profession (some sports come with a level of risk not acceptable in other professions). This can be done by continuing some form of testing, without going all the way as in today’s testing. For example, a no-starting rule for a haematocrit above a given level, however the way it got to that level, is a pragmatic way to prevent excess use of red cell mass stimulation regimes that lead to a health hazard. Sure enough, athletes will find ways to cheat a bit around such strategies, but that would be part of the game while keeping the problem within acceptable boundaries by associating such a rule with some other rules like the exclusion of plasma expanders, if warranted. The argument that it would change sports into an arena akin to Formula 1 where the best engineering team wins is only partly correct. It will still take talent, a lot of hard work and some luck to become a champion. And then, it is likely that such a scenario is already in place anyway; today well-assisted athletes may engage in complex training regimes and strategic doping while remaining undetected. Third, the list of forbidden substances can be shortened, leaving on the list only those substances with actually proven performance enhancing effects and major health hazards. For example, cannabis derivatives can be taken off the list, allowing athletes to be dealt with in the same way as the general population. The current arguments to keep cannabis on the list are flawed. There are no well-controlled trials that show any performance enhancing effect, while there is evidence for performance decreasing effects [12012].

With regard to the general population, instead of a crackdown on steroid users in gyms and fitness clubs with compulsory testing as in Denmark, a harm reduction approach is probably better. This has already been shown in the UK where so-called steroid clinics, giving out clean syringes and thus lowering the threshold to medical care, have led to the number of
syringes handed out now outnumbering those exchanged for injection for psychotropic drugs. These clinics, offering mostly free and anonymous services, make it possible to reach a previously hidden population. Potential advantages of providing harm reduction measures, besides health benefits, include the personal and direct contact with a hidden population allowing it to be informed of the risks and dangers of doping substances, and helping to take well informed decisions whether to continue use and if so in what way. In Switzerland the federal commission on drug-related affairs developed a conceptual model (‘the cube’) considering that for every substance, with different risk profiles, different levels of use exist (non-problematic, problematic, dependence), needing different levels of intervention at the level of prevention, treatment, harm reduction and regulation. Such a model might help to conceptualise alternative policies on performance enhancing substances respecting public health and ethical principles [12012].

One would have to distinguish between elite athletes, amateur athletes, minors, gym users and the public in general, since it can be expected that the answers to these questions would vary between groups. It is impossible to predict what would happen in these different groups. In elite athletes one might expect limited harm since medical supervision and health oriented testing would constrain the possibilities. In amateur athletes the possibility of refraining from sourcing substances from the black market and having access to general information and proper methods of use, might perhaps have a positive effect. It will of course be difficult to devise an optimal strategy to regulate for children specifically. Since athletic careers often start very early, the protection of young talents would be mandatory. Alternative policies should of course be continuously and extensively evaluated for desired outcomes and unintended negative consequences, carefully balancing the two [12012].

A continuing discussion is needed

Even if sufficiently complete and accurate data on the negative aspects of anti-doping policy are still lacking, it is suggested that the taboo on debate and reform also be broken in this field, now and not in 40 years. It may not be ignored the side effects of current anti-doping policy for society in general. We suggest experimentation with and evaluation of alternative ways of dealing with doping in elite (and amateur) sports, inspired by the experience gained with alternative drug policies, that are scientifically sound, respect human rights and public health, and treat athletes as ordinary humans and not as potential criminals. The modern globalised sport entertainment industry with its almost unlimited financial means should not be allowed to hijack worldwide legal frameworks and orient society towards a zero-tolerance approach to both psychotropic and performance enhancing substances. Those who are advocating harm reduction strategies to help society live with psychotropic drugs at the lowest cost for the individual and the community should therefore be concerned about these developments [12012].

The reasons for anti-doping rules

The considerations of devising bans on drug use in sports have been based on the following Considerations [06006].

- Doping in sports is cheating and unfair. It can be argued that doping should be banned because it is cheating or unfair. The problem with this position is that usually an activity is considered “cheating” or “unfair” only when there is a rule prohibiting it. Without the rules, there may be no issue of cheating and unfairness. Others have suggested that an action can be inherently unfair even if there is no rule prohibiting it,
but a sport is inherently a rule-driven enterprise and without rules, questions of inherent unfairness and cheating would be very difficult to resolve in sports.

- Doping harms the athletes. Here the suggestion is that doping should be banned to protect the athletes who dope. It may be argued that this rationale is paternalistic, inconsistent, and incomplete. It is paternalistic because we do not generally permit intrusion into the lives of competent adults under the guise of protecting them from perceived harms. It is inconsistent because a sport, in particular an elite-level sport, is often a hazardous enterprise. It is not clear why athletes should be protected from the harm that doping may inflict when we do not protect them from possible dangers of the training and performance of these same sports. The argument is incomplete because evidence for harm in doping is mixed. For example, while steroids in high doses may cause adverse side effects, steroids in relatively low doses probably do not. Autologous blood doping has not been shown to have any adverse side effects.

- Doping harms even nondoping athletes. The argument based on the interests of other “clean” (nondoped) athletes is that doping can be coercive. Because doping may improve results, there is coercive pressure “to keep up” placed on those who wish to compete without doping. This argument has some merits, but is incomplete because an elite-level sport is already highly coercive. For example, when full-time training, attitude training, or diet control are shown to produce better results, everyone is forced to adopt these measures to keep up. It is unclear why doping is any more coercive and sufficiently so to warrant being banned than say, training 6–8 hours a day. On the other hand, the coercion argument has merit if it can be shown that doping detracts from what is important to sports. If sports, sporting excellence, and sporting contests are about testing skills, then it can be argued that the improved performance that comes with doping is not about that test of skill. If doping does not enhance the development of sports and sporting excellence, we can choose to reject it as being unnecessarily coercive, as compared to, for example, extended training that may improve one’s skill at the contest at hand.

- Doping harms society. This position is based on the assumption that doping harms others in society, especially children who see athletes as role models. This argument works in two ways. One, if children see athletes having no respect for the rules of the games they play, there will be a tendency to undermine respect for rules, and law, in general. The second version sees doping and athletic drug use as part of a wider social problem of drug use. The argument here is that if children see athletes using doping to attain sporting success, then other drugs may also be seen as a viable means to other ends. The limitations of this argument are that there are many things that we consider appropriate for adults but not for children. Alcohol and cigarettes are obvious examples, as is sex, and although we attempt to control these behaviors, we do not generally ban these substances or activities for adults because of their potential harmful effect on children.

- Bans must be enforceable and therefore require complex infrastructures for fair and just implementation. Many layers of intrusive and expensive testing and monitoring must be established to detect instances of forbidden drug use both in-competition and out-of-competition, to evaluate and judge the results of investigations, to provide mechanisms for appeal and to levy and enforce punishment – fines, suspensions and even at times criminal punishment. It is also necessary to develop and implement programs for responding to proven instances of doping – suspensions from competition, fines, etc. All these are expensive and potentially intrusive into the private lives of the athletes.

- Doping represents a perversion of sports. It converts the beauty of sports, the glory of striving and achieving and outdoing physical limitations into “mere” biotechnology – into rewards for the most clever biological and genetic engineer instead of the swiftest, the strongest. Sport is a social construct that relies on an agreement on the
part of all to abide by sets of rules, no matter how arbitrary, that are the agreed underlying principles. Taking part in organized sport is, contrary to some views, not a human right but rather a voluntary act by athletes who, by the simple act of agreeing to participate, agree to the rules and restrictions of that sport. Of course, one of the human rights that athletes must be allowed to retain is the right to refuse to take part in doping control. No one, athlete or not, should be forced to accede to intrusive monitoring and screening programs without permission and without giving fully informed and voluntary consent. But if an athlete wishes to refuse to accede to doping control measures, he or she relinquishes the privilege of taking part in the sports competition.

- Doping is unnatural and dehumanizing. The unnaturalness argument does not get very far for two reasons. First, we do not have a good account of what would count as "unnatural." Second, we are inconsistent. For any account of "natural" and "unnatural," few things designated "unnatural" would be permitted (e.g. spiked shoes) while other "natural" ones (e.g. testosterone) are on the banned list. The dehumanization argument is interesting but incomplete, since we do not have an agreed-upon conception of what it is to be human. Without this it is difficult to see why some practices should count as dehumanizing. There is also a problem with consistency. Some practices, such as "psychodoping," the mental manipulation of athletes using the techniques of operant conditioning, are not banned, whereas the reinjection of one’s own blood is. There is an attempt later to provide some framework for defining human excellence, thereby allowing us to see how the pursuit of athletic excellence can, and should, be limited in ways that exclude doping from the pursuit of sports.

**Sports as part of the society**

An additional facet is the greater willingness to recognize the broader use of illicit substances in the society. It is noted that many users are not elite athletes at all, but young people who are preoccupied with body image. This point alludes to the relevance of broader cultural studies of body modifications when considering the use of enhancement technologies in sport. While it is tempting to believe that the rationale for any athlete’s use is merely to gain an edge over other competitors, other values are at stake. Yet, related studies of the cultural context of performance enhancement are often overlooked in the debate about the ethics of sporting performance. One could also be skeptical of the claim that society broadly is unhappy about enhanced athletes. Rather, one might more adequately claim that the media discourses surrounding the doped athlete generate a justification for a culture of anti-doping. The discussions on the ethics of hypoxic chambers in elite sport demonstrate how technology gives rise to a mixed reception and that the ethical stance taken by athletes or lay spectators or sports fans is malleable. The suggestion that sport enhancement issues are converging with broader medical enhancement debates is reflected in the activities of key legislative agencies and advisory committees. For example, the Australian Law Reform Commission in 2003 published an extensive document on the use of genetic information within a range of social contexts, one of which includes sport. Also, the UK Government Select Committee for Science and Technology launched a public inquiry into the use of Human Enhancement Technologies in Sport in 2006. To this extent, it is useful to employ a convergent metaphor in the analysis of converging legislation surrounding human enhancement technologies. Nevertheless, of critical value is to understand following section outlines various forms of technology within sport, which establishes a critical response to how technology is framed by sports authorities as a diminishing influence. In short, there is no ethical view “out there” that can justify the current approach to evaluating the role of
technology in sport [06168].

**Doping as a sign of dehumanization**

The are concerns about doping in sport also reveal a rhetoric of “dehumanization” in sport, where technology might reduce the athlete’s role in performance and, in so doing, diminish the value of competition. This view of dehumanization also emerges from a “mechanization” thesis that describes the scientification of sport as bringing about feelings of alienation: the manufacturing of athletes. Such an evaluation of contemporary, elite sports, may describe the athlete as a product of a scientific or technological process, somehow automated in performance. Thus, one might describe a sense of anxiety over tampering with biology on a global scale. Yet, even in these cases, it is unclear why such tampering should matter morally. A further example that raises questions about whether there is a broad social concern about enhancement technologies is *cosmetic surgery* (or more broadly body modification). Very little is known about whether athletes would use elective reconstructive surgery for sports performance. While one might consider aesthetic interventions given the importance of gaining sponsorship within the sports world, one might also envisage other surgical procedures that could enhance the body. Indeed, there is some evidence of athletes undertaking risky, experimental surgical procedures when injured, hoping that their ability will be restored [06168].

It may be put into question whether the human athlete or the technology has achieved the performance. However, to answer such a question requires being able to make clear distinctions between each. This category presumes that something clear can be said about humanness that is lessened or removed by the use of some technology. Nevertheless, the purpose of this categorization can be to demonstrate ideas about the moral implications of technology so as to identify the kinds of argument that are being made about the effects of technology. While various authors discuss how these technologies alter what it means to be human, adding content to such claims is more problematic as identifying the salient characteristics of humanness that are removed or lessened by such technology is not easy [06168].

**Making sport possible**

An initial category of effect for technology involves the constitutive function of technology within sports. The category raises questions about the politics of defining technology, since it reminds us that sports have always been technological and the moral evaluation of this relationship shifts over time. Technology (primitive or sophisticated, premodern or post, recent or ancient) is unequivocally a necessary characteristic of many sports without which they would not be possible. It is thus, no surprise to notice that, as the technology evolves, so too do the sports. In Formula One motor racing, it is possible to see this most clearly where advances in motor engineering vastly affect the outcome and demands upon a driver and race team. In such a performance-driven sport, the technology has often been argued as being the determining factor of success, where the driver plays merely a secondary role. Yet, such a view would be naïve or, at least, incomplete since even those who reject the most recent advances in technology that they consider to have reduced the skills required to be a driver, no such views would argue for a return to cars from the earlier parts of the 20th century. To this extent, one might describe that the relationship between technology and sports has an optimal limit beyond which something critical about the sports particular character is compromised. One important conclusion that must be drawn from this is to
realize that technologies are not antithetical to sports and that it can only be the way in which they develop – rather than their very existence in sport – that raises ethical problems [06168].

**Technology introduced but changing the sport**

One of the central aims of technological change in sport has been to improve safety and reduce the risk of harm. Many rule changes within sports can be viewed as *technologies of knowledge* that aim to restructure the range of technological interactions – such as the foot against the floor or a shoulder’s movement when swinging a racket. Other examples include the redesigning of the javelin in the 1980s, when athletes were throwing dangerously close to the spectators. The only reasonable solution to this impending problem was to change the specifications of the javelin so that the athletes could not throw it as far. This resulted in a change in the kinds of athlete that were successful as javelin throwers, from the strongest to the technically proficient. Other examples include:

- improved floor surfaces within sports halls to reduce shock to athletes when landing or bounding
- introduction of better helmets in American Football and ishockey to reduce head injury
- more sophisticated shoe design for more support to foot during athletic events
- spring board surface in diving to prevent slip and increase resiliency of board tips to reduce injury
- sturdier epee and foil in fencing, as well, Kevlar jackets for more protection but with no loss to movement
- navigational equipment in sailing
- carbon composite poles in pole vaulting and enhanced safety pits, allowed more daring contest and higher vaults

These examples identify the imperative for sports federations or governing bodies of sport to strive for their practices to be less dangerous for the competitors by introducing new technological measures. Their ethical justification derives from an interest in athlete safety and, generally, allowing the athlete to perform at an optimal level without placing undue stress on the body. However, other examples may be more controversial since their implementation can change the kind of test that is constituted by the competition [06168].

Technological innovations can alter the way that sports are played. They can change the conditions of training that are required to be successful at a particular skill, and can even make it easier to perform the required skills. Examples of such technologies include:

- U-groove golf clubs that allowed greater accuracy on stroke
- depth finders in fishing to make it easier to locate large schools of fish to enhance prospects of catching
- superman cycling position that allowed more streamlined position for greater speed
- breathable clothing material used to regulate body temperature in extreme climates

However, innovation considered to have democratized the skills of a sport may devalue or deskilled the activity. While these devices would seem quite useful for a novice who may require assistance to engage in the activity in a meaningful way, their application to competitive sports is implied – yet, it is unclear that such things are beneficial within elite competition [06168].
Doping must be concerned about the human condition and the degree to which enhancement technology can alter it. The ethical debate must take into account the risks to vulnerable groups, such as children or athletes who enhance because they feel coerced and the liberties of adults who make lifestyle decisions about body modification. Yet, it must also consider the limits of ethical policy making within the world of sport and the relationship of this to broader structures of ethical governance within society. When considering what should be the strategy for anti-doping officials in relation to, for example, gene doping, it is necessary to return to fundamental questions about the value of sport, consider how these values might have changed, and recognize the broader bioethical context within which decisions about medical technology are made. This requires that elite sports organizations reevaluate established systems of rewarding excellence, in order to promote a moral climate in sport that takes into account inherent natural and social inequalities, which are constitutive of sports practices. The conceptual framework of technological effects is useful for:

- establishing how ethical issues arise in the context of technological change
- clarifying the interrelatedness of effects arising from any one technology
- revealing that the debate surrounding enhancement as a doping infraction is only one component of a broader relationship between sport and technology

As human enhancements become a constitutive element of broader social circumstances the concept of enhancement and of the natural human will become even more difficult to sustain. In such a future, sports authorities might still attempt to protect a particular way of life for an athlete, though athletes – as humans – might no longer see either the need or the relevance.

**Increased participation and spectatorship**

One of the major interests of a sport governing body is to maximize the breadth of inclusion within the given sport. This ambition often translates into the development of technology that can allow sport to become more accessible to prospective participants. The example is slightly different from developing technologies to make the sport easier, as the main aim here is the maintenance of standards, with the broadening of participation. Alternatively, equipment is often developed that can even exclude particular kinds of individual from participation. For example, the sophistication of technology may demand a level of finance that is beyond many individuals. Examples of such technology include the following:

- artificial turf for field sports
- U-grooved golf clubs
- carbon composite tennis racquets and mass production of other kinds of equipment
- the carving ski (alpine) that makes it easier to learn skiing
- different-sized tennis balls
- varying speeds of squash ball for different levels of competence.

The benefits of such technology are complex. The ability to reach a wider audience can seem a worthwhile ambition. However, the ends of such ambitions can be problematic for the sport. For example, in sports, such as climbing or skiing, there exist limited natural resources, the overuse of which could seriously damage the environment and lessen the aesthetic experience of the performance. These varied examples provide some basis for understanding the complexity and effect of technologies in sport and the range of values that are engaged when considering the ethical implications of any proposed technological
innovation. In addition to these effects, one must also recognize that there are further concerns about the unknown consequences of new technologies. Indeed, it is crucial to recognize how anti-doping authorities develop policy on the basis of lacking scientific evidence that can demonstrate safety [06168].

Alternate conceptualizations

Within the conceptualizations there is the degree of overlap among the different technological effects. For example, the improvement of floor surfaces within sports halls that can significantly reduce injury and which would thus, fit within the safety category, also reskills the activities. As such, the categorization vastly simplifies any single example of technology within sport and, therefore, does not suitably characterize it. Consequently, it is tempting to draw some further categorization about them in an effort to find some conceptual framework that demarcates technologies from nontechologies. Thus, one might separate them into such categories as body, external, internal, environment, or something similar. It is not reasonable to expect that the categorization alone will yield answers to which ones are acceptable or not. Instead, the reason for undertaking this conceptualization is to reveal the range of technological effects that arise within sport and to demonstrate the range of moral narratives that they provoke [06168].

It has been argued that only virtuous nurturing of natural talents is valued in sports. To this extent, they note that an athlete who benefits from the knowledge of an excellent coach, engages with some form of relationship that implies their interacting. Yet, is such a view a reasonable articulation of the athlete–coach relationship? The athlete will not have undertaken any virtuous sacrifice to access such knowledge. The role of virtuous action here is unclear but doubtful. Nevertheless, if virtue were present here, one would not expect the dismissal of a coach merely due to failure to deliver results. Yet, this is the established ethos of sports practices. To this extent, it is false to suggest that the spirit of sport necessitates that only virtuous action is valued. Consequently, one can accept without controversy that nonvirtuous action—actions lacking virtuous content, rather than unvirtuous acts, such as cheating—can also have value in sport. By proposing a virtue theoretical view of ethics, it neglects other ways in which people value sport—for instance the value of witnessing misbehavior on a playing field. While a response to an ethics position does not reject the claim that “the means” are ethically relevant in sport, it does not accept the notion that only virtuous means are valued. Requiring that any enhancement be earned through virtuous action is too great a requirement, which should not be interpreted as too high an ideal. Nonvirtuous action does not mean that it lacks value [06168].

The appeal of making a clear distinction between the athlete and the supportive system through which an athlete journeys to become elite derives from concerns about athletes’ vulnerability to the political will of such systems. It must be remembered the haunted stories of the GDR (East Germany), where the political value of sporting success gave rise to unacceptable exploitation and manipulation of individual athletes. Moreover, it may be expected that any state-funded program to improve athletes will have such a character. This is more broadly contextualized within views about human enhancement more generally. Without a vigilant permissive environment for human enhancements, this will remain a prospect. As such, the burden must be on critically establishing the conditions through which legitimate human enhancements could be permissible [06168].

Ethical aspects of “harm” in sports
Some of the arguments against all forms of doping, including genetic doping in sport revolve around the various forms of harm that would ensue. At least four types of harm or potential harm can generally be envisioned including:

- harm to users
- harm to other athletes
- harm to society
- harm to the sports community

The most obvious kind of harm would result from the known harmful effects of many of the drugs classically used in sport doping in general and from the scientific and medical unknowns that still permeate the field of gene transfer in human subjects and patients in the gene therapy setting [06304].

**Harm to the athlete**

One of the common ethical arguments justifying a ban on doping in sport is the potential for harm to the athlete, that the athlete requires protection, that such protection could be provided by banning the offending substance or procedure. The assertion that the use of gene transfer technology for enhancement will harm the user is not unreasonable. It seems reasonable to suppose that the likelihood of harm likely to befall a healthy athlete or other healthy subject, taking doping substances or taking part in a gene transfer approach to doping without medical indication, is greater than the likelihood of harm that would befall someone suffering from an illness for which the same agent represents a therapy. At least the ratio of harm to benefit would be far greater in normal young subjects than in ill patients [06304].

The desire to act on behalf of others or to protect others from the consequences of their own actions is known as paternalism. Obviously, in the case where potentially injurious actions are being undertaken by minors or people who are otherwise medically and medico-legally incompetent because of illness, age, or injury, paternalism is acceptable, legal, and ethical. Virtually everyone can accept the need for drug and genetic regulation and even banning of doping by minors. But most athletes are not incompetent; most are adults who are fully competent from all ethical and medico-ethical perspectives. Although most elite athletes are competent adult athletes, some argue that banning doping by them could be considered a form of acceptable paternalism — an attempt to protect the health or well-being of a competent adult athlete or to prevent some of the other forms of harm that result from doping. On the other hand, paternalistic interventions in the lives of competent adult athletes can be seen by others to be unwarranted — that others know better than the athletes themselves how to achieve a more general good that could deny for them the very attributes that we so highly value: self-reliance, personal achievement, and autonomy. But of course the flaw in that argument is that sports ethics is not the same as medical ethics. Drug bans are meant not only to protect athletes from harm but also to preserve the concept and ethos of sport [06304].

It can therefore be concluded that the argument in favor of drug bans based largely on the need to protect athletes from harm is an important but an incomplete justification. However, in the case of a technology as immature as gene transfer approaches to sport doping, we find a particularly convincing argument of athlete protection. The state of the technology underlying this approach to doping is extremely immature and full of recognized and even more unrecognized dangers. Autonomous choices are autonomous only if they are enlightened and that a gene-based doping application under the current conditions of
inadequate scientific knowledge and probable secrecy and stealth that would almost certainly be involved, a decision to protect athletes from such inappropriate genetic applications would certainly be an example of acceptable paternalism. Once the tools and methods of gene therapy will have become much more fully established and proven to be safe, the issue of personal safety by itself will become a much less convincing justification for a ban on genetic doping [06304].

Harm to other athletes

The second form of harm from drug- or gene-based doping is not the harm that gene transfer technology could cause to users, but rather the harm that could befall other athletes. The “others” in this argument are usually deemed to be other “clean” (undoped) athletes and the harm comes through “coercion.” If a successful athlete is known to be doping, then others who wish to compete and succeed at that level might feel compelled to resort to the same kind of illicit methods to have a realistic prospect for success. Thus, doping is a harm because it is coercive and puts the well-being and life goals of others in jeopardy. Competitors require protection from the risks of doping and from the damage caused to them and to their careers. In principle such protection might be provided by a ban on the substance or the technique in question [06304].

Harm to society

Any form of doping, whether it be drug- or gene-based, also may harm another group of people, the general public and, in particular, children. People admire prominent successful athletes and view them as role models. We often try to emulate the nobler activities and qualities of great athletes – their struggles against great odds, their tenacity, and their dedication to a goal – and extrapolate their achievements to many nonsports domains of the society. Whether this is a fair or an appropriate burden to put onto athletes rather than other public figures is irrelevant, it is a fact. The trust that we place onto athletes seems to be a societal “good” and anything that brings that trust into question or into disrepute must be a form of harm. From a societal perspective, if the hero or heroine is tainted and becomes morally suspect, the very young may have difficulty distinguishing between the athletic triumphs of their heroes or heroines and the moral or ethical blots on them. The ennobling influence of the hero becomes a crushing negative influence of a fallen idol. Interestingly, the downfall of a hero might not be intrinsic to doping itself but rather could merely be due to the revelation of doping that results from breaking the rules of the sport [06304].

Ethics of the athletes regarding doping

One study presented an opportunistic examination of the theoretical tenets outlined in the Sport Drug Control Model using questionnaire items from a survey of 643 elite Australian athletes. Items in the questionnaire that related to the concepts in the model were identified and structural equation modelling was employed to test the hypothesised model. Morality (cheating), benefit appraisal (performance), and threat appraisal (enforcement) evidenced the strongest relationships with attitude to doping, which in turn was positively associated with doping susceptibility. Self-esteem, perceptions of legitimacy and reference group opinions showed small non-significant associations with attitude to doping. The hypothesised model accounted for 30 and 11 percent of the variance in attitudes to doping and doping susceptibility, respectively. These present findings provide support for the model even though the questionnaire items were not constructed to specifically measure concepts
Sports Federations’ attitudes

It was determined the priorities and activities of International Sport Federations (IFs) with respect to the promotion of health in their sport and for the general population. All 35 IFs participating in Olympic Games in 2014 or in 2016 were asked to rate the importance of 10 indicated topics, and to report their programmes, guidelines or research activities on 16 health-related topics using an online questionnaire (response rate 97%). On average, the “fight against doping” had the highest priority followed by “health of their elite athlete” and “image as a safe sport”. The topics with the lowest importance ratings were “health of their recreational athlete”, “increasing the number of recreational athletes” and “health of the general population”. All except one IF reported to have health-related programmes/guidelines/research activities; most IFs had 7 or 8 of the listed activities. Eight IFs (24%) stated to have activities for “prevention of chronic diseases in the general population” but only FIFA and FINA reported related projects. It was concluded that IFs aimed to protect the health of their elite athletes through a variety of activities, however the health and number of their recreational athletes was of low importance for them. Thus, IFs are missing an important opportunity to increase the popularity of their sport, and to contribute to the health of the general population by encouraging physical activity through their sport. FIFA's “Football for Health” and FINA’s “Swim for All” projects could serve as role models [13765].

Litigation in sports medicine

As with other medical specialties, litigation in sports medicine appears to be on the increase. In most countries, the applicable legal standard is "good medical practice" as identified with reference to the physician's own field of specialisation: what is commonly done by physicians in the same specialty generally serves as the standard by which a physician's conduct is measured. To enhance the quality of sports medicine practice, medical societies have been issuing guidelines for use by sports physicians, and a number of courts have recognised guidelines as evidence of good medical practice. One potential field of malpractice in sports medicine relates to privacy issues: an athlete should be asked to fill in a consent form if the medical information needs to be shared with other parties. Another relevant field is doping: for any act of drug prescription to be legally sound, sports physicians have to be aware of the requirements of the World Anti-Doping Agency Code and its international standards. Ultimately, the best way for sports physicians to avoid sources of liability is for them to keep up to date with the latest research and to act in a careful and diligent manner [13766].

Physician's role in doping

Sports physicians occupy a specific set of roles. For example, they may carry out the role of an athlete patient’s general practitioner; a team doctor for a single club; the sport physician for a national sports federation or an international sports federation; an independent consultant to an employer of the athlete patient; an event physician whose services have been engaged by event organisers; and a specialist consultant in a legal process. Each of these roles brings ethical challenges, but between them there may be conflicts of expectations or duties. Although sports physicians may occupy other medical and healthcare functions beyond their sports medicine practice, the proposals below refer specifically to their
interaction with any athlete patient. Where there is overlap between their role as consulting physician (i.e. general practitioner) and sports physician, it is the duty of the physician clearly to distinguish these and to communicate them both to patients and other interested parties. In all the scenarios that sports medicine presents the sports physician, it is recommended that the sport physician is focused on the care they give to their athlete patients. Best practice may be difficult to determine in a young medical specialisation, where the nature of individual care and the demands upon athlete patients may appear ambiguous. It is not always clear how to interpret the best interests of the patient. Nevertheless, if sports physicians are to give their athlete patients the highest level of care they are able, to it is of the highest importance that they develop trusting relationships. Athlete patients who do not trust their sports physicians to act always in their best interest are unlikely to share with them such information as may help diagnosis, cure and prevention of athletic injuries and other deleterious conditions. In order to provide their athlete patients with the highest level of care, it will be necessary, therefore, for a clear separation of roles where possible between the sports physician, the athlete patient and the relevant third parties such as team coaches or managers; club owners, press officers; and those involved in team or squad selection. While this is not always possible, and while the sports physician may be burdened with a number of potentially conflicting roles, they should always seek to clarify and minimise such risks before the engagement of their services, consulting with colleagues and up-to-date sources of professional guidance [11550].

Athletes may rely on sports medicine physicians for guidance on performance-enhancing substances. The involvement of sports physicians with the “doping” of athletes dates back more than 100 years. Despite the fact that it is unethical to encourage the use of banned substances, there have been well-documented cases of physician involvement with the doping of athletes. Two prominent examples are the Ben Johnson steroid scandal at the 1988 Olympic Games in Seoul and the 1998 Tour de France scandal during which many riders were found guilty of doping with erythropoietin (EPO) and other drugs. Concerning illegal or banned substances, physicians and athletes are bound by the decisions of legislature and sports governing bodies. According to the FIGS, the use of banned substances is unethical and strictly forbidden because they may provide unfair advantages to the athlete and may cause harmful side effects. When counseling an athlete on illegal substances, the physician must respect the law and uphold the dignity and honor of the medical profession; hence, such information should be kept confidential but the physician should denounce usage. The use of legal, approved performance-enhancing substances is not necessarily unethical, but physicians must still proceed with caution. Physicians may counsel athletes about legal performance-enhancing substances provided they are not dangerous, but again this is a gray area. Are analgesics that enable athletes to continue participating while injured considered perform-enhancing substances? Some may say yes. Regardless of whether they are considered performance-enhancing or not, are they dangerous? In the short term, they are probably not, but long-term risks such as the potential acceleration of degenerative joint disease that may occur if the athlete returns to play while still injured are more difficult to quantify. However, physicians are ethically bound to discourage substances that are unfairly available to a limited population, which thereby violates the spirit of the rules of competition. The team physician’s first obligation is protect the player from potential harm, whether short term or long term, associated with performance-enhancing substances, whether illegal or legal. The physician should not terminate the relationship just because an athlete does not heed this warning. The physician should follow the health of the athletes and continue to inform them of the risks based on available scientific evidence, reminding them that it undermines the sport and is potentially unfair to opposing athletes. The physician should not sacrifice his or her own credibility by exaggerating the evidence to dissuade an athlete from using a drug; this would violate the basic tenant of the relationship – trust [07398].

2100
There is little data in India on the use of performance enhancing drugs in sports. But personal and incidental information shows that their use is far more extensive than is believed. This use occurs beyond the arena of high-level competitive sports. Even if the guidelines of the national and world anti-doping agencies were to become effective, they would not impact the larger environment where such drug use appears to be extensive. Which ethical guidelines advise the sports medical practitioner in prescribing medicines and training regimes for the athlete? Of particular concern is the role of paediatricians since training for sports or physical fitness is increasingly a youth phenomenon [13767].

Recent positive doping cases and a series of mistakes of medical doctors of the International Federation of Basketball have reopened the debate about the role of medical doctor in elite sport. This study shows that some sports physicians involved in recent positive doping cases are insufficiently aware of the nuances of doping regulations and, most importantly, of the list of prohibited substances. Moreover, several team doctors are shown to have exercised poor judgement in relation to these matters with the consequence that athletes are punished for doping offences on the basis of doctors' negligence. In such circumstances, athletes' rights are jeopardised by a failure of the duty of care that (sports) physicians owe their athlete patients. It was argued that, with respect to the World Anti Doping Code, antidoping governance fails to define, with sufficient clarity, the role of medical doctors. There is a need for a new approach emphasising urgent educational and training of medical doctors in this domain, which should be considered prior to the revision of the next World Anti Doping Code in 2013 in order to better regulate doctor's conduct especially in relation to professional errors, whether negligent or intentional [13768].

**The challenge of working in sports medicine**

All physicians are faced at some time with fundamental challenges while striving to respect the principle canons which define a physician's ethical code. These canons are:

- primacy of patient interests
- patient confidentiality
- informed consent
- maintenance of a high standard of care

Athletes, because of their focus on performance, often present unique situations which lead to ethical challenges not seen in the general patient population. Adherence to the four principle ethical canons guides physicians to make ethical decisions when dealing with these unique patients. Athletes as patients are a unique group of individuals who test the foundation of medical ethics and deserve special consideration. Olympic gold medalist Vince Matthews offered insight when he proclaimed “Twenty years from now, I can look at this medal and say: “I was the best quarter-miler in the world on that day. If you don’t think that’s important, you don’t know what’s inside an athlete’s soul.” The athlete patient is driven to perform and pursues the extremes of physical capacity to compete. Long term health may take on an importance secondary to achievement. After injury, he often searches for a quick fix to overcome a situation that compromises performance. Speed of recovery becomes a main priority. Extensive training also affords a unique knowledge of his own body, a factor that serves as an asset during medical evaluation and treatment. Respect for this awareness facilitates the decision making process. By nature, the athlete patient is usually very motivated and prepared to commit to a rehabilitation program, eager to push the limits of the healing process. A physician may be drawn into and caught up in this fan mentality or feel a
sense of obligation towards the success of the team that employs him. Ultimately, he must wade through these multiple roles of team employee, businessperson, and fan to focus on the principal role as a physician who is primarily concerned for the health of the patient. The National Collegiate Athletic Association Sports Medicine Handbook declares: “The team physician has the final responsibility to determine when a student-athlete is removed or withheld from participation due to an injury, an illness, or a pregnancy. In addition, clearance for that individual to return to activity is solely the responsibility of the team physician.” Legal precedent has protected this responsibility, citing college sport as a privilege and not a right. The advent of the widespread use and abuse of Performance Enhancement Substances (PES) has resulted in unique ethical challenges for physician and athlete. Advancements in medicine have produced chemical compounds capable of boosting physical performance. When disparities in talent are minimal, an intervention that provides an edge can mean the difference between victory and defeat. Much attention has been paid to drug use by athletes, and the list of banned substances in competitive sport is lengthy and growing. At first glance, the very notion of banning drug use appears to violate respect for autonomy. After all, the risks of using chemical enhancements are assumed entirely by the individual. “Greater risks for greater gains” is a philosophy familiar to competitive sport whether referring to individuals or game management decisions made by a coach. Rules of sport are arbitrary but together combine to define the activity itself. Performance enhancing drugs do not fall within the borders that have been determined as the court of play. While an argument made in this way is sufficient to justify the stance, it is somewhat unsatisfying. Adding substance to the dialogue is a philosophical perspective. The nature of sport is not only in the final performance but in the means to the capacity for such a performance [12486]

Environmental factors

To examine the ethical challenges of upholding patient confidentiality in sports medicine and the practical responses of clinicians to these challenges a questionnaire survey and follow-up semi-structured interviews were performed with the members of the British Olympic Association's Medical Committee and Physiotherapy Forum. Clinicians identified three contextual factors that influenced issues related to patient confidentiality in sports medicine: the use of confidentiality waivers; the facilities available for treatment; and the cultural norms of elite sport. They further identified interpersonal strategies used to lessen or eradicate conflicts, including emphasising the benefits and avoidance of disbenefits for athletes and the potential negative consequences for others. It was concluded that aspects of clinicians' practice environment should be designed to enable compliance with the highest levels of ethical conduct. Professional associations should establish guidelines for clinicians' interpersonal conduct in dealing with confidentiality issues and consider their provision of ethics-based continuous professional development. They should also petition for the establishment of athletes' codes of conduct which identify a context-relevant understanding of “serious harm” and how that might impact on information disclosure [13769].

Case reports of the doctor’s fault but athlete’s verdict

Recent positive doping cases and a series of mistakes of medical doctors of the International Federation of Basketball have reopened the debate about the role of medical doctor in elite sport. This study shows that some sports physicians involved in recent positive doping cases are insufficiently aware of the nuances of doping regulations and, most importantly, of the list of prohibited substances. Moreover, several team doctors are shown to have exercised poor judgement in relation to these matters with the consequence that athletes are punished for doping offences on the basis of doctors' negligence. In such circumstances, athletes' rights
are jeopardised by a failure of the duty of care that (sports) physicians owe their athlete patients. It was argued that, with respect to the World Anti Doping Code, antidoping governance fails to define, with sufficient clarity, the role of medical doctors. There is a need for a new approach emphasising urgent educational and training of medical doctors in this domain, which should be considered prior to the revision of the next World Anti Doping Code in 2013 in order to better regulate doctor's conduct especially in relation to professional errors, whether negligent or intentional [13776].

Rumanian gymnast

Notwithstanding collusion by physicians in systematic doping, the most important case of doctor fault in relation to doping offences was probably that of Andrea Raducan's case in the Olympic Games in Sydney, when she was stripped of her Gold medal after testing positive for pseudoephedrine which was contained in nurofen, a common over-the-counter anti-inflammatory medicine. Andrea Raducan, one of the greatest gymnasts of her generation, was born in 1983. She started to train at the age of 4, while by the time, she was 14, she represented the Senior Romanian team, and made her debut at the Sydney Olympic Games when she was aged only 16. In 1999, she won gold as an individual in the Floor Exercises and gold in the Team Event at the World Gymnastics Championships, and silver on the Beam. At the Sydney Olympics, she won gold in the gymnastics (artistic) women's team finals and won an individual silver medal on the vault. From 1996, she was under the control and direction of, among others, Dr Ioachim Oana, the Romanian gymnastics team doctor. During the competition at the Olympic Games, she reported a headache, a running nose and a feeling of congestion to Dr Oana, who prescribed and issued her a nurofen, an anti-inflammatory drug. He gave her a second nurofen tablet during the warm-up women's individual all-around event. She won gold in the gymnastics (artistic) women's individual all-around event. Subsequently, however, she failed a doping control, testing positive for pseudoephedrine and was stripped of her gold medal by the International Olympic Committee (IOC). Raducan said that she bore no responsibility for the antidoping rule violation (ADRV), since the nurofen pills were given to her by her team doctor with whom she had a relationship of trust, and that the pills had not been performance-enhancing. She competed weighing only 37 kg, a statistic that is important when considering the effects regarding the concentration of the drug. Nevertheless, because of the strict liability condition, the IOC antidoping panel and later the Court of Arbitration for Sport (CAS) were implacable. The World Anti Doping Code (WADC) makes it clear that there is no need to prove the intent to cheat via the use of performance-enhancing substances, but merely the presence of prohibited substances in the athlete's body is enough. Athletes have a duty to avoid the presence of such substances within their person. This is known as “strict liability”. The case generated a significant amount of media attention about the role of team doctor. The team doctor who administered the nurofen was banned for two Olympic cycles. It is noteworthy, however, that the then WADC and antidoping regulations did not precisely define the role of medical doctor. The situation persists today, though greater clarity exists of the role of physicians in relation to the therapeutic use exemption certificate for athletes who have a clinical need for substances that are simultaneously on the prohibited list (PL) because of their (potential) ergogenic or (potential) harmful effects [13776].

Serbian handball player

It was analysed four result management decisions done by the Antidoping Agency of Serbia and the International Basketball Federation (FIBA) in 2010 which involved team doctors: one regarding an international Serbian handball player and three doping cases of FIBA. An international Serbian handball player was tested positive in June 2010 for the substance of hydrochlorothiazide during in-competition testing at the French national championship.
According to his medical history, he had been treated by ACE inhibitors, calcium antagonists and diuretics since 2008 because of hypertension. The therapy is prescribed by a cardiologist from Belgrade, confirmed by the team doctor of the Handball Club Partizan, Belgrade, Serbia, and then by the team doctor of the Dunkerque Handball Club: HB Grand Littoral, Dunkerque, France, and finally by the team doctor of the Handball Club Kolubara, Lazarevac, Serbia. What is important here is that the player has been seen by various medical doctors. What is even more important is the player has informed French doping control officer during doping control about his use of the diuretic, which is on World Anti-Doping Agency’s (WADA) PL. Yet, there are hypertension treatments available that are not on the PL, a point that the physician ought to have been aware of. Nevertheless, the doping control officer did not put it on the list of medications the one the athlete had taken during the week prior to the control. What is clear here, that as an adult, the athlete themselves bears some responsibility (not just liability) to present themselves at competition in such a way that does not fall foul of the WADC’s regulations. Finally, the player was given a 10-month ban, while financial penalties were subjected to the two medical doctors by the civil courts in Serbia [13776].

**Russian basketball player**

Another case can be seen to fall somewhere between the cases of the handball player and Raducan in terms of the role played by sports physicians. A young Russian basketball player, committed an ADRV by the use of nandrolone. He had been treated by a Russian team doctor following two fractures (the instep bone of the right hand, and left fibula). The physician ought to have chosen another medication with similar effects that was not on the PL. In spite of this offence, the player argued that he had no idea that the injections contained substances on the PL, that he had not committed previously any ADRV, and that he was unable to properly give consent as a minor. Nevertheless, under the auspices of strict liability, he received a 1-year punishment while the team doctor received a lifetime ban from FIBA. What is further worthy of note here is the discretion of the FIBA panel. Had the doping offence been detected by, for example, a more lenient antidoping panel, it is not immediately clear that a 1-year sanction would be handed down, given the (fairly clearly) accidental nature of the ADRV from the athlete's perspective [13776].

**French basketball player**

The third case is that of French basketball player, who underwent an in-competition doping test in July 2010 in Zadar, Croatia, on the occasion of the France-Spain semifinal of the FIBA Europe U-20 Men's Championship. Upon being found to have committed a doping offence, he was handed a 1-month ban while there was no punishment for the team doctor concerned. The player had filed a declaration of use for ventolin (salbutamol) with the French National Anti Doping Organization (Agence Française de Lutte Contre le Dopage) (NADO (AFLD)). During the game, however, he suffered an asthma attack and was urgently treated by the team doctor (whom the athlete did not choose, but may reasonably have assumed, was familiar with the PL), with an inhaler containing terbutaline. The team doctor had treated him in the mistaken belief that the declaration of use covered all beta₂-agonists. The physician thus mixed different beta-agonists, and though sabutamol and terbutalin are from the same group, he did not use the drug that had been registered on the therapeutic use-exemption (TUE) certificate. This oversight caused the ADRV to arise in the doping control. Unsurprisingly, it was argued that the player bears neither fault nor negligence for this ADRV, since this was clearly a mistake by the team doctor and that he had committed no previous ADRV. Again, from the athlete's perspective, this is one of the difficulties of the WADC regarding strict liability [13776].
The fourth and final case to be considered is that of a Spanish basketball player, who underwent an in-competition doping test on July 2010 in Toulouse, France, after the end of the USA versus Spain quarter-final of the FIBA U17 Women’s World Championship. The analysis showed the presence of the prohibited substance chlorthalidone in the player's sample. Problems began for the athlete in spring 2010 when, it is alleged, she gained weight as a result of stressful school exams. The Spanish national team coach asked the player's parents to monitor her weight and initiate a diet with the purpose of rapid weight loss. After having unsuccessfully tried to lose weight, she was contacted by the team doctor of the Spanish Basketball Federation responsible for the U-17 Women’s team who recommended a supplement named “Obesity A”. It should be noted that a TUE would not normally be granted for this product. Upon joining the national team's training camp in early July, however, the team doctor asked her to discontinue taking the pills. Despite this, she continued using the drug, so it is clear that her doping offence could at best be considered careless and, at worst, a case of intentional doping. Upon committing the ADRV, she received a ban of 9 months.

**Regulations**

“Athlete-support personnel” (often called the “athlete entourage”) comprises any coach, trainer, manager, agent, team staff, official, medical, paramedical personnel, parent or any other Person working with, treating or assisting an athlete participating in or preparing for sports competition. The WADA code defines, in very general terms, the role and competencies of medical doctors in relation to doping in article 21.2:

- To be knowledgeable of and comply with all antidoping policies and rules adopted pursuant to the code and which are applicable to them or the athletes whom they support (article 21.2.1)
- To cooperate with the Athlete Testing programme. (article 21.2.2)
- To use their influence on athlete values and behaviour to foster antidoping attitudes. (article 21.2.3).

Finally, the code defines punishment of medical doctors in article 10.3.2. For violations of articles 2.7 (trafficking or attempted trafficking) or 2.8 (administration or attempted administration of prohibited substance or prohibited method), the period of ineligibility imposed shall be a minimum of 4 years up to lifetime ineligibility. An ADRV involving a minor is considered especially serious because of the failure of a heightened fiduciary obligation, and, if committed by athlete-support personnel for ADRVs other than specified substances referenced in article 4.2.2, shall result in lifetime ineligibility for athlete-support personnel.

**Aims of the regulations**

The central aim of the WADA code with respect to athlete-support personnel is that those who are involved in “physician-assisted doping” in a strong sense, or assisting athletes in masking doping practices should be subject to sanctions that are more severe than the athletes who test positive. The athlete is always responsible for any prohibited substance in his body (article 2.1) under strict liability, but the period of ineligibility shall be reduced or even eliminated if player can establish that they bear no fault or negligence. In line with strict liability, antidoping panels typically argue that players did not ensure that no prohibited substances enter their body, and because of this, they cannot shift their responsibility under the rules to support personnel. Nevertheless, antidoping tribunals may hold that a player's
negligence is not insignificant and that it is, therefore, appropriate to impose variable sanctions on them [13776].

Athletes are expected to bear most of the responsibility for taking medical drugs and supplements that are potentially performance enhancing, harmful, and/or contrary to the spirit of sport, yet sport physicians are responsible to athletes for questions regarding antidoping and medical care. If athletes cannot rely on the trustworthiness of physicians, particularly in relation to their competence regarding anti-doping regulations, then it would seem that their right to proper healthcare in the contexts of elite sports medicine is jeopardised. On the other hand, one can ask whether the supply of qualified sports physicians may dry up if colleagues are repeatedly found guilty of ADRVs [13776].

From another aspect, medical doctors are often seen to be held responsible by sport administrators, athletes and the general public. The main accusations made are, first, that some are engaged in “physician-assisted doping”, and second, that they supply athletes with doping agents, through carelessness. It has been shown that general practitioners’ (GPs) knowledge of prohibited substances in sport is poor. In one survey it was shown that only 53 percent of GPs were aware of banned drugs, and that 12 percent believed that medical practitioners were allowed to prescribe anabolic steroids for non-medical reasons. A Dutch study of 1000 GPs was even clearer: 85 percent of the respondents admitted that they were not familiar with banned drugs or their side effects. If, as in this study, doctors are the most common source of information for the athletes (61 %) then the situation become more problematic [13776].

What is also clear is that WADA are somewhat impotent in the process of disciplining members of the athletic entourage. National and International Sports Federations can apply sanctions to prevent doctors, physiotherapists and other healthcare professionals from working with individuals or teams. What is more likely to be effective is interagency collaboration between WADA, Institute of National Anti-Doping Organisations (or international antidoping organisations such as Europe’s CAHAMA group) in order to bring pressure to set international antidoping education guidelines. They ought also, however, to bear on individual healthcare professionals via their licensing associations. For the most egregious of infractions, the temporary revoking of licenses might be considered. This would not be without precedent. Indeed, the physician involved in that case, back in 1989 in Canada in the wake of the Ben Johnson incident, was held not to be fit to practice and had his licence revoked [13776].

**Legislative structures on enhancement**

With the development of highly sensitive drug testing technologies that can detect a minute quantity of a prohibited substance in an athlete's body, accidental contamination through contact with publicly circulated materials can more readily result in a "positive" reading. To discharge the burden of a positive finding, the athlete must show the “factual circumstances” in which the prohibited substance entered his/her system. In cases of accidental contamination, the athlete generally cannot even know how it occurred, as there are many known and unknown possible sources of contamination. When an athlete does give an account, it cannot generally be proven or disproven. Outside the realm of sports anti-doping, the use of scientifically established thresholds for drug testing is standard practice. Basic logic dictates that thresholds would enable one to differentiate between relevant and irrelevant amounts in the context of a possible sports doping offence. Such a threshold should be functionally motivated, i.e., enable the differentiation between relevant and irrelevant quantities in the context of a possible doping offence, rather than based on instrument performance limits [12487].
Since the early part of the 20th century, various sports organizations have employed an anti-doping policy, though it was 1967 when the International Olympic Committee first organized a Medical Commission whose primary role was to address the use of doping substances. The main concern of this committee involved the risks to health that doping entailed for athletes, which, expectedly, was also seen to diminish the values of Olympism. In particular, the televised death of Tommie Simpson in the Tour de France in 1967 began a cultural turn in how the doped athlete was represented. His image of a doped athlete has become characteristic of the abjection associated with unnatural enhancements, which sustains part of the political will surrounding anti-doping. In 1998, the Tour de France again was monumental in transforming this political landscape. The images of athletes under siege by police provoked the world of sport to rethink its approach to doping and the World Anti-Doping Agency (WADA) was born soon after. The current international standard for doping technologies is the World Anti-Doping Code, which indicates that two of three conditions must be met in order for a technology to be considered for prohibition from sport. These consist of the following:

- is the technology harmful to health?
- is it performance enhancing?
- is it against the “spirit of sport?”

It is widely recognized that determining whether these conditions are engaged is not simple and requires some form of discursive process to resolve. However, this process does not apply to all forms of enhancement technology, which are not considered in relation to the Code. For instance, when a new design element of a tennis racquet is introduced—such as the use of piezoelectric dampening technology—the anti-doping code is not engaged. Rather, the specific sport’s federation will consult its own guidelines on technical specifications to determine whether the innovation is acceptable.

Since its beginning, WADA’s role has been to harmonize policy and it has gradually worked toward independence from the International Olympic Committee at a time when the International Olympic Committee was under scrutiny for allegations of corruption. During this time, it has succeeded in working with UNESCO to develop a Convention on doping and its relocation to Montreal has been accompanied by renewed efforts from a range of countries whose recent actions suggest greater, rather than less controls over athletes’ actions. In particular, president George W Bush has included references to the “war on drugs” 2004 and 2005. The Hastings Center, has undertaken continual research in this area since the 1980s. In 2006, it was made first substantive intervention by concluding that the use of hypoxic environments (also known as altitude chambers) should be deemed an infraction of the WADA Code because they violate the “spirit of sport.” In 2003, the now infamous Bay Area Laboratory Co-Operative (BALCO) affair reminded anti-doping authorities that designer substances are completely unknown and it will be near impossible developing direct tests for them in advance. Indeed, the challenge of proving positive doping cases has been one of the major obstacles for anti-doping authorities. This challenge has also recently given rise to changes in the law, where the emergence of a nonanalytical positive—a doping infraction without the need for a urine or blood test—means that athletes now face possible disqualification (and sometimes prosecution) based on evidence other than unequivocal facts. These circumstances are also accompanied by an emerging willingness to criminalize doping infractions and to discuss doping as underpinned by an international criminal drug mafia. These terms reshape what is at stake in the issue of doping, transforming a matter related to fairness and ethics in sport to a moral panic over drug use.
Frequent battles occur between drug cheats, antidoping agencies, and the lawyers representing all sides. Elite sport has entered the world of forensics, where winners and losers of competitive events can be declared in the courtroom, not the playing field. Further, legal proceedings take months. Because of forensic procedures, the 2006 Tour de France will not declare a winner until months after the finish of the race [07153].

Evidence-based doping?

Evidence-based medicine makes an important distinction between statistical significance and clinical relevance: real effects may be too small to be therapeutically useful. This is very important in a clinical context; for example, cholinesterase inhibitors have a statistically significant effect on formal measures of cognitive function demonstrable in groups of patients with Alzheimer’s disease, yet individually many such patients and their carers do not notice an improvement, and treatment should continue only if worthwhile improvement is noted on an individual basis. When drugs are used in sport this situation is stood on its head, since a marginal improvement in performance (< 1 %), which would be extremely difficult to detect experimentally even in a randomized controlled trial, could nonetheless make the difference between winning and losing. None of the drugs used in sport (including anabolic agents, erythropoietin, human growth hormone, insulin, beta2-adrenoceptor agonists and others) have been convincingly demonstrated to enhance athletic performance, but this absence of evidence has not impressed contenders in the past half century and is unlikely to do so in future [12003].

Motherhood goes with gold?

Physiological actions of female sex hormones on muscle metabolism, and effects of increased blood volume and oxygen delivery are surely consistent with this possibility – although this is of course a far cry from definitive evidence. Despite this draconian instance, taking advantage of a natural physiological state such as pregnancy could hardly be called into question [12003].

Legitimacy of ban on cannabis and cocaine

The Olympic movement was the driving force behind the anti-doping efforts that led to the establishment of the World Anti-Doping Agency in 1999. A series of widely publicized doping scandals and public outrage in the nineties triggered this increasingly strong movement advocating doping-free sports. WADA aims at eradicating doping by harmonizing anti-doping practices worldwide from a zero-tolerance standpoint. It is backed by the UNESCO anti-doping convention, now signed by a majority of UN member states. These anti-doping efforts were recently dubbed “war on doping”, echoing the declaration of the “war on drugs” by president Nixon in 1971. These wars on drugs and on doping share various features, such as similarities between policies based on zero-tolerance, repression and surveillance, black markets controlled by organized crime, attempts to shape internationally harmonized legal frameworks, ideology and political convenience anchored in media-fuelled moral outrages. Furthermore, when WADA was established and drafted its first list of forbidden substances, the question rose on whether cannabis derivatives should be on the list. They were included largely because of pressure from the ‘war on drugs’ movement, even though there are no known proven performance enhancing effects but rather evidence for the contrary. Even
though only forbidden during competitions, regularly athletes are indicted because of urine traces of cannabis metabolites, which may remain measurable up to weeks after use. Cocaine metabolites are also regularly found and the public announcement of such cases often leads to important media coverage, strongly condemning the athlete, even if the substance was taken in a recreational context and not for sport performance enhancement. Whereas the “war on drugs” proved to be a failure and public debate is now slowly shifting towards finding better policies – based on public health principles – to deal with psychotropic drug use in society, in sport current policy is still essentially based on repression and surveillance from a zero-tolerance viewpoint [12012].

The complexity of anti-doping

Upon first glance the anti-doping rule may seem reasonable and simple, but when looking more closely at the consequences of the rule, questions arise. Some recent examples of indictments for doping, illustrating the complexity of anti-doping policy implementation, are given hereunder. Dwain Chambers, a famous British 100 m runner, tested positive for THG (tetrahydrogestrinone) in 2003 and was banned from competition for 2 years. The British Olympic Association, on the basis of a bylaw, excluded him for life from participation to the Olympics. The Court of Arbitration for Sports (CAS) overruled this decision in April 2012 after an appeal by WADA, opening the way for Chambers to compete in this summer’s Olympics. The case is illustrative for several reasons. First because of the substance THG. It was designed by a clandestine laboratory specifically for doping purposes, and by consequence unknown to the scientific community and anti-doping laboratories in particular. It was discovered when a coach sent a syringe containing traces of the substance to the USA anti-doping agency. Second because there are no published experimental data confirming the alleged performance enhancing effects of the substance. Third, since WADA convinced CAS to overturn the ruling of BOA on the basis of non-compliance to universally applicable WADA rules. And fourth, because of the strong condemning of this CAS ruling by many prominent members of the British sports-establishment which seemed to indicate that a doping offence is not seen in the same way as most other offenses in society; if in general, upon punishment for transgression of a rule, one is offered a second chance, a doping offense is deemed essentially unforgivable and worth exclusion of sports for life. As Sebastian Coe, chairman of the London Organising Committee for the Olympic Games, said: “I am clear cut on the Chambers case – I don’t think there is room for drugs cheats in sport” [12012].

Alberto Contador, a famous Spanish road-cyclist and Tour-de-France winner, was indicted in 2012 for trace levels of clenbuterol in urine samples obtained during the 2010 Tour. Several aspects set this case apart. First because of the long time it took to condemn Contador, contrasting his case with several other similar cases in other, perhaps less famous athletes. Second, the traces found were so low as to exclude any significant physiological performance enhancing effects around the time of sampling. Third, the excuse used by the defence: ingestion of contaminated meat. And fourth, the widely publicized rumours about possible blood doping as the source of the substance, by transfusion of Contador’s own blood, extracted and stored at an earlier time when doping, on the basis of traces of plastic residues in his blood, compatible with the use of blood bags and tubing, even though his blood parameters did not indicate blood doping [12012].

Christine Ohuruogu is a very successful British athletics sprinter who was suspended from competition in 2006, not because of doping, but because she missed three unannounced out-of-competition drug tests. She received a one-year ban for missing these tests, even though she was repeatedly tested at other occasions in the same period as the missed tests, without any adverse findings. This would rather indicate negligence on informing the
authorities on her “whereabouts” and not intentional doping-hiding behaviour. Nevertheless BOA initially imposed a lifetime ban from competing at future Olympics. Her Olympic ban was finally overturned in November 2007. Yanina Wickmayer is a talented young tennis player from Belgium whom end 2009 was initially suspended for a year by the Flemish anti-doping authority. She had failed three times to inform about her whereabouts upon entering the Women’s Tennis Association top-50 and by consequence becoming part of the athlete pool obliged to inform about her whereabouts. She was able to defend herself in a Belgian court, pointing out shortcomings and administrative errors of the official bodies overseeing her introduction to whereabouts obligations and had the ban overturned, allowing her to play again, but her image was probably tainted forever. But her case is not over yet. Even though WADA, claiming a 2-year suspension, has decided to withdraw its appeal against the Flemish anti-doping authority following the decision of a Belgian court to invalidate the authority’s decree, the procedure between the player and the Flemish Tennis Federation has only been suspended for the moment [12012].

Claudia Pechstein, a very successful German speed skater, was frequently tested throughout her long career, but never failed a test. On the basis of fluctuations in the number of young red blood cells in her blood (reticulocytes), she was declared guilty of blood doping in 2009 and banned from competitions for two years. This case is interesting because it was the first time that an athlete was considered guilty of doping on indirect evidence indicating the possible use of a substance that, in itself or its metabolites, were not directly identified. Perhaps the fact that Pechstein’s career started as an East German skater created a climate of suspicion because of state-organized doping practices in former East Germany. But in hindsight it is now highly likely that Pechstein’s higher than “normal” levels of reticulocytes result from a genetic anomaly, and are, in her case, physiological and not the result from doping. In all there remains considerable scientific doubt on the likelihood that Pechstein did indeed use forbidden substances or methods. The case also highlights the difficulties for the CAS to rule in such complicated cases, because of the entangling of scientific, legal, economical, political and personal interests [12012].

It was reviewed a series of cases of doping in tennis. There were 40 cases in the 5-year period 2003-2007, but in only 13 of these a prohibited substance was taken to enhance performance. In the other cases (68 %) it was accepted at independent hearings that there was “no intent to enhance performance” or “no (significant) fault or negligence”. Recreational drugs made up 40 percent of the cases (11 cases of cannabis, 5 of cocaine) [12012].

The ethics of anti-doping

There have been several sceptical challenges to the legitimacy of the antidoping position arising from both philosophers working in the field of medical ethics and sports ethics. They argue, typically, that the bans on certain performance-enhancing processes and substances rest on principles that are inconsistently applied. Sport, it is widely canvassed, is about healthy, natural and ethically regulated activity. The WADA itself employs three criteria, of which at least two must apply in order for a product or process to be proscribed: it should be performance enhancing; it should present an actual or potential health risk and it should violate the spirit of sport (WADC Article 4.3). Performance enhancement per se, is of course the heart of elite sport. The other criteria establish means by which it is unacceptable. In response, sceptics typically argue that:

- doping is no more unnatural than the muscle-bound and technologically saturated athletes and sports equipment, prostheses, and so on
- athletes who train harder do not coerce their opponents to follow likewise and doping should be thought no different
- doping is no more harmful than other legitimated behaviours such as punching in boxing, or brutal tackling in rugby or American football
- doping confers no more of an unfair advantage than is enjoyed by athletes or teams from economically or technologically superior countries/clubs/systems

A more passive case made by the antidoping lobby is that by failing to proscribe socially undesirable behaviours, it would celebrate bad role models and promote undesirable lifestyles. Such a stance is consistent with public health policies against smoking or the use of marihuana (even when the harmed are solely the users themselves). To this, the sceptics may argue that the undesirability of doping would be chimerical if antidoping rules were repealed and not forced upon athletes seeking only to optimise their own athletic potential while only (potentially) harming themselves. Each of these sceptical challenges has some merit. In addition, the ethical and legal legitimacy of doping control may diminish if undetectable gene technology comes into widespread use. Nevertheless, what deflects sceptical challenges is the fact that the sporting practice communities themselves have rejected doping through their engagement in the processes of the formulation of antidoping policies and practices [10270].

It has been argued that the risk to athletes' welfare provides the only legitimate ground for restricting the use of performance enhancing drugs in sport. In one paper, it was argued that the idea of "sport", properly understood, provides further reason to impose such restrictions. A "balance of excellences" argument is proposed whereby doping is considered objectionable on account of its disrupting the relation between the excellences around which sporting competition is organised. There are therefore reason to restrict the use of performance enhancing drugs in sport not only because of the threat they pose to athletes' health but also because of the threat they pose to athletes' displaying the relevant types of sporting excellences [11305].

It was offered criticisms of an earlier article where it was argued that there is no clear reason for thinking that doping in sport is morally wrong. It was sketched a view on which the risk profiles of different sports may make doping permissible in some and impermissible in others. Second, it was suggest that safety-based arguments assume that doping opponents are bent on harm elimination, rather than harm management. Society clearly thinks that some safety measures in sports, such as helmets in cycling, are reasonable. It may therefore be that limiting or eliminating doping is reasonable in the same way. Because sports involve different risks, there may be more reason to limit doping in some sports than in others, so that one cannot say generally that doping is permissible or wrong. There are several responses to make. First, one should note that the argument about safety did not assume that doping's opponents desire harm elimination. The argument was that since many sports tolerate substantial levels of risk related to usual practice and competition, and since many sports – or their characteristics that engender risk – are morally permissible, the fact that doping involves risks does not by itself show that it is morally wrong. Thus it may be happily conceded that harm management in sports is reasonable and even that it could include efforts to curtail doping. One need not regard something as morally wrong in order to restrict it: moral considerations are not the only grounds for rules. It is not, for example, clearly wrong to drink sugary beverages, but it may be reasonable to limit persons' access to them and to create a system of incentives (e.g. taxes) that reduces their consumption. There are a variety of reasons to ask whether doping is morally wrong per se. First, conventional attitudes about doping treat it as something that is deeply wrong rather than as something that is merely unwise. Second, current anti-doping strategies incorporate severe punishments for violators. But if a system involving such punishments is to be justified, a
moral justification should be required. It would be absurd to ruin athletes’ lives to promote their well-being, just as it would be absurd to imprison someone for a year because he failed to wear his seatbelt. A bit more might be said regarding the suggestion that doping may have a different status in different sports, depending on their other risks. First, it is unclear how or why the difference between sports would have this effect. Second, this strategy would represent a weakening of the anti-doping position. Even if we were to tie imprudence to wrongness, to hold that doping should be treated differently in different sports would surely mean that some instances of doping are (considering safety only) morally permissible. Moreover, if the complexity of risk assessments were fully embraced, one would probably find that some types of doping should be broadly permitted. After all, some performance-enhancing drugs are safer than others. Albuterol, for example, is relatively innocuous in comparison to anabolic steroids. And even the most dangerous drugs are probably safe when used in moderation. A touch of EPO – enough to raise one’s hematocrit from 45 to 50 percent, for example – might not be especially dangerous, even though a large amount of EPO is dangerous indeed. And though it would restore consistency for opponents of doping to argue that doping and more conventional risk-laden sporting practices are wrong because they are unsafe, this would be a costly retreat. It would, obviously, imply that society should disband or alter many popular professional sports, which is counterintuitive (indeed, this was the force of my reductio mentioned earlier). It might also have unsavory implications for other realms of conventionally permissible human activity. And it would require opponents of doping to overcome various argumentative hurdles, such as demonstrating that a certain degree of imprudence is morally wrong. Finally, the cost of abandoning a safety-based anti-doping argument is relatively minor: it is to concede not that doping is permissible but only that considerations of safety alone do not show it is wrong [11306].

Education in moral judgment of participants in team sports

The aim of one study was to investigate the effect of age and education on the moral reasoning of the same 535 individuals in sports for whom nature of sport experience was reported. All 535 participants (medium age 25 years3) were involved in sports at the time of the study as athletes (n=342), referees (n=145), or coaches (n=48), and had a wide range of education. Analysis of variance of scores on the Defining Issues Test of Rest showed moral judgment in sports differs significantly amongst different age groups and amounts of education. Generally, with more education, higher moral judgment can be expected. It is apparent that moral development in sport is related to age and education, as also holds for a wider social setting [06303].

Professionalism and the ethics of the sports physician

The physician working on the sidelines of a public sporting event may encounter a unique set of ethical dilemmas. Many of the ethical pitfalls result from the physician’s responsibilities, not only to the patient, but also to teams and events. Standard rules of confidentiality and patient autonomy may not apply. It was proposed using the concept of “professionalism” to fill the gap between the ethical standards of office practice and the modified ethical standards necessary to practice as a sideline physician. Professionalism in medicine demands adherence to principles such as honesty, integrity, reliability, responsibility, respect for others, self-regulation, and, above all, doing what is best for the patient despite outside pressures. A central tenet of most theories of professionalism involves the recognition of responsibilities not only to one’s self and one’s patient, but also to the profession itself. That is, each profession has its own character to maintain and defend. Indeed, much of allopathic
medicine’s power resides with its trusted and respected good name. In general, any factor that moves the physician away from the professional role as an objective medical expert using skills solely for the purpose of evaluation and treatment of the athlete presents a moral pitfall [06302].

Conflicts of interest: the need to minimize

Excessive ties to the success of a team, whether financial or not, may set up a conflict of interest, or at the very least the appearance of a conflict of interest. It is best to keep these to a minimum. For example, although cheering is a natural human reaction toward the team with whom you work, the physician must do everything possible to be and appear as an objective medical expert. When the physician becomes a fan, an investor, or simply rests his or her pride on serving as the team physician, one might begin to question clinical decisions that benefit the home team or burden the opponent [06302].

Need to recognize the limits of athlete’s autonomy

Respect for patient autonomy is a fundamental principle in bioethics that must be balanced against other fundamental principles such as beneficence, justice, and others. Although many bioethical issues arise out of a failure of physicians to respect patient autonomy, there are limits to the scope of choices appropriate to offer patients. Respecting patient autonomy means respecting the choices they make, not necessarily facilitating anything they want to do. The sideline physician may place tighter limits on the choices open to the patient/athlete than the office physician. These limits actually arise from an implicit agreement between the players and the team organization that gives the sideline physician significantly more control than an office physician over the patient/athlete’s actions, at least within the confines of the contest [06302].

The need to maintain informed consent

A number of common dilemmas facing sideline physicians hinge on the potential for outside pressures to compromise the patient/athlete’s right to informed consent. It is imperative that the sideline physician resist any temptation to deviate from the rules of informed consent as it is routinely practiced. The necessary conditions for legitimate, informed consent as it pertains to the sideline physician are that all relevant information that a reasonable person in this player’s position would want to know regarding the proposed treatment, nontreatment, and alternative treatments must be explained to the player in an appropriate fashion and that players must have the capacity to understand this information and appreciate how it applies to them [06302].

Confidentiality in doping

Normally, physicians respect patients’ confidentiality except in rare instances of mandatory reporting laws or imminent danger. However, in the role of the physician covering the team, the scope of confidentiality is not nearly so broad. The dilemma set up by the physician’s competing obligations to both maintain patient confidentiality and serve the team administration can be mitigated. By informing athletes in advance that, unlike a standard
doctor-patient relationship, confidentiality may not be guaranteed, the physician discloses his or her obligations and lessens the dilemma. Critics of this approach might argue that such warnings will ultimately prove dangerous for athletes. That is, informing athletes that information may be forwarded to the coach could result in the dangerous under-disclosure of pertinent medical history. For example, many athletes may be reluctant to reveal a history of concussions – or doping – if aware that it may bar them from competing. Not knowing which facts may be revealed to the coach, athletes might withhold sensitive or embarrassing information that may be very relevant to their general health [06302].

It should come as no surprise that healthcare professionals have been engaged in unethical conduct in sports and notably with respect to doping. This is true in such famous events as the Tour De France and in less elite and sometimes adolescent cases. Although no one suspects that these interventions are the norm, the pressures in elite sports and the money that is often at stake render it likely that the temptation to medically assist doping will always remain. The work of every healthcare professional is guided by ethical considerations over which their relevant professional body has legitimate governance. Doping has itself been the object of discussion over a number of years within sports-related healthcare professions, such as the British Association of Sport and Exercise Medicine, the International Federation of Sports Medicine (FIMS), the Association of Chartered Physiotherapists in Sports Medicine and the International Federation of Sports Physiotherapy (IFSP). Most have publicly declared the unacceptability of doping in position statements. Advice regarding what professionals may and may not do with respect to doping forms a part of their clinical professional guidance. The sources of guidance vary for the healthcare professional working in sports medicine from their profession to the World Anti-Doping Agency (WADA). There may be a potential conflict in the duties of a healthcare professional who cannot simultaneously serve the patient's best interests while disengaging from giving advice regarding doping behaviours. In such a dilemma, the healthcare professional may either find that they are culpable of a doping offence or, in disclosing the confidential information of such, be "struck off" from their respective profession. However, the manner in which healthcare and medical professionals serve their athlete patients is governed by a variety of relevant codes of conduct. A range of codified rules is presented that refer both the welfare of the patient and the maintaining of confidentiality, which is at the heart of trustworthy relations. The 2009 version of the World Anti-Doping Code (WADC), however, appears to oblige all healthcare professionals not to assist athletes if they are known to be engaged in doping behaviours under fear of removal from working with athletes from the respective sports. In contrast, serving the best interests of their athlete patients may oblige healthcare professionals to give advice and guidance, not least in terms of harm minimisation. Although there are nuanced differences among these rules in relation to various aspects of professional performance, there are also easily discerned shared commitments. Among them, the following are of particular significance:

- human dignity
- protection of health and safety
- confidentiality and privacy
- informed consent
- duty of care.

Thus, according to the UK Health Professions Council (2008) – for example, the duties of a registrant demand that

1. you must act in the best interests of service users.
2. you must respect the confidentiality of service users.
3. you must behave with honesty and integrity and make sure that our behaviour does not damage the public's confidence in you or the profession

In a similar vein, the UK General Medical Council advises its members to

- make the care of your patient your first concern
- protect and promote the health of patients and the public
- respect patients’ right to confidentiality

In so far as the professional conduct of a healthcare professional is guided both by professional code and World Anti-Doping Code (WADC), they are obliged to fall foul of one or the other. It was called for urgent and pressing inter-professional dialogue with the World Anti-Doping Agency to clarify this situation [11307].

The 2009 World Anti-Doping Code which is the second version, has been accepted by >100 member states of the UNESCO. Its scope is greater than that possessed by the previous two. Although the processes of its development incorporated widespread consultation, certain aspects of its regulatory framework have brought considerable opposition. One aspect of the WADC not commented upon is the tightening of regulations relating to the medical support team. The rationale for this tightening is well founded. Clearly, where doping was widespread in some sports, it was not the effect of isolated individuals trying to gain illicit advantage. Rather, access, prescription, dosage and removal of doping products/processes were the object of systematic organisation and control by the sports support system that included doctors, physiotherapists, sports massage therapists and coaches/managers. Clearly, then, in attempting both to deter and, where necessary, punish members of the support system, greater attention was required to call to account the full range of individuals contributing to the doping offence. The section of the code stipulating antidoping violations was therefore modified to include the following article, relating specifically to administration of banned substances by a third party. The offence carries with it certain prohibitions that should be put into effect by the relevant sports bodies themselves. WADA has no jurisdiction to punish sports medicine professionals. Two issues arise here. They both relate to the jurisdiction of governance. First, there will be variability as to how any particular professional body will implement the sanction to practitioners in breach of WADC. Other countries will also vary in their interpretation and application of the rule(s). International harmonisation of responses here is unlikely to be achieved, although one might ask whether global bodies such as FIMS or IFSP, or indeed the World Medical Association or the World Congress of Physical Therapy ought to take a policy lead for the sake of consistency. Only bodies who are signatories to the WADC are likely to implement its sanctions. Second, WADA recommends, although it has no power to do more than this, that the offending individual be banned from working with athletes within that body. (It is not, however, possible to ban them from all sports-related assistance. The scope of the ban refers predominantly to the sports governing body in which the offence emerged, though it extends to all signatories). At first sight, this appears to be precisely the kind of regulation required to capture fully the offending parties in the sports medicine community. On closer inspection, however, the list of verbs that enunciate the sanctionable offence may give rise to considerable professional and ethical concern. It is worth citing the list of verbs: “assisting, encouraging, aiding, abetting, covering up or any other type of complicity involving an anti-doping rule violation”. Each of these verbs can be used to capture wrongful conduct for which a sanction may be applied. Take one example from the list to serve as an illustration of the problem faced by the healthcare practitioner: What precisely is “aiding and abetting” to be taken to mean? There is no particular legal or medical meaning of these terms. Courts, no less than healthcare professionals, must use the everyday meanings of these words, which are open to considerable ambiguity and interpretation. A number of everyday scenarios might reasonably
be envisaged, therefore, that would render the healthcare professional vulnerable to a charge of "aiding and abetting" a doping offender. For the purposes of illustration, we shall now discuss one such difficulty in terms of conflicts of duties in a realistic hypothetical scenario. Perhaps the most widely shared healthcare or medical norm is that of serving the patient's best interests while, ceteris paribus, respecting their autonomous decision-making as to the nature and means of any professional intervention. Thus, the healthcare professional, in line with the recent urgings of medical ethicists and sports medics, is deeply concerned with the health of the athlete in their care (understood as their patient). Therefore, in line with general medical norms of respect for autonomy and acting in their best interest, they would consider it important that the athlete comprehends any information and advice imparted. Now imagine further that a patient informs the healthcare professional that they have, for example, been using off-label performance-enhancing products using the information on the web to determine their own dosages and cycles. Then they approach the healthcare professional, concerned with what they perceive to be a moderately serious condition. Let us imagine that our hypothetical healthcare professional is committed to doping-free sport. Nevertheless, healthcare professionals also feel compelled to make their patient aware of the potential consequences of inter alia continued use, lowering doses, arranging cycles in the least harmful way and doing their best to persuade the athlete to cease their doping practices. All to no avail, the apparently well-informed patient argues that it is their body and no one else's that is at risk, and that they deem continued doping a risk worth taking. To cap it all, they state in no uncertain terms, that the professional may, under no circumstances, inform third parties regarding the consultation. They threaten legal action if this route is taken by the healthcare professional. Every healthcare professional is thus charged with serving the best interests of their patient. Part of this will entail respecting patient autonomy by imparting the relevant information and advice. An hypothetical colleague appears to have met this obligation by informing the patient of dangers and recommending the cessation of doping. However, there is an obvious difficulty in what to do with this information, or "guilty knowledge." Are the best interests of the patient served by releasing this information into the public domain? The client has forbidden this possibility and the healthcare professional is properly aware of their duty to respect the patient's autonomous decision-making. It is at this point, mindful of their differing frameworks for professional governance, that the relevant codes are consulted [11307].

Patient confidentiality

A variety of ethical questions may have arisen in the mind of the committed antidoping healthcare professional. Should they deliberately overestimate risks in their communication to their patient? With whom, if anyone, should they share the information? Should they write up the notes in full or fail to document incriminating data? Should they leave such notes, full or otherwise, in the purview of others who might discover them? It might be concluded that the duties of care and of confidentiality appear to have priority. The sources of the duty of care, of which confidentiality is a key part, are threefold. They may arise individually or jointly from contract, law or professional codes. Recall that the second duty of a healthcare professional as stated by the UK Health Professions Council is to the confidentiality of patient data, i.e. you must treat information about service users as confidential and use it only for the purposes they have provided it for. You must not knowingly release any personal or confidential information to anyone who is not entitled to it, and you should check that people who ask for information are entitled to it. You must only use information about a service user to continue to care for that person, or for purposes where that person has given you specific permission to use the information. Patients also have a right to expect that information about them will be held in confidence by their doctors. Confidentiality is central to trust between doctors and patients. Without assurances about confidentiality, patients may be reluctant to
give doctors the information they need in order to provide good care. If you are asked to provide information about patients you must:

- inform patients about the disclosure, or check that they have already received information about it
- anonymise data where unidentifiable data will serve the purpose
- be satisfied that patients know about disclosures necessary to provide their care, or for local clinical audit of that care, that they can object to these disclosures but have not done so
- seek patients’ express consent to disclosure of information, where identifiable data are needed for any purpose other than the provision of care or for clinical audit – save in the exceptional circumstances described in this booklet
- keep disclosures to the minimum necessary
- keep up to date with and observe the requirements of statute and common law, including data protection legislation

Patients should be able to expect that information about their health, which they give in confidence, will be kept confidential unless there is a compelling reason why it should not. There is also a strong public interest in maintaining confidentiality so that individuals will be encouraged to seek appropriate treatment and share information relevant to it. Therefore, in the prosecution of this advice, everything is going to hang on whether there is a “compelling reason” to disclose the doping athlete patient. Yet it is far from clear what might constitute this. On the one hand, it might be said that preventing a star athlete from gaining gold, thus depriving other athletes (presumably clean) of their right to a fair contest, was compelling. However, the contrary position could also be argued. Thus, it might be argued that the dishonour brought upon relevant others by a potential doping scandal was compelling, although again a counterargument is also fairly obvious. Writing a professional code of conduct is not a task for the faint-hearted because it requires the author(s) to envisage the unlimited variety of contexts that may standardly apply in the patient–professional encounter.

Thus, rules for disclosure against the general prohibition have been made. It is a widely accepted norm that information may be shared within a healthcare team to provide treatment that is in the best interest of the patient. However, the information shared should proceed on the authorisation of the patient, in line with their conception of best interests. Against the general norm for confidentiality, disclosure may be justified:

- where to withhold it would be to put others at “risk of death or serious harm”
- that those who receive disclosure – subject to the above condition – are bound by confidentiality to
- that it may be justified in a medical emergency.

It is thus argued that there is a tension with regards to a variety of professional codes and the new WADC. Insofar as healthcare professionals must serve the best interests of their patients, they must inter alia give advice and information as to the health choices of the doping athlete as well as respecting the privacy of the clinical encounter where doping choices may be revealed. Although it may be difficult to harmonise codes that cater for a variety of professional labour, dialogue between WADA, (inter)national sports governing bodies and relevant (inter)national healthcare professions is urgently needed to protect healthcare professionals who are committed both to their clients, their own and their employers’ requirements for doping-free sport. Clearly, more precise guidelines on how such conflicts will be interpreted by both WADA and the relevant bodies should be made public to prevent professional dilemmas such as this from occurring [11307].
Fairness in sports

What does it take to keep sports fair? And what does fairness require? It’s easier to see what’s unfair in sports. Among the countless differences between competitors, from eye color to favorite food, only certain differences are meant to be highlighted in each particular sport. Successful short-track speed skaters possess explosive strength and finely honed technique. Each sport calls upon its particular mix of physical talents. Every sport requires the commitment to perfect those talents and to learn how to employ them skillfully and strategically. It may not be easy to say exactly what fairness means, but the ease with which we can call out unfairness suggests that the task is worthwhile and far from hopeless. Talent and dedication determine the winner. The varieties and degrees of impairment among Paralympians in no way detract from the talents and dedication that competitors bring to the games. But the variety also requires that the playing field be made level so that every athlete is competing against people with similar levels of impairment. In that way, talent and the many things we admire about dedicated athletes are on display and shape each athlete’s performance [10268].

The first thing to note is that a fair sports competition does not require that athletes be equal in every imaginable respect. Some basketball players are taller, stronger, quicker, or more agile than others. No one regards such differences in natural talents as unjust or unfair. Some have better coaches or more favorable training environments. At what point such differences cross the line from inevitable and acceptable to iniquitous and deplorable is something to be debated and settled by the people who participate in, understand, and love that sport – not by distant and disinterested philosophers. After initial dithering, the Fédération Internationale de Natation (FINA) – the international governing body for swimming – last year banned many suits on the grounds that they changed the nature of the sport by allowing bulky athletes to float on top of the water rather than having to push through it. Whatever one thinks of FINA’s ruling, it was right to focus on the meaning of the sport and on what characteristics lead to excellence and success. Then again, the most gifted, hardest-working athlete or team does not always win. A random bounce, a slip, a hesitation can give victory to the side that might lose nine of ten matches. That’s why we play the game [10268].

When it comes to performance-enhancing drugs, gene doping, and the panoply of manipulations banned widely in sports, the challenge is less about fairness than about meaning. If the rules ban performance-enhancing drugs, then using those drugs to gain an advantage over athletes who refuse to cheat is unfair. Antidoping skeptics, however, often proclaim that the problem isn’t with the drugs, but with the ban on drugs. It would be fairer, they argue, to give all competitors access to the same drugs. If everyone had ample supplies of anabolic steroids, erythropoietin, growth hormone, or whatever drugs boosted performance in their sport, then – they claim – unfairness would be eliminated along with the nuisances of drug testing, adjudication, and enforcement. One response to the skeptics is to ask a different question: Is it not unfair to put the athletes who want to compete without drugs or gene doping at a competitive disadvantage by permitting everything – to tilt the playing field in favor of the drug users [10268]? Any serious ethical commentary on the uses of performance-enhancing technology in sports must confront two compelling realities. First, sports science has provided a great deal of information about how to optimize training and performance. It has also led to a plethora of technologies and methods to enhance performance, from altitude chambers that allow athletes to gain the benefits of “training low, living high,” to ice-filled vests runners can wear before a long race to cool their core temperatures, to esoteric measurements of muscle and organ function. Why, the skeptics ask, should we distinguish between these technologies of
performance enhancement on the one hand and drugs like steroids on the other? Part of the answer to this challenge is to recognize that sports are about what can be accomplished under specific limitations. Soccer players, other than goal tenders, may not use their hands or arms to direct the ball, even when that would be far more convenient and accurate than one’s foot or head. Golf imposes strict limits on balls and clubs. Marathon runners may not use wheels, whether attached to their shoes. The other piece of the answer requires an understanding of what that particular sport values. What makes a great weightlifter does not make a great distance runner. Bodies that possess massive explosive strength are rarely the lithe, sinewy bodies best suited to run great distances. The limitations each sport chooses for itself reflect a shared understanding of what that sport is meant to display and reward. The rules of sports are arbitrary in the sense that they could be otherwise, and, in practice, sports modify their rules in response to changes in equipment, tactics, and athletes’ abilities. But in another sense, the rules and the changes wrought in them are far from arbitrary: they must pass muster with the community of those who play and love that sport. The community must be satisfied that the new rules keep alive what it values, what natural talents enable athletes to excel, and what, in the end, is meaningful about participating and winning [10268].

One proposed solution is to continue to ban some drugs – those deemed to be particularly harmful – but allow athletes free reign to use all others. Consider what is likely to happen. We’ll continue to need drug testing and enforcement to deter athletes from using the substances on the banned list, so all the complaints about the inconvenience and intrusiveness of testing will remain. And now athletes will feel pressured to take ever more drugs, often at higher dosages, in untested and possibly dangerous combinations. It’s hard to see that scenario as progress. Whether performance-enhancing drugs or gene doping should be permitted in sports is, in the end, a matter to be decided by the communities of athletes and those who understand and love each sport [10268].

**Criticism of the fairness of the testing procedure**

The stated mission of the World Anti-Doping Agency (WADA) is “to lead a collaborative worldwide campaign for doping-free sport”. This is (arguably) a laudable goal but a vociferous group of analytical scientists is far from satisfied with efforts to achieve it, questioning the effectiveness of anti-doping programs, the injustices created in their implementation, and the non-collaborative approach that WADA has taken. Current practice is not state-of-the-art; sub-optimal methods are being used for data analysis. Instrumentation is not the problem. What is being done with (or to) the measurement results, that’s the problem. The criteria for a positive result, that is, the decision limits, are not statistically underpinned. There is not a single test for which the risk of false-positives and false-negatives is known. The whole system is closed, which is maintained under the auspices of independent accreditation bodies. There is a lot of confirmation bias (the tendency to favor information that confirms your beliefs), under the guise that “every athlete is guilty, we just can’t prove it.” Evidence-based studies in respect to sport performance-enhancing effects and health effects are often missing. They may be under- or overestimated, but because of a lack of adequate studies, this can’t be confirmed or denied.” Unfortunately, anti-doping control does not solve the problem of doping, but rather shifts it to the abuse of sometimes more dangerous substances. Pharmacological substances still under investigation, not yet approved for clinical use, or even disapproved for clinical use, are becoming of interest. Given that the latest doping drugs are designed to be undetectable, the historical (and very long) list of prohibited substance must be constantly updated and evaluated. The list of prohibited substances and methods originated in the 1960s, without clear objective reasoning. Only afterwards was the reasoning objectified, with criteria written to extend the
list. In the early days, the list was evaluated and extended by the International Olympic Committee (IOC) mainly based on scientific grounds, but WADA’s current list is also influenced by political arguments. Politicians have more influence on WADA than they ever had within the IOC, because they finance 50 percent of WADA’s budget. For that reason, a relatively low threshold for a cannabinoid was maintained on the prohibited list longer than could be justified scientifically. Only very recently, was its low threshold upgraded from 15 ng to 150 ng/ml of urine. Analytical science is not infallible, indeed margins of error must be tolerated in all scientific data. For athletes, false positive tests for doping are a huge concern (while the “victims” of false negative results are unlikely to complain). Our panel holds that athletes who challenge a test result are treated unrighteously. Anti-doping regulation is such that the laboratory result is assumed to be reliable. One can only appeal on procedural grounds, that is, was the test properly carried out? As long as the principle of strict liability is applied to athletes (meaning that they are responsible regardless of whether they were aware or not), “fair” has a very special meaning. This is especially so if one measurement and, in theory, even one molecule, is enough to sanction an athlete. Anti-doping authorities reveal as little detail about their analytical strategies as is legally required because of potential abuse of those details by dishonest athletes. Thus, the anti-doping authorities hide themselves behind regulations, which they themselves set up and write. Thus there are several part of the procedure worth criticism:

The WADA mission

Before changes can occur at the laboratory and analyst level, there must be changes at WADA. This can begin with the mission statement: WADA and its accredited laboratories must only be concerned with monitoring those substances that can have a positive effect on athletic performance. For example, can it be clearly shown that marijuana use positively affects athletic performance? Also, there must be established cut-off levels for every banned substance. Below these levels, any indications of their presence should be considered neither capable of improving performance nor an indication of an athlete’s intention to cheat. For example, traces of clenbuterol were found in a urine sample from the cyclist, Alberto Contador. Whether these traces were or were not the result of eating meat obtained from Spain should not be the question. More importantly, about 50 percent of the convictions are questionable because thresholds are not being applied. The use of party drugs outside competition is expressly allowed in anti-doping rules; it is the negligible trace found in-competition that leads to a conviction: “Drink a few alcoholic beverages on Friday and played a match on Saturday? Not a problem, because there’s a threshold for alcohol. Smoked cannabis on Wednesday, and played a match the following weekend? Positive test and a sanction!” In theory, athletes are stakeholders of WADA and therefore have influence on the development of regulations. In practice, they are not well organized or well represented.
Analytical scientists within anti-doping laboratories also limit themselves to regulations and claim that it is not their task or responsibility to sanction. However, if analytical progress is pushing identification limits lower and lower, the science will play an increasingly important role. Analytical scientists are also stakeholders in WADA and can exert their influence and provide proper advice – while doing so, they should keep the dilemma of fair chance in their minds. This is a social responsibility, rather than their analytical responsibility [13778].

Sport and the history of ethics in sports medicine

Sport has always played an integral role in society and naturally serves as a vehicle for education, health, leadership and fair play. Fairness is one of the core principles of sport and can be a metaphor for everyday behaviour in life and communities. Whether the principle is adhered to depends on how the sport is managed, taught and practised. Sport has clearly become a global enterprise as well as a recreation for billions. In the early Olympic Games, victors were crowned with wreaths from a sacred olive tree and marched around the grove to the accompaniment of a flute in the admiration of the crowd. Nowadays, athletes can demand lucrative sponsorship contracts and appearance fees, and within moments of their triumph, their faces are found plastered on billboards and advertisements around the world endorsing some product or other. International sport dates back to the 19th century, and the commercial exploitation of sport is even older than that. What is new is the degree of commercialisation and its spread to the emerging markets. As a result, the value of victory in monetary terms has never been greater. The pressure on athletes to win has increased considerably and so too have the demands on sports-medicine doctors to facilitate these victories through fair means or foul [10269].

The adversarial relationship between sporting performance and patient welfare is not a new phenomenon and stretches back to early Greek and Roman civilisation. Aelius Galenus, one of the forefathers of sports medicine, served as a physician to the gladiators in Pergamum in AD 157. In this capacity, he learnt the importance of diet, fitness, hygiene and preventive measures, as well as living anatomy and the treatment of fractures and severe trauma. His fastidious attention to gladiators' wounds resulted in a significant reduction in the mortality, when compared with his predecessor. In spite of this, he argued vehemently against the immoderate lifestyle of athletes and their obsession with victory, which he believed was unhealthy and potentially dangerous behaviour. He wrote a small work called 'That the Best Physician is also a Philosopher,' and he saw himself as being both. His theories dominated and influenced Western medical science for well over a millennium [10269].

When there are conflicting principles it is not always easy to decide which principle should dominate. The principles framework does not take into account the emotional element of human experience. Another approach to bear in mind is the concept of virtue ethics, which emphasises the character of the practitioner, or moral agent, as the key element of ethical thinking. This approach holds that morality stems from the identity and/or character of the individual, rather than being a reflection of the actions of the individual. Once again, much of the teaching on virtue ethics is derived from the ancient Greek philosophers. Aristotle believed that a virtue lay at the centre point between two divergent vices and referred to it as "the mean by reference to two vices: the one of excess and the other of deficiency." Courage, for example, lies between foolhardiness and cowardice. Compassion lies between callousness and indulgence. Plato believed in the Four Cardinal Virtues; wisdom, justice, fortitude and temperance. Beauchamp and Childress considered there to be five virtues which were applicable to the medical practitioner: trustworthiness, integrity, discernment, compassion and conscientiousness. Yet, there is no comprehensive list of virtues. The
Scottish philosopher, MacIntyre, believed that any account of the virtues must indeed be generated out of the community in which those virtues are to be practised. His approach also seeks to demonstrate that good judgement emanates from good character. The application of virtue ethics to the sports medicine field may have some advantages over the principles approach. It considers the motivation of the team doctor (agent) to be of crucial importance. Ethical decision-making hinges on the characteristic virtuous disposition of the team doctor who typically wants to behave well and in the best interest of the player. As there are no strict rules to be obeyed, it permits the adaptation of choices to the particulars of a situation and the people involved. This flexibility promotes creative thinking and problem solving to deal with complex dilemmas. In applying virtue ethics, it is important to be aware that tragic dilemmas can rarely be resolved to the complete satisfaction of all parties and that any conclusion is likely to leave some remainder of pain and regret [10269].

Multiple obligations

Multiple obligations are most obvious when sports medical practitioners have an employment relationship that places demands on them while traditional obligations to their patients remain. For example, the desire of the coach to succeed can result in pressure on a sports medical practitioner to return an athlete to the field of play before medically indicated. Here the medical practitioner has an obligation to his employer, but also to the athlete. However, individual sports physicians varied in their perceptions and management of the complexity of their environment and their multiple obligations [09386].

As an employee, a sports doctor has obligations to their employer, but also professional and widely accepted obligations of a doctor to the patient (in this case the individual team member). The conflict is evident when sports doctors are asked by an athlete to keep personal health information confidential from the coach and team management, and yet both doctor and athlete have employment contracts specifying that such information shall be shared. Recent research shows that despite the presence of an employment contract, there appears to be a wide range of behaviours among sports doctors when an athlete requests that information about them be kept from team management. Many seem willing to honour requests to keep health information about the athlete confidential, thereby being in breach of the employment contract, while others insist on informing team management against the wishes of the athlete. There are a number of potential solutions to this dilemma from forcing doctors to meet their contractual obligations, to limiting the expectations of the employment contract. One paper suggests that at times it may be appropriate to do both, making the position of the doctor clearer and supporting the ability of this group to resist pressure by coaches and management through having a robust code of ethics [08445].

Attitudes on anti-doping

The aim of one study was to determine if there is a relationship between attitudes toward doping and achievement goal orientations of athletes. Questionnaires from 830 athletes (including 263 females) were obtained. Athletes declared moderately positive attitudes, with attitude toward anti-doping controls as the strongest and attitude toward sanctions as the weakest. Females declared significantly more favourable attitudes than males. With respect to the relationship between goal orientations and attitudes toward doping, it was found that athletes who were high task/low ego oriented declared the most favourable attitudes, while athletes who were low task/high ego oriented declared the least favourable attitudes. Multiple regression analyses confirmed that ego orientation was significantly negatively related to,
and task orientation was significantly positively related to attitudes toward doping. It means 
that with the increase in task orientation, attitudes toward doping became more favourable. 
The opposite can be said about the increase in ego orientation. It could be argued then, that 
creating a motivational climate which promotes task orientation (mastery climate) may aid 
anti-doping efforts [08446].

**Hypotheses on background of doping**

There is no reason to expect fundamental differences in the cognitive or motivational process 
involved in the athlete’s decision cycle whether it deals with acceptable performance 
enhancing or doping methods. Both need a sustained, motivated, goal-directed action. The 
difference is brought about by the current convention of the sport, in particular whether or not 
the method is deemed to be acceptable or unacceptable in it [08447].

Strelan and Boeckmann’s model of hypothetical doping use posits that personal moral beliefs 
and health concerns act as preventing factors, whereas drug testing and sanctioning have 
little deterrent effect [08448]. Interestingly, in a search for predicting factors of steroid use, no 
significant difference was found in the characteristics of the steroid users and those who 
were offered but reportedly declined the drug [08005]. Availability or access to performance 
enhancing drugs is perceived by athletes as a barrier they must overcome if they are 
determined to use such means [08449].

The degree of rationality in doping decision making is highly debated. Economic models of 
doping mainly assume that athletes act according to economic rationality. The literature in 
this area [08442-08446] considers doping as a special case of a “prisoners’ dilemma”, where 
one actor’s action has consequence for both actors and the best collective strategy is difficult 
to reach due to lack of information on, and trust for, the other actor’s decision. To translate 
the dilemma into sports, athletes’ best case would be to compete at doping-free events. 
However, the widespread suspicions and speculations about other athletes’ possible actions, 
coupled with the lack of information about the others’ doping behaviours have the potential to 
bias most athletes in favour of doping: game-theoretic modelling suggests that the majority of 
competitors are likely to see doping as their best option and, under certain circumstances, 
the only feasible strategy to ensure winning [08450].

Whilst economic models of doping have ignored individual dispositions toward doping when it 
comes to decision making, they emphasise the importance of a broader situational context, 
within which decisions are not only made on individual preferences but in consideration of 
others’ actions. Existing behavioural doping models have made attempts to incorporate 
personality, decision making rationality and situational context, including peer group and 
subculture influences [08451-08457].

The widespread medicalisation of life creates an environment in which using medical or 
chemical assistance to life is widely accepted and normal. Many athletes believe that they 
need assistance in order to cope with the physical demand of training, workload, injury and 
recovery. Under the current anti-doping regulation, athletes may turn to performance 
enhancing methods and substances that are not prohibited in order to eliminate the risk of 
being caught, play by the rules and conform to the ethical or moral principles imposed on 
them by their social environment [08458].

One of the more sensational and oft-cited studies in the sports medicine literature and 
popular media on doping in sport is the Faustian bargain offered by Goldman’s dilemma. In
Goldman’s dilemma, elite athletes are asked if they would take a drug that guaranteed sporting success but would result in their death in 5 years time. The first iteration of Goldman’s dilemma was posed to 198 world class athletes in 1982 in which 52 percent (103/198) answered in the affirmative. Goldman continued to pose evolving and improved variants of the initial dilemma and expanded the subject pool with bi-annual surveys from 1982 to 1995. Goldman notes the results have been the same each time the study has been run; approximately half of the athletes accept the deal to take the drug and win, but die within 5 years. It was now again tested the Goldman’s dilemma on a general population sample by asking whether they would take the Faustian bargain of a drug that guaranteed sporting success but would result in their death in 5 years’ time. Between 1982 and 1995 a bi-annual survey using this dilemma suggested half of all elite athletes would take the drug. Respondents were presented with one of two differently worded Goldman dilemmas, counterbalanced for presentation of success and death outcome: “Would you take an illegal performance enhancing drug that was undetectable:

- condition 1: “and guaranteed you would win an Olympic gold medal, if it would kill you in five years?” (n=125, 65 % male, mean age 34 years)
- condition 2: “but going to kill you in five years, if it guaranteed you won an Olympic gold medal?” (n=125, 59 % male, mean age 33.4 years)

In both condition 1 and condition 2 only one out of the 125 respondents gave a positive response (0.8 %). The size of the discrepancy between 50 percent and 0.8 percent negated the need for statistical testing. Analysis by demographic or sports engagement would be meaningless given the low rate of positives. The results provide compelling evidence that athlete responses to the Goldman dilemma vary markedly from the general population. The results raise serious concerns about the reliability of official prevalence rates. The consequences of these concerns become even more profound when considered in the context of the 2009 revision of the World Anti-Doping Code (WADC), in which the culpability of support personnel (such as sports medical practitioners) is placed as equal to and sometimes above that of the athlete. Testing the Goldman dilemma on a control group raises a problem for prevalence rates. The rate of temptation among athletes suggests that if any non-trivial proportion (say, 10 %) succumbs the incidence of performance-enhancing drug use in sport may be well above that reported by anti-doping agencies around the world (typically <2 %). However, in the absence of a reliable epidemiology of sport estimates of performance-enhancing drug usage remain educated guesses. The epidemiological ignorance raises serious concern. First, the testing regimes of the World Anti-Doping Agency and the National Anti-Doping Organisations must be questioned as the anecdotal evidence, including the Goldman dilemma, indicates a much higher use rate. Therefore, the tests are either flawed in administration (athletes can avoid tests or manage their drug use) or accuracy (laboratories cannot detect substances or the limits are too high). The strongest evidence of the problems with testing comes from high-profile doping cases in Europe (Madrid Cycling) and the USA (BALCO). Marion Jones was the highest profile athlete caught as a result of the BALCO investigation and has been struck from the Olympic record books. Importantly, it was investigation rather than testing that caught Jones – who had returned negative results for banned substances at the Sydney Olympics. This raises a profound challenge to anti-doping education and enforcement as the official prevalence rates appear to reflect the unlucky or pharmacologically unsophisticated and fail to reflect actual use. A complementary explanation is that the elite athlete subpopulation is a discrete group with a set of norms, values and beliefs that are quite different to those of the wider population. This is a compelling argument given anecdotal evidence of the obsessive and perverse nature of elite athletes. This body of evidence indicates that athletes, to reach the elite level, must display a singular focus and desire often to the exclusion of other life-affirming activity. Furthermore, the intense desire to win, fuelled by this commitment may make it more likely
that they would accept such a bargain. We do know that some athletes will accept such a deal without the guarantee of success, as shown by those who are caught. It is important for sports medicine practitioners and sports psychologists to recognise that athletes demonstrate this alarming flaw in health decision-making when winning is given precedence over survival. Part of the explanation for this alarming flaw in health decision-making comes from a growing literature that recognises the peculiar social circumstance of the athlete [09387].

Youth and adolescents

Until recently, much of the extant literature of anabolic steroids use in youth and adolescents focused on participation in organised sport as the primary risk factor, based on the historical relationship between sports and AAS use and the face validity of the AAS use and “win at all costs” relationship of elite sports. However, emerging evidence indicates that this model may be outdated, prejudicial to young athletes and, ultimately, detrimental to adequately addressing the use of AAS in the children and teenagers because it fails to recognise AAS use in this population as a public health issue with more complex mechanisms driving it. It has been found health-, social- and personality-related factors including average/low self-esteem and school achievement, and high immigrant status to be “significantly and independently associated with lifetime use of AAS in male adolescents.” Expanding this approach, it has been presented three theoretical models:

- the sports perspective (motivation for use is related to desire to win)
- the “ideal body” perspective (to increase self-concept and/or be more attractive to potential partners)
- “problem behavior” theory (anabolic steroid use is part of a larger syndrome of problem behaviours).

Results indicated that “AAS use was first and foremost associated with types of problem behaviours, that is, drug involvement and aggressive-type conduct problems” and there “was no difference in AAS use among sports competitors and noncompetitors,” although involvement in power sports was associated with increased lifetime prevalence. In another study it was found that “use of anabolic steroids was associated with the use of other forms of drugs, which indicates that use of anabolic steroids may be part of a general pattern of drug use and risk-taking behavior” and not driven by the pursuit of athletic success. It has also been reported significant associations between AAS use and other illicit drug use as well as a variety of deviant behaviours, in line with problem behaviour theory, that were consistent across six European countries. They also examined the association between lifetime AAS use and sports participation. However, this variable was confounded by the inclusion of exercising in the participation question. Although a significant association between AAS use and daily physical exercising was identified (odds ratio 1.4, 95 % confidence interval 1.06 to 1.85), it is not possible to discern the independent effect of organised sports participation on AAS use as exercising to improve appearance occurs in non-sports playing AAS users. Previous studies that examined the relationship between sports participation and AAS use may also be compromised by confounding sports participation with non-specific exercising or physical appearance criteria. It has been concluded that high school athletes were significantly less likely to use AAS than those not participating in sports, and males who used AAS were significantly more likely to use other drugs. Improvement in appearance was cited as the main motivation for AAS use [09024].

Environmental factors
Environmental factors include the socio-cultural, political milieu, the legislative system, as well as the availability of drugs, new drug discoveries and permitted alternatives, such as nutritional supplements, minerals, herbs and non-herb non-mineral substances. The importance placed on sporting success in a society and the direct and indirect reward for such success influence the motivational climate in which athletes prepare and compete. Criminalisation or decriminalisation of the performance enhancing drugs may only have an effect on the level of use via the distribution mechanism. Studies show that decriminalisation of social drugs do not have the effect on the prevalence rate [08459-08462].

**Anti-doping programs**

Factors that may avert individuals from using performance enhancing drugs are related to the current punitive-sanctioning anti-doping system, cultural – religious norms, moral values, social pressure from close relatives and friends and health concerns. Some personality traits can act as inhibitors of doping engagement (e.g. positive and stable self-esteem, conscientiousness and low risk-taking propensity). Intervention as a preventive factor has been the most extensively researched aspect. Gender specific, team centred education has been shown to result in self-reported behaviour change in the Adolescents Training and Learning to Avoid Steroids (ATLAS) [08462, 08463], Athletes Targeting Healthy Exercise and Nutrition Alternatives (ATHENA) [08464, 08465] but effectiveness of such education programmes should be validated beyond self-reports.

**The life-cycle model of performance enhancement**

The current anti-doping policy has received criticism for its elite focus, sanction-based approach and associated costs [08466-08470]. However, the growing number of educational programmes are designed and implemented by the sport governing bodies to target varying groups from top performing athletes to young talents focus on the principles of performance enhancement and fair play. A holistic approach with the emphasis on choices, health issues and broader life goals to the individual and the systemic factors is needed in order for athletes to make informed decisions about their performance enhancement, which may lead – at the population level – to a sustainable change in doping behaviour. Overall, anti-doping interventions are likely to benefit from a dual focus on the risk factors and doping expectancies, as well as from targeting the athlete population from preadolescents to adults at all stages of their athletic life-cycle [08446].

The use of performance enhancing methods is unlikely to be an accident. It requires sustained, self-regulated, goal-directed effort [08471]. Doping use is assumed to exhibit similar characteristics to “functional drug use” which has been recognised as a specific from of drug use [08472, 08473]. Functional drug use is distinct from experimental, recreational or dependent use (abuse/addiction) and it refers to a strategic use of substance to achieve a set goal (i.e. improve a function or skill). Examples for functional use include but are not limited to using stimulants to increase alertness or balance long working hours; or taking hypnosedatives to help coping with anxiety, stress or depression. Functional drug use is not necessarily problematic in the sense of addiction although physical and psychological dependence may develop from functional use. Athletes’ reasons for taking performance enhancing substances are in keeping with the definition of functional drug use. One of the main advantages of the life-cycle model over the traditionally used traitor situational models is that the developmental nature of the proposed model offers various intervention points and suggests a varying set of methods to match those points [08446].

Chronologically, the first intervention points focus on the risk factors by preventing the onset of risks or transforming risks that are already present. Whilst these options are considered
less effective in substance abuse, the unique nature of performance enhancing substance use offers scope for intervention at this stage by changing not the athlete but the environment that influences the onset of doping use. With that in view, the responsibility for deterrence is broadened from individual athletes to the inter-related system of rules, regulations, and expectations by coaches, support personnel and policy makers. An intervention approach that aims to alter expectancy trajectories or modify current maladaptive expectancies (e.g. in relation to steroid use which is prone to developing physiological and psychological dependence) is likely to produce more lasting effects. Based on research on substance abuse [08474], it is envisaged that preventing the development of positive doping expectancies before the onset of a doping-related event may work well with pre-adolescents, whereas athletes with doping experience or in positions to seriously contemplate the use of prohibited methods may respond better to modifications of expectancy pathways, especially if comparable and acceptable alternatives are offered [08432].

A gold medal but also death in 5 years’ time?

The “Goldman dilemma” is one of the most cited results in the antidoping literature. The dilemma presents a Faustian bargain to athletes, asking if they would trade longevity for Olympic success by taking a drug that not only guaranteed a Gold Medal but also their death in 5 years’ time. Goldman is reported to have presented this dilemma to world-class athletes biannually between 1982 and 1995. He reported a remarkably stable set of results with about half accepting the gold for death deal. There has been little in the way of replication of the Goldman dilemma since 1995, with sporadic adaptations for different contexts showing athletes of various levels to be less likely to take the bargain. Despite the extensive reporting of Goldman’s results and the adaptations, questions remain around the validity and reliability of the dilemma to accurately capture an athlete’s willingness to trade longevity for Olympic success. The first weakness of Goldman’s work is that no comparable measure of acceptance exists among the general population. That is, there are no data to suggest whether the athletes are responding in the same manner or differently to members of the general population. Contemporary data suggest that the general population take a very conservative approach to the dilemma; out of a representative sample of n=250 Australians, only two respondents accepted the bargain. That is, if athletes respond to the dilemma in the same way as the general population, approximately 1 percent of athletes would take the Faustian bargain. The second weakness in Goldman’s work is found in the wording of the questions. The question presented the outcome (Olympic gold) followed by the consequence (death). The dilemma responses may thus represent a positive response bias as a function of wording, necessitating replication using the counterbalanced presentation. There is a growing literature on the social circumstance of sport and the drivers of behaviours defined as “illegal”, which indicates that athletes, to reach the elite level, must display a singular focus and desire often to the exclusion of other life-affirming activity. Further, the intense desire to win, fuelled by this commitment, may make it more likely that they would accept such a bargain. It is clear that some athletes will accept such a deal without the guarantee of success, as shown by those who are caught doping. The current study provides data on the proportion of athletes willing to accept the Faustian bargain offered by misuse and abuse of performance-enhancing drugs. This research evaluated the dilemma with contemporary elite athletes. Participants at an elite-level track and field meet in North America were segregated into an interview or online response. After basic demographics, participants were presented with three variant “Goldman” dilemmas counter-balanced for presentation order. Only 2 out of 212 samples (119 men, 93 women, mean age 20.89) reported that they would take the Faustian bargain offered by the original Goldman dilemma. However, if there were no consequences to the (illegal) drug use, then 25/212 indicated that they would take the substance (no death condition). Legality also changes the acceptance rate to 13/212 even
Regression modelling showed that no other variable was significant (gender, competitive level, type of sport) and there was no statistical difference between the interview and online collection method. The results show that the proportion of athletes willing to take the Faustian bargain offered by the Goldman dilemma has changed significantly, approximating the proportion observed in the only sample of general population responses. This indicates that responses to the dilemma from 1982 to 1995 should no longer be taken to reflect the approach taken to the use of drugs in sport by contemporary athletes. The counterbalancing of question design had no effect on acceptance of the bargain, and neither did the response format. Future research on the dilemma can use any version of the wording in an online survey. Athletes were sensitive to the consequences of performance-enhancing drug use (death vs non-death) and the legality of substances. This was consistent with other work showing that athletes are sensitive to the health and legal implications of using performance-enhancing drugs. The radical change in proportion of athletes willing to accept the dilemma is explained in two ways, although others are equally plausible alternative explanations. The problem with defining an explanation in this context lies in the significant changes in the social and sportive contexts. Attempting to explain them fully is to attempt to describe the evolution of drugs in sport since 1982. The first explanation flows from the significant impact of the consequences and legality on acceptance. The social context of the original Goldman results may have had a very different understanding of the consequences of using performance-enhancing drugs. There is also the possibility that the subset of athletes (power-sports) that Goldman approached is not representative. Doping knowledge was usually obtained informally via word-of-mouth or underground handbooks rather than medical advice, and was often erroneous. As a result, the consequences of doping were uncertain. Unsupervised experimentation with erythropoietin among endurance athletes revealed the danger of misuse and abuse. In terms of legality, the epoch around the original Goldman results was one of uncertainty arising from imprecise testing technology. The second explanation flows from the social marketing of antidoping. The original studies were conducted during the debate around the role of drugs in sport, which led to the current legalistic prohibitionist model. The moral stance on the role of drugs in sport was being thrashed out and was therefore ambiguous. Contemporary athletes now contend with an ethically unambiguous (although arguably morally ambiguous) statement that “doping is fundamentally contrary to the spirit of sport”. The current study shows that the results collected in 1982–1995 no longer have relevance in the contemporary context. The wisdom that athletes are willing to die to win applies to only a handful of athletes. Put simply, the sensational reporting of the 1982 to 1995 responses to the Goldman dilemma is no longer relevant to the contemporary debate around the role of drugs in sport [13770].

Prevention of athletes from harm

The prevention of harm to the athlete, the guarantee of fair play, and a level playing field for all competitors are the basis of the current anti-doping strategies. As healthcare systems are forced to allocate increasing resources to prevent and treat the prevailing pathologies worldwide, funding for anti-doping campaigns will necessarily be restricted. Ideally, additional resources should be devoted to increasing the number of athletes tested, the panels of tests used, and the frequency of out-of-competition controls. Since doping prevention cannot be considered a priority for most healthcare systems, such an approach is unaffordable and an alternative framework should be devised, focused primarily on harm reduction rather than fair play. The identification of abnormal deviations from reference values, regardless of pathological or artificial causes, would allow the athlete to be followed and tested using conventional laboratory tests, which are affordable to governments and healthcare systems and available to clinical laboratories. Although this strategy would not detect cheating, it would safeguard athletes' health [08475].
It was discussed the assumptions underpinning the current drugs-in-sport policy arrangements by examine the assumptions and contradictions inherent in the policy approach, paying particular attention to the evidence that supports different policy arrangements. It was found that the current anti-doping policy of the World Anti-Doping Agency (WADA) contains inconsistencies and ambiguities. WADA's policy position is predicated upon four fundamental principles; first, the need for sport to set a good example; secondly, the necessity of ensuring a level playing field; thirdly, the responsibility to protect the health of athletes; and fourthly, the importance of preserving the integrity of sport. A review of the evidence, however, suggests that sport is a problematic institution when it comes to setting a good example for the rest of society. Neither is it clear that sport has an inherent or essential integrity that can only be sustained through regulation. Furthermore, it is doubtful that WADA's anti-doping policy is effective in maintaining a level playing field, or is the best means of protecting the health of athletes. This means that the WADA anti-doping policy is based too heavily on principals of minimising drug use, and gives insufficient weight to the minimisation of drug-related harms. As a result drug-related harms are being poorly managed in sport. It was argued that anti-doping policy in sport would benefit from placing greater emphasis on a harm minimisation model [08476].

**On cheating**

One frequently used argument in the discussion on human enhancement is that enhancement is a form of cheating. This argument is well-known in relation to doping in sports, but recently it has also been used with regard to cognitive enhancement in the context of education and exams. One paper analysed the enhancement-is-cheating argument by comparing sports and education, and by evaluating how the argument can be interpreted in both contexts. If cheating is understood as breaking the rules in order to gain an unfair advantage over others, it can be argued that some enhancements are a form of cheating. This problem of cheating is, however, relatively easy to remedy by either changing the rules, or by instituting controls and sanctions. This does not, therefore, constitute a categorical objection to enhancement. A further analysis of the intuitions behind the enhancement-is-cheating argument, however, shows that if sports and education are understood as "practices", with their own internal goods and standards of excellence, some potential problems of enhancement can be articulated. These concern the internal goods and standards of excellence that are characteristic of specific practices. Seen from this perspective, the important question is how enhancement technologies might be embedded in specific practices – or how they might corrode them [08477].

**Different of shades of blood doping**

Blood doping (reputedly favoured by cyclists) exemplifies the shades of grey, as well as some of the problems of detection: transfusion of heterologous packed blood cells with intent to boost athletic performance rather than to treat intercurrent illness seems eminently unfair (and easy to detect), autologous transfusion of one’s own harvested and stored blood seems no better (though harder to detect), injecting oneself with epoietin is cheating (and can be detected through differences in the exogenous and endogenous human hormone), training at high altitude when one’s home is say in Ethiopia is hard to find fault with, but how about sleeping in a low oxygen tent at night – and how could this be detected after the event? This raises the semantic question of whether oxygen is a drug, and if so whether lack of oxygen – and hence an inert displacing gas such as nitrogen – is also a drug. If a bedroom is shared
with the “wrong end” of an oxygen concentrator which delivers oxygen to a patient with chronic obstructive pulmonary disease in the adjacent room would she be receiving therapy but I am guilty of a lifestyle offence by virtue of the erythropoietin I secrete in response to the partly oxygen-depleted nitrogen that is breathed overnight? [12003].

The grey zone of undiscovered doped

An unknown number of athletes likely remain undiscovered and get away with some forms of doping. This is because of the limits to surveillance and laboratory testing technology. The ideal situation would be black and white: the forbidden substance is present or is not present in a urine or blood sample. Those two extreme cases exist, but there is, depending on the substance, often a large area of uncertainty. A test can be positive (showing the presence of a substance) when it is indeed present (true positive) or not present (false positive); conversely, a test can be negative when there is indeed no substance present (true negative) or when in fact the substance is present (false negative). Anti-doping policy enforcers need to keep false positives as low as possible, while striving for the highest sensitivity possible. The probability for false positives rises with the number of tests performed, as well as with a drop in prevalence of actual doping. Furthermore, for some forms of doping practices there exist no laboratory tests. WADA does not want to publish WADA-accredited laboratories’ test performance, saying that this would permit athletes tailoring doping practice to current testing technology. At first sight, this seems reasonable, but, at the same time, it leaves room for doubt about the impartial nature of anti-doping testing. The absence of transparency is not a good gatekeeper for quality assurance [12012].

Perversely, anti-doping is thus limited in its scope since, in fine, a “clean” sample will never allow to fully exclude doping, while occasional sacrifice of innocent athletes from false positives appears inevitable. Even if anti-doping efforts certainly have changed current doping practices – certain types of doping cannot be used anymore because too easily discovered – the purpose of anti-doping, the celebration of clean athletes with a strong degree of confidence, or even certainty, thus remains an unattainable objective. One is forced then to question whether the champions are clean; a question that unfortunately remains unanswered. So, if the principle of the anti-doping rule may initially seem simple, one can see that its implementation is complicated, very technical, highly costly, only partially successful and condemns athletes who did not dope or had no intent to dope [12012].

Enforcement of anti-doping policy today

Anti-doping is enforced by a combination of repression and surveillance. The latter includes the so-called “whereabouts” rule, or the obligation for a selected pool of elite athletes to inform the anti-doping authorities where they will be each day of the year, to allow unannounced out-of (and in)-competition testing, with the obligation to be present at the announced site for one specific hour per day. The athletes have to provide this information to the authorities in advance, four times a year for three months periods at a time, using electronic and paper-based means and informing in time of any changes. This rule aims at preventing out-of-competition doping in preparation for competition. To force athletes to comply, three missed tests within an 18-months period constitute a doping offence, as happened in the Ohuruogu and Wickmayer cases mentioned, and regularly occurs for other athletes. The actual testing involves providing urine samples (produced in full view by an anti-doping officer), consenting to blood sampling, and in some instances also providing hair samples for doping history and tissue for gene profiling for forensic practices. Longitudinal
testing, looking for fluctuations in certain blood parameters compatible with doping, is now also being introduced. This practice, known as the athlete biological passport (ABP), has recently led to the first indictments of athletes, based on indirect indices of presumed doping rather than laboratory tests directly showing the presence of the forbidden substances or their metabolites in urine or blood. The authorities see the ABP as an improvement of anti-doping. But the ABP may produce false-positive results due to analytical variability and outlying individual patterns resulting from the effects of behaviour (training, altitude exposure) and genetics [12012].

Mostly related to its enforcement strategies, anti-doping has a non-negligible cost. The IOC finances half the budget of the WADA, while the other half comes from national governments. National anti-doping agencies are mostly co-financed by national sports federations and governments. Overall the tendency is towards increasing costs with a new costly anti-doping industry steadily asking for more. The application of new national anti-doping legislations also comes with an increase in cost.Taken together, all of these costly surveillance practices seriously impinge upon the privacy of athletes and set them apart from the general population, for whom the protection of the private sphere and autonomy are generally respected in democratic societies [12012].

**Smart drugs (“brain doping”)**

Debates about the feasibility of cognitive enhancement rarely begin with what seems to be a pertinent question: How effective are cortical networks in performing the complex steps underlying serial thought, planning, memory retrieval, and other operations that go into cognition? If the substrates are not particularly efficient, then there should be numerous opportunities for improvement. Conversely, networks that are finely tuned with regard to cognition would presumably not be amenable to selective enhancement, at least with current technologies. Another natural question is whether improvements in one dimension of performance (e.g. speed, or accuracy) will necessarily lead to improvements in others (e.g. creativity, or judgment). The reason that these points are not generally discussed is, of course, that, despite enormous advances in neuroscience over the past few years, we still know very little about the neurobiology and operating characteristics of cognition-related networks. But perhaps the room for improvement issue can be recast in terms of brain evolution by asking whether comparative anatomical evidence points to strong adaptive pressures for designs that are logically related to improved cognitive performance [11434].

Whether drugs that enhance cognition in healthy individuals will appear in the near future has become a topic of considerable interest. It was addressed this possibility using a three variable system (psychological effect, neurobiological mechanism, and efficiency vs capabilities) for classifying candidates. Ritalin and modafinil, two currently available compounds, operate on primary psychological states that in turn affect cognitive operations (attention and memory), but there is little evidence that these effects translate into improvements in complex cognitive processing. A second category of potential enhancers includes agents that improve memory encoding, generally without large changes in primary psychological states. Unfortunately, there is little information on how these compounds affect cognitive performance in standard psychological tests. Recent experiments have identified a number of sites at which memory drugs could, in principle, manipulate the cell biological systems underlying the learning-related long-term potentiation (LTP) effect; this may explain the remarkable diversity of memory promoting compounds. Indeed, many of these agents are known to have positive effects on LTP. A possible third category of enhancement drugs directed specifically at integrated cognitive operations is nearly empty. From a neurobiological perspective, two plausible candidate classes have emerged that both target
the fast excitatory transmission responsible for communication within cortical networks. One acts on nicotinic receptors (alpha7 and alpha4) that regulate release of the neurotransmitter glutamate while the other ("ampakines") allosterically modulates the glutamate receptors mediating the post-synaptic response (EPSCs). Brain imaging in primates has shown that ampakines expand cortical networks engaged by a complex task; coupled with behavioral data, these findings provide evidence for the possibility of generating new cognitive capabilities. Finally, it was suggested that continuing advances in behavioral sciences provide new opportunities for translational work, and that discussions of the social impact of cognitive enhancers have failed to consider the distinction between effects on efficiency versus new capabilities [11434].

Anatomists often resort to allometry when dealing with questions of selective pressures on brain regions. Applied to brain proportions, this involves collecting measurements for the region of interest – e.g. frontal cortex – for a series of animals within a given taxonomic group and then relating it to the volume or weight of the brains of those animals. This can establish with a relatively small degree of error whether a brain component in a particular species is larger than would be predicted from that species’ brain size. While there is not a great deal of evidence, studies of this type point to the conclusion that cortical subdivisions in humans, including association regions, are about as large as expected for an anthropoid primate with a 1350 cm³ brain. The volume of area 10 of human frontal cortex, for example, fits on the regression line (area 10 vs whole brain) calculated from published data for a series composed of gibbons, apes and humans. Given that this region is widely assumed to play a central role in executive functions and working memory, these observations do not encourage the idea that selective pressures for cognition have differentially shaped the proportions of human cortex. Importantly, this does not mean that those proportions are in any sense typical. The allometric equations involve different exponents for different regions, meaning that absolute proportions (e.g. primary sensory cortex vs association cortex) change as brains grow larger. The balance of parts in the cortex of the enormous human brain is dramatically different than found in the much smaller monkey brain: area 10, for instance, occupies a much greater percentage of the cortex in man. But these effects seem to reflect expansion according to rules embedded in a conserved brain plan rather than selection for the specific pattern found in humans [11434].

What constitutes a cognitive enhancer? Would this include agents that only secondarily affect cognition via actions on broader psychological variables? Should distinctions be made between drugs influencing psychological processes (e.g. short-term memory) that feed into cognition versus those acting on higher, integrative activities? Rather than trying to reach agreement on such questions, it may be more useful to classify potential enhancers according to multiple dimensions of action. A critical first dimension then involves the issue of “how”, in psychological terms, the treatment acts to change cognition (dimension I). There can be little question that fundamental states such as arousal and alertness affect complex cognitive operations; similarly, it seems only reasonable to assume that drugs with positive effects on psychological operations subsidiary to cognition, such as attention and the encoding of memory would have. A provisional classification scheme for candidate cognitive enhancers with an “x” axis (dimension “I”) could list possible psychological processes affected by the compound. The other two axes indicate neurobiological mechanisms (y; dimension II), and the question of whether the compound affects the efficiency of cognition or allows the subject to exceed normal boundaries (z; dimension III). The axes are collections of associated variables that have no quantitative relationship with each other. Finally, enhancement could, in principle at least, be achieved by actions on the integrated mental activities incorporating planning, cataloguing, memory retrieval, etc. that underlie seconds-long cognitive episodes ("integration"). Neurobiological mechanisms provide a second dimension for defining enhancers (dimension II) and one that helps deal with dimension I
problems that have long plagued preclinical attempts to develop such drugs. Specifically, how can one be confident that behaviors used to assess cognition in animals engage the same psychological processes employed by humans? Most learning tests involve pre-determined (by the experimenter) optimal behavior; similarities between species could result from forcing of very different brain processes to reach the same computational end points. Finally, there is the question of whether a proposed treatment affects the efficiency versus the capabilities of cognition (dimension III). Consider, for example, a complex problem that an alert, healthy individual solves with a given accuracy and with expected improvements over successive trials. An effective enhancer in this instance could reduce errors during early testing and/or the amount of sampling needed to reach asymptotic performance –in essence an increase in efficiency. A somewhat different case concerns the effects of the treatment on asymptotic scores that hold for a large population of over-trained subjects, values that might be thought of as a species limit. Such a limit could also be described as an empirically defined level of problem difficulty at which no member of a large population achieves more than a minimal level of performance [11434].

The introduction of cognitive enhancers would have profound and unpredictable consequences for society. Some authors take a generally positive stance towards the potential for such drugs to enhance human life, arguing they should be generally classed with “education, good health habits, and information technology” as means of cognitive enhancement, but warn that their risks must be identified and managed (neither simply left to the mercies of market forces nor addressed primarily through legislation). It has been discussed potential problems including questions of fairness (whether to those unenhanced in competitive situations, or cost and availability considerations), of safety (both for healthy and non-healthy individuals over time, and particularly for developing brains of children), and of personal freedom: whether the freedom to choose to use cognitive enhancing drugs on the one hand, or the potential for explicit or implicit coercion to improve performance (e.g. by employers, in the military, or in the classroom) on the other. It has been recommended a four-fold approach to managing the risks and promoting the benefits of cognitive enhancement, including increased research into their effects; collaboration among doctors, educators, and regulators to develop appropriate policies; public dissemination of their risks, benefits, and alternatives; and “careful and limited legislative action. Drugs that act on ascending biogenic amine projections and thereby change psychological state will be limited in their use because these state variables are, for reasons discussed, likely to be greater than their actions on cognitive efficiency. The state effects in other words may be the larger, and more familiar, issue for society. But compounds such as modafinil that couple moderate effects on catecholamines with actions on hypothalamic systems and thereby improve attention and working memory without pronounced arousal effects are good fits for the issues raised in the above discussions of social issues. It is suggested that the advantages associated with such drugs are somewhat limited, mainly involving conditions in which sleepiness is a factor or artificial testing circumstances that involve heavy loads on operations that feed into cognition. But there is little reason to think that such drugs will in any sense constitute “smart pills” – something that will give healthy, alert individuals any intellectual advantages in real world circumstances. Agents that selectively enhance components of cognition, and in particular memory encoding, also raise regulatory questions that are described in the above noted reviews. But one would suggest that computational neuroscience points to additional, even more difficult to evaluate societal issues. Specifically, modeling work using biologically realistic networks and empirically derived synaptic learning rules based on LTP strongly suggest that accelerated learning will change the manner in which newly acquired information is organized. The simulated networks not only store memory but also place it into hierarchical categories, without outside supervision. Changing the synaptic rules, the functional effect of selective memory enhancing drugs, not only increases the speed of acquisition in the models but also alters the size of categories (does
this item belong or not) and the number of exemplars needed to form them. These observations lead to the idea that the use of selective memory enhancing drugs could cause people to create cognitive structures of a type that do not occur within the range of normal human experience. Regulatory considerations in this case would not be restricted to acute advantages (e.g., learning specific material for a test) gained by using memory enhancers but would also require weighing the consequences to society of individuals who gradually develop a world view that may differ in unique ways from that shared by the general population. There is no way, given our current very limited understanding of how networks generate cognition, of predicting whether these internal constructions would be more or less effective than the baseline human condition. If benign or positive, then there would have been agents that both accelerate learning and have the potential for producing what would literally be a new way of seeing things. Why would society prevent the introduction of such drugs? Perhaps the most obvious reason goes to the predictability problem noted earlier: would the steady accumulation of novel cognitive architecture eventually affect inter-personal relations, a person's integration into society, emotional life, and so forth? Since cognitive neuroscience can't begin to answer such questions, it will not be possible to develop a risk-benefit analysis for drug effects on normal subjects. But the point can be accommodated empirically by running long-term tests on a population of carefully monitored individuals. Furthermore, devices with cognition enhancing properties have been introduced into the public at least since paleolithic times (e.g. painting) and never more so than today. There can be no question that such inventions have altered the human experience in ways that were unforeseen at their introduction. In the end, only further research and long-term trials can provide the material needed for an evaluation of the opportunities and problems that will accompany the arrival of memory enhancers. Others have considered the potential impact of a "smart pill" with regard to fairness -- who will get the pill? -- and related issues. Humans have mental abilities such as language that are barely detectable in closely related primates and, again, most researchers assume that this reflects the physical expansion of networks in large areas of cortex. The sudden appearance of new abilities would likely have profound and quite possibly irreversible effects on society. They could, for example, lead to concepts and arguments that would be difficult to translate back into the world of normal cognition. And once having experienced new abilities, wouldn't a person be reluctant to give these up and return to what might be perceived as a more limited form of mental life? Questions of this kind could prove to be the most difficult issues in any debate about the regulation of cognitive enhancers [11434].

One article challenged recent assumptions that physicians may ethically and legally prescribe psychopharmacological enhancement drugs to patients and the counterintuitive notion that in some cases ingesting an enhancement drug constitutes the more ethical choice than foregoing this option. Although our society seems to be engaged in a pharmacological arms race of efficiency, competition, and self "betterment," the FDA has not approved stimulant drugs such as modafinil for PESA (performance enhancement and sleep avoidance). The drive to seek out stimulants including modafinil is strongly linked to cultural perceptions related to achievement, accomplishment, and efficiency. Use of modafinil to improve concentration, alertness, or forgo sleep would be classified as an enhancement because it constitutes "an intervention designed to improve human form or functioning beyond what is necessary to sustain or restore good health." Our culture fundamentally values the capacity for autonomy, self-improvement, and contributions to the world. An individual at rest is inherently unconnected to society and viewed through this standard as idle and unproductive. The pressure for enhancement is ingrained in both social and workplace environments, where individuals feel a duty to improve one's self and one's performance capacity and output. As a result, the off-label use of modafinil for PESA means these individuals are part of a large-scale experiment that poses serious immediate and long-term side effects to the individual user as well as society. More importantly, a physician's
practice of prescribing a controlled substance such as modafinil for PESA runs contrary to a physician’s ethical duty to the patient and the standard of practice set forth in legal requirements governing the prescription of controlled substances. Exploiting and ignoring these legal standards of practice will put the patient, the physician, and society at risk for dangerous health and social consequences. Enhancement proponents have touted modafinil as an ideal mechanism to improve concentration, alertness, and forego sleep and keep pace with our society's demands. However, patients who use modafinil for these reasons risk potentially severe side effects and addiction, and face unintended consequences related to their cognitive, emotive, and physiological functioning. Importantly, prescribing a controlled substance such as modafinil for performance enhancement and sleep avoidance runs contrary to a physician’s ethical duty to the patient and the standard of practice set forth in legal requirements governing the prescription of controlled substances. Obtaining a prescription for modafinil serves the purpose of utilizing technology in such a manner to accomplish personal and professional outcomes that we would normally attain through slower and less efficient methods. If this technology will be embraced and continue on the path of the “psychopharmacological arms race” marked by eagerly accepting, and even demanding, drugs to facilitate our progress, then the future population may be “stuck in overdrive, searching out the last bits of competitive advantage, business insight, and radical innovation” [11412].

Currently, few sectors of society openly endorse the use of stimulants for PESA purposes. The military is one arena that directly promotes the use of stimulants (and sedatives) for use in combat or in circumstances of “operational necessity.” If soldiers encounter fatigue during continuous or sustained operations, the military classifies this fatigue as a commodity to be managed. Counter-fatigue training declares that all commanding officers and squadrons should adopt this philosophy by utilizing a combination of stimulants and sedatives to achieve the performance goals of optimal productivity with minimal adverse impact on safety, health, and well-being. Under the US Uniform Code of Military Justice, soldiers are mandated to accept medical interventions that make them fit for duty, which suggests that utilization of PESA drugs is not merely optional, but a job requirement in these circumstances. The military sets forth use indication for situations when a soldier will be placed in an unpredictable setting when attention to detail and sustained vigilance is required for perceived job performance success. Scholars have recently suggested that some proponents of psychopharmacological enhancement will use similar rationale to justify expanded usage of PESA drugs such as modafinil into the civilian sector. Numerous publications connect the professional demands of select military operations to physician residents and surgeons, who may experience fatigue as a barrier to mental acuity and alertness during sustained continuous work. One study examining health care workers who experience fatigue concluded that taking modafinil would improve their professional judgment and performance compared to health care workers who would not take the drug [11412].

Pharmacological neuroenhancement refers to the use of psychoactive substances by healthy subjects with the purpose of cognitive enhancement, e.g. vigilance, concentration, memory, or mood. "Brain doping", however, refers to the illicit use of a subcategory of these substances such as prescription drugs. This subcategory includes psychostimulants (e.g. amphetamines, methylphenidate), modafinil, antidepressant drugs (acetylcholine-esterase inhibitors, memantine), and antidepressants (selective serotonin reuptake inhibitors) which are being prescribed for the treatment of ADHD (attention deficit/hyperactivity disorder), Alzheimer's disease, and depression. Only psychostimulants and modafinil show significant effects on concentration, attentiveness, and vigilance in healthy subjects. However, a general use by healthy persons can not be justified because of relevant side effects and safety risks. Caffeine for pharmacological neuroenhancement can be seen as an equally effective alternative. "Brain doping" raises numerous ethical and social concerns that require a
continued discussion. Demands of liberalization should be critically questioned [10311].

The term neuroenhancement refers to improvement in the cognitive, emotional and motivational functions of healthy individuals through, inter alia, the use of drugs. Of known interventions, psychopharmacology provides readily available options, such as methylphenidate and modafinil. Both drugs are presumed to be in widespread use as cognitive enhancers for non-medical reasons. Based on a systematic review and meta-analysis we show that expectations regarding the effectiveness of these drugs exceed their actual effects, as has been demonstrated in single- or double-blind randomised controlled trials. Only studies with sufficient extractable data were included in the statistical analyses. For methylphenidate an improvement of memory was found, but no consistent evidence for other enhancing effects was uncovered. Modafinil on the other hand, was found to improve attention for well-rested individuals, while maintaining wakefulness, memory and executive functions to a significantly higher degree in sleep deprived individuals than did a placebo. However, repeated doses of modafinil were unable to prevent deterioration of cognitive performance over a longer period of sleep deprivation though maintaining wakefulness and possibly even inducing overconfidence in a person's own cognitive performance [10421].

Memory, attention and creativity represent three different cognitive domains, which are interconnected and contribute the "mental performance" of an individual. Modern neuroscience has investigated some of the neuronal circuits and of the neurotransmitters and molecular events underlying the above-mentioned cognitive functions. Within this renewed reference context, some of the properties of the components of the remedies to increase mental performance have been studied and validated in experimental models and, to date, these substances are named "smart drugs", "memory enhancing drugs" or "nootropic drugs" (from the Greek root noos for mind and tropein for toward). Recently pharmaceutical industries are increasingly focusing on the research for potential substances in this field: several "smart drugs" are in clinical trials and could be on the market in few years. Furthermore, a quick survey from Internet highlights the presence of a great variety of both approved and non-approved drugs, with some of them addressing to only medical and others to performance-oriented use, opening room to some reflections or speculations from scientific and ethical points of view. In order to point out the effect of nootropic drugs on cognition of healthy people, it was reviewed the literature on drug enhancement of various cognitive functions, including memory, attention and creativity. As their simplest, memory is regarded as the ability to remember events or learned material, attention is the cognitive process of selectively concentrating on one aspect while ignoring distracters and creativity could be described as the ability to create products or ideas which are original and which possess a social usefulness. Reports from literature reveal that some medications currently available to patients with memory disorders may also increase performances in healthy people and that drugs designed for psychiatric disorders can also be used to enhance certain mental functions. However, the long-term effects of these drugs are unknown, but their apparent effectiveness allows room to their use and misuse. At variance with these literature data showing scientific, even if poor, evidence of the effect of smart drugs in the field of memory and attention, only indirect information on creativity can be obtained by studies of the effects of diseases and drugs on the artistic productivity of classic painters and famous authors, offering a link to understand the neuronal basis of this cognitive function and a cue to understand how drugs (used to correct the illness) may affect the function [08478].

The subject of cognitive enhancement is always topical and has been considered from numerous different angles. The issues addressed cover concerns over unfair advantage and cheating, indirect coercion, safety, and the practical difficulties involved in regulation. It should be noted that the level of risk in the use of cognitive enhancers will be a key factor in determining the appropriateness and necessity of regulation, and calls, as others have done,
for further investigation into safety and efficacy aspects of cognitive-enhancing drugs in the healthy [09388].

The use of medications to enhance performance in healthy individuals is increasingly being propagated even by neuroscientists under such colorful terms as "neuro-enhancement". A large number of medications, including psychostimulants have been advocated in this context. Recent data from the German health insurance company DAK indicate that a number of employees already take medications to fulfill their professional needs and enhance performance. The use of new drugs in the healthy has even been advocated by prominent neurobiologists in a commentary in a recent edition of Nature. There are a number of ethical objections to this use and there is an apparent risk of addiction. To date German psychiatrists have surprisingly not been outspoken on this issue. The author would like to make an emphatic plea against "brain doping" in healthy individuals [09407].

In ancient Greece, it is said that students would entwine rosemary sprigs into their hair in the belief that it would improve their memory. Although the desire to enhance one's cognitive abilities has not abated since then, modern advances in psychopharmacology now offer the possibility of one day realising this ancient dream. Cognitive enhancing drugs, smart drugs or "nootropics" (from the Greek roots noo-, mind and -tropo, turn, change), not only represent important pharmacotherapies for neurocognitive disorders such as dementia, attention deficit disorder and schizophrenia, but might also augment the minds of the healthy. The possibility of purchasing "smartness in a bottle" is likely to have broad appeal to students with normal or above average cognitive functioning to begin with. Reports in the popular press suggest that smart drugs or "nootropics" such as methylphenidate, modafinil and piracetam are increasingly being used by the healthy to augment cognitive ability. Although current nootropics offer only modest improvements in cognitive performance, it appears likely that more effective compounds will be developed in the future and that their off-label use will increase. One sphere in which the use of these drugs may be commonplace is by healthy students within academia. However, although several authors have considered the issue of "academic doping", none have examined the main ethical issues to any large extent. This is despite the widespread non-medical use of psychostimulants such as methylphenidate across universities for the purposes of enhancing concentration. It seems apparent that cognitive enhancing drugs would be highly attractive to high school and university students, and the largest non-therapeutic market for future nootropics could very well be this demographic. As a corollary, the ethical and pragmatic issues that will emerge from the use of nootropics by students warrants earnest consideration. In the absence of any existing ethical framework with which to view this issue, it may be relevant to examine the one paradigmatic human endeavour that has already wrested with the problem of performance-enhancing drugs for several decades: competitive sport. One article reviewed the ethical and pragmatic implications of nootropic use in academia by drawing parallels with issues relevant to the drugs in sport debate. It is often argued that performance-enhancing drugs should be prohibited because they create an uneven playing field. However, this appears dubious given that "unfair" advantages are already ubiquitous and generally tolerated by society. There are concerns that widespread use will indirectly coerce non-users also to employ nootropics in order to remain competitive. However, to restrict the autonomy of all people for fear that it may influence the actions of some is untenable. The use of potentially harmful drugs for the purposes of enhancement rather than treatment is often seen as unjustified, and libertarian approaches generally champion the rights of the individual in deciding if these risks are acceptable. Finally, whether the prohibition of nootropics can be effectively enforced is doubtful. As nootropics use becomes widespread among students in the future, discussion of this issue will become more pressing in the years to come [09389].

Whether drugs that enhance cognition in healthy individuals will appear in the near future has
become a topic of considerable interest. It was address this possibility using a three variable system (psychological effect, neurobiological mechanism, and efficiency vs capabilities) for classifying candidates. Ritalin and modafinil, two currently available compounds, operate on primary psychological states that in turn affect cognitive operations (attention and memory), but there is little evidence that these effects translate into improvements in complex cognitive processing. A second category of potential enhancers includes agents that improve memory encoding, generally without large changes in primary psychological states. Unfortunately, there is little information on how these compounds affect cognitive performance in standard psychological tests. Recent experiments have identified a number of sites at which memory drugs could, in principle, manipulate the cell biological systems underlying the learning-related long-term potentiation (LTP) effect; this may explain the remarkable diversity of memory promoting compounds. Indeed, many of these agents are known to have positive effects on LTP. A possible third category of enhancement drugs directed specifically at integrated cognitive operations is nearly empty. From a neurobiological perspective, two plausible candidate classes have emerged that both target the fast excitatory transmission responsible for communication within cortical networks. One acts on nicotinic receptors (alpha7 and alpha4) that regulate release of the neurotransmitter glutamate while the other (‘ampakines’) allosterically modulates the glutamate receptors mediating the post-synaptic response. Brain imaging in primates has shown that ampakines expand cortical networks engaged by a complex task; coupled with behavioral data, these findings provide evidence for the possibility of generating new cognitive capabilities. Finally, it was suggest that continuing advances in behavioral sciences provide new opportunities for translational work, and that discussions of the social impact of cognitive enhancers have failed to consider the distinction between effects on efficiency versus new capabilities [11309].

Drugs developed to treat cognitive impairments are proving popular with healthy college students seeking to boost their focus and productivity. Concerned observers have called these practices a form of cheating akin to athletes’ use of steroids, with some proposing testing students’ urine to deter “academic doping.” The ease with which critics analogize the academic enterprise to competitive sport, and the impulse to crack down on students using study drugs, reflect the same social influences and trends that spur demand for these interventions—our hyper-competitive culture, the commodification of education, and our attraction to technological quick-fixes. Rather than focusing on the technologies that are being put to troubling uses, it would be better served reforming the culture that makes these practices attractive [12433].

One study tested the hypothesis that college students’ substance use problems would predict increases in skipping classes and declining academic performance, and that nonmedical use of prescription stimulants (NPS) for studying would occur in association with this decline. A cohort of 984 students in the College Life Study at a large public university in the US participated in a longitudinal prospective study. Interviewers assessed NPS; Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) cannabis and alcohol use disorders; and frequency of skipping class. Semester grade point average (GPA) was obtained from the university. Control variables were race, sex, family income, high school GPA, and self-reported attention deficit hyperactivity disorder diagnosis. Longitudinal growth curve modeling of four annual data waves estimated the associations among the rates of change of cannabis use disorder, percentage of classes skipped, and semester GPA. The associations between these trajectories and NPS for studying were then evaluated. A second structural model substituted alcohol use disorder for cannabis use disorder. More than one-third (38%) reported NPS for studying at least once by Year 4. Increases in skipping class were associated with both alcohol and cannabis use disorder, which were associated with declining GPA. The hypothesized relationships between these trajectories and NPS for studying were confirmed. These longitudinal findings suggest that escalation of substance
use problems during college is related to increases in skipping class and to declining academic performance. NPS for studying is associated with academic difficulties. Although additional research is needed to investigate causal pathways, these results suggest that nonmedical users of prescription stimulants could benefit from a comprehensive drug and alcohol assessment to possibly mitigate future academic declines [12484].

**Performance-enhancing drugs create an uneven playing field**

One of the most frequently invoked arguments against the use of performance-enhancing drugs in sport is that they confer an unfair advantage to those who use them. If the difference between winning and losing were determined not on the running track but in the chemical laboratory, it would result in an “uneven playing field” because athletes would not be competing on equal grounds. It is often concluded, therefore, that doping in sports is a form of cheating, because it provides doping athletes an unfair advantage over their clean competitors. Unsurprisingly, cognitive ability is a significant predictor of academic performance and twin studies indicate that IQ has a heritability of approximately 50 percent. That is, a sizeable proportion of one’s academic successes are due to the genes with which one has been naturally endowed. To be sure, nootropics would probably make an already uneven playing field more unfair, and one that is likely only to favour the wealthy who can afford to purchase them. Not only do the rich get richer, but in the future it seems that they might also get smarter. However, using unequal distribution to justify the prohibition of nootropics is akin to prohibiting private tuition, which also increases academic performance while exacerbating educational inequalities between social classes. If socioeconomic inequalities in education are readily tolerated by society, then it would be hypocritical to apply this criterion selectively to nootropics and not to other performance-enhancing strategies. If nootropics represented the most cost-effective means of enhancing academic performance, social programmes might seek to make them accessible to the underprivileged. Moreover, it is entirely possible that some nootropics would primarily benefit those in whom cognitive deficits are present, with little, no, or perhaps even deleterious effects upon the healthy. This appears to be the case with modafinil, in which the greatest improvements in cognitive performance are seen in those with lower IQs [09389].

**Everybody else is taking them**

Some athletes are motivated to use performance-enhancing drugs because they believe their competitors are doing so. Although it is difficult to determine the prevalence of drug use in sports, anecdotal reports few successful Olympians do not dope. Therefore, in order to compensate for what might be considered an unfair advantage against them, an athlete who would otherwise not be compelled to dope may decide that this is the only avenue through which they can remain competitive against those who do. One concern surrounding the widespread use of nootropics is that it may indirectly coerce other students into taking them in order to keep up with their peers. For example, if the majority of students were to use modafinil and their doing so vastly improved their academic performance, then the remaining non-users would feel a certain amount of pressure to follow suit in order to remain competitive. The Red Queen Principle applies here, in which an individual must continue developing in order to maintain their fitness relative to others with whom they are competing. In the absence of empirical data, one can only speculate if any of these factors presently hold true in academia. For example, caffeine is a widely used nootropic that can reduce fatigue and promote alertness and vigilance, but it is unlikely that its use is necessary for academic success and that many feel coerced into consuming it. It has been reported that in the USA the non-medical use of methylphenidate and amphetamine in the previous year is as high as 25 percent in some college campuses. The most commonly cited reason for using these stimulants is to enhance concentration (58 %) and increase alertness (43 %),
indicating that they are being used for their performance-enhancing properties. However, difficulties in this reasoning arise when considering indirect coercion with respect to dangerous or toxic nootropics. Should individuals be protected from the pressure of taking potentially dangerous drugs such as methylphenidate in order to succeed academically? What if the nootropic were innocuous? Would this relegate indirect coercion regarding caffeine use as they would towards methylphenidate. It is apparent then, that the issue of indirect coercion to use performance enhancers hinges upon the safety profile of the drug in question and that this may be a major determinant of future policy towards nootropics use [09389].

**Performance-enhancing drugs are dangerous**

According to the World Anti-Doping Agency (WADA) one criterion for prohibiting a drug in sport is whether or not it poses an actual or potential risk to an athlete’s health. Although the dangers of drugs are often overstated, these dangers seemingly justify their prohibition because legalisation may be perceived as tacit endorsement of their use. Indeed, the safety profile of a performance-enhancing drug appears to be a large determinant of whether or not it is prohibited. Caffeine, for example, reliably increases performance in a range of sports including swimming, cycling and running at doses allowed by WADA. Yet despite being a form of “cheating” in the same vein as anabolic steroids, caffeine’s use in sport is permitted because it is relatively harmless. For nootropic psychostimulants such as methylphenidate, the dangers are real and relatively well known. Aside from its abuse potential, methylphenidate may aggravate mental illness, produce sleep disturbances and is associated with cerebrovascular complications. It is clear that there are risks inherent in the use of any drug, and given that the use of nootropics by the healthy would be for the purposes of enhancement rather than treatment, some clinicians would deem any risk unacceptable. On the other hand, the general libertarian perspective argues that provided the individual is cognisant of the potential side effects, they are free to make their own decision to take nootropics. It would appear that both extremes are untenable – on one hand people should have a right to decide whether or not the risks of nootropics are acceptable, but civil liberties must also be balanced by the need to safeguard the public good [09389].

**Drug use would be almost impossible to control**

The widespread access to and use of performance-enhancing drugs in sport despite their prohibition suggests that current anti-doping measures are inadequate. The competitive advantages derived from their use, the low likelihood of drug testing and the relatively minor punishment for getting caught make them attractive to many athletes. This is not influenced by ethical considerations concerning such use, but rather the belief that any attempt at prohibition is not pragmatic and possibly more harmful than regulation. As in the case of controlled substances such as methylphenidate and amphetamine, the high rates of non-medical use and the ease with which they can still be obtained demonstrate the inability of prohibition to control their illicit supply effectively. As nootropics would probably have legitimate therapeutic applications in the treatment of neurocognitive disorders such as dementia, diversion from legitimate sources would be highly likely. Considerations of supply notwithstanding, just how the prohibition of nootropics in academic contexts could be enforced remains unclear. One conjures to mind the scenario of students taken to one side, cup in hand, and asked to provide a urine sample to test officials. Scandal would erupt and rumours abound when the magna cum laude is stripped of his title for testing positive for modafinil – a drug that gave him near-superhuman levels of mental endurance. As laughable as it may seem, it is possible that scenarios such as this could very well come to fruition in the future. However, given that the benefits of nootropics can also be derived from periods of
study at any time leading up to examinations, this would also require drug testing during non-exam periods. If the current situation in competitive sport is anything to go by, any attempt to prohibit the use of nootropics will probably be difficult or inordinately expensive to police effectively [09389].

**Danish ban on gyms not adhering to doping-tests**

If anti-doping would only concern elite sport, one might accept the arguments in favour of the exceptions made in sports, for the sake of what sports aspires to be. But anti-doping has unintended side effects outside elite sports. One illustrative example of how anti-doping policies directly influence society outside the scope of competitive sport is the 2005 extension of Danish national anti-doping policy to commercial fitness clubs (gyms) in which clients engage into weight lifting and other types of exercise for health and appearance purposes, but not necessarily for sports competition. Danish gyms have the obligation to put either a happy green smiley on the entrance, indicating adherence to Anti-Doping Denmark, which includes surprise urine testing of clients, or an unhappy red smiley with the explicit message that the club does not adhere to anti-doping Denmark. About 20-25 percent of the samples are found to contain (forbidden) anabolic steroids. As a consequence these clients are excluded from the gym in question for 2 years, and from all other gyms that adhere to the rule. According to the law the client should also be excluded from all sports in Denmark. And, as in elite sport, a refusal to be tested is counted as a positive test. This example illustrates the potential for generalization of anti-doping surveillance practices in society in general. This practice is not far from the introduction of testing of students for cognitive performance enhancing substances and other drugs, and possibly other groups, like teachers, trainers, coaches, sports referees, police personnel, amateur athletes, etc. Such increased surveillance and testing would lead to increased numbers of convictions, with an important burden imposed on the judicial system and the families of the convicted. For simple reasons of stochastic and procedural error frequency, a greater number of tests would lead to a greater number of false positives, wrongly accusing innocent citizens. The prospect of such a development has worrying characteristics of a dystopia of Orwellian kind. It appears paradoxical that gym users, generally conscious about their health and complying with general preventive principles like regular exercise and a healthy diet, making a balanced decision on steroid use to aid them in attaining their aspired body form, are punished for anabolic steroid use, while the general population can freely engage in dangerous behaviour combining bad nutrition, lack of exercise, tobacco and alcohol use without much of a constraint [12012].

**Cannabis**

Contrary to health risk and performance enhancement, the spirit of sport criterion does not rely on established scientific facts; rather, it relies more on ethical and societal considerations encompassing a wider view of sport beyond physical achievements and health. Therefore, the fundamental rationale for this aspect of the Code does not include a strict definition of the spirit of sport, but instead provides a collection of essential values to be shared in sport. The values included are ethics, fair play and honesty, health, excellence in performance, character and education, fun and joy, teamwork, dedication and commitment, respect for rules and laws, respect for self and other participants, courage, community and solidarity. These values are in essence contrary to doping. Such essential principles guide WADA scientists and ethicists when determining whether a substance or a method violates values embedded in the spirit of sport. Cannabis is classified as an illegal substance in most of the
world, with penalties ranging from no action to long-term incarceration. The consumption of cannabis and other illegal drugs contradicts fundamental aspects of the spirit of sport criterion. The international anti-doping community believes that the role model of athletes in modern society is intrinsically incompatible with use or abuse of cannabis. Although some anti-doping officials proposed also banning cannabis for out-of-competition testing, this appeared beyond the anti-doping mandate and it was believed to violate athletes’ privacy. For these reasons, cannabis use is prohibited only in competition. Use of illicit drugs that are harmful to health and that may have performance enhancing properties is not consistent with the athlete as a role model for young people around the world. Banning a substance only in competition creates challenges in differentiating new cannabis smoking during competition from evidence of prior out-of-competition cannabis use [11584].

Gender as more than a binary quantity

The case of Caster Semenya provides a vivid illustration of the ways in which natural genetic variation can generate large differences in athletic performance. But since we normally segregate athletic sports along the lines of this particular variation-gender, her case also highlights problems with the current approach to justice in sporting competition. Female athletes seem to have a valid complaint when they are made to compete against athletes who are, in one sense or another, male. But once we recognise that gender is not a binary quantity, sex segregation in competitive sport must be seen as an inconsistent and unjust policy, no matter what stance we take on the goals of sport or on the regulation of doping [10422].

On how to make illegal drugs less dangerous

Substances, such as alcohol, opiates and cannabis, have been used by humans for millennia. Today, a much wider range of substances are used for a range of purposes, including the enhancement of performance during university studies, sexual experiences, sports, exercise, at celebrations, socializing and the experience of art and music. Substance use is also associated with a range of harmful effects to the individual and society as a whole. Prohibitions, regulation, prevention and treatment have all been used to protect against this harm. In this commentary, it is argued that public health interventions should target relevant harms and not to evaluate which aspects of human endeavors and experiences should be enhanced and which should not. It is argued that interventions should directly target the harmful effects, using the best available evidence. Two examples are given of substances that may be altered to prevent serious harm – one for alcohol and one for cannabis. In the case of alcohol, the addition of dissolved oxygen could reduce both the risk of accidents and the risk of liver damage associated with alcohol consumption. In the case of cannabis, there is strong indication that the reduction of content Delta-tetrahydrocannabinol and the increase of cannabidiol could reduce the risk of psychoses and the addiction associated with its use. The aim of one article was to show that responsible regulation should not necessarily be restricted to preventing the use and/or (in the case of alcohol) a reduction in the amounts and frequency of its use, but should also aim to include a range of other strategies that could reduce the burden of illness associated with illicit substance use [10423].

Hidden assumptions and inherent contradictions in anti-doping policy

2142
There is little disagreement that drug use in sport is problematic, but the rationale for and mechanisms of drug control are a subject of debate. On one hand, powerful global sport authorities such as the International Olympic Committee (IOC) the World Anti-Doping Agency (WADA) and international sport federations claim that the use of drugs in sport is cheating and should be eliminated through the imposition of punitive measures. An alternative approach is one that is more concerned with the protection of athlete health and societal impact of drug use. In short, there is an ongoing tension between the benefits of a deterrence-only model of drug control (as enacted by WADA) versus a multi-level approach of harm minimisation (as adopted by many drug education and treatment support agencies). One paper therefore considered the assumptions underpinning the current drugs-in-sport policy arrangements. It was examined the assumptions and contradictions inherent in the policy approach, paying particular attention to the evidence that supports different policy arrangements. It could be found that the current anti-doping policy of the World Anti-Doping Agency (WADA) contains inconsistencies and ambiguities. WADA’s policy position is predicated upon four fundamental principles; first, the need for sport to set a good example; secondly, the necessity of ensuring a level playing field; thirdly, the responsibility to protect the health of athletes; and fourthly, the importance of preserving the integrity of sport. A review of the evidence, however, suggests that sport is a problematic institution when it comes to setting a good example for the rest of society. Neither is it clear that sport has an inherent or essential integrity that can only be sustained through regulation. Furthermore, it is doubtful that WADA’s anti-doping policy is effective in maintaining a level playing field, or is the best means of protecting the health of athletes. This, it was concluded that the WADA anti-doping policy is based too heavily on principals of minimising drug use, and gives insufficient weight to the minimisation of drug-related harms. As a result drug-related harms are being poorly managed in sport [10312].

Setting a good example

One of the first claims made by sport policy makers is that athletes in particular, and sport in general, have an obligation to set a good example, as many young people are influenced by sporting heroes and use them as role models. Under these conditions it might make sense to implement punitive policies that discourages drug use. However, this policy position rests upon two key propositions: first, that sport can positively shape the moral behaviour of its participants and followers, and secondly, that heavy punishment for drug use in sport will lead ultimately to abstinence. While these propositions are intuitively appealing, there is little evidence to support them. The idea that sport should set good examples for impressionable children and provide them with a reliable moral compass is widely held, and is mirrored in the long list of personal and social benefits ascribed to sport participation. It is linked to improvements to mental health and self-esteem, mental toughness, the control of stress, anxiety and depression, better physical development, community-building and diminished health spending. However, the way in which sport influences moral development remains unclear. Indeed, there is evidence that sport can actually increase the risk of injury, encourage binge drinking, undermine an athlete's long-term health prospects and facilitate cheating. In other words, sport can just as easily act as a catalyst for socially dysfunctional behaviour. This consequently weakens the argument that drug-free sport will ensure its integrity and set clear moral guidelines for participation. The concept of sport as an example-setter must also be balanced against the fact that sport holds winning as sovereign, which in turn produces a demand for anything that gives athletes a competitive edge. The hyper-competitive nature of sport and its emphasis on achievement and rewards encourages drug taking, and in some cases the combination of self-gratification and public approval may be a kind of addiction. The incentives for drug use are therefore substantial. In addition, the combination of immense pressure for success and severe punishment for failure teaches
young athletes another important lesson, which is to avoid getting caught [10312].

**A level playing field**

A second assumption made by WADA and the IOC is that their drug code is essential to the maintenance of a level playing field where no athletes are disadvantaged unfairly. On the surface this is a reasonable argument, as sport should be about an equal chance of success for all competitors. However, this level playing-field argument is fraught with inconsistencies. In the first instance, the scientisation and medicalisation of sport means that only certain privileged athletes have access to the latest training advantages that will give them a competitive edge. While erythropoietin (EPO) (a drug which increases the oxygen-carrying capacity of blood) may be a banned substance, those who can afford to train at high altitude or sleep in an altitude chamber can obtain legally a lesser but similar benefit. Furthermore, all athletes respond differently to training and nutritional regimens, while others bring unique genetic advantages, such as the naturally occurring gene mutation which helped Eero Mäntyranta secure two gold medals at the 1964 Winter Olympics. In fact, there is a multitude of non-drug-related factors that can provide a competitive edge and tilt the playing field in favour of better-endowed and better-resourced athletes. This begs the question as to whether it would be appropriate to handicap athletes with extraordinary natural abilities. This is effectively the intention behind the use of weight-classes in boxing, wrestling and rowing. In some professional sports, leagues go to great lengths to regulate the competition in order to achieve competitive balance. Indeed, by radically amending the rules of a game and restricting the movements of able-bodied players, it may be possible to allow disabled athletes to compete with a chance of winning. Similarly, it may be possible to regulate sport activities in such a way as to allow mixed-gender participation. At one level this provides equity for everyone, but at another level becomes a bizarre exercise in equalisation that can never lead to 'true' equality. WADA is not concerned with inequality as such; it accepts, for example, that the naturally occurring ratio of testosterone to epitestosterone can vary between individuals and confers a relative advantage to some. What WADA does not accept is the boosting of individual advantage through the use of certain designated drugs. In general, sporting competitions are inherently unbalanced owing to such factors as genetic advantage, gender bias and differing levels of socio-economic access to training technology. A second ambiguity can be found in the fact that not all performance-boosting drugs and substances are universally banned, caffeine being a prime example. In addition, some drugs that clearly reduce performance are also forbidden. The inconsistency is compounded when we find that alcohol and tobacco, two of society’s most destructive drugs, are tacitly accepted. It therefore comes as no surprise that WADA’s policy has similar punishments for performance-reducing and performance-enhancing drugs. This confusion over which drugs are problematic, and the penalties for using banned drugs, is partly a symptom of the method used to determine which substances are prohibited. To be included on the WADA prohibited list, a substance must either be a potential masking agent or must meet two of the following three criteria set out by WADA:

- the substance is performance-enhancing
- the use of the substance poses health risks to the athlete
- the use of the substance violates the spirit of sport

Marijuana, for instance, meets criteria 2 and 3 and is therefore banned even though it actually reduces performance. In contrast, over-the-counter substances such as bicarbonate/citrate, creatine and caffeine are performance-enhancing but, because they only meet criteria 1, are not banned. The social acceptance of different drugs therefore plays a significant role in determining whether the use of a substance violates the ‘spirit’ of sport. WADA’s criteria for determining which substances are prohibited therefore leads to the
banning of some drugs that do not enhance performance, while allowing others that do. It is therefore unclear as to how elements of WADA policy work to maintain a level playing field. A third contradiction in WADA’s claim for a level playing field is that in some sports where performance-enhancing drugs offer a substantial advantage and are used commonly by elite performers, parity is more likely to come from complete de-regulation rather than further regulation and testing. Allied to this problem are the mixed messages that bombard the sport-watching market-place. On one hand, the general public condemns athletes for using drugs, but on the other hand they laud their record-breaking performances [10312].

**Protecting the health of athletes**

The dangers of unregulated drug use in sport, both of the performance-enhancing and performance-reducing variety, have been clearly established. There is also agreement that sport and its regulating agencies must take some responsibility for the health of athletes. Risk is an inherent part of sport, and governing bodies attempt to mitigate it wherever possible. However, sports such as American football, mountaineering, base-jumping and motor racing continue to be played despite warnings of the risks of serious injury. In fact, to remove all the risk is to remove an intrinsic part of sport itself. Given that athletes are free to engage in sports with substantial risks, why are they not also free to utilise performance enhancements that are, in some cases, less risky than the sports in which they engage? A punitive drug use policy that is defended on the grounds that it protects the health of players sits uncomfortably with a tacit acceptance of sports such as boxing, where the intent of the participants is to inflict serious harm. It also sits uncomfortably with a sporting tradition that embraced a close association with tobacco products for so long, and supports continuing association with alcohol-based products, both of which come with a serious community health risk. Moreover, the policy of banning drugs has made it more difficult for athletes to obtain medical advice that might reduce the health damage of the drugs they are using. It has been shown that athletes who self-medicate tend to use substantially more than necessary, thereby amplifying their risk of illness and injury. The issue here is to strike an appropriate balance between widespread drug use under a legalised system and less prevalent but higher-risk drug use patterns under an anti-doping regimen. There is also the problem of the market-place reaction to a culture of legalised drug use among athletes. Would fans exert pressure on athletes to abstain, and unintentionally promote masking and experimental drug intake, or would they concede that bolstering testosterone levels in a medically safe manner is as socially acceptable as undergoing a breast augmentation? The fact remains that in both scenarios drug use to enhance performance will be an ongoing feature of sport, and the critical issue is to identify the approach that best protects the health of athletes and minimises the cost to society. Most sporting activities, especially at elite level, require athletes to perform at the outer limit of their physical capacity and therefore demand risk-taking and pain tolerance. A masculine ethos holds risk-taking at its core, and the combination of illegality, risk of exclusion and potential for physical damage can be part of the attraction of taking drugs. A punitive anti-doping policy may therefore have the unintended consequence of making drug use even more attractive to some hyper-masculine athletes because of its association with deviant and high-risk behaviour. On the other hand, a policy that acknowledges the logic of using drugs to enhance performance might normalise its consumption, and provide space for a more open public debate on drug use in sport. By focusing upon the importance of performance and winning, sport also provides favourable conditions for its scientisation and medicalisation. Even the use of approved drugs for rehabilitation encourages risky behaviours, such as the use of pain-killers to allow players to re-take the field after injury. Athletes now operate in a sporting culture which supports the use of medical treatments and substances to boost and sustain performance, and managers of professional sport teams have a vested interest in getting injured players back onto the field of play in the shortest possible time, using pain-killing and anti-inflammatory drugs to
speed up the process. However, in so doing they put the long-term health of players at risk by increasing their likelihood of sustaining chronic injury problems [10312].

Preserving the integrity of sport

The final assumption underpinning WADA policy reflects the imperative to protect sports' public image and reputation. In a sport official's ideal world, players will volunteer their free time to assist disadvantaged groups, treat women and people of other races respectfully, obey all traffic laws, drink alcohol within legal limits and in general be model citizens. The thing they fear most is an allegation that one of their players has taken either a performance-enhancing or illicit drug. In this context drug use is particularly vexing because, like match-fixing, it goes against the fundamental ethic of sport, which is all about adhering to a set of intrinsic rules and the values they mirror. Performance-enhancing drugs are seen to threaten sports' integrity by removing any sense of fair play, while the illicit (mainly performance reduction) drugs threaten sports' integrity by tarnishing its public image. However, all this strong rhetoric begs the question as to just how effective a punitive policy will be in eliminating drug use and shoring up sports' public appeal and good standing. The evidence is ambiguous in this regard. Whereas a lack of vigilance in testing may lead to more drug use, the punishments handed out to the few who are caught using anabolic steroids are not effective in discouraging use. While heavy sanctions and punishments may play a role in discouraging drug use in sport, these types of regulations are just some of many of factors that impact on players' decision to use drugs. WADA also claims that taking drugs to enhance sport performance is inappropriate because it compromises the ethical foundations of sport and reflects poorly on its organisation and management. In other words, doping practices should be punished because they undermine the social value of sport and its fundamental authenticity. However, the idea that all sport is bound by the same values and customs is a romantic one, and ignores the peculiar cultural histories and evolution of different sports and the impact of science, technology and commercialisation on their structure and operation [10312].

Policy implications

The realities of sport are that, even in drug-free situations, athletes do not set particularly good examples, sport is not a level playing field, attempts to protect athlete's health are often no more than token gestures and the integrity of sport is determined just as much by its structures, management systems and culture as it is by the behaviour of its players. As a result it is fanciful to think that a selective and punitive anti-doping policy will, of itself, ensure the social and moral progress of sport. Indeed, draconian polices that are embedded with heavy penalties can just as easily force players to take even greater risks in the quest for sporting stardom. For these reasons we argue that anti-doping policy in sport could learn from the harm minimisation principles advocated by agencies managing illicit drug use in the broader community. Policies that consider only the reduction of drug use (such as the number of people using drugs or the amount of drugs being used) are not concerned predominantly with the relative danger of the different types of drugs being used or whether they are used in a high-risk or low-risk manner. They also have a limited capacity to inform the differing domains of education, law, rehabilitation and public health. Policies that aim to reduce drug use can also promote "collateral harms". For example, intensive policing and punishments have been shown to increase the risk of harms associated with illicit drug use. Furthermore, evidence suggests that not only will prohibition fail to reduce drug use, but the cost of enforcement may also lead to an increase in the street-price of drugs, thereby making their trafficking more appealing. In contrast, harm minimisation, which covers policies that aim to reduce drug-related harm, is concerned primarily with addressing the negative

2146
consequences of use, rather than the act of use itself. The harms associated with drug use can include health-related dangers such as risk of death and serious illness, as well as social stigmatism and loss of personal dignity. While harm minimisation policy may incorporate strategies to promote the reduction of drug use, it does so in a harm-sensitive manner so as to avoid unwanted collateral problems. There are three elements in a harm minimisation model which deserve special attention in the sporting context, and they include, first, the importance of context in determining a harm minimisation policy, secondly the development of strategies to reduce demand, and thirdly an emphasis on prevention and early intervention. However, WADA’s anti-doping policy aims to reduce drug use, not harm, and therefore overlooks many of these domains. In addition, drug use in elite sport occurs in an environment where there is significant emphasis on winning, with associated social and economic benefits. Furthermore, social values in the West condone and promote the use of technologies to gain a personal advantage, such as increased physical attractiveness or improved physical capacity. It is consequently unrealistic to expect that performance-enhancing drugs can be eliminated from the sporting milieu, given the situational incentives for their use. Another element of harm minimisation models which deserves consideration in sport is its emphasis on prevention and early intervention. Importantly, this includes the prevention of escalating patterns of drug use. Progression of this type is not being addressed by WADA, which relies on its zero-tolerance, sanction-only approach. While the anti-doping policy of WADA may appear to be promoting harm minimisation by deterring the use of drugs in the first place it may actually encourage high-risk drug use, as the negative outcomes of prohibition include increased risk from unsafe use. Therefore, if prohibition is to be used, it needs to be managed in a harm-sensitive manner. In the context of sport, harm minimisation reflects three empirically tested principles. First, drug use is not simply a sporting matter, nor is it a criminal or legal matter. Instead, drug use in sport is a serious societal issue. Secondly, harm minimisation obviates the need for any form of moral certitude. Instead, it accepts that drug use exists in sport, and will never be completely eliminated. Thirdly, although harm minimisation does not condone the use of drugs in sport, it acknowledges that when it does occur policy makers have an obligation to develop public-health measures that reduce drug-related harm to athletes at all levels, irrespective of whether they compete or qualify for testing. From a harm minimisation perspective, the key question is whether it is preferable to be interested in the short-term brand equity and credibility of elite sport, or in the long-term best interests of athletes. Rather than eliminating the use of drugs, draconian rules and sanctions will only send it further underground as players search for more exotic and less detectable options. The need for a broad-based drug management policy in sport is therefore paramount. Moreover, any drug management policy should include not only performance-enhancing drugs, but all other drugs, illicit or not, that may undermine the long-term health prospects of players and the sustainability of their sport. This means that alcohol and tobacco should fall within the purview of a balanced drugs-in-sport policy. Given the complexities that characterise the drugs-in-sport landscape, it is not surprising that polices designed to punish athletes for taking drugs have not been successful in removing drugs from sport. In addition, there is little evidence that indicates any significant improvement in the health and well-being of players resulting from the current anti-doping policy arrangements. The alternative model is a harm minimisation policy that allows athletes to manage their usage in a safe environment free from ill-informed advice, contaminated supply and the threat of severe shame and punishment. Although controversial in a sporting context, it accepts that drugs will always be part of a risky and tilted playing field full of moral ambiguity. It was argued that a socially responsible philosophy that focuses on the reduction of collateral harm, and seeks out a sound evidence base, should be sovereign in determining future drugs-in-sport policy [10312].
WADA provides the following information: WADA is extremely careful with investigators conducting research activities on its behalf to ensure they work with occasional or recreational athletes to circumvent the risk of exposing elite athletes to prohibited drugs or methods. Even when working with occasional or recreational athletes, WADA ensures that sufficiently long wash-out periods are applied to guarantee that no unfair advantage is provided to volunteers participating in research studies [13774].

The WADA response to research on doping is thus very clear, especially point 8, which states their position in no uncertain manner: “8. WADA considers that conducting research studies with elite athletes should not expose them to prohibited substances and methods unless specific dispositions are made such as retiring the athletes as active athletes for a considerable period” [13775].

Ethical codes

A code of ethics for sports physicians needs to be clear, appropriate and practically useful to clinicians in everyday clinical circumstances and for situations that may be difficult or contentious. The code of Australasian College of Sports Physicians (ACSP) was recently rewritten based on research into the ethical concerns of sports doctors and physicians in New Zealand. Further appraisal of the existing code in the light of these findings led to concerns about its adequacy. The previous ACSP code had not been updated in 25 years, and had gaps in topic areas and errors within it that made it potentially confusing. Any code written for a specialist group must acknowledge the context of its governance. By virtue of their medical registration, sports medical practitioners are required to comply with the code written for all registered medical practitioners in their local jurisdiction. They may also be subject to specialty codes written specifically for physicians who have received further training in sports medicine, and there may be consensus guidelines written on various topics [09386].

A code of ethics with a foundation in evidence

To ensure that a new code meet the needs of physicians and covered appropriate areas requires that it be informed by evidence. It had previously been carried out qualitative research with 16 sports medical practitioners working with elite athletes and teams in New Zealand. Sports medical practitioners were asked to identify and discuss a range of ethical concerns they experienced in their work. There were three key findings from this research [09386]:

- sports medical practitioners work within a complex and pressured environment that has the potential to compromise patient welfare and limit a doctor’s ability to provide quality care or demand better conditions for their patients
- sports medical practitioners may have multiple obligations to others including individual patients and employers. At times these responsibilities may conflict when meeting one obligation will result in neglecting others
- sports medical practitioners vary widely in their perceptions in two particular aspects of practice

The complex environment of elite sport

Sports medicine at the elite level occurs within a complex setting that may include the pressure of large amounts of money riding on results, together with a high level of media
attention into the wellbeing of athletes. Those two elements are further intertwined as media attention can attract sponsorship and advertising and even greater medical services if the athlete/team is successful. Coaches, team management and sponsors can seek to transfer this financial pressure to sports doctors. Although some coaches respect the doctor’s knowledge and experience, this was not the case among all medical practitioners interviewed. Some sports medical practitioners have fought difficult battles with coaches, sponsors and governing bodies, sometimes dealing with entrenched views about the nature of injury and rehabilitation. Some participants described situations in which their decisions were overridden, disrespected and in which the athlete’s wellbeing was overlooked by others with divergent aims. In this kind of environment sports medical practitioners may lack the independence and support required to attend to the needs of their patient group [09386].

Sharing personal information about athletes with others

Employment contracts commonly oblige medical practitioners to share health information with coaches and team management. Correspondingly, employment contracts between athletes and team management make similar demands to share health information. Despite this, athletes may request sports medical practitioners to withhold health information from the coach and management [09386].

Risk taking by athletes

When an athlete wished to take a course of action with a significant risk to health, all sports medical practitioners took an educational role seriously, but there is a lack of consistency about whether to support or limit an athlete’s ability to assume risk. For example, one doctor said he would do whatever the patient requested so long as it was not illegal, whereas another has it written into the athlete’s contract that the sports medical practitioner has the final say on who can play. Although these responses may be acceptable depending on the individual clinical situation faced, ambiguity exists about how medical practitioners should respond [09386].

Aims for a new code of ethics

A code of ethics serves a number of purposes. These include articulating professional standards for its members, ensuring the protection of the public and to enhance the trust society has in this group. Codes provide an opportunity to express the shared values of the group and the profession. On a practical level, codes can be used to support members with ethical decision making, and can act as a shield to protect practitioners from unacceptable demands and external pressures. Codes of ethics also set out standards of behaviour to be used as a yardstick against which to measure the actions of its members. For example, as a more organised group with clear expectations and limits sports physicians could respond more effectively to new developments in sport that have the potential to affect athlete wellbeing negatively, including new forms of high-risk sport, new cell technology and genetic enhancement [09386]:

- *Comprehensible* (accessible). A code of ethics is, in part, a form of communication between the general public and the profession, and as such it needs to be accessible to both patients and clinicians. The document must therefore be written without jargon and in plain language
- *Unambiguous*. A code of ethics must avoid confusion so it must be plainly expressed, clear in its requirements and not contain unintended double meanings
- *Compatible with existing codes and laws*. A code of ethics should seek to be compatible with legislation governing the practice of medicine in the relevant country
or state. Although medical codes should always reserve the right not to comply with any law considered unjust, in general codes should comply with legislation. A code of ethics written for a specialist medical group should also be compatible with relevant codes written for all registered doctors in that jurisdiction.

- **Must/should.** The must/should structure allows the document to set minimum standards expected of all physicians expressed through the term "must", whereas the term "should" was used to convey aspirational aims of the college. The use of "should" statements allows for guidance in situations in which no strict rule would be appropriate or possible. Problems exist in deciding where to place the division between “must” and “should”. Setting expectations for behaviour too high will result in “must” statements that are unachievable. The use of the word “should” in the wrong place would result in a failure to impose minimal standards.

- **General/specific.** Excessive detail renders the code long and unwieldy and threatens its usefulness. It is impossible to imagine every clinical scenario. Any attempt to do so within a code will inevitably lead to some unconsidered possibility being overlooked, leaving the clinician unsure how the code applies. If the code is too general we also run into problems. A code that has grand statements such as “always act for the good of the patient” or “always act with the highest integrity” without further detail can be banal and of little practical use. It is hard to know how such general statements apply in specific situations. Such injunctions also fail to provide standards to measure a physician against.

- **Reflecting patient needs.** Physicians as stakeholders in the new code will bear the greatest burden from any obligations set out therein, but patients are also stakeholders as they clearly have an interest in the behaviour and obligations of their physicians. No input can be sought from patient groups in the development of the code, partly due to limited time, but also because it was considered that an improved code could only be an advance for athletes. It was thought that if physicians were strengthened in their ability to resist demands that eroded their commitment to patients then patients would ultimately benefit.

- **Implementation.** To implement the new code effectively will require member support of the code. To achieve this, members need to be informed about the existence of the new code and how their obligations may have changed. An education campaign of members must be undertaken. Because it is not possible to police every action taken by a physician we must rely on the commitment of members, so each individual member must feel that the code is appropriate and fits with the ethos of the group.

- **Administration of the code.** Members will quickly lose respect for a code that is not applied appropriately, in a timely fashion, or fairly. Therefore any complaints must be dealt with in a procedurally just and appropriate manner and disciplinary action must be consistent, fair and in proportion with the breach by the member. Obviously, a good organisational structure is required to be able act on complaints about members. On occasions breaches may be dealt with by governmental bodies set up to deal with complaints regarding patient care and so the organisation needs to be aware of any legal obligations to direct complaints elsewhere.

**Practicalities and negotiating the politics**

Banned performance enhancing drugs in sport is one area where the author wished to clarify expectations but was unaware of the politics involved. This should not be interpreted to mean that the code development group did not want the area to be covered, but there were concerns about where such duties should originate from. Another matter that generates discussion is the inclusion of mental health and eating disorders. The reasons for including these two topics were based on the research. Some sports medical practitioners had expressed concern over dealing with them, particularly mental health issues. For example,
some created fictitious physical injuries for their patients with mental health problems so that coaches would understand the patient needed to take time off. Also, as medical practice evolves and new developments occur in sports science, sporting practices, or law that affects medical practice, such change will need to be reflected in the code [09386].

Scientific cooperation

There are many areas of common interest between anti-doping laboratories and those working in the clinical, legal and forensic fields. In addition to methodological similarities, there are aspects of the findings in sport drug testing that overlap with other fields in such a way that sport drug testing and clinical, legal or forensic work may benefit from mutual interaction. Three recent examples are presented from the author’s experience. Case report 1 concerns the clinical relevance of hCG findings in sport drug testing as potential indicators of the presence of a (testicular) tumour in athletes. Case report 2 refers to difficulties that accredited laboratories can encounter due to differences between national legal systems and the administrative regulation systems of sport authorities. The example involves a network of blood collection for further autologous transfusion. Case report 3 relates to additional forensic-type investigations needed to interpret a situation where intoxication of a whole delegation was responsible for apparent doping cases. Clinical, legal and forensic fields must recognize the added value that some results and developments coming from anti-doping laboratories may have. At the same time anti-doping analysts should be aware of new issues, methodologies and problems appearing in related fields [09390].

The formal ethics of research with human subjects

All gene transfer studies in human subjects or patients for the purpose of preventing or treating even the most fearful and dire disease are highly experimental. As we have seen in the cases of immune deficiency diseases, there are many ways in which such procedures can go seriously wrong, but we all – patients, doctors, and society – all accept such methods in the cause of easing suffering. All progresses in medicine require multiple layers of research and testing; some in the laboratory in model systems, some with test animals, and some necessarily with human subjects. Each layer of research and testing requires a set of appropriate ethical standards for how such research should be conducted. Research, at all of these levels, is appropriate and necessary, and there is nothing intrinsically wrong or unethical in experimentation with human beings, as long as such studies conform to socially approved and agreed-upon standards. At this stage of development of gene transfer technology in human beings, human gene transfer and gene therapy studies are highly experimental and, therefore, must be subject to the accepted norms and standards that pertain to all human experimentation. As is true in all other areas of human clinical research and experimentation, failure to comply with these, or other comparable universally accepted standards, must rightly be considered medical malpractice and professional misconduct when carried out by licensed professionals or even criminal in cases in which the use of drugs and other materials or devices is not in accordance with governmental licensing and commercial requirements [06310].

Following World War II, the most influential of these codes was the set of principles that were enunciated as part of the Nürnberg War Crimes Doctors’ trial in 1947. This code identified the following 10 conditions that must be satisfied in order for any experiment with human subjects to be ethically acceptable [06310]:

2151
- The voluntary consent of the human subject is absolutely essential. This means that the person involved should have legal capacity to give consent; should be so situated as to be able to exercise free power of choice, without the intervention of any element of force, fraud, deceit, duress, overreaching, or other ulterior form of constraint or coercion; and should have sufficient knowledge and comprehension of the elements of the subject matter involved as to enable him to make an understanding and enlightened decision. The duty and responsibility for ascertaining the quality of the consent rests upon each individual who initiates, directs, or engages in the experiment. It is a personal duty and responsibility which may not be delegated to another with impunity.
- The experiment should be such as to yield fruitful results for the good of society, unprocurable by other methods or means of study, and not random and unnecessary in nature.
- The experiment should be so designed and based on the results of animal experimentation and a knowledge of the natural history of the disease or other problem under study that the anticipated results justify the performance of the experiment.
- The experiment should be so conducted as to avoid all unnecessary physical and mental suffering and injury.
- No experiment should be conducted where there is an a priori reason to believe that death or disabling injury will occur; except, perhaps, in those experiments where the experimental physicians also serve as subjects.
- The degree of risk to be taken should never exceed that determined by the humanitarian importance of the problem to be solved by the experiment.
- Proper preparations should be made and adequate facilities provided to protect the experimental subject against even remote possibilities of injury, disability or death. 8. The experiment should be conducted only by scientifically qualified persons. The highest degree of skill and care should be required through all stages of the experiment of those who conduct or engage in the experiment.
- During the course of the experiment the human subject should be at liberty to bring the experiment to an end if he has reached the physical or mental state where continuation of the experiment seems to him to be impossible.
- During the course of the experiment the scientist in charge must be prepared to terminate the experiment at any stage, if he has probable cause to believe, in the exercise of the good faith, superior skill and careful judgment required of him, that a continuation of the experiment is likely to result in injury, disability, or death to the experimental subject.

At the heart of the code are the principles that participation in experimental studies must be voluntary based on informed consent and justified by a potential for benefit that outweighs the potential for harm. Being “informed” requires that the study participants understand what will be done and agree to bear the expected risks and reap the anticipated benefits. These principles have served as the basis for many variations and subsequent modifications by worldwide medical and scientific bodies, including the influential codes developed by the World Medical Association in the form of its Declarations of Helsinki; first stated in 1964, and amended and extended many times, most recently in 2004. Parts of the Helsinki Declaration as revised in 2004 that are relevant to the potential inclusion of healthy, young subjects in nontherapeutic research state that it is the duty of the physician in medical research to protect the life, health, privacy, and dignity of the human subject [06310]:

- Medical research involving human subjects must conform to generally accepted scientific principles, be based on a thorough knowledge of the scientific literature,
other relevant sources of information, and on adequate laboratory and, where appropriate, animal experimentation.

- Appropriate caution must be exercised in the conduct of research which may affect the environment, and the welfare of animals used for research must be respected.
- The design and performance of each experimental procedure involving human subjects should be clearly formulated in an experimental protocol. This protocol should be submitted for consideration, comment, guidance, and where appropriate, approval to a specially appointed ethical review committee, which must be independent of the investigator, the sponsor or any other kind of undue influence. This independent committee should be in conformity with the laws and regulations of the country in which the research experiment is performed. The committee has the right to monitor ongoing trials. The researcher has the obligation to provide monitoring information to the committee, especially any serious adverse events. The researcher should also submit to the committee, for review, information regarding funding, sponsors, institutional affiliations, other potential conflicts of interest and incentives for subjects.
- The research protocol should always contain a statement of the ethical considerations involved and should indicate that there is compliance with the principles enunciated in this declaration.
- Medical research involving human subjects should be conducted only by scientifically qualified persons and under the supervision of a clinically competent medical person. The responsibility for the human subject must always rest with a medically qualified person and never rest on the subject of the research, even though the subject has given consent.
- Every medical research project involving human subjects should be preceded by careful assessment of predictable risks and burdens in comparison with foreseeable benefits to the subject or to others. This does not preclude the participation of healthy volunteers in medical research. The design of all studies should be publicly available.
- Physicians should abstain from engaging in research projects involving human subjects unless they are confident that the risks involved have been adequately assessed and can be satisfactorily managed. Physicians should cease any investigation if the risks are found to outweigh the potential benefits or if there is conclusive proof of positive and beneficial results.
- Medical research involving human subjects should only be conducted if the importance of the objective outweighs the inherent risks and burdens to the subject. This is especially important when the human subjects are healthy volunteers.
- Medical research is only justified if there is a reasonable likelihood that the populations in which the research is carried out stand to benefit from the results of the research.
- The subjects must be volunteers and informed participants in the research project.
- In any research on human beings, each potential subject must be adequately informed of the aims, methods, sources of funding, any possible conflicts of interest, institutional affiliations of the researcher, the anticipated benefits and potential risks of the study, and the discomfort it may entail. The subject should be informed of the right to abstain from participation in the study or to withdraw consent to participate at any time without reprisal. After ensuring that the subject has understood the information, the physician should then obtain the subject’s freely given informed consent, preferably in writing. If the consent cannot be obtained in writing, the nonwritten consent must be formally documented and witnessed.

In summary, all experimental procedures in human patients or normal volunteers must conform to these standards or to one of many other codes that have been derived from these original sets of principles [06310].
The ethical principles used by review bodies

Given the understanding that some experimental studies in human subjects and patients are an acceptable part of acquiring knowledge of normal human biology, all the review and regulatory bodies involved in gene transfer studies are charged with two principle tasks common to all human experimentation. The first is to minimize risks of harm to research subjects and to assure that the risks are reasonable in relation to the expected benefits to the subject or in relation to the importance of the knowledge likely to be derived. Harm could include physical harm such as pain and serious injury, psychological damage such as stress or guilt, invasion of privacy, and breach of confidentiality. Risk varies from minimal to severe, with minimal risk generally taken to mean a risk of harm no greater than a subject would encounter in daily life or during routine performance of physical or psychological testing. An undeliverable or excessive promise of reward or benefit can be considered another form of harm; a particularly appropriate issue in the case of healthy young athletes in the context of genetic enhancement applications. Identification of benefits or potential benefits is also a vital part of the decision process in these panels. Benefits include potential increased well-being of the subjects, but since most gene therapy studies to date have been phase I studies in which the goal is merely to establish safety and not efficacy, research participants cannot expect to derive any direct benefit [06310]

The decision to enter into an experimental procedure requires full disclosure by the investigator, informed and voluntary consent by the subject, with the word informed underscored in the context of potential genetic doping. There are some basic requirements that must be satisfied when seeking informed consent from research subjects. It should be clearly stated that the subject is being invited to participate in a research project. There should be a comprehensible description of reasonably foreseeable harms (physical, psychological, social) and benefits that may arise from participation. Assurance that prospective subjects are free to decline their participation must be provided and that subjects have the right to withdraw at any time without prejudice. The possibility of commercialization of research findings and the presence of any actual or potential conflicts of interest on the part of researchers, their institutions, or sponsors [06310].

Further amendments

It has also been agreed on a series of conclusions on gene technology, some general and other specific to sports [06308]:

General principles
A. Gene transfer technology, which is still at the investigational stage, is nevertheless already beginning to demonstrate clinical efficacy
B. While genetic technologies hold immense therapeutic promise, there is potential for their misuse, including attempts at the enhancement of athletic performance
C. The collective efforts of scientists, ethicists, athletes, sports authorities, medical practitioners, professional societies, pharmaceutical and biotech industries, and public authorities (including governments) will be required to avert such misuse
D. The compliance with established international standards pertaining to genetic experimentation involving human subjects, such as the Helsinki, Geneva, and Lnuyma Declarations that prevent unethical research is essential. The application of genetic transfer technologies should be consistent with established standards of professional behavior
E. The pace of research in the field of genetic transfer technology is such that governmental
and other regulatory agencies must work with a continued sense of urgency to establish a social and policy framework to guide this research and its applications and sanction breaches of the framework.

F. Broad public discussion and the development of social and policy frameworks must surround the distinction between genetic therapy and genetic enhancement. The time for the social framework to be established is before abuses occur, not after-the-fact.

**Sports specific**

A. Athletes, in common with other people in society, are entitled to the benefits of genuine therapeutic applications to treat injuries and other medical conditions.

B. There are evident risks that genetic transfer technologies might be used in a manner that would be contrary to the spirit of sports or potentially dangerous to the health of athletes. Akin to doping in the present generation, genetic transfer technology that is nontherapeutic and merely performance enhancing should be prohibited.

C. The definition of doping used by WADA, the IOC, international sports federations (IFs), and national authorities should be expanded to include the unapproved use of genetic transfer technologies.

D. One of the benefits of genetic technology is its potential use in the detection of prohibited substances and methods.

E. The scientific community has recognized the need for the continued development and refinement of methods that will permit the detection of the misuse of genetic transfer technologies in sports. It has been noted there are a number of approaches that currently exist, or are in development, that will permit such detection.

F. The present focus of WADA’s research grants toward the study of the detection methods for the misuse of oxygen-carrying agents and growth factors should be extended to include the detection of genetic transfer technologies and their effects.

G. The World Anti-Doping Code, which is planned for implementation by 2004, should include language prohibiting the use of genetic transfer technologies to enhance athletic performance.

H. WADA calls upon its government members, in particular, to expedite the development of a global social framework for the application of genetic transfer technologies that address the potential misuse of these technologies in sports and a publicly stated deadline for the adoption of that framework.

I. WADA calls upon governments to consider the following recommendations for inclusion in the regulatory framework pertaining to genetic transfer technologies and related research:

- Address breaches of the social framework within the criminal or penal realm.
- Extend corporate liability to directors, officers, and senior employees.
- Extend civil and criminal. There are evident risks that genetic transfer technologies might be used in a manner that would be contrary to the spirit of sports or potentially dangerous to the health of athletes. Akin to doping in the present generation, genetic transfer technology that is nontherapeutic and merely performance enhancing should be prohibited.
- Require detailed record-keeping in respect of all applications of gene transfer technologies with independent audit requirements.
- Expand standards of medical and professional behavior to prohibit the improper use of genetic transfer technologies and that such rules be actively enforced.

J. WADA calls upon governments and the sports movement to establish and fund educational and ethics programs designed to prevent the possible misuses of genetic transfer technologies in sport. WADA is willing to coordinate the design and dissemination of such programs.

K. WADA and the scientific community will establish a mechanism for continuing dialogue and consultation around the subject of genetic transfer technologies.
Sport as an occupation

Occupational medicine deals with all work related aspects of health that affect the employee's ability to function effectively: the workplace itself, the type of work, the state of health of the employee. In addition to purely physical aspects, social and psychological influences must also be considered. It is easy to see that construction workers who are paid according to how much work they complete will be subject to greater stress than, say, a gardener or office worker employed on standard terms. Moreover, within any occupation there are those – often a considerable percentage – who will regularly need medicines to function properly—for example, those with diabetes, high blood pressure, allergies, rheumatic disorders. In such cases, any extra stress in the work environment can easily lead to a situation where the ability of the person to function is close to the borderline of what can be physically expected. These people can often become incapable of continuing in the job or of only doing so under medical supervision and with the prescription of suitable medicines.

There are definite limits to the level of stress under which such people can function and it is the concern of occupational medicine to recognise and deal with these limits. Occupational medicine aims to point out to both employer and employee that only under certain specified conditions will optimum performance be possible. The conditions that could be recommended in such cases might include changes in the workplace, in working hours, in the pressures of the job, or might specify regular medical treatment for the employee—for example, prescription medicines to protect the employee from the effects of workday stress, such as beta-blockers. If we now consider a sport such as football, a number of examples can be identified. The proportion of players who have allergies is similar to that in the general population, and the treatment will be the same—that is, appropriate therapy often involving the taking of medicines, especially during those times of the year when the allergen count is high. But when we are dealing with open air sports, the treatment prescribed could lead to problems since many of the drugs usually prescribed are on the list of banned substances (such as corticosteroids) even though their prescription is medically justified. An example of an American professional international woman player makes the situation clear. She has a relatively rare disease that makes her blood pressure and fluid balance subject to extreme variations; this in turn makes it impossible for her, without medical help, to pursue her profession at the required level. She needs ongoing treatment with a mineralocorticoid (fludrocortisone). However, in contrast with those mentioned above, this medicine has neither an anabolic nor an anti-inflammatory effect and is thus not technically a doping substance in the true sense of the term. This raises the question whether it really constitutes doping if a player can perform at the expected level only after taking such a medicine. It is suggested that this is a problem that falls within the scope of occupational medicine. If such treatment is prescribed for genuine medical reasons and involves taking a drug that in itself has no doping effect, then we cannot be talking about a case of doping, rather merely of enabling a professional player to exercise his or her normal profession. Occasional treatment with banned substances for "bona fide" medical reasons should be permitted if the facts of the case are presented openly to the doctors in charge of the doping control. A quite different question is whether the ever increasing demands faced by professional footballers, in terms of the number of matches and tournaments in which they are expected to play, can be compensated for by taking medicines so that the required level of performance can be achieved over and over again. Playing so frequently, in football as in other sports, under circumstances necessitating more or less continual treatment with painkillers and anti-inflammatory agents, can have serious long-term consequences that really cannot be justified on the basis of occupational medicine or medical ethics. In this case, the limits of doping are recognisable [06001].
Admittedly there is no doping in the first two examples in terms of performance enhancing drugs being taken. However, in the sense of medical treatment being used to suppress the symptoms of injuries and overexertion, clearly there is an aspect of doping involved. The workplace pressures on players in the short term lead to long term effects being ignored. As long as the players in question and their associations all have the same approach, only a firm stand by sports and occupational medicine will have the effect of providing the players with at least partial protection from such long term damage. This is further reason why the campaign against real doping must be actively pursued [06001].

**Legislation of drugs aimed for doping**

The arguments for and against the legalization of performance-enhancing drugs in sport operate on two different levels. On one level, there are pragmatic arguments concerned with the effort required to establish and enforce controls, the quality and quantity of these controls, and the responsibility for and costs of regulations. Also on this level are arguments concerning the need to preserve the audience’s trust in sport, freedom of choice for athletes, the justification for introducing additional risks and the need to avoid risk, especially in children and adolescents. On another level, there are also arguments that touch on the “spirit of sport” and the “naturalness” of performance in sport. Whether this “spirit of sport” has a “central constitutional quality” which one may not change under any circumstances, or whether in fact it can be modified, remain as controversial as the question of whether doping is consistent with the true “spirit of sport” or not. Even if it were thought acceptable to abolish normative behaviour consistent with “the spirit of sport” and that it would be then still possible to perform with a degree of “naturalness”, this step should be taken only if advantages could be expected to ensue. Doping also entails avoidable risks that are not necessary to increase the attractiveness of the sport. Furthermore, many risks, particularly over the long term, are difficult to anticipate. Legalization would not reduce the restrictions on athletes’ freedom; the control effort would remain the same, if not increased. Extremely complicated international regulations would have to be adopted. Above all, the function of sport as a role model would clearly be damaged [11308].

The doping problem in sport has yet to be solved. One must continue to assume that controls do not identify all athletes who use performance enhancing drugs. As a result, a general suspicion has arisen that some of the most outstanding achievements in sport may have been achieved by doping. For this reason, several authors have claimed that controlled use of performance-enhancing drugs in sport should be permitted. If that were to happen, the central argument against doping – i.e. the fairness argument – would immediately be rendered irrelevant (assuming that all athletes used performance-enhancing drugs within the permitted boundaries), and a ban on doping would be more difficult to justify. However, any legalization of performance-enhancing drugs in sport, if it were to occur, would need to be subject to limitations. This is not disputed by either opponents or supporters, for complete legalization would also sanction actions that introduced risks and possibly irreversible damage to an athlete’s health. That would certainly be unacceptable, even if the athlete were willing to accept the risks and damaging effects, because it is inconsistent with the favourable health requirements of sport. In extreme cases, the medically induced, transient success achieved by doping would be paid for with definite and permanent damage to health or even loss of life. This is considered to be too high a price to pay in sport, even in a society that permits self-destructive behaviour. One review therefore examined whether performance-enhancing drugs should be permitted in sport under the control of physicians, and evaluates the expected outcomes of such a scenario. Such a change in regulation would need to be tightly controlled because of the risks involved. The results of legalizing
performance-enhancing drugs in competitive sport would be either unhelpful or negative, and the unwanted aspects of doping control would not disappear. Athletes, including children and adolescents who wanted to pursue competitive sports, would be forced to take additional, avoidable health risks. How the appropriate limits of the use of performance-enhancing drugs can be determined is by no means self-evident and requires further investigation. The current lack of knowledge means deciding which doping activities lead to which unwanted effects is often difficult to determine, particularly with regard to the long-term perspective. This lack of knowledge is particularly problematic in relation to new substances. Also, no biological agent powerful enough to achieve major changes in body or mind is likely to be entirely safe or without side effects. Moreover, if a legalization of performance enhancing drugs in sport were to be introduced, it would need to be clarified who should determine the permissible limits of use of such drugs. This could not be left to the discretion of an individual physician, as assessments of the acceptability of risks in doping may vary. Moreover, athletes who were willing to take risks would search for the most helpful doctor. Thus, the concept of equal opportunities for all athletes would be compromised by a physician factor. To avoid this, the limits of doping would need to be specified in advance and independent of the physician-patient relationship. Furthermore, to ensure comparability of conditions for athletes, such rules would need to be established and ratified internationally. Thus, an international organization with the required expertise and authority to make such evaluations would still be needed to determine the permissible limits of doping in sport. All limits on doping would then be based on whether the risk to the athlete was still considered acceptable. Ensuring the safety of athletes in the event of a legalization of performance-enhancing drugs would require internationally coordinated, costly and complicated regulations that would require considerable effort and result in extensive controls. There might be rare instances of doping in sport that had acceptable side effects, but making these permissible would add further difficulties in terms of defining limits and introducing further controls. The “natural lottery” of athletic talents would be compensated for only partially by use of performance-enhancing agents. It would also be complemented by another “natural lottery” of variable responses to doping measures, combined with the inventiveness of doping doctors. There would be no gain in “justice” (i.e. fairer results that reflected efforts made) for athletes as a result of legalizing doping. Legalization would not reduce restrictions on athletes’ freedom; the control effort would remain the same, if not increased. Extremely complicated international regulations would have to be adopted. The game of the “tortoise and the hare” between doping athletes and inspectors would remain because prohibited but not identifiable practices could still provide additional benefits from use of permissible drugs. Audience mistrust, particularly toward athletes who achieved outstanding feats, would remain because it would still be possible that these athletes were reliant on illegal doping practices. Doping entails exposing the athletes to avoidable risks that do not need to be taken to increase the appeal of a sport. Most importantly, the function of sport as a role model would definitely be damaged. It is not necessary to clarify the question of what constitutes the “spirit of sport” and whether this may be changed. From a practical point of view, a legalization of performance-enhancing drugs in sport should not be considered for the simple reason that it has no advantages but many disadvantages [11308].

What role would be left for physicians if performance-enhancing drugs were to be legalized under medical supervision? Medical supervision would be concerned only with the development and, if necessary, production of performance enhancing drugs, their use within the permissible boundaries and controlling their effects. Further responsibilities and, in particular, assessing which risks are acceptable for the athlete to take, should not be assigned to the physician. Nevertheless, even with pre-determined limits on the permissibility of performance-enhancing drugs, physicians would always retain a degree of autonomy in terms of determining the optimal doping regimen for their athletes. Enforcement of the present ban on performance enhancing drugs depends on extensive and logistically complex

2158
controls which, if they are effective at all, considerably limit the athlete's freedom. Supporters of a legalization of performance enhancing drugs might believe that concerns about athletes' health would lead to more tests when the use of such drugs is permitted. However, it is important to note that certain health problems manifest themselves only over the long term and cannot be detected by close medical inspection. Furthermore, if proponents of limited legalization advocate banning all doping practices with potential long-term risks, the great temptation remains for athletes to do these things illegally. In this respect, nothing would be gained. Thus, the key argument against limited legalization under medical supervision becomes clear, namely, that no advantage would be obtained in terms of reducing the current difficulties of implementing doping controls. There would always be those who attempted to use new, performance-enhancing methods that are not permitted and have yet to be discovered. For these reasons, if limited legalization of performance-enhancing drugs did ensue, an unpleasant development in athletic sports, which has spoiled the relationship between the audience and the sport, would continue. This refers to the fact that when an athlete achieves outstanding results in sport, the suspicion is automatically raised that this was achieved by doping. In other words, sports fans have become skeptical. This situation would probably not change with a limited legalization; there would still be the possibility that an excellent performance was achieved through the use of doping practices that are not within the rules. Thus, even the lack of trust in athletes would not disappear.

The argument for legalization is usually based on the fact that athletes take risks in sport anyway, and banning doping therefore smacks of unacceptable paternalism. However, this argument fails to observe an important distinction: the risks of doping in sport are additional and avoidable, whereas other risks in sport are unavoidable. It is impossible to play football or other kinds of sport without risk of injury. Furthermore, while in many other kinds of sport the precautions taken can lower the risks, they cannot eliminate them completely. Conversely, as noted, the risks of performance enhancing drugs add to those that already exist in sport and can be completely avoided by doing without drugs all together. However, this raises the question of whether it is beneficial to take extra, avoidable risks in sport, e.g. to make the sport more attractive, an issue that is discussed further in the next section. The concept of “inherent coerciveness” would assume greater importance if limited legalization of performance-enhancing agents in sport were to come into effect. All competitive athletes have to make adjustments in many areas of their lives if they want to be successful in their given sports. Thus, the athlete has liberty to act but in the knowledge that his/her actions will have certain consequences. If the athlete were to forgo certain performance-enhancing behaviour, he/she would be less successful. If one allows the use of performance-enhancing drugs within certain boundaries, then all athletes who wished to be successful would have no choice but to use the substances that are allowed by the rules. They would have “free choice under pressure” in this respect. They would be forced to take actions that entail risks that are unnecessary in sport and confer no advantages upon their sport. In this respect, a limited legalization of performance-enhancing drugs would unnecessarily put further pressure on athletes to do more risky things. Conversely, “an effective policy for eliminatin performance-enhancing drug use would harm no one, except those who profit from it”.

The fact that a legalization of performance enhancing drugs would not be advantageous to sport can be seen by analysing how the use of these drugs would affect performance. The following possibilities arise:

1. All athletes respond to the approved doping measures in the same way and their performance improves in the same way. In that case, the finishing order of cyclists in the Tour de France, for example, would remain unchanged. The event would be slightly shorter in duration with the use of performance-enhancing drugs than without them. However, that would be of no benefit to the competition. All of the athletes
would have put in considerably greater effort and would have been required to take more risks with no change in the result of the event. Furthermore, the generations of athletes who were not allowed to use performance-enhancing substances would have more difficulty being included on lists of the “alltime best athletes” based on absolute values of times, weights, lengths, etc.

2. The previous point explores the consequences of legalized doping in sport if the upshot is that all athletes respond in the same manner. However, it is improbable that all athletes will respond to doping options in the same way because different measures would probably be used; and athletes respond differently to performance-enhancing drugs. The use of different doping measures is possible when there is flexibility in prescription (e.g. dosage) and enforcement of permissible doping practices. In such circumstances, athletes will strive, with the help of their physicians, to identify and use the best method for enhancing performance within the permitted limits. Thus, the outcome would reflect not only the athletes' performance, training methods, discipline and talent, but also the cleverness of their supervising physicians in finding and using the optimal doping aids within permissible boundaries. This technical extension of the competition in addition to current medical care in sport would become increasingly complicated and expensive as more substances were included on the permitted list. Different responses of athletes to performance enhancing drugs would also be expected to occur because of genotypic differences alone.

“Naturalness” in sports

If a legalization of performance enhancing drugs became a reality, the new lottery of differences in response to performance enhancing drugs discussed in the previous section would be combined in most cases with the ingenuity of the particular sports physician and other existing factors (natural talent, discipline, training) to determine the outcomes of athletic events. It must also be reiterated that a limited legalization would not exclude continued use of prohibited doping methods, perhaps in addition to use of permitted agents. It also seems likely that the more the permitted drugs were limited to minimize risks, the greater the temptation would be to use prohibited doping measures. Crucially, a legalization of performance enhancing drugs would have a massive impact on the perception of sport. It would ultimately compromise the currently, widely accepted “spirit of sport”. Sport is an artificial setting, created by human beings, in which the competitor is required to perform, at least according to current, widely prevalent belief, with a degree of “naturalness”. The sports-watching audience is interested in “athletic performance, not biochemistry.” “The fascination of sports mainly comes from the demonstration of what people are able to do on their own. Doping destroys this fascination. "However, it is important to clarify three aspects of “naturalness of performance” in sport. The first is the difficulty of determining what constitutes a “natural” measure of improving performance. Many permissible training methods and food supplements are in some ways less “natural” than other things that athletes may do. However, the fact that defining an acceptable limit for such measures, particularly when the dividing line appears to be opinion-based and is established on a more or less continuous spectrum, does not necessarily mean that we should dispense with such limits. Furthermore, this is not the approach taken in other areas of life. The difficulties inherent in putting forward arguments as to why one substance or another should or should not be on the World Anti-Doping Agency list are not sufficient reasons to characterize this list as completely arbitrary and, therefore, irrelevant. Second, it must be clearly stated that “naturalness” in sport is not considered as a value in itself, but only as a value in this specific context. In sport, great importance is attached to the “naturalness” of achievements, whereas in other areas of life this is not necessarily the case. Third, according special attention and value on
“naturalness” of performance in sport means that sport is considered different to other areas of life, in which certain “artificial” measures of obtaining improvement are allowed [11308].

An example for the society

Another argument for the need to protect the “spirit of sport” can be put forward. There can be no doubt that sport, playful in nature, but still in accordance with the rules, sets an example for society. As Albert Camus once said, “After many years during which I saw many things, what I know most surely about morality and the duty of man I owe to sport.” Sport shows, with its rules and requirement for fairness, how to deal with other problems in society. It conveys an attitude that acts as a role model in many other areas of human life and “in a sense, it can be a model for a better society.” On this issue, three different facets of the functions of role models need to be distinguished. An aspect of society can take on the function of a role model if it sets special, exemplary standards; respects certain standards in a special and exemplary way; or controls or ensures compliance with the standards in an exemplary way. First, it is useful to consider the ongoing impact of sport as a role model in these three areas if the ban on performance-enhancing drugs remained in place as follows:

- with respect to setting standards, sport would remain a model at least for most citizens
- continued violations of the norm (standard) would be anticipated and the function of sport as a role model in terms of respecting standards in a special and exemplary way would continue to be debatable
- the system of controlling or ensuring compliance with standards in sport is currently unconvincing, with many doping violations remaining undiscovered. Improving the control system would depend on further technical developments (e.g. in the collation of indirect evidence), which would make the system more convincing and therefore more able to act as a role model

Second, it is important to consider how the exemplary role of sport could change if doping were legalized as follows:

- at least for a significant part of society, sport would lose its function as a role model because the model standard it exemplifies would be abolished
- with a limited legalization of performance enhancing agents, continued violations of the new norm would be anticipated because the potential for the use of additional banned but performance-enhancing substances would remain
- the cost of control would remain unchanged and the suspicion that the control system was not effective would remain. Again, therefore, nothing would be gained in these respects compared with the existing ban. The function of the role model would also still be dependent on further technical development.

To summarize, a legalization of performance enhancing drugs would definitely result in some lessening of the exemplary role of sport in terms of setting standards. The same challenges that exist at present would need to be faced with respect to the other facets of role model function. Overall, the function of sport as a role model would be reduced. A legalization of performance enhancing drugs would diminish the function of sport as a role model, and this would particularly be the case with respect to children and adolescents. Self-restraint would be abandoned and the message would be that one must be willing to do anything for success. This boundless willingness is not a preferred role model, especially for youth. It is doubtful whether one should raise children according to a life plan which links life satisfaction to the boundless willingness to provide peak performance.” A total ban on doping for children and adolescents when there is simultaneous legalization for adults is impracticable and
would not seem to be feasible. Also, the manner in which children and adolescents under the age of 18 years (which is an advanced age in many sports) react to performance enhancers is not known. However, supporters of a legalization of performance enhancing drugs do not exclude children and adolescents. Rather, they justify approval of doping in these age groups by pointing out that competitors at this stage are taking various other risks in sports anyway [11208].

**Law versus ethics**

There have been several sceptical challenges to the legitimacy of the antidoping position arising from both philosophers working in the field of medical ethics and sports ethics. They argue, typically, that the bans on certain performance-enhancing processes and substances rest on principles that are inconsistently applied. Criticisms of the ethical justification of antidoping legislation are not uncommon in the literatures of medical ethics, sports ethics and sports medicine. Critics of antidoping point to inconsistencies of principle in the application of legislation and the unjustifiability of ethical postures enshrined in the World Anti-Doping Code, a new version of which came into effect in January 2009. Critical discussion has focused on the legitimacy of the use of steroids, genetic manipulation and other forms of illicit performance enhancement. Surprisingly little discussion has been had on the interface between law, medicine and ethics as they converge in sports medicine and elite sports. Athletes, whether they choose to or not, provide role models for society, and their better performances are not morally admirable when their record-breaking feats are not the product of natural talents. Developing coherent ethical and legal responses to the use of doping is difficult partly because of the challenges ethical postures have traditionally created for the law [10270].

The World Anti-Doping Agency (WADA), established in 1999, is based on the cooperation between sports organisations and governments, and is financed by sports organisations and governments on an equal basis. Concerning doping, therefore, WADA and the WADC enjoy a hegemonic position with respect to medical, policy, scientific, as well as juridical matters. The WADC is predicated upon the evidence of sports medicine and sports science experts who determine which substances or processes are to be prohibited. The determination of the resultant list of prohibited substances and methods is juridically final. This position has, however, never been challenged in any court. Antidoping rules are juridical norms and belong to the area of sports law, whose relationship with public legislation is not always clear. This means not only that athletes are uncertain of the legitimacy of the legislation, but so too are physicians and healthcare professionals who are part of the sports medical entourage. Typically sports are organised nationally, but fall under the jurisdiction of international sports federations and, when relevant, the International Olympic Committee. Nearly all major sports federations now have their own antidoping rules; nevertheless, the WADC obliges them to apply the obligatory articles of the WADC and thus to follow the principles of the WADC. In this way the juridical norms of the WADC now concern not only the athletes but also other people taking part in one or other way in the sport concerned under the jurisdiction of a signatory of the WADC. Doping has been criminalised in some European countries (e.g. France, Italy, Slovenia), but seldom beyond there. Doping in criminal law is often more limited in scope than in sports legislation. The differences between public law and private law have kept these two sets of procedures juridically distinct. On one hand, sports organisations or their tribunals apply their antidoping rules with disciplinary sanctions, whereas on the other hand criminal courts apply the state law concerning doping punishments. One significant consequence of this dual legal economy has been that the same antidoping violation can now be, and often is, punishable both as a crime in a criminal court and as a disciplinary offence in a sports organisation or its tribunal (or a surrogate such as the CAS). The
incidence of these cases has greatly increased in recent years [10270].

When cases of the dual prosecution of athletes and their medicoscientific support systems become more common, the question of whether the principles of criminal law should be applied to doping disciplinary processes will be accentuated. At least three ethicolegal dimensions of doping prosecution deserve critical scrutiny:

- notions of guilt, negligence and liability
- aspects of punishment
- privacy

Rule breaking exhibits degrees of intentionality. It also typically elicits guilt. Culpability is not limited to premeditated acts. The rugby player who stretches his foot out to trip his opponent, or the football player who swears at the referee in response to a perceived poor judgement intend their acts and may or may not feel guilty. Equally, players may feel guilty for accidental career-ending injuries they inflict unintentionally on another professional. The establishment of an offence without mens rea is not without precedent in sports rules, but a particularly strong variant arises in antidoping policy when a prohibited substance is found to be present within an athlete’s body tissue or fluids. Ought then the principle of nulla poena sine culpa (no punishment without guilt) to be applied in doping offences without intention? It is important to note that culpa, guilt, may be constituted by an act or omission. The common omission is that of negligence. Guilt may indeed be relatively blameless in the case of the accidental or unwitting ingestion of banned substances provided by other parties. Yet beyond the legal sphere, it could be argued that this strict liability is in conflict with the more general presumption of innocence. It might be argued that doping offences ought not to be considered an exception to the general ethical norm of demonstrating culpability [10270].

One of the leading principles in criminal law and part of everyday morality is that for one and the same crime only one punishment can and ought to be imposed, ne bis in idem (not twice for the same). Only the punishment by a criminal court is a punishment in the sense of criminal law, whereas the other is better conceived of as a sanction. The doping sanction by a sports organisation or its tribunal is a thus disciplinary measure. The first one belongs to the area of public law, the latter of private law. Can the separateness of these two sanctions still stay without offending the principle ne bis in idem? It seems not. Rather, the athlete merely has to pay twice for one act, only the recipient is separate. From the athlete’s point of view there is no difference in fines between public and private law because the consequence is the same. One potential exception arises in the case of the private sponsorship of sports teams and individual athletes therein. Athletes and members of the support team frequently make an agreement with third parties for different kinds of economic and other benefits and entitlements (such as state-funded health care). In these agreements it is possible that the athletes commit themselves to compensate to their federation for the loss to their image and/or economic losses in the case of a doping offence of which the athlete is found guilty. There may be cases then when there can be in one and the same doping offence three different sanctions: punishment according to criminal law; disciplinary sanctions according to the national sports federations antidoping rules and contractual penalties (financial compensation) according to private law and the agreement between the athlete and his/her sports federation [10270].

In the area of genometry—the nascent field of science and technology that proposes to apply enhanced understanding of the human genetic code to reshaping our individual and collective destinies—no topic has generated more interest among the general public, as well as in the athletic community, than the potential for physical enhancement of the human body and its performance. Genometric experiments have produced physically enhanced mice, and
the production of similarly enhanced humans may not be far off. Although it is not the
objective of most genometric research, the day will come when gene-based "treatments" will
enable individuals to build muscle or increase endurance faster than is possible through
conventional methods. One article describes developments in the area of physical
enhancement that may find application in the "gene doping" of athletes. For example, human
performance-related genes may be delivered to athletes using tools developed for research
in gene therapy; the protein products of these genes may be administered in recombinant
form; and recently discovered small-molecule activators of the major genetic regulatory
pathways of physical prowess may be taken orally, providing "exercise in a pill". This article
also describes US and international attempts to regulate and punish the use of prohibited
techniques for performance enhancement among athletes. As science advances, defining
and detecting "gene doping" becomes increasingly complex. Thus, the study of physical
enhancement provides an ideal starting point for the interdisciplinary Redefined Destinies
Colloquium's examination of the intersection between law and science [10271].

Undoubtedly, what has been the most contentious of the revised WADC has related to the
privacy of the athlete. There are two cases that may be thought problematical: urine sample
provision and the athlete's location and availability for testing. The ability of police officers to
undertake bodily searches is forbidden in law in all but highly serious criminal cases. By
contrast, in doping control all athletes have an obligation to give a urine or blood sample in
any place at any time upon request. These samples have to be given under the supervision
of a doping control officer so that he/she can observe urination at all times. This ruling was
established in order to prevent athletes using a catheter to provide "clean"urine samples,
which were stored at a time when they were not on a doping cycle. Clearly, there is no
privacy in this operation. In democratic societies one may move freely without announcing to
public authorities where one is going. Yet elite athletes belonging to a doping testing pool in
each sport are required to give whereabouts information. Typically, this means nominating
one hour per day months in advanced when they must consider it their duty to be present.
The information must thus be accurate and predictive. Three failures to comply within an 18-
month period constitute an antidoping violation. The surrender of certain freedoms of
movement from surveillance is a highly controversial issue. One justification for the privacy
limitations is that the athletes have agreed to observe all the sports rules when they
compete. They cannot select which to observe and which not. A rejoinder might be that they
have no choice other than compliance but that they do not assent to its legitimacy. It may
well be thought that the request for whereabouts information is a coercive offer; that elite
sportsmen and women can only ply their trade effectively in one arena, and thus that the
controls undermine autonomous assent [10270].

The idea that sport is somehow beyond the ethics of everyday living and law has long been
jettisoned. The legal peculiarities highlighted here and their ethical implications reveal how
antidoping legislation and rules appear to differ from other areas of law and commonsense
morality. Although it has sometimes been argued that doping legislation is unacceptably
burdensome, it has been attempted to disambiguate certain apparent tensions between
criminal law, private law and everyday ethics. Nevertheless, the nearly unanimous decision
of national sports federations and sports federations to regulate against doping has been a
response to a genuine crisis in the representation of the values of sport themselves and
serves to protect the interests of all engaged therein. Sports physicians, medical ethicists
and technologists generally have recently argued for the liberalising of regulations
concerning human enhancement in sports. Critical discussion has focused on the legitimacy
of the use of steroids, genetic manipulation and other forms of illicit performance
enhancement. Surprisingly little discussion has been had on the interface between law,
medicine and ethics as they converge in sports medicine and elite sports. The use of a wide
variety of banned and non-banned supplements is prevalent among casual gym users, those
active in sports, and is by no means restricted to elite athletes. This development is to be seen in the context of changes in social attitudes to medical and pharmaceutical products and services that have developed in relation to the supratherapeutic goals of medicine. Athletes, whether they choose to or not, provide role models for society, and their better performances are not morally admirable when their record-breaking feats are not the product of the “virtuous perfection of our natural talents”. Developing coherent ethical and legal responses to the use of doping is difficult partly because of the challenges ethical postures have traditionally created for the law. Therefore, criticisms of the ethical justification of antidoping legislation are not uncommon in the literatures of medical ethics, sports ethics and sports medicine. Critics of antidoping point to inconsistencies of principle in the application of legislation and the unjustifiability of ethical postures enshrined in the World Anti-Doping Code, a new version of which came into effect in January 2009. One article explored the arguments concerning the apparent legal peculiarities of antidoping legislation and their ethically salient features in terms of: notions of culpability, liability and guilt; aspects of potential duplication of punishments and the limitations of athlete privacy in antidoping practice and policy. It is noted that tensions still exist between legal and ethical principles and norms that require further critical attention. Doping has been criminalised in some European countries (e.g. Sweden, France, Italy, and Slovenia), but seldom beyond there. In some member states of the European Union related acts such as drug abuse or the smuggling of medicines are criminal acts. In other cases, tax law, for example, has been used by state authorities to use coercive powers such as search and seizure for the detection of crimes to prosecute the case. It is important to note that doping has not, however, usually been defined in criminal codes exactly in the same way as in sport. Doping in criminal law is often more limited in scope than in sports legislation. The validity of a doping violation is established by a sports tribunal, which is convened by national sports federations or international sports federations. Sanctions normally take the form of ineligibility and the loss of medals, prize money and so forth. These override rights to compete and reward, which are internal to the sport and its governance. In cases of dispute, and in accordance with the WADC, the Court of Arbitration for Sport (CAS) arbitrates between parties. It is noteworthy that this is obligatory in cases of antidoping under the auspices of the WADC, whereas in other disputes both parties must normally consent for the case to be heard there and to abide by its rulings. By contrast, antidoping rules of sports organisations have emerged within the sphere of private law and, in most cases, remain there.

International doping policy: the WADA and the WADC

The World Anti-Doping Agency (WADA), established in 1999, is based on the cooperation between sports organisations and governments, and is financed by sports organisations and governments on an equal basis. Its most notable achievement has been the worldwide WADC in 2003 and its revision implemented in 2009. The rationale behind the WADC is the harmonisation of antidoping rules and measures. Nearly all international sports federations have accepted the WADC. Concerning doping, therefore, WADA and the WADC enjoy a hegemonic position with respect to medical, policy, scientific, as well as juridical matters. The WADC is predicated upon the evidence of sports medicine and sports science experts who determine which substances or processes are to be prohibited. The determination of the resultant list of prohibited substances and methods is juridically final. This position has, however, never been challenged in any court. Antidoping rules are juridical norms and belong to the area of sports law, whose relationship with public legislation is not always clear. This means not only that athletes are uncertain of the legitimacy of the legislation, but so too are physicians and healthcare professionals who are part of the sports medical entourage. Despite co-funding and legitimation by national sports federations and governments on an equal basis, the juridical norms of the WADC are not generally binding and apply only to the international sports federations who are signatories to the WADC. They do not apply directly
to athletes themselves. Instead, athletes fall under the jurisdiction of their own national sports federation antidoping rules, which themselves are governed by the WADC. Typically sports are organised nationally, but fall under the jurisdiction of international sports federations and, when relevant, the International Olympic Committee. Nearly all major sports federations now have their own antidoping rules; nevertheless, the WADC obliges them to apply the obligatory articles of the WADC and thus to follow the principles of the WADC. In this way the juridical norms of the WADC now concern not only the athletes but also other people taking part in one or other way in the sport concerned under the jurisdiction of a signatory of the WADC. This development is an important development because it is now well known that the athlete engages in doping as part of a systemic effort between coaches, masseuse, physicians, physiotherapists, team management and so on. The clearest examples of this systemic sports medicine and sports science development in former times was the East German state sports science apparatus, and more recently the Tour de France 2007, in which, it is widely thought, that the majority of professional teams were engaged in doping practices to some degree. Article 2.8 may now be employed to hold sports physicians to account for their complicity with doping violations. A sports organisation may impose a sanction for this violation in accordance with its rules. This is not a punishment in the same sense as in the criminal code, but is better thought of as a disciplinary consequence or sanction. These sanctions are limited to the powers of a private organisation. So, if these doping rules are broken, the question is not typically one of a crime being committed but rather the lesser one of a violation of the rules of a private organisation.

Public law versus sport's law

More countries have included doping offences in their criminal legislation, the supervision of doping offences has expanded and, when previously only athletes were punished, now the focus is also on the elite sports support system including sports physicians. This dual legal economies have sometimes converged. A cursory examination of this convergence is found in the following recent and high profile examples. The Tour de France doping scandal in cycling in 1998 started from police investigations, and the Chinese doping scandal in swimming in 1998 started from Australian customs officers’ seizure of human growth hormones entering Australia for the world championships of that year. Similarly, in Spain Operation Puerto was conducted by the Spanish authorities into doping practices that followed the seizure of prohibited substances and other material by the Spanish police in 2006. It should be noted, here, however, that tax evasion legislation initially uncovered an illegal pharmacology trade, and the fallout led to the revelations that led to UK sprinter Dwayne Chambers’ ban from international athletic competition for 2 years and his lifetime ban from representing Britain at the Olympic Games. In the Athens Olympic Games in 2004 two Greek sprinters, Kenteris and Thánou, evaded doping control officers. Perhaps the most recent high profile case are the investigations in the USA into Balco Laboratories, where tax investigations uncovered widespread illicit doping, which saw the greatest ever American female athlete being imprisoned. We will comment on this below. These high profile cases seem to reinforce the idea that there is a certain dependency on the powers of state authorities if antidoping rules are to be effective. In the following section we probe this dual legal economy between sports antidoping rules and criminal law.

Guilt, negligence and liability

Rule breaking exhibits degrees of intentionality. It also typically elicits guilt. Culpability is not limited to premeditated acts. The rugby player who stretches his foot out to trip his opponent, or the football player who swears at the referee in response to a perceived poor judgement intend their acts and may or may not feel guilty. Equally, players may feel guilty for accidental career-ending injuries they inflict unintentionally on another professional. Moreover, there are
many instances during games when the official decides that a pattern of rule-breaking behaviour, which, although it does not appear premeditated, exhibits intentionality in the habitual nature of the act. Aside from these cases, there are others in which a rule is determined to have been broken when the athlete fails in some other duty. So, the relay runner who steps on or over the inside lane marking is deemed not to have completed a minimum of 400 m thereby and is disqualified irrespective of the absence of *mens rea* (guilty mind). The establishment of an offence without *mens rea* is not without precedent in sports rules, but a particularly strong variant arises in antidoping policy when a prohibited substance is found to be present within an athlete's body tissue or fluids. Article 2.1 in the WADC wording states that an offence is merely for “the presence of a prohibited substance or its metabolites or markers in an athlete's sample". The wording of this violation indicates that this type of doping offence can include wider liability than other types of doping offences in which liability is estimated in accordance with normal juridical principles. Ought then the principle of *nulla poena sine culpa* (no punishment without guilt) to be applied in doping offences without intention? It is important to note that *culpa*, guilt, may be constituted by an act or omission. Guilt may indeed be relatively blameless in the case of the accidental or unwitting ingestion of banned substances provided by other parties. Yet beyond the legal sphere, it could be argued that this strict liability is in conflict with the more general presumption of innocence. It might be argued that doping offences ought not to be considered an exception to the general ethical norm of demonstrating culpability. The application of strict liability is not unique. There exist numerous other examples in which the level of care demanded is as high when imposing sanctions; such as in the transport of radioactive substances and wastes, or in dealing with hazardous chemicals or medicines, in dangerous building works and so on. Here the sanction operates to prevent harm to others and the self engaged in dangerous practices. The concept of “strict liability”, as it has been used in doping cases, as it has been argued, does not entail intentionality. The sanction is an inevitable consequence, if a doping offence has been established [10270].

**Privacy**

Undoubtedly, what has been the most contentious of the revised WADC has related to the privacy of the athlete. There are two cases that may be thought problematical: urine sample provision and the athlete's location and availability for testing.

- The ability of police officers to undertake bodily searches is forbidden in law in all but highly serious criminal cases. By contrast, in doping control all athletes have an obligation to give a urine or blood sample in any place at any time upon request. These samples have to be given under the supervision of a doping control officer so that he/she can observe urination at all times. This ruling was established in order to prevent athletes using a catheter to provide "clean" urine samples, which were stored at a time when they were not on a doping cycle. Clearly, there is no privacy in this operation, and this is confounded in the case of athletes who are legal minors, when a chaperone is required.
- In democratic societies one may move freely without announcing to public authorities where one is going. Yet elite athletes belonging to a doping testing pool in each sport are, according to Article 14.3 of the WADC, required to give whereabouts information. Typically, this means nominating one hour per day and 3 months in advance when they must consider it their duty to be present. The information must thus be accurate and predictive.

One justification for the privacy limitations is that the athletes have agreed to observe all the sports rules when they compete. They cannot select which to observe and which not. A rejoinder might be that they have no choice other than compliance but that they do not
assent to its legitimacy. It may well be thought that the request for whereabouts information is a coercive offer; that elite sportsmen and women can only ply their trade effectively in one arena, and thus that the controls undermine autonomous assent. The imposition on the athlete to surrender an aspect of their privacy non-elite athletes enjoy may also comprise a coercive offer. This contextual element increases the burden upon the WADA to justify its application. A key concern here will be one of proportionality. Does the surrender of one's privacy need to be so severe? Clearly the issue of weighing the demand to surrender privacy and to examine the latitude of testers merits further discussion [10270].

**Physician's responsibility**

The manner in which healthcare and medical professionals serve their athlete patients is governed by a variety of relevant codes of conduct. A range of codified rules is presented that refer both the welfare of the patient and the maintaining of confidentiality, which is at the heart of trustworthy relations. The 2009 version of the World Anti-Doping Code (WADC), however, appears to oblige all healthcare professionals not to assist athletes if they are known to be engaged in doping behaviours under fear of removal from working with athletes from the respective sports. In contrast, serving the best interests of their athlete patients may oblige healthcare professionals to give advice and guidance, not least in terms of harm minimisation. In so far as the professional conduct of a healthcare professional is guided both by professional code and World Anti-Doping Code, they are obliged to fall foul of one or the other [10272].

Sport is conducted in a highly charged and emotional environment. Doctors who engage in sports medicine frequently get involved in sport because they too are passionate about the sport. This passion may conflict with the necessity to be dispassionate about the outcome of the game when dealing with injured players. Sports-medicine doctors must remember at all times the importance of ethical medical practice and professional conduct. Prior to each game or session, team doctors should remind themselves of the basic principles of virtuous practice and the paramount importance of player autonomy. The sports team doctor should avoid becoming overinvolved with the team management to ensure that ethical principles do not get overlooked in the pursuit of victory. It is imperative that a degree of professional distance is maintained in order to achieve this [10272].

“I am in blood Stepp’d in so far that, should I wade no more, returning would be as tedious as to go o’er” is from Macbeth: Act III, Scene IV, by William Shakespeare. There are many ethical dilemmas that are unique to sports medicine because of the unusual clinical environment of caring for players within the context of a team whose primary objective is to win. Many of these ethical issues arise because the traditional relationship between doctor and patient is distorted or absent. The emergence of a doctor-patient-team triad has created a scenario in which the team’s priority can conflict with or even replace the doctor’s primary obligation to player well-being. As a result, the customary ethical norms that provide guidelines for most forms of clinical practice, such as patient autonomy and confidentiality, are not easily translated in the field of sports medicine. As a result, the ethical norms that provide guidelines for most forms of clinical practice, such as patient autonomy and confidentiality, are not easily translated in the field of sports medicine. The team doctor, as an individual, is not infallible, and medical decisions may be influenced by the appeal of status, admiration and gratitude. Such behaviour is self-gratifying, and it should be remembered that passion must not be allowed to compromise judgement. Sports doctors are thus frequently under intense pressure, whether implicit or explicit, from management, coaches, trainers and agents, to improve performance of the athlete in the short term rather
than considering the long-term sequelae of such decisions. A myriad of ethical dilemmas are encountered, and for many of these dilemmas there are no right answers. Informed consent in clinical sports medicine takes on a greater level of importance than in normal clinical circumstance because of all the extra pressures and influences. The ramifications of the player’s decision extend further than his own well-being and have an effect on his team and coach. The consent process may be threatened by the fact that different parties in the triad of relationships may have different values and priorities, and therefore might choose different options. This case raises a number of important questions: should informed consent be aimed at the team authority, such as the coach or owner? In what ways can the sports-medicine doctor recognize that the team has a legitimate stake in the outcome and yet remain loyal to the player? Should the physician seek consensus with all the parties involved? Although these are all very relevant and sensible questions, the answer is simple. The primary obligation of the sports-medicine doctor is to the patient. Patient autonomy always supplants the doctor’s partiality. Although the paymaster in professional sport is the team, sports-medicine doctors cannot abdicate their responsibility to the individual player. The burden of obligation to the team should be removed from the team doctor, as it is the player’s right to determine what is in their best interest. However, as a patient advocate, the doctor must be cognisant of the fact that the player is often under external pressure from teammates, coaches and agents as well as internal drives and goals that may influence their treatment decisions. In fact, there is a responsibility on the team doctor to tease out the extent of influence on a player to make a certain decision in the process of informed consent [10269].

The cliché – there’s no “I” in team – is a frequent exhortation in prematch team talks. It advocates neutralising individualism which might detract from the team effort. While there’s no ‘I’ in team, there is an “a,” and “a” stands for autonomy. Respect for a patient’s autonomy is considered a fundamental ethical principle. Autonomy refers to the capacity of a rational individual to make an informed, uncoerced decision. This belief forms the central premise of the concept of informed consent. Included in this concept also is the principle of confidentiality. The player must give informed consent for confidential information to be divulged to the management team. This area is of particular relevance to sports-medicine doctors when dealing with an injured player who is faced with a treatment choice. The sports doctor must work as a patient advocate to ensure the player understands the risks and benefits of all possible treatment options [10269].

Healthcare professionals should always aim to "do good" and promote the interest of their patients. It is one of the core values of healthcare ethics and is important in elucidating the nature and goals of medicine as a social practice. The very nature of sport is that it can occasion harm and involve various degrees of risk, and thus raises the question of how of a doctor can stand idly by and watch this happen without intervening. Players participate in sport of their own volition and need to be aware of the inherent risks they face. The principal motivation of the sports-medicine doctor is one of beneficence, and the primary aim is to "do good" for the patient by treating any injuries that may occur and prevent any further harm. One can find conflicts between beneficence and non-maleficence in almost any clinical situation. The dichotomy between the two principles is the foundation for “risk/benefit” analysis. The principle of beneficence and non-maleficence should be considered together and aim at producing a net benefit over harm, in keeping with traditional Hippocratic moral obligation. The obligation to provide net benefit to patients requires that there is a clear distinction between risk and probability when an assessment of harm and benefit is made [10269].

Healthcare professionals should also act fairly when the interests of different individuals or groups are in competition. The obligations of justice may be divided into three categories: fair
distribution of scant resources (distributive justice), respect for people's rights (rights based justice) and respect for moral acceptable laws (legal justice). Distributive justice is relevant to sports medicine in the context of limited resources. If resources are scarce, they should be distributed equally based on need and not on the basis of star talent. Concerning rights-based justice, the team doctor should respect each individual's right to treatment, should they require it. Failure to act because of personal bias or contrary beliefs would be unjust. Finally, the principle of legal justice holds that the team doctor must not willfully cause bodily harm to a player or do anything in contravention of morally acceptable laws [10269].

Self-reporting on doping

In spite of the limited validity of self-reports in socially sensitive behaviour being well documented, how this discrepancy affects the conclusions drawn on the differences in social cognitive measures between those involved versus those who are abstinent remains unknown. Whereas social psychology research routinely considers the effect of social desirability on explicitly assessed data, we are unaware of studies that investigated differences in related social cognition under different scenarios where user vs. non-user groups were established based on self-report admissions, chemical findings or validated self-reports, and used both explicit and implicit assessments. Social science studies of doping practices in sport rely predominantly on self-reports. The majority of the quantitative research into doping behaviour has been based on self-reports, where athletes are not only asked to report on their own attitudes, perceived injunctive and/or descriptive norms but also asked to confess their compromising behaviour (i.e. taking prohibited substances). Self-reports among athletes in Olympic sports have yielded prevalence data ranging between 1 and 30 percent, which itself is higher than the yearly rate (about 2 percent) of adverse analytical findings in the World Anti-Doping Agency accredited laboratories [274]. Studies of psychoactive drug use indicate that self-reporting is characterised by under-reporting. Likewise doping practice is likely to be equally under-reported, if not more so. This calls for more sophisticated methods for such reporting and for independent, objective validation of its results. Social science doping research has a long standing tradition in investigating social cognition (attitudes, norms, beliefs) and personality traits in a quest to find a set of characters that clearly distinguishes athletes who engage in doping practices and those who do not [10275-10280]. Based on these differences, past research has strived to establish behavioural models [10281-10286] with the ultimate aim of being able to predict doping use and to inform anti-doping programmes for potential intervention points and strategies. Previously, researchers assumed that social cognitive determinants of behaviour are accessible and explicitly endorsed by individuals, hence relied exclusively on individual's self-reports when investigating thoughts and feelings that underlie human behaviour. However, over the past two decades, convincing evidence has led to suggestions that the human mind operates in dual, conscientious and unconscious modes [10287-10289], therefore key components of the cognitive processes influencing behaviour are partially hidden from people's awareness or under limited ability to control. Owing to this phenomenon, it has been acknowledged that self-report measures are restricted in capturing the complexity of the cognitive processes that underlie social actions, thus social psychologists have turned to incorporating implicit assessment of the relevant cognitions. This approach has particularly intrigued researchers in socially sensitive domains where it is fair to assume that socially desirable responding is likely to confound explicit assessments [10267] A new doping attitudes questionnaire was developed and combined with a response latency-based implicit association test and hair sample analysis for key doping substances in 14 athletes selected from a larger sample (n=82) to form contrast comparison groups. Results indicate that patterns of group differences in social projection, explicit attitude about and perceived pressure to use doping,
vary depending on whether the user and non-user groups are defined by self-report or objectively verified through hair analysis. Thus, self-confessed users scored higher on social projection, explicit attitude to doping and perceived pressure. However, when a doping substance was detected in the hair of an athlete who denied doping use, their self-report evidenced extreme social desirability (negative attitude, low projection and low perceived pressure) and contrasted sharply with a more positive estimate of their implicit doping attitude. It was concluded that hair analysis for performance enhancing substances has shown considerable potential in validating athletes' doping attitude estimations and admissions of use. Hair samples from the participants in a previous study were tested for performance enhancing and social drugs. Of the 82 athletes, 12 (15%) reported having personal experience with prohibited performance enhancing substances, one with therapeutic use exemption. Twelve hair samples were positive for anabolic steroids and/or erythropoietin (EPO), of which 10 (12%) were confirmed with no overlap between confessed lifetime experience and current use. None of the positives reported medical use of anabolic steroids or EPO. The pattern was very similar for social drugs with 15 percent overlap between self-reported use (27, 33%) and current use (12, 15%). Three of the confirmed doping positives also tested positive for social drugs. The observed discrepancies between self-reports and objectively verified social drug taking behaviour is in line with previous research and although not surprising, they highlight the fact that a significant proportion of respondents simply choose to deny their real current or recent behaviour, even under circumstances when the verification is known to the participants. This phenomenon that has already cast doubt over drug use survey research expands to, or even magnifies the unreliability of doping use epidemiology surveys. The evaluation of anti-doping interventions is seriously hindered by the absence of reliable information on athletes’ true behaviour; opens the field to wild guesses and speculations, often about other athletes, sports and nations. Devising more reliable ways to gauge this crucial information is an important issue but beyond the foci of this research and shall be addressed by future research. The results not only confirm the need for improved self-report methodology for future research in socially-sensitive domains but also indicate where the improvements are likely to come from: as chemical validation remains expensive, a more realistic promise for large scale studies and online data collection efforts is held by measures of implicit social cognition. It may be concluded that incorporating developments in hair sample analysis for the detection of performance enhancing substances, this initial study examined the prospects of objective validation of athletes’ doping attitude estimations and admissions of use. Overall the results indicate that patterns of group differences in deliberately expressed attitudinal outcomes, such as social projection, explicit attitude to doping and perceived pressure to use, vary depending on whether the user and non-user groups are defined by self-report or by objective verification such as hair sample analysis. When user and non-user groups were defined by self-report, the differences between them on several attitudinal outcomes were observed in the expected direction (i.e. self confessed user groups scored higher on social projection, explicit attitude to doping and perceived pressure to use). However, data from hair analysis revealed that deliberate response distortion may have biased these results. Subjects, whose hair sample returned positive for doping but who denied doping use in self-reports, were observed to manipulate their questionnaire responses to a greater degree than all other groups. Implicit doping attitude and its correlation to the explicit attitude towards doping are indicative of this distorted responding. Therefore, the observed discrepancy between self-report and objectively (e.g. chemically) validated behavioural data needs to be considered when drawing conclusions from self-report findings [10267].

It is important to note the distinction between two types of information. In the questionnaire phase, participants are asked if they have ever used performance enhancing substances or social drugs. Hence an affirmative to this question does not necessary mean current or recent use. Hair analysis covered approximately the last 3 months (minus the last 2 weeks
when the hair is still in the body); therefore results reflect relatively recent use. It should be noted that the hair analysis at this stage was limited to the list of most often used performance enhancing and social drugs. Contradicting answers can be derived from two legitimate sources: respondent answered truthfully about having an experience but the last occasion when drugs were used happened before the 6-month maximum detection window; or the drugs used were not among those tested for. Theoretically there is also a possibility that a respondent did not answer truthfully but there is very little reason to admit a socially unacceptable behaviour when it in fact did not happen. On the contrary, a “no” answer on the questionnaire coinciding with positive analytical results in the matching hair sample can be seen as a denial on the self-report because the denied ‘ever use’ is contradicted by the very presence of a drug or drugs in the hair. Three out of 4 of the self-admitted users believed that most high-performing athletes used performance enhancing substances in training and competition with the 4th athlete believing that doping is used by most athletes in training but not in competition. Of those who denied doping use but their hair samples indicated otherwise, half (3/6) agreed that performance enhancing substances are used in both training and competition by most high performing athletes, followed by 2/6 stating that most athletes do not use doping (1 in each “denier” group) with 1 athlete believing that doping is used by most high performing athletes but used only in competition. This view was generally shared by the clean athletes, where 2 of the 4 thought that doping is used in both training and competition with the remaining 2 votes being split between training only and competition only. Theoretically there are two fundamental and mutually exclusive assumptions underpinning the observed low scores on explicit social cognition measures among verified doping users. On the one hand, it may be reduced introspective accessibility of the constructs in question: having no insight into their feelings and biases the respondents produced low scores are no reflection of their actual doping-related cognition, but instead represent an extraneous influence, such as generic social desirability. On the other hand, answers on the explicit tests are consciously and deliberately distorted in order to create a favourable (but false) impression. There are results, however, that suggest that objectively verified doping users had, in fact not only introspective access to the construct (doping attitude) but also had positive feelings toward it [10267].

Despite the widespread use, self-report techniques come with considerable limitations. With regard to self-reported behaviour, it must be assumed that individuals are willing to disclose this, often discriminating, information to the researcher. When self-reports are used to assess social cognitive processes, it is further assumed that people have introspective access to the construct in question (e.g. attitude) and have no intention of distorting their responses. Violations of either of these two assumptions negate the validity of self-report assessment and conclusions derived solely from self-declared data. Doping is a decidedly ostracised behaviour. Admitting use or even expressing supportive opinions against the general view is likely to prompt many athletes to conceal their true behaviour and thoughts about doping if they could be discriminating for the person or the group he/she represents. Recently, researchers have recognised this problem and made attempts to use indirect methods to obtain information on doping behaviour. One notable example being the use of the Random Response Technique (RRT) where estimation of doping prevalence is made on aggregated levels [10290]. Another line of research has made attempts to estimate the likelihood of self-involvement in doping utilising the False Consensus Effect (FCE) which has been evidenced in various socially sensitive situations [10291]. Despite the advances these latter approaches have brought to doping behaviour research, results still carry the inevitable caveat of being based on self-declarations. Independent validation or calibration [10292] of these results remains an issue [10267].

**Hypoxic tents**
The influence of altitude training (i.e. hypoxic environments plus exercise training regimens) was first realized in 1968 during the Mexico City Olympics, and has been used by many competitive athletes since that time. Today, there is an active debate in the sport community around the moral nature of various hypoxic devices used in coordination with training regimens by athletes to enhance aerobic performance. The World Anti-Doping Agency (WADA) had considered banning the use of these devices. WADA's Ethical Issues Review Panel determined that hypoxic tents are performance enhancing and are a violation of the spirit of sport. However, WADA appears to be somewhat ambivalent about its stance on the matter of health risks regarding hypoxic tents. Despite the “two out of three” rule being met, WADA chose to gather further input. The result, announced in September 2006, was that WADA has cautiously refrained from banning hypoxic tents and intends to monitor their health risk. WADA was clear about its stance on the spirit of sport, claiming that the passive use of technology was lacking in virtue and thus was not in line with its perspective of the spirit of sport. Although the first two criteria WADA employs are available for physiological evidence and fact, its third criteria, the spirit of sport, is open for philosophical debate. In one paper, it was provided an overview of the physiological background and then discussed the moral aspects of the “spirit of sport” from three disparate perspectives. In addition, we address the concept of authentic physiology in an effort to provide a foundation for a reasoned debate that can endure the rigours of logic and tests of consistency for other ergogenic aids [07133].

However, the appeal to empiricism fails when we look to the spirit of sport. Here, one must look toward philosophy in general, morals and logic in particular, to fully understand the meaning of and criteria for the spirit of sport. WADA (2003) defines the spirit of sport as the celebration of the human spirit, body and mind, and is characterized by the following values: ethics, fair play and honesty; health; excellence in performance; character and education; fun and joy; teamwork; dedication and commitment; respect for rules and laws; respect for self and other participants; courage; community and solidarity. Each of the components of this definition falls under the general heading of morality. Further, each component is addressed by one or more of the following theories that attempt to explain morality (i.e. how we ought to live). Therefore, to clarify the understanding of what constitutes the spirit of sport, it is needed to comprehend the ways in which morality is approached theoretically. Generally, there are two dominant schools of thought, and at least one non-traditional perspective worthy of our attention. Each comes from a disparate philosophical background and each manifests a distinct intent in the pursuit of how one should live. The first school of thought is broadly termed teleology (from the Greek root telos, the end purpose) or consequentialism. This perspective considers the outcome or consequence of our action as the criteria for what is considered moral (e.g. "excellence in performance"); the means or intent we select to accomplish these goals are of secondary importance. Utilitarianism is a sub-theory of teleology that argues that should select actions and (or) rules that will lead to the greatest pleasure (or happiness/good) and the least pain for the greatest number. This theory is flexible enough to accommodate the will and perception of the majority’s rule with each individual counting as one. It is a theory that argues that the primary intent of behavior should be outcome based and situational as opposed to a process-based duty. The second classical approach to morality is termed deontology (from the Greek root deon, an obligation or duty) or non-consequentialism. This theory, and its related subtheories, is focused on our duty to adhere to particular principles, policies, and codes. In contrast to teleology, the outcome of our action is less important than our intent to do our duty. In a sport context, the old adage that "it is not whether you win or lose, but how you play the game" can be construed as a deontological statement in so far as it suggests that we ought to focus on our duty by abiding by the spirit and rules of the game, with the outcome as a secondary. The principles that must be followed as deontologists may come from a variety of sources: divine, intuitive, and
societal or cultural. Divine deontology is based in religious contexts. The laws or principles or commandments based upon the words of deity form our understanding of duty (e.g. duty based upon the Bible or Koran). Intuitive deontology places emphasis on our capacity to reason. Because humans have this ability, we are able to establish universal laws of moral conduct. Kant's categorical imperative is such an example. It states that one should "act only according to that maxim by which you can at the same time will that it should become a universal law". Both divine and intuitive approaches attempt to be universal in their application.

Social contract morality establishes principles through societal agreement (e.g. the "rules and laws" governing any sport are based upon social contract theory). Once principles or codes are established, it is then incumbent on the members of the community (or organisation) to adhere to (or to modify when necessary) these rules as their duty. If one agrees to be a member of the organisation, then he or she is formally or informally agreeing to follow the rules governing that organisation (this stance is played out in detail in Plato’s dialogue, the Crito). To do otherwise would contravene a societal code that encourages us to negotiate in good faith. In the case of sport, the community “agrees” to the formal rules of play, the size of fields, the weight of implements, etc, and assumes that all competitors have implicitly agreed to abide by them. It must be pointed out that deontology is not necessarily based in any empirical findings (as teleology often is), or science-based logic, but rather is a dictum or a code of conduct sent down from a position of authority or one designed by and committed to by the group (e.g., the World Anti-Doping Agency). If the rules of the particular social contract fail to meet the needs of the current context, then rules can and should be modified to more accurately reflect situational demands. For example, in a landmark work of social psychologist identified a cognitively heightened stage of moral reasoning in terms of social contract deontology. In this stage of development, the individual comes to appreciate that rules can be modified if they are deemed to be unjust (e.g. Dr. Martin Luther King Jr.’s rejection of unjust laws of segregation in the USA). In the same manner, if an athlete, coach, or administrator perceives a rule to be unjust, he or she has a duty to voice disapproval and to challenge the legitimacy of the rule. A case in point was the protest against racism in the United States by Americans Tommie Smith and John Carlos in the 1968 Mexico City Olympics. Under the spectre of significant public criticism and pressure, they “voiced” their dissatisfaction with the state of American race relations. To summarize, the intent of deontological conduct is to adhere to one’s duty in its various forms and to recognise that the outcome of our behaviour is secondary.

A third approach to moral conduct rejects the intent of both the teleological and deontological perspectives. The existentialist suggests that focusing on pleasure, either individual pleasure or the will of the majority, as the criteria for moral conduct is demeaning (i.e. a lower order good), and that to blindly follow rules issued by an external authority (e.g. the church or the coach) is to fail to take full responsibility for one’s own actions and to acknowledge one’s freedom to choose. Rather, moral conduct is linked to the acknowledgement of our free will, our responsibility for all decisions we make, and our intent to act authentically. It must be noted that authenticity, freedom, and responsibility are not the exclusive domain of this school of thought. However, unlike other moral approaches, these concepts are the primary focus of existentialism (i.e. as opposed to outcome or duty). Authenticity, as a central feature of this school of thought, implies an awareness of one’s own reality as distinct not only from the reality of other individuals, but also from the perception of the illusion of a reality that all share. In other words, the existentialist will argue that I grasp the meaning of sport as seen through my unique perspective, coloured by my feelings, values, etc, and that this perspective is not the same as any other, though on the surface it may appear to be so. Further, there is not and cannot be one exclusive perspective or meaning that we all share. Having said this, there is something called “sport”, in as much as there is something we call
“music”; however, the existentialist will view these two phenomena as “my sport” and “my music”. The essence of this line of thinking is that what we ought to do is to constantly strive to be aware of our own essence (philosophical or physical) without being deluded into thinking that we must adopt the perspective of the norm. In terms of authentic behavior, argues that the existentialist recognises his or her own “radical” freedom to choose a particular course of action. This action is true for him or her, and not necessarily what is expected, predicted, or valued by others; he terms this acting “good faith”. Further, the individual cannot choose anything, in good faith, as better unless it is better for all. This sense of universality can be found in the following quotation from Sartre: “When we say that man chooses his own self, we mean that every one of us does likewise; but we also mean by that that in making this choice he also chooses all men. In fact, in creating the man that we want to be, there is not a single one of our acts which does not at the same time create an image of man as we think he ought to be.” In contrast, “bad faith” reveals itself when an individual acts not according to his or her own will, but denies his or her freedom and does the bidding or will of others. For example, an athlete who acts morally or immorally as a result of the dictum of the coach demonstrates his or her rejection of freedom to choose [07133].

To meet the teleological standard, the spirit of sport must demonstrate that it will result in the greatest pleasure or happiness and least amount of pain or unhappiness for the greatest number. Deontologically, the spirit of sport must foster our sense of duty, both in a universal sense of respect for the dignity of others and to our adherence to establish socially acceptable norms, rules, and laws. Finally, the spirit of sport ought to provide a medium through which individuals may develop authentically. The specific concern for WADA is that the use of passive technology (hypoxic tents) violates this spirit or moral ideal. Passivity implies that there is little or no external physical interaction with a device; it acts on the athlete’s internal physiology and requires nothing more than involuntary physiological adaptation (i.e. “a flick of a switch”). Thus a device like a hypoxic tent is considered passive by WADA, as it claims that the athlete needs to do nothing but sleep to have gains in performance and this contravenes WADA’s notion of the spirit of sport. In the following section we discuss this concern from the viewpoint of moral theory. The criterion for moral non-consequentialism is then whether or not a particular behavior has contravened an accepted notion of divine, intuitive, or social contract duty. In the case of hypoxic tents, invoking a religious duty seems remote. Though some religious orders may rule out the use of any technology whatsoever, passive or otherwise (e.g. the Amish). However, the Kantian imperative and social contract theory do resonate in this case. The categorical imperative suggests that if an act is moral it must be universalisable. In other words, would we wish that all athletes, who could gain relevant physiological effect from passive technology, be able to do so? Or would we condemn globally the practice? If we condemn the practice universally, then a myriad of “acceptable” regimens must be banned in addition to devices such as hypoxic tents, such as listening to music as a motivational device. Is this a reasonable principle? Is it a principle that WADA will or could apply universally? One would have to consider the “spirit” of other forms of hypoxic and passive training to determine if WADA’s criticism can stand up to the logic of consistency and Kantian universalisability. For example, is training at sea level during the day and being driven to altitude in the mountains to sleep at night a regimen that goes against the spirit of sport because it is perceived to be “passive”? If so, then this too must be considered a breach of the spirit of sport. Further, based upon the premise of passivity, one might also believe that the intake of a well-balanced meal, meditation, mental imagery, or rest and recovery as passive approaches to performance enhancement [07133].

From an existential perspective, training that awakens or encourages self-discovery and “opens-up” the individual to his or her own (social, emotional, cognitive) possibilities would be
training in “good faith”. For example, this would be the case for an athlete who is able to discover more about his or her abilities, standards of excellence, levels of commitment, etc. as a function of this training. The test of authenticity fails at the philosophical level when the athlete participates in a training regimen to satisfy an agenda that is not his or her own, or one that does not lead to an awareness of the authentic self (bad faith). For example, suppose an athlete succumbs to pressure to participate in a particular training regimen and also fails to see any meaning behind participation, then he or she fails the test of authenticity. These two scenarios are reasonably straight forward if the training regimen is not contentious (e.g. lifting weights). However, if the method is out of the ordinary, then another test of authenticity concerning physiological adaptation can be considered. To answer this question, we begin by proposing the following definition of authentic physiology: the adaptation of the human body, through its genetic potential, to an external stimulus that is non-hormonal, non-drug and non-invasive. This definition places emphasis upon the natural or authentic response to a stimulus. Further it places particular emphasis on the natural limit to adaptation. For example, weight training without steroid use results in strength gains mediated by the body’s genetic potential, including its own hormone synthesis; weight training with steroids, which may be natural or synthetic analogues, leads to levels that cannot be self-produced, and therefore would be classified as inauthentic according to this definition. The use of either increased elevation or hypoxic tents creates a stimulus and causes the body to naturally adapt to this stimulus. It is not invasive, hormonal, or synthetic and it does not push the athletes’ physiological response past its genetic potential. In contrast, the use of recombinant EPO is invasive, it is a manufactured agent and it does stimulate the body’s response past its genetic potential and thus is physiologically inauthentic. It cannot be convincingly argued that hypoxic tents are physiologically inauthentic in terms of the body’s adaptation to the stimulus provided. It is true that the environment in the tent is not in itself a natural environment, but rather it is a replication of a natural environment. However, similarly, a fitness centre in not a natural environment and the athlete is allowed to train in this environment and is not forced to chop wood or pick up large rocks to induce a training effect, though an axe in the example given could be considered non-natural [07133].

The teleologist’s concern is outcome. In particular, the utilitarian’s standard for moral conduct is the greatest goodness for the greatest number. Thus, the utilitarian must demonstrate that the use of passive technology generally and hypoxic tents specifically either fails or meets the test of maximizing pleasure or happiness. In the case of hypoxic tents, the empirical evidence available shows overwhelmingly that these devices do no harm when used as directed and that enhanced performance outcomes, though not dramatic, do occur. Further, proponents argue that these devices enable all athletes to have access to this training regimen at a significantly reduced cost in travel and intrusiveness (i.e. time away from employment and family to train at sites where there is sufficient altitude available), and reduced incentive to seek out illegal and potentially harmful means (e.g. synthetic EPO) to bypass the resource issues of traditional altitude training. The third criterion for WADA, the “spirit of sport”, is less obvious from a utilitarian perspective, as it is difficult to judge not only the process of establishing that the spirit has been transgressed, but also that this transgression will result in the greatest unhappiness. Although a survey of athletes has not been conducted by this research team or by WADA, it would seem that WADA is the only public voice making this claim, whereas those disputing this interpretation seem to be wide and varied [07133].

Hypoxic devices in combination with proper physical training regimens have been associated with significant improvements in performance and have been shown to pose no known health risk to the user. The controversy stems primarily from the interpretation of WADA’s principle, “spirit of sport”, and the extent to which a training regimen is employed, either passively or
actively, by the athlete. It has been suggested that many training regimens are passive in nature and are accepted by the sport community implicitly and explicitly. The position taken in this paper is that the concept of the “spirit of sport” needs to be refined and we argue that this should include the notion of authenticity, both physiological and philosophical. Combined with the criteria of consequentialism and non-consequentialism, authenticity can more clearly define “natural” or “genuine” competition in a much more philosophically sound manner than the current documentation [07133].

Pain medication

Many athletes have promoted a culture of acceptance regarding pain and sport. “No pain, no gain” resonates in athletic venues worldwide. Although some exertion-related soreness is to be expected, there also is a degree of pain that is abnormal when attributed to exercise. Pain may be a sign of injury that if ignored or masked by analgesics could lead to worsening of the root condition. To some extent, the perception of pain is an evolutionary adaptation to prompt the injured to take time for rest and allow for healing. In recent years, television commercials have touted the use of various over-the-counter (OTC) and prescription medications for treating pain. Many people of all activity levels take widely available analgesics in response to pain resulting from athletic activity. The general acceptance of exercise coexisting with pain has led to regular use of medications, prescribed or not, to alleviate physical activity related pain, especially when related to acute injury [07216].

A survey of 563 National Collegiate Athletic Association (NCAA) Division I athletes demonstrated that 165 (29 %) felt there was nothing wrong with using painkillers on the day of competition to cope with injury-related pain. Ethical considerations include the voluntary nature of sports, treating athletes under the legal age of consent, and blurring the lines between what is most important to a player: short-term pain relief for performance or longer-term consequences of potential increases in injury severity [07216].

Injection therapy with local anaesthetics

Sports medicine physicians often use injections for the targeted delivery of medications. Whether it is anesthetics, corticosteroids, NSAIDs, or other injectables, this treatment method is akin to a “smart bomb.” Injections avoid most of the systemic side effects and deliver higher doses to the intended tissue compared with the same medication administered orally. However, the provider must be aware that some agents may have some absorption beyond the target tissue, although the systemic levels typically are much lower than levels achieved via enteral administration. Injecting requires skill, familiarity with anatomy, and knowledge of the medication’s benefits and risks. Sterile preparation may minimize infection risk but often proves challenging in the training room. Injections pose a risk of bleeding and injury to adjacent structures. As with dispensing medications, informed consent may be obtained prior to administering injections. Most high school athletes are too young to legally provide consent; thus, parents must be consulted if injections are considered as a part of the pain management plan [07216].

Injections often are viewed as more aggressive treatment typically reserved for higher-level athletes. Using injections to treat sports-related injury pain is not unheard of, yet the medical literature does not lend support to the practice. It was published the results of a case series involving professional Australian football and rugby players treated with injection of local anesthetics (without corticosteroid) to facilitate quicker return to play. This was an important first step to try to adequately describe the benefits and risks associated with injections for
sports injury. Over the course of 6 years, in his role as team physician, the author treated 2851 injuries in professional Australian football and rugby players. Of the 2851 injuries, 221 (8 %) were treated with injection of the local anesthetic bupivacaine. These included injuries to the ribs, iliac crest (hematomas), acromioclavicular joint, fingers, thumb, ankles, metacarpals, sternum, and toes. A total of 86 (39 %) of these injections were administered to treat acute injury with the game in progress, whereas the other treatments were administered for both acute and chronic pain prior to a game to allow the athlete to participate. Complications were broken down into major or minor. Out of 221 injections, there were 17 complications (8 %); six (3 %) were major and 11 (5 %) minor. All six of the major complications did well with eventual return to play. Some of these injuries needed surgery to provide definitive treatment, but the author believed it was possible that some of those injuries would have needed surgery regardless of the injection to allow for return to play, and the injections allowed the athlete to continue playing until season’s end [07216].

Injection therapy with local corticosteroids

Various corticosteroids often are used in combination with anesthetics. Steroids’ role in these types of injections is controversial. Steroid injections can produce pain relief of much longer duration than anesthetic alone can produce in certain conditions. Such relief has even been demonstrated in conditions in which inflammation plays little role (such as chronic tendinopathy), which suggests the mechanism of action is beyond anti-inflammatory action alone. Although these injections yield less-than-ideal results for providing cure or extended pain relief in chronic tendinopathy, many physicians still use these treatments in noninflammatory processes. Steroid injections also carry more risks than nonsteroid percutaneous injections. Adverse events include fat atrophy, skin lightening, blood sugar elevation (particularly in diabetics), and a theoretical risk of suppression of immune response to an infection mistaken for inflammation. Whereas teaching in medicine commonly discourages injection of corticosteroids directly into tendons and muscles, it has been done successfully in the highest level of athlete. After a retrospective review of the records for one NFL team, it was noted that 58 players suffered a severe hamstring injury with associated palpable defect in the muscle. These players were treated with corticosteroids and analgesics injected directly into the injury site. The injection was administered after the injured player identified the area of pain by pointing. The physician then prepped the area in sterile fashion and injected intramuscularly 3 mL of 1 percent lidocaine and 1 mL of dexamethasone (4 mg) via a 25-gauge needle. A compressive device was applied afterward, and the player held out of all activities for 48 hours. None of the players had any complications, and only nine (16 % of the 58) missed any games as a result of treating the hamstring injury this way [07216].

Concern of delayed healing or facilitating tendon rupture has prompted many practitioners to avoid injecting tendons directly, so the reporting of such treatments was a bold and significant contribution to the literature. However, it should be noted that a retrospective review had no control group or blinding to the procedure. Furthermore, the NFL athlete represents a unique patient population with different pressures and responsibilities than the average athlete; thus, generalization to all athletes might be unwise [07216].

Concluding remarks

High-quality pain control and sports injury studies are lacking. Although there are some prospective, double-blind, randomized controlled trials, the sample sizes are often small, and the study designs flawed. As with many aspects of musculoskeletal medicine, there is no iron-clad, evidence-based medicine regarding pain. This requires the sport medicine
physician to synthesize the available data and combine it with experience, anecdotal reports, and common sense. Therein lies the art of medicine. When using NSAIDs, the aim should be to use the lowest effective dose for the shortest duration to avoid adverse events. More aggressive treatments, such as anesthetic injections, depend on the injury’s location and severity and the level of competition [216].

Publication ethics
For research that involves human participants or animals to be published in the International Journal of Sports Medicine (IJSM) it has been recognised ethical standards and national and international laws. Authors are required to confirm that these standards and laws have been adhered to by formally citing this editorial within the methods section of their own manuscript. Authors should confirm that research using human participants has been conducted ethically according to the principles of the Declaration of Helsinki. The Declaration is intended to be read as a whole and every principle is equally important, but those points most-commonly considered by sport and exercise scientists may be summarized [09391]:

- **Basic principles.** Respect the rights and welfare of participants which must take precedence over all other interests
- **Ethical review.** Before research begins and before amendments are applied, research must be reviewed and approved by an appropriate ethics committee
- **The research protocol.** The study, research design and statistical analysis must be clearly described, justifiable and appropriate. In drawing up the research protocol, the researcher must
  o consider ethical issues in accordance with the Declaration of Helsinki,
  o provide information regarding funding, sponsors, institutional affiliations, other potential conflicts of interest,
  o consider the contribution to new knowledge and consider the environment,
  o include details of any incentives for participants and provisions for treating and/or compensating participants who are harmed as a consequence of participation in the research study,
  o describe the arrangements for post-study access by all participants to interventions identified as beneficial in the study or access to other appropriate care or benefits.
- **Consent.** Informed consent should be provided freely by the participant and should ideally be in writing. If written consent cannot be obtained, or is not appropriate, then oral consent should be formally documented and witnessed. Research that involves children or other populations that cannot consent (e.g. vulnerable populations) should seek consent from an appropriate person and assent from the participant. Research involving participants who are physically or mentally incapable of giving consent may be undertaken only if the physical or mental condition that prevents giving informed consent is a necessary characteristic of the research population. Informed consent/assent must include the
  o aims of the research
  o methods
  o sources of funding
  o conflicts of interest
  o institutional affiliations
  o anticipated benefits and potential risks
  o potential discomfort
  o right to refuse to participate or withdraw consent without reprisal
- **Conduct.** Research must be conducted
  o in accordance with appropriate risk management
  o by appropriately qualified researchers and support staff
  o with skill and care
  o in an appropriate setting
  o in order to protect the privacy of participants and confidentiality of their personal information
  o in accordance with laws and regulations of the country or countries in which the research is to be performed as well as international norms and standards.
Specific laws relevant to research ethical may regulate the collection, use and/or storage of human tissue; the protection of individuals that lack the capacity to consent; data protection; and the use of drugs in research.

- **Governance.** Serious adverse events occurring during the study must be reported to the ethics committee that ethically reviewed and approved the research.

Specific issues relevant to sports medicine are [09391]:

- **Retrospective ethics.** Data are routinely collected from individuals for various purposes. For example, sport scientists may monitor physiological function of an athlete in order for him or her to gain an edge over their rivals. Data collected exclusively for one purpose cannot be used for another purpose (research) unless consent for the use in research is subsequently given and the research ethically approved. An exception to this would be where the data collected for the primary purpose is anonymised prior to use in a research study (second purpose) which has ethical approval. Retrospective ethical approval cannot be granted for any research study.

- **The use of placebo.** The inclusion of a placebo group in a research study may challenge the principle of equipoise. Ideally, participants should be randomly assigned to experimental or placebo groups. In healthy volunteers, where possible, the type of treatment should be blinded, for example, comparator (control) participants could be given a fitness or lifestyle information sheet. After a finite length of time those participants in the comparator group could be offered the experimental condition, or an experiment could be halted if at any point it became clear that the placebo group was fairing more poorly. In more medical research where participants are patients or clients extreme care must be taken to avoid the abuse of placebo. In this type of research, the use of placebo is acceptable when no current proven intervention exists, or when the participant will not be at risk of serious or irreversible harm.

- **Deception.** The use of deception in research (e.g. in a pacing strategy study in which time trial distance is deceived) must be merited such that there are no reasonable alternatives for obtaining the data, as long as there is no reasonable expectation to cause pain or severe emotional distress. If deception is to be used, then the participants must be accurately informed of the risks and be debriefed at the conclusion of the study with the option to withdraw their data.

- **Good research practice.** The UK Medical Research Council has outlined some basic principles of good research practice which may help to ensure that research is conducted ethically. These include planning, conduct, recording data, reporting results, applying the results. Relevant issues not specifically raised in the Declaration of Helsinki include the use, calibration and maintenance of equipment, COSHH, documentation of standard operating procedures, retention of data, publication policy, authorship, correction of errors and retraction of published findings and intellectual property rights.
Bacterial hydrolysis of urine without doping substances

For almost two decades it has been known that enzymatic hydrolysis of "normal" urine samples from the entire male horse using Escherichia coli (E. coli) followed by solvolysis (ethyl acetate:methanol:sulphuric acid) results in the detection of significant amounts of estr-4-ene-3,17-dione (19-norandrost-4-ene-3,17-dione) along with estr-4-en-17beta-ol-3-one (19-nortestosterone, nandrolone) in extracts of the hydrolysed urine and that both steroids are isolated from the solvolysis fraction. This solvolysis process is targeted at the steroid sulphates. Also it has been shown that 19-norandrost-4-ene-3,17-dione and 19-nortestosterone are isolated from testicular tissue extracts. Subsequently, evidence was obtained that 19-nortestosterone detected in extracts of "normal" urine from male horses may not be derived from the 17beta-sulphate conjugate. However, following administration of 19-nortestosterone based proprietary anabolic steroids to all horses (males, females and castrates), the urinary 19-nortestosterone arising from the administration is excreted primarily as the 17beta-sulphate conjugate. Thus, if the 19-nortestosterone-17beta-sulphate conjugate arises only following administration this has interesting implications for drug surveillance programmes to control administration of 19-nortestosterone based anabolic preparations to male horses. These results have led to consider that the precursors to 19-nortestosterone and 19-norandrost-4-ene-3,17-dione, present in the urine prior to the hydrolysis steps, have the same basic structure except for the functionality at the 17-position. It has been used preparative high pressure liquid chromatography (LC) and LC fractionation to separate these precursors from the high amounts of oestrogenic sulphates present in "normal" urine from the entire male horse. Purified fractions have then been studied by liquid chromatography-mass spectrometry (LC-MS) and gas chromatography-mass spectrometry (GC-MS) to identify the precursors [06312].

Contaminated food for animals

Presence of drugs is completely prohibited in post racing urine samples by most of racing and competition authorities, even if environmental contamination might occur. To assess the daily dose of several contaminants absorbed through the diet that would result in detectable concentrations in urine caffeine, theobromine, theophylline, atropine, scopolamine, bufotenine, DMT or morphine were administered orally to 6 horses, in different dosages, for 3 days before their urine was sampled for regular anti-doping tests. Theobromine, theophylline, bufotenine and morphine daily intake >10 mg, 2 mg, 10 mg and 200 microg, respectively, by a performance horse, were found to result in detectable urinary concentrations. At the 2 tested doses, atropine (5 and 15 mg) and dimethyltryptamine (3 and 10 mg) were not detected in urine. For caffeine and scopolamine, even the lowest dosage tested (5 mg/horse/day and 2 mg/horse/day respectively) induced detectable concentrations of the molecule in urine. It was concluded that horses fed dietary contaminants, even at level much below the effective dosage, may be positive to antidoping urine analysis. Thus, selection of feed materials appears to be of great importance to prevent non voluntary positive result to anti-doping tests [06313].

Screening
It was presented at one time employed four liquid chromatography/mass spectrometric (LC/MS) methods for the detection of a large variety of drugs in equine urine. Drug classes covered by these methods included anti-diabetics, anti-ulcers, cyclooxygenase-2 (COX-2) inhibitors, sedatives, corticosteroids, anabolic steroids, sulfur diuretics, xanthines, etc. With the objective to reduce labour and instrumental workload, a new ultra performance liquid chromatography/tandem mass spectrometric (UPLC/MS/MS) method has been developed, which encompasses all target analytes detected by the original four LC/MS methods. The new method has better detection limits than the superseded methods. In addition, it covers new target analytes that could not be adequately detected by the four LC/MS methods. The new method involves solid-phase extraction (SPE) of two aliquots of equine urine using two Abs Elut Nexus cartridges. One aliquot of the urine sample is treated with beta-glucuronidase before subjecting to SPE. A second aliquot of the same urine sample is processed directly using another SPE cartridge, so that drugs that are prone to decomposition during enzyme hydrolysis can be preserved. The combined eluate is analysed by UPLC/MS/MS using alternating positive and negative electrospray ionisation in the selected-reaction-monitoring mode. With this newly developed UPLC/MS/MS method, the simultaneous detection of 140 drugs at ppb to sub-ppb levels in equine urine can be achieved in less than 13 min inclusive of post-run equilibration. Matrix interference for the selected transitions at the expected retention times is minimised by the excellent UPLC chromatographic separation. The method has been validated for recovery and precision, and is being used regularly in the authors' laboratory as an important component of the array of screening methods for doping control analyses of equine urine samples [11311].

Liquid chromatography-mass spectrometry (LC-MS) has been widely used in doping control laboratories over the last two decades. Currently, simple quadrupole, triple quadrupole and ion trap are the most commonly employed analyzers in toxicological analysis. Nevertheless, the main lack of these technologies is the restricted number of target compounds simultaneously screened without loss of sensitivity. In one article it was presented an innovative screening approach routinely applied in the French horse doping control laboratory based on high resolution (50000) and high mass accuracy (<5 ppm) in full scan MS mode for more than 235 target analytes screened from an initial volume of 5mL of urine. The sample preparation was classically founded on solid phase extraction by means of reverse phase C18 cartridges. LC-MS analyses were carried out on a Shimadzu binary HPLC pumps linked to a C18 Sunfire column associated with the high resolution exacteive benchtop orbitrap mass spectrometer. This screening was performed alternatively in positive-negative ionization mode during the same run. Thus, the identification of compounds of interest was made using their exact mass in positive-negative ionization mode at their expected retention time. All data obtained were processed by ToxID software (Thermo-FisherScientific) which is able to identify a molecule by theoretical mass and retention time. In order to illustrate this innovative technology applied in our laboratory, sample preparation, validation data performed on 20 target compounds from 16 different horse urine samples, chromatograms and spectra was discussed [11312].

In one study a general screening protocol was developed to detect prohibited substances and metabolites for doping control purposes in equine sports. It was based on the establishment of a unified sample preparation and on the combined implementation of liquid and gas chromatographic MS analysis. The sample pretreatment began with two parallel procedures: enzymatic hydrolysis of sulfate and glucuronide conjugates, and methanlysis of the 17-beta-sulfate steroid conjugates. The extracts were treated for LC-TOF-MS, GC-HRMS and GC-MS assays. The majority of the prohibited substances were identified through a high mass accuracy technique, such as LC-TOF-MS, without prior derivatization. The sample preparation procedure included the formation of methylated and trimethylsilylated derivatives common in toxicological GC-MS libraries. The screening method was enhanced by post-run
library searching using automated mass spectral deconvolution and identification system (AMDIS) combined with deconvolution reporting software (DRS). The current methodology is able to detect the presence of more than 350 target analytes in horse urine and may easily incorporate a lot of new substances without changes in chromatography. The full scan acquisition allows retrospective identification of prohibited substances in stored urine samples after reprocessing of the acquired data. Validation was performed for sixty representative compounds and included limit of detection, matrix interference - specificity, extraction recovery, precision, mass accuracy, matrix effect and carry over contamination. The suitability of the method was demonstrated with previously declared positive horse urine samples [13779].

Anabolic steroids, general

One paper describes the application of gas chromatography-mass spectrometry (GC-MS) for in vitro and in vivo studies of 6-OXO in horses, with a special aim to identify the most appropriate target metabolite to be monitored for controlling the administration of 6-OXO in racehorses. In vitro studies of 6-OXO were performed using horse liver microsomes. The major biotransformation observed was reduction of one keto group at the C3 or C6 positions. Three in vitro metabolites, namely 6alpha-hydroxyandrost-4-ene-3,17-dione (M1), 3alpha-hydroxyandrost-4-ene-6,17-dione (M2a) and 3beta-hydroxyandrost-4-ene-6,17-dione (M2b) were identified. For the in vivo studies, two thoroughbred geldings were each administered orally with 500 mg of androst-4-ene-3,6,17-trione (5 capsules of 6-OXO®) by stomach tubing. The results revealed that 6-OXO was extensively metabolized. The three in vitro metabolites (M1, M2a and M2b) identified earlier were all detected in post-administration urine samples. In addition, seven other urinary metabolites, derived from a further reduction of either one of the remaining keto groups or one of the remaining keto groups and the olefin group, were identified. These metabolites included 6alpha,17beta-dihydroxyandrost-4-en-3-one (M3a), 6,17-dihydroxyandrost-4-en-3-one (M3b and M3c), 3beta,6beta-dihydroxyandrost-4-en-17-one (M4a), 3,6-dihydroxyandrost-4-en-17-one (M4b), 3,6-dihydroxyandrostan-17-one (M5) and 3,17-dihydroxyandrostan-6-one (M6). The longest detection time observed in urine was up to 46 h for the M6 metabolite. For blood samples, the peak 6-OXO plasma concentration was observed 1 h post administration. Plasma 6-OXO decreased rapidly and was not detectable 12 h post administration [10424].

Anabolic and androgenic steroids (AASs) are synthetic substances related to the primary male sex hormone, testosterone. AASs can be abused in both human and equine sports and, thus, are banned by the International Olympic Committee and the Association of Racing Commissioners International (ARCI). Enforcement of the ban on the use of AASs in racehorses during competition requires a defensible and robust method of analysis. To address this requirement, a high-throughput ultra high-performance liquid chromatography-mass spectrometric (UHPLC-MS) method was developed for the detection, quantification and confirmation of 55 AASs in equine plasma. AASs were recovered from equine plasma samples by liquid-liquid extraction with methyl tert-butyl ether (MTBE). Analytes were chromatographically separated on a sub-2 microm particle size C18 column with a mobile phase gradient elution and detected by selected-reaction monitoring (SRM) on a triple quadrupole mass spectrometer. AASs with isobaric precursor ions were either chromatographically resolved or mass spectrometrically differentiated by unique precursor-to-product ion transitions. A few of them that could not be resolved by both approaches were differentiated by intensity ratios of three major product ions. All the epimer pairs, testosterone and epitestosterone, boldenone and epiboldenone, nandrolone and epitestosterone, were chromatographically base-line separated. The limit of detection and that of quantification was
50 pg/ml for most of the AASs, and the limit of confirmation was 100-500 pg/ml. Full product ion spectra of AASs at concentrations as low as 100-500 pg/ml in equine plasma were obtained using the triple quadrupole instrument, to provide complementary evidentiary data for confirmation. The method is sensitive and selective for the detection, quantification and confirmation of multiple AASs in a single analysis and will be useful in the fight against doping of racehorses with AASs [10425].

It was developed a method for the simultaneous analysis of 11 anabolic steroids: fluoxymesterone, 17alpha-methyltestosterone, mestanolone, methandienone, methandriol, oxymetholone, boldenone, furazabol, methenolone, nandrolone, and stanozolol, for possible application to a doping test in racehorses. It was selected 15 kinds of target substances for a doping test from the main metabolites of these anabolic steroids, and established a method for simultaneous analysis. Urine was hydrolyzed and subjected to solid-phase extraction. Then, the residue from the extracts was derivatized by trimethylsilylation. The derivatized samples were subjected to ion-trap gas chromatography-tandem mass spectrometry, and their mass chromatograms and product ion spectra were obtained. The limit of detection of the target substances was 5-50 ng/mL, and the mean recovery and coefficient of variation were 71-105 percent and 1.1-10 percent, respectively [08186].

AASs can be abused in both human and equine sports and, thus, are banned by the International Olympic Committee and the Association of Racing Commissioners International (ARCI). Enforcement of the ban on the use of AASs in racehorses during competition requires a defensible and robust method of analysis. To address this requirement, a high-throughput ultra high-performance liquid chromatography-mass spectrometric (UHPLC-MS) method was developed for the detection, quantification and confirmation of 55 AASs in equine plasma. AASs were recovered from equine plasma samples by liquid-liquid extraction with methyl tert-butyl ether (MTBE). Analytes were chromatographically separated on a sub-2 µm particle size C₁₈ column with a mobile phase gradient elution and detected by selected-reaction monitoring (SRM) on a triple quadrupole mass spectrometer. AASs with isobaric precursor ions were either chromatographically resolved or mass spectrometrically differentiated by unique precursor-to-product ion transitions. A few of them that could not be resolved by both approaches were differentiated by intensity ratios of three major product ions. All the epimer pairs, testosterone and epitestosterone, boldenone and epiboldenone, nandrolone and epinandrolone, were chromatographically base-line separated. The limit of detection and that of quantification was 50 pg/ml for most of the AASs, and the limit of confirmation was 100-500 pg/ml. Full product ion spectra of AASs at concentrations as low as 100-500 pg/ml in equine plasma were obtained using the triple quadrupole instrument, to provide complementary evidentiary data for confirmation. The method is sensitive and selective for the detection, quantification and confirmation of multiple AASs in a single analysis and will be useful in the fight against doping of racehorses with AASs [10426].

In 2008, Pennsylvania became the first State in the USA to ban and enforce the ban on the use of anabolic and androgenic steroids (AAS) in equine athletes by using plasma for analysis. To enforce the ban, a rapid and high-throughput method for analysis of 60 AAS in equine plasma was developed by liquid chromatography-tandem mass spectrometry (LC-MS/MS). Analytes were recovered from plasma by liquid-liquid extraction (LLE) using methyl tert-butyl ether, separated on a reversed-phase C₁₈ column and analyzed by electrospray ionization mass spectrometry. Multiple-reaction monitoring (MRM) scan was employed for screening. When the MRM signal of an analyte exceeded 1000 counts per second (cps), information-dependent acquisition (IDA) triggered generation of an enhanced product ion (EPI) scan of the analyte. A library for the analytes was simultaneously established using the EPI spectrum. Unambiguous identification of any of the 60 AAS in a test sample was based on both the presence of MRM response within the correct retention time (tR) window and a
qualitative match between EPI spectrum of the test sample and that of the reference drug standard stored in the library. Total analysis time was 7 min. The limit of detection (LOD) and limit of confirmation (LOC) for most of the analytes were 0.01-2 ng/mL and 0.1-10 ng/mL, respectively. Recovery of the analytes from plasma by LLE was 74-138 percent. The method was successfully verified and is routinely used in the screening of post-race equine plasma samples for the presence of these 60 AAS. The method is rapid, sensitive, reproducible, and reliable [11313].

It was presented at one time employed four liquid chromatography/mass spectrometric (LC/MS) methods for the detection of a large variety of drugs in equine urine. Drug classes covered by these methods included anti-diabetics, anti-ulcers, cyclooxygenase-2 (COX-2) inhibitors, sedatives, corticosteroids, anabolic steroids, sulfur diuretics, xanthines, etc. With the objective to reduce labour and instrumental workload, a new ultra performance liquid chromatography/tandem mass spectrometric (UPLC/MS/MS) method has been developed, which encompasses all target analytes detected by the original four LC/MS methods. The new method has better detection limits than the superseded methods. In addition, it covers new target analytes that could not be adequately detected by the four LC/MS methods. The new method involves solid-phase extraction (SPE) of two aliquots of equine urine using two Abs Elut Nexus cartridges. One aliquot of the urine sample is treated with beta-glucuronidase before subjecting to SPE. A second aliquot of the same urine sample is processed directly using another SPE cartridge, so that drugs that are prone to decomposition during enzyme hydrolysis can be preserved. The combined eluate is analysed by UPLC/MS/MS using alternating positive and negative electrospray ionisation in the selected-reaction-monitoring mode. With this newly developed UPLC/MS/MS method, the simultaneous detection of 140 drugs at ppb to sub-ppb levels in equine urine can be achieved in less than 13 min inclusive of post-run equilibration. Matrix interference for the selected transitions at the expected retention times is minimised by the excellent UPLC chromatographic separation. The method has been validated for recovery and precision, and is being used regularly in the authors' laboratory as an important component of the array of screening methods for doping control analyses of equine urine samples [11314].

During last decades, the use of natural steroids in racing and food producing animals for doping purposes has been flourishing. The endogenous or exogenous origin of these naturally occurring steroids has since remained a challenge for the different anti-doping laboratories. The administration of these substances to animals is usually made through an intra-muscular pathway with the steroid under its ester form for a higher bioavailability and a longer lasting effect. Detecting these steroid esters would provide an unequivocal proof of an exogenous administration of the considered naturally occurring steroids. A quick analytical method able to detect at trace level (below 50 pg/mL) a large panel of more than 20 steroid esters in serum and plasma potentially used for doping purposes in bovine and equine has been developed. Following a pre-treatment step, the sample is submitted to a solid phase extraction (SPE) before analysis with UPLC-MS/MS. The analytical method's efficiency has been probed through three different in vivo experiments involving testosterone propionate intra-muscular administration to three heifers, 17-estradiol benzoate intra-muscular administration to a bull and a heifer and nandrolone laurate intra-muscular administration to a stallion. The results enabled detecting the injected testosterone propionate and 17-estradiol benzoate 2 and 17 days, respectively, post-administration in bovine and nandrolone laurate up to 14 days post-administration in equine. The corresponding elimination profiles in bovine serum and equine plasma have been established. The first bovine experiment exhibited a maximal testosterone propionate concentration of 400 pg/mL in one of the three heifer serum within 5h post-administration. The second bovine experiment reported a maximal 17-estradiol benzoate concentration of 480 pg/mL in the same matrix recorded 9 days after its administration. The last equine experiment resulted in a maximal nandrolone laurate
concentration of 440 pg/mL in horse plasma 24h after administration [13782].

**Anabolic steroids in dogs**

Effective control of the use of anabolic-androgenic steroids (AASs) in animal sports is essential in order to ensure both animal welfare and integrity. In order to better police their use in Australian and New Zealand greyhound racing, thorough metabolic studies have been carried out on a range of registered human and veterinary AASs available in the region. Canine metabolic data are presented for the AASs boldenone, danazol, ethylestrenol, mesterolone, methandriol, nandrolone and norethandrolone. The principal Phase I metabolic processes observed were the reduction of A-ring unsaturations and/or 3-ketones with either 3alpha,5beta- or 3beta,5alpha-stereochemistry, the oxidation of secondary 17beta-hydroxyl groups and 16alpha-hydroxylation. The Phase II beta-glucuronylation of sterol metabolites was extensive [13783].

**In hair**

The detection of the abuse of anabolic steroids in equine sport is complicated by the endogenous nature of some of the abused steroids, such as testosterone and nandrolone. These steroids are commonly administered as intramuscular injections of esterified forms of the steroid, which prolongs their effects and improves bioavailability over oral dosing. The successful detection of an intact anabolic steroid ester therefore provides unequivocal proof of an illegal administration, as esterified forms are not found endogenously. Detection of intact anabolic steroid esters is possible in plasma samples but not, to date, in the traditional doping control matrix of urine. The analysis of equine mane hair for the detection of anabolic steroid esters has the potential to greatly extend the time period over which detection of abuse can be monitored. Equine mane hair samples were incubated in 0.1M phosphate buffer (pH 9.5) before anabolic steroids (testosterone, nandrolone, boldenone, trenbolone and stanozolol), anabolic steroid esters (esters of testosterone, nandrolone, boldenone and trenbolone) and associated compounds (fluticasone propionate and esters of hydroxyprogesterone) were extracted by liquid-liquid extraction with a mix of hexane and ethyl acetate (7:3, v:v). Further sample clean up by solid phase extraction was followed by derivatisation with methoxylamine HCL and analysis by UHPLC-MS/MS. Initial method development was performed on a representative suite of four testosterone esters (propionate, phenylpropionate, isocaproate and decanoate) and the method was later extended to include a further 18 compounds. The applicability of the method was demonstrated by the analysis of mane hair samples collected following the intramuscular administration of 500 mg of Durateston® (mixed testosterone esters) to a Thoroughbred mare (560 kg). The method was subsequently used to successfully detect boldenone undecylenate and stanozolol in hair samples collected following suspicious screening findings from post-race urine samples. The use of segmental analysis to potentially provide additional information on the timing of administration was also investigated [13784].

**Differentiation between endogenous steroids and synthetic homologues in cattle**

Although substantial technical advances have been achieved during the past decades to extend and facilitate the analysis of growth promoters in cattle, the detection of abuse of synthetic analogs of naturally occurring hormones has remained a challenging issue. When it became clear that the exogenous origin of steroid hormones could be traced based on the $^{13}$C/$^{12}$C isotope ratio of the substances, GC/C/IRMS has been successfully implemented to this aim since the end of the past century. However, due to the costly character of the instrumental setup, the susceptibility of the equipment to errors and the complex and time
consuming sample preparation, this method is up until now only applied by a limited number of laboratories. In this review, the general principles as well as the practical application of GC/C/IRMS to differentiate between endogenous steroids and exogenously synthesized homologous compounds in cattle will be discussed in detail, and will be placed next to other existing and to be developed methods based on isotope ratio mass spectrometry. Finally, the link will be made with the field of sports doping, where GC/C/IRMS has been established within the World Anti-Doping Agency (WADA) approved methods as the official technique to differentiate between exogenous and endogenous steroids over the past few years [13785].

Testosterone

In one work, a disposable immunosensor for the detection of testosterone, an endogenous steroid hormone, in bovine urine has been developed using screen-printed electrodes (SPEs). Due to concerns over the use of steroid hormones as growth promoters, the EU prohibits their use in food producing animals. Consequently, rigorous screening procedures have been implemented in all member states to detect the illegal administration of such compounds. Competitive immunoassays were developed, initially by enzyme linked immunosorbent assay (ELISA), and subsequently transferred to an electrochemical immunosensor format using disposable screen-printed carbon electrodes. Horseradish peroxidase (HRP) was the enzyme label of choice and chronoamperometric detection was carried out using a tetramethylbenzidine/hydrogen peroxide (TMB/H₃O₂) substrate system, at +100 mV. The EC₅₀ values obtained for the assay in buffer and urine gave relatively comparable results, 710 pg/mL and 960 pg/mL, respectively. The linear range obtained for the assay in buffer extended from 0.03 ng/mL to 40 ng/mL; while that in urine ranged from 0.03 ng/mL to 1.6 ng/mL. The corresponding limits of detection (LOD) in buffer and urine were 26 pg/mL and 1.8 pg/mL. Cross reactivity profiles of the antibody have been examined, with notable cross reactivities with 19-nortestosterone (11.6 %) and boldenone (9.9 %). Precision studies for the sensor demonstrated adequate reproducibility (CV<13 %, n=3) and repeatability (CV<9 %, n=3). Recovery data obtained showed good agreement between spiking studies and known concentrations of analyte. Sensors showed stability for 4 days at +4 degrees C. A sensitive, highly specific, inexpensive, disposable immunosensor, showing excellent overall performance for the detection of testosterone in bovine urine, has been developed [06317]

Doping control of anabolic substances is normally carried out with urine samples taken from athletes and horses. Investigation of alternative specimens, e.g. hair samples, is restricted to special cases, but can also be worthwhile, in addition to urine analysis. Moreover, hair material is preferred in cases of limited availability or complicated collection of urine samples, e.g. from horses. In this work, possible ways of interpretation of analytical results in hair samples are discussed and illustrated by practical experiences. The results demonstrate the applicability of hair analysis to detect anabolic steroids and also to obtain further information about previous abuse. Moreover, the process of incorporation of steroids into hairs is described and the consequences on interpretation are discussed, e.g. on the retrospective estimation of the application date. The chosen examples deal with the detection of the anabolic agent testosterone propionate. Hair samples of an application study, as well as a control sample taken from a racing horse, were referred to. Hair material was investigated by a screening procedure including testosterone, nandrolone and several esters (testosterone propionate, phenylpropionate, decanoate, undecanoate, cypionate; nandrolone decanoate, dodecanoate and phenylpropionate; limits of detection (LODs) between 0.1 and 5.0 pg/mg). Confirmation of testosterone propionate (LOD 0.1 pg/mg) was carried out by an optimised sample preparation. Trimethylsilyl (TMS) and tert-butyl dimethylsilyl derivatives were
detected by gas chromatography-high-resolution mass spectrometry (GC-HRMS) and gas chromatography-tandem mass spectrometry (GC-MS/MS) [08437].

Pennsylvania State Racing Commissions regulate the endogenous androgenic steroid, testosterone (TES), in racing intact males (RIM) by quantification of TES in post-race samples. Post-race plasma samples (2209) collected between 2008 and 2010 were analyzed for TES, nandrolone (NAN), and other anabolic steroids (ABS). Of the 2209 plasma samples, 2098 had quantifiable TES ≥25 pg/mL. Plasma (mean ± SD) concentrations of TES and NAN in RIM were 329 ± 266 and 96 ± 68 pg/mL, respectively. Only 65 percent of RIM had quantifiable concentration of NAN, and there was no relationship between TES and NAN. Plasma TES concentrations were significantly higher during the months of April, May, June, July, and August. A significantly higher plasma TES was observed in thoroughbred (TB) versus. that in standardbred (STB). Plasma concentrations of TES from breeding stallions (BS) were 602 ± 357 pg/mL. Statistically significant lower plasma concentrations of the two steroids were observed in RIM horses. Based on quantile distribution of TES in the RIM and BS populations, 99.5 percent were at or below 1546 and 1778 pg/mL, respectively. Based on this population of RIM, the suggested upper threshold plasma concentration of endogenous TES in horses competing in PA should remain at 2000 pg/mL [11315].

Analysis of equine plasma samples to detect the abuse of anabolic steroids can be complicated when the parent steroid is endogenous to the animal. Anabolic steroids are usually administered intramuscularly as synthetic esters and therefore detection of the exogenous esters provides unequivocal proof of illegal administration. An ultra high performance liquid chromatography tandem mass spectrometric (UPLC-MSMS) method for the analysis of esters of testosterone (propionate, phenylpropionate, isocaproate, and decanoate) and boldenone (undecylenate) in equine plasma has been developed. Esters were extracted from equine plasma using a mixture of hexane and ethyl acetate and treated with methoxyamine hydrochloride to form methyloxime derivatives. Metenolone enanthate was used as an internal standard. After chromatographic separation, the derivatized steroid esters were quantified using selected reaction monitoring (SRM). The limit of detection for all of the steroid esters, based on a signal to noise ratio (S/N) of 3:1, was 1-3 pg/mL. The lower limit of quantification (LLOQ) for the all of the steroid esters was 5 pg/mL when 2 mL of plasma was extracted. Recovery of the steroid esters was 85-97% for all esters except for testosterone decanoate which was recovered at 62%. The intra-day coefficient of variation (CV) for the analysis of plasma quality control (QC) samples was less than 9.2 percent at 40 pg/mL and less than 6.0 percent at 400 pg/mL. The developed assay was used to successfully confirm the presence of intact testosterone esters in equine plasma samples following intramuscular injection of Durateston® (mixed testosterone esters) [11316].

1-Testosterone (17beta-hydroxy-5alpha-androst-1-en-3-one), a synthetic anabolic steroid, has been described as one of the most effective muscle-building supplements currently on the market. It has an anabolic potency of 200 as compared to 26 for testosterone. Apart from its abuse in human sports, it can also be a doping agent in racehorses. Metabolic studies on 1-testosterone have only been reported for human in the early seventies, whereas little is known about its metabolic fate in horses. One paper described the studies of in vitro and in vivo metabolism of 1-testosterone in horses, with the aim of identifying the most appropriate target metabolites to be monitored for controlling the misuse or abuse of 1-testosterone in racehorses. Six in vitro metabolites, namely 5alpha-androst-1-ene-3alpha,17beta-diol (T1a), 5alpha-androstane-3beta,17beta-diol (T2), epiandrosterone (T3), 16,17-dihydroxy-5alpha-androst-1-ene-3-one (T4 & T5), and 5alpha-androst-1-ene-3,17-dione (T6), were identified. For the in vivo studies, two thoroughbred geldings were each administered orally with 800 mg of 1-testosterone by stomach tubing. The results revealed that the parent drug and eight metabolites were detected in urine. Besides the four in vitro metabolites (T1a, T2, T3, and
T5), four other urinary metabolites, namely 5α-androst-1-ene-3β,17α-diol (T1b), 5α-androst-1-ene-3β,17β-diol (T1c), 5α-androstane-3α,17α-diol (T7) and 5α-androstane-3β,17α-diol (T8) were identified. The study shows that the detection of 1-testosterone administration is best achieved by monitoring the parent drug, which could be detected for up to 30 h post-administration [12492].

**Testosterone and nandrolone**

Pennsylvania (PA) State Racing Commissions regulate the endogenous androgenic steroid, testosterone (TES), in racing intact males (RIM) by quantification of TES in post-race samples. Post-race plasma samples (2209) collected between 2008 and 2010 were analyzed for TES, nandrolone (NAN), and other anabolic steroids (ABS). Of the 2209 plasma samples, 2098 had quantifiable TES ≥ 25 pg/mL. Plasma (mean ± SD) concentrations of TES and NAN in RIM were 329 ± 266 and 96 ± 68 pg/mL, respectively. Only 65 percent of RIM had quantifiable concentration of NAN, and there was no relationship between TES and NAN. Plasma TES concentrations were significantly higher during the months of April, May, June, July, and August. A significantly higher plasma TES was observed in Thoroughbred (TB) (348 ± 289 pg/mL) versus that in Standardbred (STB) (315 ± 248 pg/mL). Plasma concentrations of TES from breeding stallions (BS) were 602 ± 357 pg/mL. Statistically significant (P < 0.0001) lower plasma concentrations of the two steroids were observed in RIM horses. Based on quantile distribution of TES in the RIM and BS populations, 99.5% were at or below 1546.1 and 1778.0 pg/mL, respectively. Based on this population of RIM, the suggested upper threshold plasma concentration of endogenous TES in horses competing in PA should remain at 2000 pg/mL [12493].

**Nandrolone**

19-Norandrostenedione (NAED) and nandrolone are anabolic-androgenic steroids (AASs). Nandrolone was regarded solely as a synthetic AAS until the 1980s when trace concentrations of apparently endogenous nandrolone were detected in urine samples obtained from intact male horses (stallions). Since then, its endogenous origin has been reported in boars and bulls; endogenous NAED and nandrolone have been identified in plasma and urine samples collected from stallions. More recently, however, it was suggested that NAED and nandrolone detected in urine samples from stallions are primarily artifacts due to the analytical procedure. The present study was undertaken to determine whether NAED and nandrolone detected in plasma and urine samples collected from stallions are truly endogenous or artifacts from sample processing. To answer this question, fresh plasma and urine samples from ≥8 stallions were analyzed for the two AASs, soon after collection, by liquid chromatography hyphenated to tandem mass spectrometry (LC-MS/MS). NAED and nandrolone were not detected in fresh plasma samples but detected in the same samples post storage. Concentrations of both AASs increased with storage time, and the increases were greater at a higher storage temperature (37°C versus 4°C, and ambient temperature versus 4°C). Although NAED was detected in some fresh stallion urine samples, its concentration (<407 pg/mL) was far lower (<0.4 %) than that in the same samples post storage (at ambient temperature for 15 days). Nandrolone was not detected in most of fresh urine samples but detected in the same samples post storage. Based on these results, it is concluded that all NAED and nandrolone detected in stored plasma samples of stallions and most of them in the stored urine samples are not from endogenous origins but spontaneously generated during sample storage, most likely from spontaneous decarboxylation of androstenedione-19-oic acid and testosterone-19-oic acid. It was the first time that all NAED and nandrolone detected in plasma of stallions and most of them detected in the urine have
been shown to be spontaneously generated in vitro during sample storage. This finding would have significant implications with regard to the regulation of the two steroids in horse racing [12494].

A method to quantify metabolites of 17beta-nandrolone (17betaN) in boar and horse urine has been optimized and validated. Metabolites excreted in free form were extracted at pH 9.5 with tert-butylmethylether. The aqueous phases were applied to Sep Pak C18 cartridges and conjugated steroids were eluted with methanol. After evaporation to dryness, either enzymatic hydrolysis with beta-glucuronidase from Escherichia coli or solvolysis with a mixture of ethylacetate:methanol:concentrated sulphuric acid were applied to the extract. Deconjugated steroids were then extracted at alkaline pH with tert-butylmethylether. The dried organic extracts were derivatized with MSTFA:NH4I:2-mercaptoethanol to obtain the TMS derivatives, and were subjected to analysis by gas chromatography mass spectrometry (GC/MS). The procedure was validated in boar and horse urine for the following metabolites: norandrosterone, noretiocholanolone, norepiandrosterone, 5beta-estrane-3alpha, 17beta-diol, 5alpha-estrane-3beta, 17beta-diol, 17alpha-diol, 17alpha-nandrolone, 17betaN, 5(10)-estrane-3alpha, 17alpha-diol, 17alpha-estradiol and 17beta-estradiol in the different metabolic fractions. Extraction recoveries were higher than 90 percent for all analytes in the free fraction, and better than 80 percent in the glucuronide and sulphate fractions, except for 17alpha-estradiol in the glucuronide fraction (74 %), and 5alpha-estrane-3beta, 17alpha-diol and 17betaN in the sulphate fraction (close to 70 %). Limits of quantitation ranged from 0.05 to 2.1 ng/mL in the free fraction, from 0.3 to 1.7 ng/mL in the glucuronide fraction, and from 0.2 to 2.6 ng/mL in the sulphate fraction. Intra- and inter-assay values for precision, measured as relative standard deviation, and accuracy, measured as relative standard error, were below 15 percent for most of the analytes and below 25 percent, for the rest of analytes. The method was applied to the analysis of urine samples collected after administration of 17betaN laurate to boars and horses, and its suitability for the quantitation of the metabolites in the three fractions has been demonstrated [06318].

The Commission Decision 2002/657/EC is a fundamental reference document for the UE laboratories involved in residue analysis although its implementation has caused some difficulties in the requirements interpretation. In this work a pragmatic validation approach of a quantitative confirmatory method for the detection of 17-alpha-(alpha-NT) and 17-beta-19-nortestosterone (beta-NT) in bovine urine by gas chromatography mass spectrometry is proposed. The 19-nortestosterone is a banned anabolic steroid for which no minimum required performance limit (MRPL) has been laid down, therefore the limit reported in Italian Residue Monitoring Plan (2 microg/L) has been considered the reference level to evaluate the method performances. The decision limit (CCalpha) and the detection capability (CCbeta) were obtained by the calibration curve procedure. The minimum required performance level (MRPL), which represents the starting concentration of the calibration curves, was preliminary fixed estimating the results dispersion of blank urine samples fortified at 2 microg/L for each isomer. The found CCalpha and CCbeta were 1.5 and 1.9 microg/L for alpha-NT and 1.2 and 1.4 microg/L for beta-NT. The precision (repeatability and within-laboratory reproducibility) and recoveries were suitable for the investigated concentration range (1-3 microg/L). Finally, the method ruggedness (minor and major changes) has been also demonstrated [06319].

Following administration of the anabolic steroid 19-nortestosterone or its esters to the horse, a major urinary metabolite is 19-nortestosterone-17beta-sulphate. The detection of 19-nortestosterone in urine from untreated animals has led to it being considered a naturally occurring steroid in the male horse. Recently, it was demonstrated that the majority of the 19-nortestosterone found in extracts of normal urine from male horses arises as an artefact through decarboxylation of the 19-carboxylic acid of testosterone. The aim of one
investigation was to establish if direct analysis of 19-nortestosterone-17β-sulphate by liquid chromatography/tandem mass spectrometry (LC/MS/MS) had potential for the detection of 19-nortestosterone misuse in the male horse. The high concentrations of sulphate conjugates of the female sex hormones naturally present in male equine urine were overcome by selective hydrolysis of the aryl sulphates using glucuronidase from Helix pomatia; this was shown to have little or no activity for alkyl sulphates such as 19-nortestosterone-17β-sulphate. The free phenolic steroids were removed by solid-phase extraction (SPE) prior to LC/MS/MS analysis. The method also allowed for the quantification of the sulphate conjugate of boldenone, a further anabolic steroid endogenous in the male equine with potential for abuse in sports. The results indicate that while 19-nortestosterone-17β-sulphate is present at low levels as an endogenous substance in urine from normal male horses, its use as an effective threshold substance may be viable [08436].

5α-Estrane-3β,17α-diol is the major metabolite of nandrolone in horse urine. The presence of 5α-estrane-3β,17α-diol in female and gelding urines is prohibited by Racing Rules and its natural presence in male urine led regulation authorities to establish a concentration threshold of 45 ng/mL. One paper described a rapid, simple and stereoselective synthesis of 5α-estrane-3β,17α-diol, providing horseracing laboratories with an essential reference material for their antidoping performance [11317].

**Stanozolol**

Within equine drug surveillance, there is significant interest in analyzing intact phase II conjugates of drugs in urine, but progress has been limited by a lack of reference material. In one study, in vitro techniques using equine liver fractions were employed to produce glucuronide and sulfate conjugates of stanozolol, 16β-hydroxystanozolol and nandrolone, the glucuronide conjugate of morphine and the glutathione metabolite of chlorodinitrobenzene for the first time in equine sports drug surveillance. The glucuronide conjugate of the synthetic progestagen altenogest was also produced in vitro, removing the requirement for sample hydrolysis during routine urinalyses. It was concluded that these results highlight the potential of in vitro studies for the production of phase II reference material, allowing the development of assays based on intact conjugates [10537].

**Methyltestosterone and mestranolone**

Anabolic steroids with the 17α-methyl,17β-hydroxyl group, which were developed as oral formulations for therapeutic purposes, have been abused in the field of human sports. These anabolic steroids are also used to enhance racing performance in racehorses. In humans, structurally related 17α-methyltestosterone (MTS) and mestanolone (MSL), which are anabolic steroids with the 17α-methyl,17β-hydroxyl group, have metabolites in common. The purpose of this study was to determine metabolites common to these two steroids in horses, which may serve as readily available screening targets for the doping test of these steroids in racehorses. Urine sample collected after administering MTS and MSL to horses was treated to obtain unconjugated steroid, glucuronide, and sulfate fractions. The fractions were subjected to gas chromatography/mass spectrometry (GC/MS), and 17α-methyl-5α-pregn-3β,17β-diol, 17α-hydroxymethyl-5α-pregn-3β,17β-diol, 17α-methyl-5α-pregn-3β,16β,17β-triol, and 17α-methyl-5α-pregn-3β,16α,17β-triol were detected as the common metabolites by comparison with synthesized reference standards. The urinary concentrations of these metabolites after dosing were determined by GC/MS. 17α-Methyl-
methyl-5alpha-androstan-3beta,16beta,17beta-triol was mainly detected in the sulfate fractions of urine samples after administration. This compound was consistently detected for the longest time in the urine samples after dosing with both steroids. The results suggest that 17alpha-methyl-5alpha-androstan-3beta,16beta,17beta-triol is a very useful screening target for the doping test of MTS and MSL in racehorses [06322].

**Mesterolone**

Mesterolone (1alpha-methyl-5alpha-androstan-17beta-ol-3-one) is a synthetic anabolic androgenic steroid (AAS) with reported abuses in human sports. As for other AAS, mesterolone is also a potential doping agent in equine sports. Metabolic studies on mesterolone have been reported for humans, whereas little is known about its metabolic fate in horses. One paper described the studies of both the in vitro and in vivo metabolism of mesterolone in racehorses with an objective to identify the most appropriate target metabolites for detecting mesterolone administration. In vitro biotransformation studies of mesterolone were performed by incubating the steroid with horse liver microsomes. Metabolites in the incubation mixture were isolated by liquid-liquid extraction and analysed by gas chromatography-mass spectrometry (GC-MS) after acylation or silylation. Five metabolites (M1-M5) were detected. They were 1alpha-methyl-5alpha-androstan-3alpha-ol-17-one (M1), 1alpha-methyl-5alpha-androstan-3beta-ol-17-one (M2), 1alpha-methyl-5alpha-androstane-3alpha-17one (M3), 1alpha-methyl-5alpha-androstane-3beta-17one (M4), and 1alpha-methyl-5alpha-androstane-3,17-dione (M5). Of these in vitro metabolites, M1, M3, M4 and M5 were confirmed using authentic reference standards. M2 was tentatively identified by mass spectral comparison to M1. For the in vivo metabolic studies, Proviron (20 tablets x 25 mg of mesterolone) was administered orally to two thoroughbred geldings. Pre- and post-administration urine samples were collected for analysis. Free and conjugated metabolites were isolated using solid-phase extraction and analysed by GC-MS as described for the in vitro studies. The results revealed that mesterolone was extensively metabolised and the parent drug was not detected in urine. Three metabolites detected in the in vitro studies, namely M1, M2 and M4, were also detected in post-administration urine samples. In addition, two stereoisomers each of 1alpha-methyl-5alpha-androstane-3,17alpha-diol (M6 and M7) and 1alpha-methyl-5alpha-androstane-3,16-diol-17-one (M8 and M9), and an 18-hydroxylated metabolite 1alpha-methyl-5alpha-androstane-3,18-diol-17-one (M10) were also detected. The metabolic pathway for mesterolone is postulated. These studies have shown that metabolites M8, M9 and M10 could be used as potential screening targets for controlling the misuse of mesterolone in horses [07399].

**Methandienone**

Methandienone, methandriol, and oxymetholone, which are anabolic steroids possessing 17alpha-methyl and 17beta-hydroxy groups, were developed as oral formulations for therapeutic purposes. However, they have been used in racehorses to enhance racing performance. In humans, it has been reported that structurally related anabolic steroids having the 17alpha-methyl and 17beta-hydroxy groups, including 17alpha-methyltestosterone, mestanolone, methandienone, methandriol, and oxymetholone, have metabolites in common. In one study, it was found that metabolites common to those of 17alpha-methyltestosterone and mestanolone were detected in horse urine after the administration of oxymetholone, methandienone, and methandriol. Based on analytical data, it was confirmed these to be the common metabolites of five structurally related steroids, 17alpha-methyltestosterone, mestanolone, oxymetholone, methandienone, and methandriol.
Furthermore, it was detected hitherto unknown urinary metabolites of methandriol and oxymetholone in horses. The parent steroid itself was detected in horse urine after the administration of methandriol, other than metabolites common to 17alpha-methyltestosterone and mestanolone. On the other hand, the major metabolite of oxymetholone was mestanolone, aside from metabolites presumed to be the stereoisomers of 2-hydroxymethyl-17alpha-methyl-5alpha-androstan-3,17beta-diol and 2,17alpha-dihydroxymethyl)-5alpha-androstan-3,17beta-diol. The simultaneous detection of common metabolites and other main metabolites would help narrow down the candidate-administered steroid for the doping tests in racehorses [08438].

**Boldione, boldenone and boldenone esters**

Conflicting findings regarding the boldenone content of bovine faeces suggest it may be synthesized de novo in emitted faeces. It was tested this hypothesis by analysing uncontaminated urine, fresh and various forms of dried faeces from 10 calves (not given boldenone) by liquid chromatography/tandem mass spectrometry for 17alpha- and 17beta-boldenone (alpha and beta BOL); 1,4-androstadiene-3,17-dione (ADD); 4-androstone-3,17-dione (AED), testosterone (T) and epitestosterone (ET). Urine contained no alpha BOL, beta BOL or ADD. The analysed substances were variably present in the rectal faeces, and at generally higher levels in faeces scraped from skin or stall floor. In pooled rectal faeces naturally dried for 13 days, alpha BOL, ADD, AED and ET levels were extremely high (much higher than accounted for by increases due to drying), and beta BOL and T were absent. It is concluded that de novo synthesis of alpha BOL and metabolites occurs naturally in bovine faeces and only uncontaminated urine should be analysed for illegal boldenone [06320].

Electrochemical based immunosensors for the detection of boldenone and methylboldenone in bovine urine were described in this paper. The immunosensors were fabricated by immobilizing boldenone-bovine serum albumin conjugate on the surface of screen-printed electrodes (SPEs), and followed by the competition between the free analyte and coating conjugate with corresponding antibodies. The use of anti-species IgG-horseradish peroxidase conjugate determined the degree of competition. The electrochemical technique chosen was chronoamperometry, performed at a potential of +100 mV whereby the product of the catalysis of 3,3',5,5'-tetramethylbenzidine undergoes reduction produced by the enzyme label. The limits of detection of assay were 31 pg/mL for boldenone and 120 pg/mL for methylboldenone, respectively. Results of repeated analysis of each androgen carried out using three different batches of electrodes indicate suitable repeatability. Urine samples were determined directly after a single dilution step, omitting extraction and hydrolysis. This method offers the advantage to pick up both boldenone and its major metabolites in an efficient manner due to the high cross-reactivity pattern of alpha-boldenone with this antibody. The concentration of methylboldenone in urine detected by developed methods does indicate methylboldenone administration to heifers. Gas chromatography coupled to mass spectrometry analysis was performed to quantitate the individual metabolites present in urine samples, and results were validated with both ELISA and immunosensor data [06321].

Boldenone is banned in the European Union (Directive 96/22/EC) as growth promoter for meat producing animals. Boldione (ADD), boldenone and boldenone esters (mainly the undecylenate form) are commercially available as anabolic preparations, either to the destination of human, horse or cattle. Since the late 90s, the natural occurrence of boldenone metabolites has been reported in cattle. According to EU regulation, the unambiguous demonstration of boldenone administration in bovine urine should be provided on the basis of boldenone identification in the corresponding conjugate fraction. An analytical
The method has been developed and validated according to current standards with main concern to the measurement of intact 17beta-boldenone-sulphate. The analytical procedure included direct extraction-purification of target analyte on octadecylsilyl cartridges and direct detection of phase II metabolite by liquid chromatography (negative electrospray), tandem mass spectrometry (QqQ) or high resolution mass spectrometry. Decision limit (CC-alpha) and detection capability (CC-beta) were respectively 0.2 microg/L and 0.4 microg/L on triple quadrupole and 0.1 microg/L and 0.2 microg/L on hybrid system. The method was successfully applied to the analysis of incurred samples collected in different experiments. 17beta-Boldenone-sulphate was measurable up to 36h after oral administration of boldione, and 30 days after 17beta-boldenone undecylenate intra-muscular injection. This conjugate form was never detected in non-treated animals, confirming its status of definitive candidate marker for boldenone administration in calf [09399].

**Trenbolone and estradiole**

The increasing size of concentrated animal feeding operations has led to a concomitant increase in the land-application of manure, which has spawned research on the concentrations and environmental risk assessment of natural and synthetic hormones in animal manures. 17beta-trenbolone acetate (TBA) is widely used in the United States for improving daily gains in beef cattle and is often administered in combination with 17beta-estradiol (17beta-E2). Trenbolone (TB) and E2 isomers and their metabolites were quantified in manure collection pits and lagoon effluent from beef cattle implanted with the commercial anabolic preparation Ravoler-S (containing 140 mg 17beta-trenbolone acetate and 28 mg 17beta-E2). Manure pit and lagoon effluent samples were collected weekly for 9 weeks post implanting and analyzed using reverse-phase liquid chromatography tandem mass spectrometry. 17alpha-TB was the most abundant androgen with the highest concentration observed 2 weeks post implant. 17beta-TB and trendione peaked at the end of week 2 and 4, respectively. For the estrogens, the highest concentrations for estrone (E1), estriol (E3), and 17alpha-E2 were observed after week 4, 6, and 8, respectively. 17beta-E2 concentrations were the lowest of the estrogens and erratic over time. In lagoon water, which is used for irrigation, 17alpha-TB and E1 had the highest detected hormone concentrations (1.53 and 1.72 microg/L, respectively). Assuming a 1-2 order dilution during transport to surface water, these hormone levels could lead to concentrations in receiving waters that exceed some of the lowest observable effect levels (LOELs) reported for hormones (e.g. 0.01-0.03 microg/L) [12495].

**Fluoxymesterone**

Fluoxymesterone, an anabolic steroid with the 17alpha-methyl,17beta-hydroxy group, has been developed as an oral formulation for therapeutic purposes. However, it is also used illegally in racehorses to enhance racing performance. In this study, it was detected 9alpha-fluoro-17,17-dimethyl-18-norandrostane-4,13-dien-11beta-ol-3-one by gas chromatography/mass spectrometry (GC/MS), which has not been reported as a fluoxymesterone metabolite so far in horse. It was synthesized for use as a reference standard, and characterized on the basis of $^1$H NMR and $^{13}$C NMR spectra, as well as GC/MS EI mass spectra of TMS derivatives. It was excreted as the main metabolite in horse urine, and its reference standard could be synthesized easily. Therefore, this metabolite could be a useful target for a doping test of fluoxymesterone in racehorses [08435].
Selective androgen receptor modulators (SARMs)

Selective androgen receptor modulators (SARMs) are a group of substances that have potential to be used as doping agents in sports. Being a relatively new group not available on the open market means that no reference materials are commercially available for the main metabolites. In one study, the in vitro metabolism of SARMs by the fungus Cunninghamella elegans has been investigated with the purpose of finding out if it can produce relevant human and equine metabolites. Three different SARMs, S1, S4 and S24, were incubated for 5 days with C. elegans. The samples were analysed both with and without sample pretreatment using ultra performance liquid chromatography coupled to high resolution mass spectrometry. All the important phase I and some phase II metabolites from human and horse were formed by the fungus. They were formed through reactions such as hydroxylation, deacetylation, O-dephenylation, nitro-reduction, acetylation and sulfonation. The study showed that the fungus produced relevant metabolites of the SARMs and thus can be used to mimic mammalian metabolism. Furthermore, it has the potential to be used for future production of reference material [12496].

Growth hormone

Growth hormone (GH) is a polypeptide suspected of being used in horse racing to speed up physical performances. Despite scientific advances in the recent years, the control of its administration remains difficult. In order to improve it, a metabolomics study through LC-high resolution mass spectrometry measurements was recently initiated to assess the metabolic perturbations caused by recombinant equine growth hormone administration. Few tens of ions not identified structurally were highlighted as compounds responsible for the modification of metabolic profiling observed in treated animals. This previous work was based on the use of Uptisphere Strategy NEC as the chromatographic column. In parallel, more and more metabolomics studies showed the interest of the use of new chromatographic supports such as hydrophilic interaction chromatography for the analysis of polar compounds. It is in this context that an investigation was conducted on Uptisphere HDO and Luna hydrophilic interaction chromatography stationary phases to generate and process urinary metabolomics fingerprints, which could allow to establish a comparison with Uptisphere Strategy NEC. The chromatographic column the most adapted for the detection of new biomarkers of GH administration has been used to set up a relevant statistical model based on the analysis of more than hundred biological samples [11318].

Erythropoietin

Horse

Doping of horses with recombinant human erythropoietin (rHuEPO) to illegally enhance their endurance capacity in horseracing has been reported during the last years. This leads to increased blood viscosity which can result in sudden death and is of concern for the horse welfare. Additionally, the horse can start production of rHuEPO antibodies, which cross-reacts with endogenous equine EPO and can lead to severe anaemia and even death. In this study, a novel micro-chromatographic method, EPO WGA MAIIA, has been tested for the capability in plasma and urine samples to detect administration of erythropoiesis-stimulating agents, like the rHuEPO glycoprotein varieties Eprex and Aranesp, to horses. After administration of 40 IU Eprex peer kg/day to seven horses during 6 days, the presence of Eprex in horse plasma was detected up to 2-5 days after last injection. In urine samples
collected from two horses, Eprex was detected up to 3 days. A single injection of Aranesp (0.39 microg/kg) was detected up to 9 days in plasma and up to 8 days, the last day of testing, in the urine sample. The LC-FAIMS-MS/MS system, with 1 day reporting time, confirmed the presence of Eprex up to 1 day after last injection for six out of seven horses and the presence of Aranesp up to 5 days after last injection in plasma samples. The MAIIA system showed to be a promising tool with high sensitivity and extremely short reporting time (1 h) [12497].

Erythropoietin (EPO) and its recombinant analogues are suspected to be illicitly administered to horses for performance enhancing purposes and, consequently, prohibited in equine sports. Recently, a new erythropoiesis-stimulating agent, peginesatide (Omontys, formerly referred to as Hematide), belonging to the upcoming class of EPO-mimetic peptides, received approval for the treatment of anaemia in humans with chronic kidney disease on dialysis. As the pegylated dimeric peptide of approximately 45 kDa without sequence homology to EPO is not detectable by conventional EPO detection assays, specific methods are bound to be established for horse sports drug testing. Thus, by fortifying equine serum with peginesatide, an approach consisting of a proteolytic digestion with subtilisin after protein precipitation was developed, eventually targeting a proteotypic and xenobiotic pentapeptide which is easily accessible to liquid chromatography-tandem mass spectrometry analysis. The method was validated for qualitative purposes and demonstrated to be specific, precise (relative standard deviations below 14 %), sensitive (limit of detection 10 ng/mL) and linear. Being simple, cost-effective and readily transferable to other doping control laboratories, a mass spectrometric assay for the detection of therapeutic concentrations of peginesatide in equine serum is, in terms of preventive doping research, applicable to routine analysis shortly after approval of the drug [12498].

Recombinant human erythropoietin (rhEPO), darbepoetin alfa (DPO) and methoxy polyethylene glycol-epoetin beta (PEG-EPO) are synthetic analogues of the endogenous hormone erythropoietin (EPO). These erythropoiesis-stimulating agents have the ability to stimulate the production of red blood cells and are commercially available for the treatment of anaemia in humans. These drugs are understood to have performance-enhancing effects on human athletes due to their stimulation of red blood cell production, thereby improving delivery of oxygen to the muscle tissues. The method officially adopted by the International Olympic Committee (IOC) and World Anti Doping Agency (WADA) for the confirmation of rhEPO and/or DPO (rhEPO/DPO) in human urine is based on electrophoresis in combination with Western blotting. A shortcoming of the WADA method is the lack of definitive mass spectral data for the confirmation of a positive finding. Recently, a liquid chromatography-tandem mass spectrometry (LC/MS/MS) method for the detection and confirmation of rhEPO/DPO in equine plasma was reported. One paper presents a method for the detection and confirmation of rhEPO/DPO, as well as the newly released PEG-EPO, in equine plasma. The procedures involve immunoaffinity extraction using anti-rhEPO antibody-coated Dynabeads followed by trypsin digestion. The injected extract was further purified and concentrated using an on-line trap column in the nano-LC system. Detection and confirmation were achieved by monitoring a unique peptide segment of rhEPO/DPO/PEG-EPO using nano-liquid chromatography-tandem mass spectrometry equipped with a nanospray ionisation source operated in the selected reaction monitoring mode. rhEPO, DPO and PEG-EPO can be confirmed at 0.1, 0.2 and 1.0 ng/mL, respectively, in equine plasma [10297].

Recombinant human erythropoietin (rhEPO) and darbepoetin alfa (DPO) are protein-based drugs for the treatment of anemia in humans by stimulating erythrocyte production. One paper described the first method for differentiation and identification of rhEPO and DPO in equine plasma by liquid chromatography coupled to tandem mass spectrometry (LC-
MS/MS). The limit of identification was 0.1 ng/mL for DPO and 0.2 ng/mL for rhEPO in equine plasma, and the limit of detection was 0.05 ng/mL for DPO and 0.1 ng/mL for rhEPO. Analyte carryover problem encountered was solved by adding 20 percent acetonitrile to the solvent of the sample digest to increase solubility of the peptides. This method was successfully applied to identification of DPO in plasma samples collected from a research horse following DPO administration and from racehorses out of competition in North America [08440].

Recombinant human erythropoietins (rHuEPOs) are glycoproteins drugs, produced by the pharmaceutical industry to restore production of red blood cells by stimulating human bone marrow for which this pathology has been diagnosed. It is suspected that these molecules are diverted as doping agents in horseracing to enhance oxygen transport and aerobic power in racehorses. Although indirect double-blotting or direct liquid chromatography-mass spectrometry (LC-MS) methods have been developed to confirm the presence of rHuEPO in a sample, the short detection time (48 h) is still a problem for doping control. In this context, gene profiling investigation through Serial Analysis of Gene Expression (SAGE) has been conducted on seven thoroughbreds treated with Eprex. This functional genomic method has been performed from total blood cells collected from each animal to assess the mRNA expression consecutive to rHuEPO injections. Sample pooling was chosen as a powerful, cost-effective, and rapid means of identifying the most common and specific changes in terms of gene expression profile and to eliminate individual variation. Consequently, three SAGE libraries were constructed, before, during, and after Eprex® treatment. More than 71 440 mRNA signatures were observed and subjected to statistical analysis; 49 differentially expressed genes were identified and analyzed by qPCR. From the selected gene list, were defined as potential biomarkers in terms of their low inter-individual variation and capacity as strong markers of rHuEPO administration up to 60 days after the beginning of the doping period. In one paper, a new strategy is proposed to the horseracing industry to prevent rHuEPO abuse [10427].

Methods have been developed to screen for and confirm darbepoetin alfa, recombinant human EPO, and methoxy polyethylene glycol-epoetin beta (PEG-epoetin beta) in horse plasma. All three methods screen samples with an enzyme-linked immunosorbent assay (ELISA) and confirm by liquid chromatography-tandem mass spectrometry (LC-MS/MS). This report focuses on PEG-epoetin beta. The ELISA assay was able to detect PEG-epoetin beta at 0.02 ng/mL in 50 µL of horse plasma. Many samples had high background levels of immunoreactivity; however, introducing polyethylene glycol 6000 (PEG 6000) into the samples before the ELISA assay removed the high background and increased the apparent concentrations of PEG-epoetin β. In samples collected following the administration of 100 µg of PEG-epoetin β by the intravenous (IV), intramuscular (IM) and subcutaneous (SC) routes, PEG-epoetin beta was detectable up to 72, 144, and 120 h, respectively. The samples were prepared for LC-MS/MS analysis by extraction with anti-rHuEPO-antibodies-coated Dynabeads followed by digestion with trypsin. The LC-MS/MS confirmation method used the multiple reaction monitoring (MRM) scan mode to monitor four precursor-product ion transitions of the EPO-derived peptide T₆. All four transitions of T₆ were detectable with S/N > 3. The limit of confirmation for PEG-epoetin beta was 1.0 ng/mL in 2 mL of horse plasma. The method successfully confirmed the presence of PEG-epoetin beta in a sample collected from a Mircera®-treated horse. Compared to PEG-epoetin beta, better sensitivity was achieved for darbepoetin alfa and recombinant human EPO. Darbepoetin alfa was detected in horse plasma four days after IM administration of 100 microg [11319].

Recombinant human erythropoietin (rHuEPO) causes an increase in red blood cell production and aerobic capacity in other species; however, data are lacking on effects in the horse. One study tested the hypothesis that rhuEPO administration would alter red cell volume (RCV),
aerobic capacity (VO_{2\text{max}}) and indices of anaerobic power. Eight healthy, unfit mares accustomed to the laboratory and experimental protocols were randomly assigned to either a control (n=4; 3 ml saline 3 times/week for 3 weeks) or EPO group (EPO, n=4, 50 iu/kg bwt rhuEPO/3 ml saline 3 times/week for 3 weeks). Exercise tests (GXT) were performed on a treadmill (6 % incline), 1 week before and 1 week after treatment. The GXT started at 4 m/sec, with a 1 m/sec increase every 60 sec until the horse reached fatigue. Oxygen uptake was measured via an open flow indirect calorimeter. Blood samples were collected before, during (each step) and 2 and 15 min post GXT to measure packed cell volume (PCV), haemoglobin concentration (Hb), blood lactate concentration (LA) and plasma protein concentration (TP). Plasma volume (PV) was measured using Evans Blue dye. Blood volume (BV) and RCV were calculated using PCV from the 8 m/sec step of the GXT. There were no alterations in any parameters in control horses. By week 3, EPO produced increases in resting PCV and Hb (37 %), RCV (26 %) and VO_{2\text{max}} (19 %) increased, but BV did not change due to decreased PV. There was a significant increase in velocity at VO_{2\text{max}} and LA\text{peak} for horses treated with rhuEPO and substantial decrease in VO_{2} recovery time when the pretreatment GXT was compared to the post treatment GXT. No differences were detected for TP, VLA4, run time or V_{\text{max}}. It was concluded that low dose rhuEPO administration increases RCV and aerobic capacity without altering anaerobic power. The study demonstrates that rhuEPO enhances aerobic capacity and exercise performance, a question relevant to racing authorities [06327].

**Dog**

Recombinant human erythropoietin (rHuEPO) doping is prohibited in animal (canine and equine) sport. The effectiveness of a range of immunoassay screening methods for the detection of rHuEPO in canine urine was evaluated. The excretion profiles following rHuEPO administration to dogs were investigated. The presence of rHuEPO in postadministration samples was confirmed using the World Anti-Doping Agency (WADA)-approved isoelectric focusing immunoblotting confirmatory technique. Following the administration study, a screening program involving approximately 6000 greyhound sport (mostly racing) samples was undertaken for rHuEPO. This resulted in the detection of the first rHuEPO positives in the world of canine or equine sport. In an additional case, endogenous HuEPO was detected in a sample submitted as greyhound urine. It was determined that this arose from the submission to control stewards, as greyhound urine, of a substance that was, in fact, human urine. This was a particularly welcome development as definitive confirmatory evidence of such sample switching can be difficult to obtain in the case of greyhounds [06328].

**Darbepoetin**

Recombinant human erythropoietin (rhEPO) and darbepoetin alpha (DPO) are protein-based drugs for the treatment of anemia by stimulating red blood cell production. Consequently, they are abused in human and equine sports. To deter their abuse in the horse racing industry, a sensitive and reliable method for confirmation of these agents in equine plasma has been in urgent need. Such a method by LC-MS/MS is described in this paper. The method involved analyte enrichment by immunoaffinity separation using anti-rhEPO antibody linked to magnetic beads, digestion by trypsin, and analysis by LC-MS/MS. Two specific proteotypic peptides, 46VNFYAWK52 and 144VYSNFLR150 from rhEPO and DPO were employed for confirmation of the analytes based on chromatographic retention times and major product ions. The limit of confirmation of this method was 0.2 ng/mL, and the limit of detection was 0.1 ng/mL for rhEPO and DPO in equine plasma. This method was successful in confirming the presence of rhEPO and DPO in plasma samples collected from research
horses to which rhEPO or DPO was administered and from racehorses following competition and in noncompetition samples in North America. To our knowledge, this is the first LC-MS method with adequate sensitivity and specificity in providing unequivocal confirmation of rhEPO and DPO in equine plasma samples. This method provides a powerful enforcement tool that was lacking in the fight against the abuse of rhEPO and DPO in the horse racing industry [07400].

**Insulin**

Insulin administration can increase muscle glycogen by utilising hyperinsulinaemic clamps prior to sports events or during the recovery phases, and increase muscle size by its chalonic action to inhibit protein breakdown. In order to control insulin abuse in equine sports, a method to detect effectively the use of insulins in horses would be required. Besides the readily available human insulin and its synthetic analogues, structurally similar insulins from other species can also be used as doping agents. One study described a method for the simultaneous detection of bovine, porcine and human insulins, as well as the synthetic analogues Humalog (Lilly) and Novolog (Novo Nordisk) in equine plasma. Insulins were isolated from equine plasma by immunoaffinity purification, followed by centrifugal filtration, and analysed by nano-liquid chromatography-tandem mass spectrometry (LC/MS/MS). Insulin and analogues were detected and confirmed by comparing their retention times and major product ions. All five insulins (human insulin, Humalog, Novolog, bovine insulin and porcine insulin), which are exogenous in the horse, could be detected and confirmed at 0.05ng/mL. This method was successful in confirming the presence of human insulin in plasma collected from horses up to 4h after having been administered a single low dose of recombinant human insulin (Humulin, Eli Lilly) [08439].

Insulin and its analogues have been banned in both human and equine sports owing to their potential for misuse. Insulin administration can increase muscle glycogen by utilising hyperinsulinaemic clamps prior to sports events or during the recovery phases, and increase muscle size by its chalonic action to inhibit protein breakdown. In order to control insulin abuse in equine sports, a method to effectively detect the use of insulins in horses is required. Besides the readily available human insulin and its synthetic analogues, structurally similar insulins from other species can also be used as doping agents. The author's laboratory has previously reported a method for the detection of bovine, porcine and human insulins, as well as the synthetic analogues Humalog (Lispro) and Novolog (Aspart) in equine plasma. This study describes a complementary method for the simultaneous detection of five exogenous insulins and their possible metabolites in equine urine. Insulins and their possible metabolites were isolated from equine urine by immunoaffinity purification, and analysed by nano liquid chromatography-tandem mass spectrometry (LC/MS/MS). Insulin and its analogues were detected and confirmed by comparing their retention times and major product ions. All five insulins (human insulin, Humalog, Novolog, bovine insulin and porcine insulin), which are exogenous in horse, could be detected and confirmed at 0.05ng/mL. This method was successfully applied to confirm the presence of human insulin in urine collected from horses up to 4h after having been administered a single low dose of recombinant human insulin (Humulin R, Eli Lilly) [11320].

**Seven peptide hormones**

In recent years, there has been an ongoing focus for both human and equine doping control laboratories on developing detection methods to control the misuse of peptide therapeutics.
Immunoaffinity purification is a common extraction method to isolate peptides from biological matrices and obtain sufficient detectability in subsequent instrumental analysis. However, monoclonal or polyclonal antibodies for immunoaffinity purification may not be commercially available, and even if available, such antibodies are usually very costly. In our study, a simple mixed-mode anion exchange solid-phase extraction cartridge was employed for the extraction of seven target peptides (GHRP-1, GHRP-2, GHRP-6, ipamorelin, hexarelin, CJC-1295, and N-acetylated LKKTETQ (active ingredient of TB-500)) and their in vitro metabolites from horse plasma. The final extract was subject to ultra-high-performance liquid chromatographic separation and analysed with a hybrid high-resolution mass spectrometer. The limits of detection for all seven peptides were estimated to be less than 50 pg/mL. Method validation was performed with respect to specificity, precision, and recovery. The applicability of this multi-analyte method was demonstrated by the detection of N-acetylated LKKTETQ and its metabolite N-acetylated LK from plasma samples obtained after subcutaneous administration of TB-500 (10 mg N-acetylated LKKTETQ) to two thoroughbred geldings. This method could easily be modified to cover more bioactive peptides, such as dermorphin, beta-casomorphin, and desmopressin. With the use of high-resolution mass spectrometry, the full-scan data acquired can also be re-processed retrospectively to search for peptides and their metabolites that have not been targeted at the time of analysis. This is the first identification of in vitro metabolites of all the studied peptides other than TB-500 in horses [13794].

Relaxine

Relaxin (RLX) is a peptide hormone belonging to the relaxin-like peptide family. Relaxin-2 (RLX-2), a heteromeric polypeptide consisting of an A-chain (24 amino acids) and a B-chain (29 amino acids) linked together by two inter-chain disulfide bonds, is the main circulating RLX hormone in human. Due to its ability to dilate blood vessels surrounding the smooth muscles via induction of nitric oxide resulting in the increase of blood and oxygen supplies to the muscles, it may enhance athletic performance and is therefore banned in horseracing, equestrian competitions, and human sports. In order to control the abuse of rhRLX-2, a definitive method is required to detect and confirm the presence of rhRLX-2 in biological samples. One paper described, for the first time, the detection and confirmation of rhRLX-2 in equine plasma by liquid chromatography-high resolution mass spectrometry (LC-HRMS) after immunoaffinity extraction. rhRLX-2 could be detected at less than 0.1 ng/mL, and confirmed at less than 0.2 ng/mL in plasma samples [13795].

Thyroid hormones

The aim of one study was to determine if topical application of dexamethasone affected the serum concentrations of thyroid hormones (triiodothyronine T3 and thyroxine T4), glucose, triglycerides, total protein and insulin in normal horses. Ten horses were treated twice daily for 10 days with 50 g dexamethasone using an ointment formulation. Thyroid hormones and insulin were assayed using standard radioimmunoassay methods, while glucose, triglycerides and total protein were determined using a standard enzymatic method and the Biuret reaction, respectively. An increase in serum glucose and triglyceride concentrations was accompanied by 2-6-fold increases in serum insulin concentrations, but there was no change in serum total protein concentration. Insulin secretion increased with concomitant hyperglycemia and hypertriglyceridemia. A non-significant decline in T4 secretion was noted. Serum T3 and T4 concentrations declined continuously below baseline values from 48 h. Glucose and insulin levels returned to baseline values 3 days after treatment withdrawal,
whereas triglycerides reverted to baseline by 7 days. In contrast, baseline values of serum T₃ and T₄ were not reached by 20 days following drug withdrawal. The results indicated that topical administration of dexamethasone affected thyroid function and physiological metabolic functions, which may have implications for potential doping cases in racing horses [10296].

**Hydrocortisone**

A liquid chromatography/time-of-flight mass spectrometry (LC/TOFMS) method was developed using the latest high-resolution LC column technology, the ultraperformance liquid chromatography (UPLC), and electrospray ionization (ESI) in the positive ion mode. Gradient UPLC separation conditions were optimized for a group of 22 analytes comprising 17 glucocorticosteroids, specific designer steroids such as tetrahydrogestrinone (THG) and specific beta₂-agonists such as formoterol. The UPLC/TOFMS separation obtained required 5.5 min only for all the substances tested. Even the critical pair of dexamethasone and betamethasone isomers was almost completely resolved. Thanks to the over 10,000 full-width at half maximum (FWHM) mass resolution and high mass accuracy features of TOFMS 50 mDa window accurate mass chromatograms could be reconstructed for the individual analytes. Sensitive screening in human and calf urine samples fortified at the glucocorticosteroids minimum required performance limit (MRPL) of 30 microg/L (human urine, sports doping) and 2 microg/L (calf urine, veterinary control) could be obtained. The potential of UPLC/TOFMS for confirmatory analysis was shown by determining the accurate mass of all compounds and fragment ions upon in-source collision-induced dissociation (CID) at different energies. The exact mass measurement errors for all glucocorticosteroids were found to be within 6 ppm. Considering veterinary control, limits of detection (LOD) and limits of quantification (LOQ) were determined for most of the analytes in calf urine and found to range from 0.1 to 3.3 and from 0.4 to 4.4 microg/L, respectively. The method can be easily extended with other banned substances of interest, as demonstrated by the addition of 21 beta₂-agonists to the original analyte mixture in urine, without causing any interferences [07401].

Two simple and rapid LC/MS methods with direct injection analysis were developed and validated for the quantification and identification of hydrocortisone in equine urine using the same sample preparation but different mass spectrometric systems: ion trap mass spectrometry (IT-MS) and time-of-flight mass spectrometry (TOF-MS). The main advantage of the proposed methodology is the minimal sample preparation procedure, as particle-free diluted urine samples were directly injected into both LC/MS systems. Desonide was used as internal standard (IS). The linear range was 0.25-2.5 microg/mL for both methods. Matrix effects were evaluated by preparing and analyzing calibration curves in water solutions and different horse urine samples. A great variation of the signal both for hydrocortisone and the internal standard was observed in different matrices. To overcome matrix effects, the unavailability of blank matrix and the excessive cost of the isotopically labeled internal standard, standard additions calibration method was applied. This work is an exploration of the performance of the standard additions approach in a method where neither nonspecific internal standards nor extensive sample preparation is utilized and no blank matrix is available. The relative standard deviations of intra and interday analysis of hydrocortisone in horse urine were lower than 10.2 and 5.4 percent, respectively, for the LC/IT-MS method and lower than 8.4 and 4.4 percent, respectively, for the LC/TOF-MS method [08441].

*Topical glucocorticoids*
There are no data available regarding the systemic (adverse) effects which might be induced by topical dermal glucocorticoids application in the horse. Besides their widespread use for the treatment of a variety of peripheral inflammatory disorders such as atopic dermatitis, eczemas or arthritis in the horse, their surreptitious application has become a concern in doping cases in competition/performance horses. Assessing both basal and ACTH-stimulated plasma cortisol as well as basal ACTH concentrations following application of dexamethasone-containing dermal ointment is necessary to determine influences on hypothalamus-pituitary-adrenal (HPA) axis. Ten clinically healthy adult standardbred horses (6 mares, 4 geldings) were rubbed twice daily each with 50 g dexamethasone-containing ointment on a defined skin area (30 x 50 cm) for 10 days. RIA and chemiluminescent enzyme immuno-metric assay were used to determine resting and ACTH-stimulated plasma cortisol and basal ACTH concentrations, respectively. HPA feedback sensitivity and adrenal function were measured by a standard ACTH stimulation test. Dermal dexamethasone suppressed significantly the resting plasma cortisol level (to 75-98 %) significantly below baseline within the first 2 days and decreased further until day 10. ACTH stimulation test showed a significantly reduced rise in plasma cortisol concentrations. Plasma ACTH level decreased also during topical dexamethasone application. The number of total lymphocytes and eosinophil granulocytes was reduced, whereas the number of neutrophils increased. No significant change of serum biochemical parameters was noted. Dermal dexamethasone application has the potential to cause an almost complete and transient HPA axis suppression and altered leukocyte distribution in normal horses. The effects on HPA axis function should be considered in relation to the inability of animals to resist stress situations. The data further implicate that percutaneously absorbed dexamethasone may cause systemic effects relevant to “doping” [09396].

The aim of one study was to determine if topical application of dexamethasone affected the serum concentrations of thyroid hormones (triiodothyronine $T_3$ and thyroxine $T_4$), glucose, triglycerides, total protein and insulin in normal horses. Ten horses were treated twice daily for 10 days with 50 g dexamethasone using an ointment formulation. Thyroid hormones and insulin were assayed using standard radioimmunoassay methods, while glucose, triglycerides and total protein were determined using a standard enzymatic method and the Biuret reaction, respectively. An increase in serum glucose and triglyceride concentrations was accompanied by 2-6-fold increases in serum insulin concentrations, but there was no change in serum total protein concentration. Insulin secretion increased with concomitant hyperglycemia and hypertriglyceridemia. A non-significant decline in $T_4$ secretion was noted. Serum $T_3$ and $T_4$ concentrations declined continuously below baseline values from 48 h. Glucose and insulin levels returned to baseline values 3 days after treatment withdrawal, whereas triglycerides reverted to baseline by 7 days. In contrast, baseline values of serum $T_3$ and $T_4$ were not reached by 20 days following drug withdrawal. The results indicated that topical administration of dexamethasone affected thyroid function and physiological metabolic functions, which may have implications for potential doping cases in racing horses [11322].

Clenbuterol and hydrocortisone

Highly luminescent Eu(3+) and Tb(3+) complexes of 10-[4-(3-isothiocyantopropoxy) benzoylmethyl]-1,4,7,10-tetraazacyclododecane-1,4,7 triacetic acid Eu(3+) is a subset of 1 and Tb(3+) is a subset of 1 were conjugated with a goat anti-rabbit IgG and a rabbit anti-mouse IgG, respectively, and applied as markers in a time resolved immunoassay for simultaneous quantitative determination of anabolic compounds clenbuterol and hydrocortisone. The assay was performed in horse urine, using a monoclonal antibody specific to clenbuterol and a rabbit polyclonal antibody specific to the free hydrocortisone.
These lanthanide chelates are very stable and highly luminescent in aqueous solution and allowed to reach 10 microg/L and 40 microg/L sensitivities for clenbuterol and for hydrocortisone, respectively. Application to the horse urine, that is a very complex matrix, has a considerable interest in the control of illegal use of these compounds [09398].

**Clenbuterol**

The pharmacokinetics of clenbuterol in equine urine and blood was investigated. Urine and blood samples were collected following 3-day multiple oral administrations. The samples were examined using enzyme-linked immunosorbent assay and further confirmed by solid phase extraction and capillary electrophoresis. Urinary clenbuterol was detectable until day 14 after the last dose. The urinary excretion of clenbuterol was characterized by a biphasic pattern. The half-lives of the bi-exponential elimination ($t_{1/2alpha}$) and $t_{1/2beta}$ for urinary clenbuterol were about 12 and 48 hours. After a single oral administration (4 microg/kg) of clenbuterol, the half-life of serum clenbuterol was approximately 11.4 hours [10298].

A sensitive method using LC/ESI-MS(n) has been developed on a quadrupole linear ion trap mass analyser for the detection of nine beta$_2$ agonists (cimaterol, clenbuterol, fenoterol, formoterol, mabuterol, terbutaline, ractopamine, salbutamol and salmeterol) in horse urine. The method consists of solid-phase extraction on CSDAU cartridges before analysis by LC/ESI-MS(n) . The efficiency of extraction combined with the sensitivity and the selectivity of MS(n) allowed the detection of these compounds at pg/mL levels. Administration studies of fenoterol and formoterol are reported and show their possible detection after inhalation. The method is applicable for screening and confirmatory analysis [11321].

The use of clenbuterol in performance horses necessitates the establishment of appropriate withdrawal times. To describe plasma and urine concentrations of clenbuterol following administration of 2 commonly used dosing regimens to racing fit thoroughbreds 22 horses received an oral dose of 0.8 μg/kg bwt of clenbuterol twice daily for 30 days. A second group of 6 horses received clenbuterol according to the escalating dose protocol on the manufacturer’s label. Blood and urine samples were collected prior to, throughout and at various times up to 35 days post administration of the final dose. Drug concentrations were measured using liquid chromatography-mass spectrometry, and plasma data were analysed using noncompartmental analysis. Behavioural and physiological effects were monitored and heart rate was recorded throughout the course of the study. Clenbuterol plasma concentrations were below the limit of quantification (10 pg/ml) of the assay by Day 4 in all horses receiving the chronic low-dose regimen and by Day 7 in 5 of 6 horses receiving the escalating dosing protocol. Urine clenbuterol concentrations fell below the limit of quantification of the assay between Days 21 and 28 in all 22 horses in the low-dose group and in 5 of 6 of the horses in the escalating dose group. Muscle fasciculations, sweating and transient increases in heart rate were noted in a small number of horses following clenbuterol administration, but tolerance to these effects occurred rapidly. Establishment of appropriate withdrawal times for specific racing jurisdictions depends upon the threshold adopted by that specific jurisdiction. The study extends previous studies describing the pharmacokinetics of clenbuterol and describes plasma and urine concentrations following administration of 2 commonly used dosing regimens to racing fit thoroughbreds, which will allow jurisdictions to establish withdrawal times in order to prevent inadvertent positive regulatory findings [13788].

The aim of one study was to evaluate the concentrations of clenbuterol residues in the red hair of Chinese Simmental beef cattle following exposure to two doses of clenbuterol for 21
days. This experiment was conducted in six male red pied Chinese Simmental beef cattle which were randomly divided into two groups (n=3). Groups 1 and 2 were administered clenbuterol at a dose of 16 and 48 microg/kg body weight (BW)/day, respectively. Hair samples were collected on Days 7, 14 and 21 during treatment, and on Days 0, 14, 28, 42 and 70 after discontinuation of medication, using liquid chromatography tandem mass spectrometry (LC-MS-MS) method. About 500 mg hair samples spiked with 50 pg/mg D9-clenbuterol internal standard were analyzed with which the method recovery was from 89 to 117 percent. The results showed that clenbuterol was significantly accumulated in hair, with a concentration of 0.98 ± 0.56 pg/mg in Group 1 and 6.34 ± 3.21 pg/mg in Group 2 on Day 7 of treatment, and the residue concentrations increased as treatment proceeded. During the early withdrawal period, the residues increased from 13.52 ± 8.69 to 17.96 ± 6.94 pg/mg in Group 1 and from 55.15 ± 4.04 to 147.79 ± 15.35 pg/mg in Group 2. No significant differences were found in the later withdrawal period in both treatment groups. The results of the present study indicated that the red hair of Chinese Simmental beef cattle has high accumulation potential for clenbuterol residues. Hair, as a target matrix, even light-pigmented hair, can be used to monitor clenbuterol abuse over a long period [13789].

**THG**

The anti-doping rules of national and international sport federations ban any use of tetrahydrogestrinone (THG) in human as well as in horse sports. Initiated by the THG doping scandals in human sports a method for the detection of 3-keto-4,9,11-triene steroids in horse blood and urine was developed. The method comprises the isolation of the analytes by a combination of solid phase and liquid-liquid extraction after hydrolysis and solvolysis of the steroid conjugates. The concentrations of THG in blood and urine samples were measured by liquid chromatography-tandem mass spectrometry (LC-MS/MS). Following the administration of a single oral dose of 25 microg THG per kg bodyweight to 10 horses, samples were collected at appropriate intervals. The plasma levels of THG reached maximal concentrations of 1.5-4.8 ng/mL. Twenty-four hours after the administration plasma levels returned to baseline. In urine, THG was detectable for 36 h. Urinary peak concentrations of total THG ranged from 16 to 206 ng/mL. For the 10 horses tested, the mean plasma clearance of THG was 2250 mL/h/kg and the plasma elimination half-life was 1.9 h [09392].

**Theobromine**

In equine sport, theobromine is prohibited with a threshold level of 2 microg/mL in urine, hence doping control laboratories have to establish quantitative and qualitative methods for its determination. Two simple liquid chromatography/mass spectrometry (LC/MS) methods for the identification and quantification of theobromine were developed and validated using the same sample preparation procedure but different mass spectrometric systems: ion trap mass spectrometry (ITMS) and time-of-flight mass spectrometry (TOFMS). Particle-free diluted urine samples were directly injected into the LC/MS systems, avoiding the time-consuming extraction step. The relative standard deviations of intra- and inter-day analysis were lower than 8.6 and 7.2 percent, respectively, for the LC/ITMS method and lower than 5.7 and 5.8 percent, respectively, for the LC/TOFMS method. The bias was less than 8.7 percent for both methods. The methods were applied to two case samples, demonstrating simplicity, accuracy and selectivity [09393].

**Flurbiprofen**
Flurbiprofen and its main acidic metabolites were detected in equine urine after a single-dose administration of 500 mg flurbiprofen to two 2.5-3.5-years-old mares, in order to be used in equine doping control routine analysis. The urine levels of the parent drug were determined using GC/MS. Five acidic metabolites were found in the urine. The structure of the proposed metabolites was confirmed by HRMS accurate mass measurements. The highest flurbiprofen concentration was 204 μg per ml at 1-3 h post administration. Flurbiprofen could be detected for 24-37 hours in urine using the standard screening procedure. All metabolites were present 25 h post administration, while 4'-hydroxyflurbiprofen could be traced for more than 48 hours and it is regarded as the long-term metabolite of flurbiprofen in horse [08434].

**Phenylbutazone**

A sensitive liquid chromatographic-tandem mass spectrometric method was developed and validated for screening, quantification, and confirmation of phenylbutazone and oxyphenbutazone in equine plasma. Analytes were recovered from plasma by liquid-liquid extraction followed by separation in a reversed-phase column and identification by mass spectrometry with selected reaction monitoring in negative electrospray ionization mode. Extraction recovery for both analytes was >80 percent. Hemolysis of red blood cells decreased analyte signal intensity but did not affect quantification results because an isotope-labeled IS was used. Analytes were stable in plasma for 24 h at room temperature, 9 days at 4 degrees C, and 45 days at -20 degrees C and -70 degrees C. The method was successfully used in screening, quantification, and confirmation of phenylbutazone in post-competition plasma samples obtained from racehorses. The method is simple, rapid, and reliably reproducible [09394].

**Salicylic acid**

In equine sport, salicylic acid is prohibited with a threshold level of 750 microg/mL in urine; hence, doping control laboratories have to establish quantitative and qualitative methods for its determination. A simple and rapid liquid chromatographic/mass spectrometric method was developed and validated for the quantification and identification of salicylic acid. Urine samples after 900-fold dilution and addition of the internal standard (4-methylsalicylic acid) were directly injected to the liquid chromatography/quadrupole time-of-flight mass spectrometry system. Electrospray ionization in negative mode with full scan acquisition mode and product ion scan mode were chosen for the quantification and identification of salicylic acid, respectively. Run time was 2.0 min. The tested linear range was 2.5-50 microg/mL (after 100-fold sample dilution). The relative standard deviations of intra- and inter-assay analysis of salicylic acid in horse urine were lower than 2.5 percent and 2.8 percent, respectively. Overall accuracy (relative percentage error) was less than 3.3 percent. Method was applied to two real samples found to be positive for salicylic acid, demonstrating simplicity, accuracy, and selectivity [09395].

**Prednisolone**

After the detection of low concentrations of prednisolone in racehorse urine samples collected at Italian racetracks, a study was initiated to investigate the accuracy of the analytical protocol used and the possible endogenous origin of detected prednisolone. Multiple reaction monitoring (MRM) MS(2) acquisition with a triple quadrupole (n=780) and
full scan MS(2) and MS(3) (n=180) acquisition with a linear ion trap were checked. As a further confirmation, ten urine samples were analysed by high-resolution mass spectrometry (HRMS). The study showed the difficulty of identifying prednisolone, probably due to interfering compounds with the same molecular weight (360 Da) present in the matrix. The characteristic transitions for prednisolone were identified, both in MS(2) and MS(3), as the ions 187 and 280; the ion 295 was also used for identification. The concentrations detected with the triple quadrupole and the linear ion trap were not statistically different. The exact mass of prednisolone formiate (the adduct acting as a molecular ion) was identified by HRMS. The very high frequency of prednisolone detection in the samples (79%), the low concentration of this steroid and, importantly, the narrow range of the 95 percent confidence limits (0.97-1.05 in MS(2) mode and 0.88-1.04 in MS(3) mode), could represent evidence that its presence is endogenous. In the light of these results, this hypothesis seems the most probable, even if further studies are required to confirm it. Furthermore, a microbiological origin (i.e. fermentation of cortisol after sample collection) could not be disregarded [12500].

**Bupivacain**

Bupivacaine is a local anaesthetic prohibited in equine sports. It is highly metabolized in the horse but a thorough description of its metabolite profile is lacking. An administration study should find appropriate analytical targets for doping control. Furthermore, knowledge of an in vitro system for production of metabolites would be beneficial. Marcain® (bupivacaine hydrochloride) was administered subcutaneously to a horse and urine samples were collected. In vitro metabolic systems consisting of the fungi Cunninghamella elegans and Cunninghamamella blakesleeeana were incubated with bupivacaine and bupivacaine-d(9). Samples were analyzed directly after dilution or cleaned up using liquid-liquid extraction. Separation was achieved with liquid chromatography. Mass spectrometric analysis was performed using positive electrospray ionization with both a tandem quadrupole and an ion trap instrument using MS(n) and hydrogen/deuterium exchange. In horse urine, seven phase I metabolites were found: 3'- and 4'-hydroxybupivacaine, N-desbutylbupivacaine, two aliphatically hydroxylated metabolites, one N-oxide, and dihydroxybupivacaine. Sulfated hydroxybupivacaine and glucuronides of 3'- and 4'-hydroxybupivacaine and of dihydroxybupivacaine were also detected. All these metabolites were previously undescribed in the horse, except for 3'-hydroxybupivacaine. 3'- and 4'-Hydroxybupivacaine were designated as appropriate targets for doping control. Interestingly, all the equine phase I metabolites were also detected in the samples from C. elegans and C. blakesleeeana. The qualitative aspects of the metabolism of bupivacaine in the horse have been investigated with many novel metabolites described. The fungi C. elegans and C. blakesleeeana have proven to be relevant models for mammalian metabolism of bupivacaine and they may in the future be used to produce analytical reference materials [12501].

**Levamisole**

Administration studies of levamisole in horses were carried out using two different levamisole preparations, namely, levamisole hydrochloride oral bolus and levamisole phosphate injectable solution. These preparations were analysed in detail for the presence of aminorex-like impurities. Both levamisole preparations were found to contain 1-(2-mercaptoethyl)-4-phenyl-2-imidazolidinone (I) and 4-phenyl-2-imidazo-lidinone (II) as degradation impurities, but neither aminorex nor rexamino was detected in these preparations. It was been established unequivocally that the normal use of levamisole products in horses can lead to the presence of aminorex, rexamino and 4-phenyl-2-imidazolidinone (II) in their urine and
blood samples. As compound II has the longest detection time, the detection of aminorex (and in some cases reexamino) in some of the official samples from racehorses can be ascribed to the use of levamisole products as long as compound II is also present as a marker. These findings should be of direct relevance to the investigation of some of the cases of aminorex detection in official doping control samples from racehorses [09397].

3,4-Methylenedioxyxypovalerone (MDPV)

3,4-Methylenedioxyxypovalerone (MDPV) is a psychoactive drug with potent stimulant properties and potential for abuse and drug dependency. MDPV was recently classified as a Class I drug by Racing Commissioners International, indicating that it is a banned substance in equine athletes because it lacks therapeutic value in horses. To enforce this ban, a sensitive and fast liquid chromatography-tandem mass spectrometry method was needed. It is for this reason that this method was developed for quantification and confirmation of MDPV in equine plasma. Sample preparation involved liquid-liquid extraction. The analyte was analyzed by a triple-quadrupole linear ion trap mass spectrometer in positive multiple-reaction-monitoring and enhanced product ion scan modes. The method was validated for precision, accuracy, limit of detection (LOD), limit of quantification (LOQ), linearity, stability, extraction recovery, matrix effect, dilution accuracy and selectivity. The extraction recovery was >90%. The linearity range was from 5 to 15,000 pg/mL. LOD and LOQ were 2 and 5 pg/mL, respectively. Intra-day and inter-day accuracies were nearly 100 percent. The method is suitable for screening, quantification and confirmation of MDPV in equine plasma and has been successfully used to detect and confirm the presence of MDPV in equine plasma obtained post-competition [12502].

Glycopyrrolate

It was described a validated, rapid, sensitive, and specific UHPLC-MS/MS method to detect and quantify glycopyrrolate in 0.5 mL of horse urine. Further, we investigated the elimination of glycopyrrolate in urine after both intravenous and oral administration of clinically relevant doses to Thoroughbred horses. Quantification was performed by weighted, linear regression analysis using a deuterated analogue of glycopyrrolate as internal standard (IS). The method was characterized by a linear range of 5-2500 pg/mL, a lower limit of quantification of 5 pg/mL and a limit of detection of 1 pg/mL. The intra and inter-batch imprecisions were <10 percent RSD and accuracy of the method ranged between 94 and 104%. Glycopyrrolate remained detectable in urine samples collected through 168 h after intravenous administration and through 24h after oral administration. Analytical method validation requirements for linearity, specificity, precision, accuracy, stability, dilution integrity, matrix effect, and ruggedness have been fulfilled. The urine method described in this report is simple and efficient and is the first reported method with sufficient sensitivity, accuracy, and precision to regulate the use of glycopyrrolate in urine samples collected more than one day after dosing of horses. Urine to plasma glycopyrrolate concentration ratios were calculated and were approximately 100:1 in samples collected from 24h through the end of sample collection [12503].

Dermorphine

Dermorphin, a hepta-peptide with potent analgesic properties, is classified as a doping agent in equine racing. Since its discovery, a number of biologically active structural analogs have
been synthesized and made commercially available so there is a need for reliable methods of detection. A sensitive detection method was developed for dermorphin and six analogs in equine urine. Peptide enrichment was achieved using weak cation exchange with subsequent separation and detection by nano-UHPLC-MS/MS. Method validation parameters included: specificity, linearity (5-10000 pg/mL), recovery (58-93 %), intra and inter-assay repeatability, LOD (5-50 pg/mL) and matrix effects. The presented method will facilitate the control of the abuse of dermorphin and selected analogs in equine sports [13790].

Capsaicin

A method involving ultra high-performance liquid chromatography-tandem mass spectrometry was developed and validated for the analysis of capsaicin and dihydrocapsaicin in equine plasma. The analytes were recovered from plasma by liquid-liquid extraction using methyl tert-butyl ether and separated on a sub-2 micron column. The mobile phase was composed of 2 mM ammonium formate and methanol. A triple quadrupole mass spectrometer was used to detect the analytes in positive electrospray ionization mode with selected reaction monitoring. The limits of detection, quantification and confirmation for both analytes were 0.5, 1.0 and 2.5 pg/mL, respectively. The linear dynamic range of quantification was 1.0-1,000 pg/mL. During storage, both analytes in equine plasma were unstable at room temperature but stable at -20 and -70°C. The retention time and product ion ratios were employed as the criteria for confirmation of the presence of the analytes in plasma. The total analysis time was 2 min. The method is fast, selectively sensitive, reproducible, reliable and fully validated [13791].

Acepromazine

It was described the population pharmacokinetics of an acepromazine (ACP) metabolite (2-(1-hydroxyethyl)promazine) (HEPS) in horses for the estimation of likely detection times in plasma and urine. ACP (30 mg) was administered to 12 horses, and blood and urine samples were taken at frequent intervals for chemical analysis. A bayesian hierarchical model was fitted to describe concentration-time data and cumulative urine amounts for HEPS. The metabolite HEPS was modelled separately from the parent ACP as the half-life of the parent was considerably less than that of the metabolite. The clearance (Cl/F(PM)) and volume of distribution (V/F(PM)), scaled by the fraction of parent converted to metabolite, were estimated as 769 L/h and 6874 L, respectively. For a typical horse in the study, after receiving 30 mg of ACP, the upper limit of the detection time was 35 h in plasma and 100 h in urine, assuming an arbitrary limit of detection of 1 lg/L and a small probability of detection. The model derived allowed the probability of detection to be estimated at the population level. This analysis was conducted on data collected from only 12 horses, but it was assumed that this is representative of the wider population [13792].

Antioxidants

The objective of this study was to determine if competition intensity would have an effect on antioxidant status in horses before and during a three-day event. Body weight, body condition score, and blood was sampled from CCI2* (n=19) and CCI3* (n=23) horses before the start of dressage, 20 to 30 min following cross-country, and 18-24 h after cross-country. Data were analyzed using a PROC MIXED in SAS. There were no differences between
CCI2* and CCI3* horses during competition for plasma cortisol, lactate, α-tocopherol, retinol, or erythrocyte glutathione peroxidase. After cross-country, CCI3* horses had higher serum creatine kinase and aspartate aminotransferase than the CCI2* horses. Plasma beta-carotene was higher in the CCI2* horses compared to the CCI3* horses. Total erythrocyte glutathione was also higher in the CCI2* horses versus CCI3* horses. These results are the first report of antioxidant status of horses competing in this level of a three-day event. The changes in antioxidant and muscle enzymes observed between divisions are likely due to the increased anaerobic and musculoskeletal demand on the upper level horses and the fitness required to compete at that level [12504].

Vitamin E

Vitamin E is a primary chain-breaking antioxidant that prevents cyclic propagation of lipid peroxidation. Across species, vitamin E is essential for normal neuromuscular function by acting as a potent antioxidant, as well as by modulating the expression of certain genes, inhibiting platelet aggregation and stabilizing plasma membranes. One review focused on vitamin E structure, absorption, metabolism, current equine dietary recommendations, the interplay between antioxidants and exercise, a discussion of the necessity of vitamin E supplementation in the horse above the Nutritional Research Council 2007 requirements, and a review of equine diseases that are associated with a vitamin E deficiency. Particular emphasis is placed on the proteins involved in vitamin E absorption, transport, and metabolism as potential candidates for vitamin E-associated diseases across species [12505].

Myo-inositol trispyrophosphate (ITPP)

Myo-inositol trispyrophosphate (ITPP) is a new drug capable of increasing the amount of oxygen in hypoxic tissues. Studies have shown that administration of ITPP increases the maximal exercise capacity in normal mice as well as mice with severe heart failure. The properties of ITPP make it an ideal candidate as a doping agent to enhance performance in racehorses. While there have been speculations in the horseracing industry that the covert use of ITPP is already widespread, no reported method exists for the detection of ITPP in equine biological samples. ITPP is a difficult-to-detect drug due to its hydrophilic nature; the complexity of equine biological matrices also adds to the problem. One paper described for the first time a method for the detection and confirmation of ITPP in equine urine and plasma. ITPP was isolated from the sample matrices by solid-phase extraction and the extract was analyzed by hydrophilic interaction chromatography-tandem mass spectrometry. ITPP could be detected at low ppb levels in both fortified equine plasma and urine with good precision, fast instrumental turnaround time, and negligible matrix interferences. This is the first report of a validated method for the detection and unequivocal confirmation of low levels of ITPP in any biological fluid [12506].

Alpha-cobratoxin

Cobra venom (Naja kaouthia) contains a toxin called alpha-cobratoxin (alpha-Cbtx). This toxin is a natural protein containing 71 amino acids (MW 7821 Da) with a reported analgesic potency greater than morphine. In 2007, in USA, this substance was found in the barns of a thoroughbred trainer and since then till date, the lack of a detection of this molecule has remained a recurring problem for the horseracing industry worldwide. To solve this problem,
the first method for the detection of alpha-cobratoxin in equine plasma has now been developed. Plasma sample (3 mL) was treated with ammonium sulfate at the isoelectric point of alpha-Cbtx, and the pellet was dissolved in a phosphate buffer and mixed with methanol for precipitation. The supernatant was then concentrated prior to its extraction on WCX SPE cartridges. The eluate was concentrated with two consecutive filtration steps before the trypsin digestion. The samples were analyzed using a LC-MS/MS Q Exactive instrument at 70,000 resolution on the product ions of the doubly charged precursor of the target peptide ((24)TWCDAFCSIR(33)). The method was validated (n=18) at 5 microg/L (640 pmol/L) according to the Association of Official Racing Chemists (AORC) requirements. The lower limit of detection was 1 microg/L (130 pmol/L). The present method has made it possible for us to confirm the presence of α-Cbtx in a horse plasma sample 24 h post the administration of alpha-Cbtx. Thus, the present method provides the first sensitive, specific, and reliable analytical method to confirm the presence of α-Cbtx in equine plasma [13793].

**Quaternary ammonium drugs**

Quaternary ammonium drugs (QADs) are anticholinergic agents some of which are known to have been abused or misused in equine sports. A recent review of literature shows that the screening methods reported thus far for QADs mainly cover singly-charged QADs. Doubly-charged QADs are extremely polar substances which are difficult to be extracted and poorly retained on reversed-phase columns. It would be ideal if a comprehensive method can be developed which can detect both singly- and doubly-charged QADs. One paper described an efficient liquid chromatography/tandem mass spectrometry (LC/MS/MS) method for the simultaneous detection and confirmation of 38 singly- and doubly-charged QADs at sub-parts-per-billion (ppb) to low-ppb levels in equine urine after solid-phase extraction. Quaternary ammonium drugs were extracted from equine urine by solid-phase extraction (SPE) using an ISOLUTE® CBA SPE column and analysed by LC/MS/MS in the positive electrospray ionisation mode. Separation of the 38 QADs was achieved on a polar group embedded C18 LC column with a mixture of aqueous ammonium formate (pH 3.0, 10 mM) and acetonitrile as the mobile phase. Detection and confirmation of the 38 QADs at sub-ppb to low-ppb levels in equine urine could be achieved within 16 min using selected reaction monitoring (SRM). Matrix interference of the target transitions at the expected retention times was not observed. Other method validation data, including precision and recovery, were acceptable. The method was successfully applied to the analyses of drug-administration samples [12116].

**Ethanol**

Ethanol elimination was studied in camels (n=8) after a single bolus intravenous dose of 0.1g/kg bodyweight (BW). Blood samples were then collected at set intervals. Ethanol and ethyl glucuronide (EtG) in blood were analysed by validated static headspace gas chromatography-mass spectrometry and liquid chromatography-mass spectrometry (LC-MS) methods, respectively. Blood-ethanol concentration-time profiles were plotted for each camel and these were evaluated. A simple linear regression model was fitted to the selected data points and the slope of the fitted line was used to estimate the elimination rate, the distribution factor and turnover rate, which were 5.15mg/dL blood/h, 0.55L/kg and 0.028g/h/kg, respectively. Blood EtG concentration-time profiles were also plotted for each camel. The elimination half-life of EtG, estimated by linear regression (using the values obtained after ethanol was completely eliminated) was 2.18h. The theoretical initial blood concentration of EtG (C(0)), obtained by extrapolation to time zero was 23.4μg/dL. The
results will be useful in monitoring alcohol doping in camels using either parent drug or metabolite [10428].

**Laboratory techniques**

*Direct-injection differential-gradient LC-LC coupled to hybrid tandem MS/MS*

A rapid, selective and robust direct-injection LC/hybrid tandem MS method has been developed for simultaneous screening of more than 250 basic drugs in the supernatant of enzyme hydrolysed equine urine. Analytes, trapped using a short HLB extraction column, are refocused and separated on a Sunfire C(18) analytical column using a controlled differential gradient generated by proportional dilution of the first column's eluent with water. Independent data acquisition (IDA) was configured to trigger a sensitive enhanced product ion (EPI) scan when a multiple reaction monitoring (MRM) survey scan signal exceeded the defined criteria. The decision on whether or not to report a sample as a positive result was based upon both the presence of a MRM response within the correct retention time range and a qualitative match between the EPI spectrum obtained and the corresponding reference standard. Ninety seven percent of the drugs targeted by this method met our detection criteria when spiked into urine at 100 ng/mL; 199 were found at 10 ng/mL, 83 at 1 ng/mL and 4 at 0.1 ng/mL [06314].

*Stable carbon isotope analysis*

The use of anabolic substances is prohibited in food-producing animals throughout the European Union. No method is available to reliably detect the misuse of natural hormones in cattle. A method was developed to detect the abuse of testosterone in cattle fattening. Synthesized testosterone is rather depleted in the $^{13}$C/$^{12}$C ratio. Hence, the method is based on gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS) analysis of urine. To select testosterone metabolites and endogenous reference compounds (ERC), the concentration of urinary steroids of cattle was investigated. Dehydroepiandrosterone and androst-5ene-3beta,17alpha-diol were chosen as ERCs to show endogenous $^{13}$C/$^{12}$C ratios. Etioclanolone and 5alpha-androstane-3beta,17alpha-diol were chosen as the most important testosterone metabolites. Other metabolites known from literature like epitestosterone were less promising. In principle, GC/C/IRMS is a nonspecific method because finally carbon dioxide is analyzed. Therefore, a dedicated cleanup procedure for the selected steroids was developed. By means of proposed confidence intervals in the isotopic composition of ERCs and metabolites, the administration of testosterone to cattle could be detected reliably. Differences of up to 11 per thousand on the delta-scale between ERC and testosterone metabolites were found after testosterone administration, whereas endogenous differences did not exceed 2 per thousand [06315].

*Solid-phase extraction and liquid chromatography-mass spectrometry*

One paper reports two highly efficient liquid chromatography-mass spectrometry (LC-MS) methods for the screening of anabolic steroids, corticosteroids, and acidic drugs for the purpose of doping control in equine sports. Sample extraction was performed using a mixed-mode C8-SCX solid-phase extraction (SPE) cartridge. The first eluted fraction (acids/neutral fraction) was base-washed and the resulting organic extract was used for the screening of anabolic steroids and corticosteroids by LC-MS using multiple reaction monitoring (MRM) in the positive electrospray ionisation (ESI) mode. The remaining aqueous extract was re-adjusted to pH 6 and acidic drugs were recovered by liquid/liquid extraction. Detection was
again achieved using LC-MRM but in the negative ESI mode. A total of 40 anabolic steroids and corticosteroids, and over 50 acidic drugs, including some cyclooxygenase-2 (COX-2) inhibitors, oxicams, anti-diabetics, sedatives, diuretics and Delta(9)-tetrhydro-11-norcannabinol-9-carboxylic acid, could be covered by the two LC-MS methods. Both methods utilized a high efficiency reversed-phase column (3.3 cm L x 2.1 mm I.D. with 3 microm particles) coupled with a fast-scanning triple-quadrupole mass spectrometer to achieve fast turnaround times. The overall turnaround times for both methods were 10 min, inclusive of post-run and equilibration times [06316].

**Liquid chromatography – Orbitrap mass spectrometry**

A recent trend in the use of high resolution accurate mass screening (HRAMS) for doping control testing in both human and animal sports has emerged due to significant improvement in high resolution mass spectrometry in terms of sensitivity, mass accuracy, mass resolution, and mass stability. A number of HRAMS methods have been reported for the detection of multi-drug residues in human or equine urine. As blood has become a common matrix for doping control analysis, especially in equine sports, a sensitive, fast and wide coverage screening method for detecting a large number of drugs in equine blood samples would be desirable. One paper presented the development of a liquid chromatography-high resolution mass spectrometry (LC-HRMS) screening method for equine plasma samples to cover over 320 prohibited substances in a single analytical run. Plasma samples were diluted and processed by solid-phase extraction. The extracts were then analyzed with LC-HRMS in full-scan positive electrospray ionization mode. A mass resolution of 60 000 was employed. Benzyldimethylphenylammonium was used as an internal lock mass. Drug targets were identified by retention time and accurate mass, with a mass tolerance window of ±3 ppm. Over 320 drug targets could be detected in a 13-min run. Validation data including sensitivity, specificity, extraction recovery and precision are presented. As the method employs full-scan mass spectrometry, an unlimited number of drug targets can theoretically be incorporated. Moreover, the HRAMS data acquired can be re-processed retrospectively to search for drugs which have not been targeted at the time of analysis [13796].

**Proteomics et al**

The combat against misuse of growth promoting agents is a major topic in agricultural meat production and human sports. In routine screening, hormone residues of all known growth promoting agents are detected by immuno assays or chromatographical methods in combination with mass spectrometry. To overcome the detection by these routine screening methods new xenobiotic growth promoters and new ways of application were developed, e.g. the combination of different agents in hormone cocktails are employed. To enable an efficient tracing of misused anabolic substances it is necessary to develop new screening technologies for a broad range of illegal drugs including newly designed xenobiotic anabolic agents. The use of omic technologies like, transcriptomics, proteomics or metabolomics is a promising approach to discover the misuse of anabolic hormones by indirectly detecting their physiological action. With the help of biostatistical tools it is possible to extract the quested information from the data sets retrieved from the omic technologies. One review described the potential of these omic technologies for the development of such new screening methods and presents recent literature in this field [09400].

**In hair**

The abuse of synthetic esters of natural steroids such as testosterone and estradiol in cattle fattening and sports is hard to detect via routine urine testing. The esters are rapidly
hydrolysed in vivo into substances which are also endogenously present in urine. An interesting alternative can be provided by the analysis of the administered synthetic steroids themselves, i.e., the analysis of intact steroid esters in hair by liquid chromatography tandem mass spectrometry (LC/MS/MS). However, retrospective estimation of the application date following a non-compliant finding is hindered by the complexity of the kinetics of the incorporation of steroid esters in hair. In this study, the incorporation of intact steroid esters in hair following pour-on treatment has been studied and critically compared with results from intramuscular treatment. To this end animals were pour-on treated with a hormone cocktail containing testosterone cypionate, testosterone decanoate and estradiol benzoate in different carriers. The animals were either treated using injection and pour-on application once or three times having 1 week between treatments using injection and pour-on application. Animals were slaughtered from 10-12 weeks after the last treatment. Both hair and blood plasma samples were collected and analysed by LC/MS/MS. From the results, it is concluded that after single treatment the levels of steroid esters in hair drop to CCbeta levels (5-20 microg/kg) after 5-7 weeks. When treatment is repeated two times, the CCbeta levels are reached after 9-11 weeks. Furthermore, in plasma, no steroid esters were detected; not even at the low microgramme per litre level but – in contrast with the pour-on application – after i.m. injection, significant increase of 17beta-testosterone and 17beta-estradiol were observed. These observations suggest that transport of steroid esters after pour-on application is not only performed by blood but also by alternative fluids in the animal so probably the steroid esters are already hydrolysed and epimerized before entering the blood [09401].

Measurement of steroid esters in bovine hair samples, using sensitive liquid chromatography-tandem mass spectrometry (LC-MS/MS), provides a powerful tool for identifying animals treated illicitly with growth promoters. The successful application of such testing requires appropriate sampling of hair from treated animals. One paper described the results of hair analysis by LC-MS/MS for two animal studies in which animals were treated with estradiol-3-benzoate and nortestosterone decanoate. The results from the first animal study indicate that animals treated with these anabolic steroids may not always be identified from analysis of hair samples; positive test results occur sporadically and only for some of the treated animals. The results from the second animal study identify conditions attaching to positive hair samples, such as, that concentrations of steroid esters in hair are related to distance of sampling from point of injection and to time post-treatment, that concentrations of steroid esters in hair are related to dose given to the animal but that this relationship may vary over time post-treatment, and that steroid esters may be measured in regrowth hair taken some weeks after treatment. Steroid esters are determined along the length of the hair, confirming that accumulation of steroid esters into hair occurs from various sources, including blood, sweat and sebum. The reported research provides some useful insights into the mechanisms governing the persistence of steroid esters in bovine hair following illicit treatment with growth promoters [09402].

The detection of the abuse of anabolic steroids in equine sport is complicated by the endogenous nature of some of the abused steroids, such as testosterone and nandrolone. These steroids are commonly administered as intramuscular injections of esterified forms of the steroid, which prolongs their effects and improves bioavailability over oral dosing. The successful detection of an intact anabolic steroid ester therefore provides unequivocal proof of an illegal administration, as esterified forms are not found endogenously. Detection of intact anabolic steroid esters is possible in plasma samples but not, to date, in the traditional doping control matrix of urine. The analysis of equine mane hair for the detection of anabolic steroid esters has the potential to greatly extend the time period over which detection of abuse can be monitored. Equine mane hair samples were incubated in 0.1 M phosphate buffer (pH 9.5) before anabolic steroids (testosterone, nandrolone, boldenone, trenbolone...
and stanozolol), anabolic steroid esters (esters of testosterone, nandrolone, boldenone and trenbolone) and associated compounds (fluticasone propionate and esters of hydroxyprogesterone) were extracted by liquid-liquid extraction with a mix of hexane and ethyl acetate (7:3, v:v). Further sample clean up by solid phase extraction was followed by derivatisation with methoxylamine HCl and analysis by UHPLC-MS/MS. Initial method development was performed on a representative suite of four testosterone esters (propionate, phenylpropionate, isocaproate and decanoate) and the method was later extended to include a further 18 compounds. The applicability of the method was demonstrated by the analysis of mane hair samples collected following the intramuscular administration of 500 mg of Durastesten® (mixed testosterone esters) to a Thoroughbred mare (560 kg). The method was subsequently used to successfully detect boldenone undecylenate and stanozolol in hair samples collected following suspicious screening findings from post-race urine samples. The use of segmental analysis to potentially provide additional information on the timing of administration was also investigated [13781].

**Identifying individual horses urine by single-nucleotide polymorphisms (SNPs)**

To construct a system for identifying individual horses from urine samples that are submitted for postracing doping tests, we developed a genotyping assay based on 26-plex single-nucleotide polymorphisms (SNPs). DNA was isolated from urine using a commercially available DNA/RNA extraction kit, and SNP genotyping was achieved with a SNaPshot™ technique. DNA profiles including 26 SNPs were acquired from urine samples and blood/hair samples. Within the studied Thoroughbred population, the 26-plex assay showed a probability of identity of 5.80 × 10⁻¹¹. Compared to the conventional short tandem repeat assay, the SNP assay used less DNA, and the rate of successful genotyping was improved to 97% using aliquots of horse urine as small as 140 microL. The urinary DNA could be successfully genotyped under proper storage concerning refrigeration or freeze-thawing. This SNP assay can be used for individual identification when suspicious results are obtained from horse doping tests [13780].

**TB-500**

The formulation TB-500 is suspected to be used as doping agent in sport. This work describes the detection and the identification of the N-terminal acetylated 17-23 fragment of human thymosin beta 4 (Ac-LKKTETQ) in TB-500 by means of high-performance liquid chromatography/high resolution mass spectrometry using an Orbitrap Exactive benchtop mass spectrometer. Ac-LKKTETQ was also synthesized by solid-phase peptide synthesis, and an analytical strategy for detection in plasma and urine by high-performance liquid chromatography/low resolution triple-quadrupole mass spectrometry was suggested [12264].

A veterinary preparation known as TB-500 and containing a synthetic version of the naturally occurring peptide LKKTETQ has emerged. The peptide segment (17)LKKTETQ(23) is the active site within the protein thymosin beta (4) responsible for actin binding, cell migration and wound healing. The key ingredient of TB-500 is the peptide LKKTETQ with artificial acetylation of the N-terminus. TB-500 is claimed to promote endothelial cell differentiation, angiogenesis in dermal tissues, keratinocyte migration, collagen deposition and decrease inflammation. In order to control the misuse of TB-500 in equine sports, a method to definitely identify its prior use in horses is required. One study described a method for the simultaneous detection of N-acetylated LKKTETQ and its metabolites in equine urine and plasma samples. The possible metabolites of N-acetylated LKKTETQ were first identified from in vitro studies. The parent peptide and its metabolites were isolated from equine urine or plasma by solid-phase extraction using ion-exchange cartridges, and analysed by liquid
chromatography-mass spectrometry (LC/MS). These analytes were identified according to their LC retention times and relative abundances of the major product ions. The peptide N-acetylated LKKTETQ could be detected and confirmed at 0.02 ng/mL in equine plasma and 0.01 ng/mL in equine urine. This method was successful in confirming the presence of N-acetylated LKKTETQ and its metabolites in equine urine and plasma collected from horses administered with a single dose of TB-500 (containing 10 mg of N-acetylated LKKTETQ). This is the first identification of TB-500 and its metabolites in post-administration samples from horses [12499].

**Primary hepatocytes as a bioassay**

Cattle hepatocytes have already been used in veterinary in vitro toxicology, but their usefulness as a multi-parametric screening bioassay has never been investigated so far. In this study, cattle hepatocytes were incubated with illicit steroids/prohormones (boldenone, BOLD; its precursor boldione, ADD; dehydroepiandrosterone, DHEA; an association of ADD:BOLD), to characterize their transcriptional effects on drug metabolizing enzymes (DMEs) and related nuclear receptors (NRs), on cytochrome P450 3A (CYP3A) apoprotein and catalytic activity as well as to determine ADD and BOLD metabolite profiling. DHEA-exposed cells showed an up-regulation (higher than 2.5-fold changes) of three out of six NRs, CYP2B22 and CYP2C87; likewise, ADD:BOLD increased CYP4A11 mRNA levels. In contrast, a reduction of CYP1A1 and CYP2C87 mRNAs (lower than 2.5(-1)-fold changes) was noticed in ADD- and DHEA-incubated cells. No effect was noticed on CYP3A gene and protein expression, though an inhibition of 6beta-, 2beta- and 16beta-hydroxylation of testosterone (higher than 60 percent of control cells) was observed in ADD- and BOLD-exposed cells. Finally, 17alpha-BOLD was the main metabolite extracted from hepatocyte media incubated with ADD and BOLD, but several mono-hydroxylated BOLD and ADD derivatives were detected, too. Collectively, cattle hepatocytes can represent a complementary screening bioassay, useful to characterize growth promoters metabolite profiling and their effects upon DMEs expression, regulation and function [12488].

**Molecularly imprinted polymer applied to the selective isolation of urinary steroids**

The use of anabolic substances to promote growth in livestock is prohibited within the European Union as laid down in Directive 96/22/EC. Nowadays, efficient methods such as steroid profiling or isotopic deviation measurements allow to control natural steroid hormones abuse. In both cases, urine is often selected as the most relevant matrix and, due to its relatively high content of potential interferents, its preparation before analysis is considered as a key step. In this context, the use of a selective sorbent such as molecularly imprinted polymer (MIP) was investigated. A MIP was synthesized based on 17beta-estradiol, methacrylic acid and acetonitrile as template, monomer and porogen, respectively. Two approaches were then tested for non-conjugated (aglycons and glucuronides deconjugated) steroid purification: molecularly imprinted solid phase extraction (MISPE) and semi-preparative supercritical fluid chromatography with a commercial MIP as stationary phase (SFC-MIP). Parameters for both approaches were optimized based on the main bovine metabolites of testosterone, estradiol, nandrolone and boldenone. The MISPE protocol developed for screening purposes allowed satisfactory recoveries (upper 65 % for the 12 target steroids) with sufficient purification for gas chromatography-mass spectrometry (GC-MS) analysis. For confirmatory purposes, the use of isotopic ratio mass spectrometry (IRMS) requires a higher degree of purity of the target compounds, which can be reached by the SFC-MIP protocol with three steps less compared to the official and current method. Purity, concentration and absence of isotopic fractionation of target steroids extracted from urine of
treated cattle (treated with testosterone, estradiol, androstenedione, and boldenone) allowed the measurement of $^{13}$C/$^{12}$C isotopic ratios of corresponding metabolites and endogenous reference compounds (ERC) and proved the relevance of the strategy [12489].

**Single-nucleotide polymorphism assay**

To construct a system for identifying individual horses from urine samples that are submitted for post-racing doping tests, we developed a genotyping assay based on 26-plex single-nucleotide polymorphisms (SNPs). DNA was isolated from urine using a commercially available DNA/RNA extraction kit, and SNP genotyping was achieved with a SNaPshot(™) technique. DNA profiles including 26 SNPs were acquired from urine samples and blood/hair samples. Within the studied Thoroughbred population, the 26-plex assay showed a probability of identity of $5.80 \times 10^{-11}$. Compared to the conventional short tandem repeat assay, the SNP assay used less DNA, and the rate of successful genotyping was improved to 97 percent using aliquots of horse urine as small as 140 microL. The urinary DNA could be successfully genotyped under proper storage concerning refrigeration or freeze-thawing. This SNP assay can be used for individual identification when suspicious results are obtained from horse doping tests [12490].

**Orbitrap**

A recent trend in the use of high resolution accurate mass screening (HRAMS) for doping control testing in both human and animal sports has emerged due to significant improvement in high resolution mass spectrometry in terms of sensitivity, mass accuracy, mass resolution, and mass stability. A number of HRAMS methods have been reported for the detection of multi-drug residues in human or equine urine. As blood has become a common matrix for doping control analysis, especially in equine sports, a sensitive, fast and wide coverage screening method for detecting a large number of drugs in equine blood samples would be desirable. One paper presented the development of a liquid chromatography-high resolution mass spectrometry (LC-HRMS) screening method for equine plasma samples to cover over 320 prohibited substances in a single analytical run. Plasma samples were diluted and processed by solid-phase extraction. The extracts were then analyzed with LC-HRMS in full-scan positive electrospray ionization mode. A mass resolution of 60 000 was employed. Benzyldimethylphenylammonium was used as an internal lock mass. Drug targets were identified by retention time and accurate mass, with a mass tolerance window of ±3 ppm. Over 320 drug targets could be detected in a 13-min run. Validation data including sensitivity, specificity, extraction recovery and precision are presented. As the method employs full-scan mass spectrometry, an unlimited number of drug targets can theoretically be incorporated. Moreover, the HRAMS data acquired can be re-processed retrospectively to search for drugs which have not been targeted at the time of analysis [12491].

**Protein biomarkers**

The development of protein biomarkers for the indirect detection of doping in horse is a potential solution to doping threats such as gene and protein doping. A method for biomarker candidate discovery in horse plasma is presented using targeted analysis of proteotypic peptides from horse proteins. These peptides were first identified in a novel list of the abundant proteins in horse plasma. To monitor these peptides, an LC-MS/MS method using multiple reaction monitoring was developed to study the quantity of 49 proteins in horse plasma in a single run. The method was optimised and validated, and then applied to a population of race-horses to study protein variance within a population. The method was finally applied to longitudinal time courses of horse plasma collected after administration of
an anabolic steroid to demonstrate utility for hypothesis-driven discovery of doping biomarker candidates [09403].

Other aspects on forensic medicine

In order to detect switching and/or manipulation of samples, the owner of a stallion asked a lab to perform a DNA test on a positive doping urine sample. The objective was to compare the urine DNA profile versus blood and hair DNA profiles from the same stallion. At first, 10 microsatellite markers were investigated to determine the horse identity. No results were obtained when horse specific markers were typed in the urine sample. In order to confirm the species origin of this sample it was analyzed the mitochondrial cytochrome b gene. This analysis from blood and hair samples produced reproducible and clear PCR-RFLP patterns and DNA sequence match with those expected for horse, while the urine sample results were coincident with human. These results allowed us to exclude the urine sample from the questioned stallion and determine its human species origin, confirming the manipulation of urine sample [08442].

Horses (in general)

In racing and other equine sports, it is possible to increase artificially both the physical capability and the presence of a competitive instinct, using drugs, such as anabolic steroids and agents stimulating the central nervous system. However, an anti-doping policy must not impede the use of legitimate veterinary medications and most regulatory bodies in the world now distinguish the control of illicit substances (doping control) from the control of therapeutic substances (medication control). For doping drugs, the objective is to detect any trace of drug exposure (parent drug or metabolites) using the most powerful analytical methods (generally chromatographic/mass spectrometric techniques). This so-called “zero tolerance rule” is not suitable for medication control, because the high level of sensitivity of current screening methods allows the detection of totally irrelevant plasma or urine concentrations of legitimate drugs for long periods after their administration. Therefore, a new approach for these legitimate compounds, based upon pharmacokinetic/pharmacodynamic (PK/PD) principles, has been developed. It involves estimating the order of magnitude of the irrelevant plasma concentration (IPC) and of the irrelevant urine concentration (IUC) in order to limit the impact of the high sensitivity of analytical techniques used for medication control. The European Horserace Scientific Liaison Committee (EHSLC), which is the European scientific committee in charge of harmonising sample testing and policies for racehorses in Europe, is responsible for estimating the IPCs and IUCs in the framework of a risk analysis, i.e. risk assessment, risk management, and risk communication. For medication control, the main task of EHSLC in the risk management procedure is the establishment of harmonised screening limits (HSL). The HSL is a confidential instruction to laboratories from racing authorities to screen in plasma or urine for the presence of drugs commonly used in equine medication. The HSL is derived from the IPC (for plasma) or from the IUC (for urine), established during the risk assessment step. The EHSLC decided to keep HSL confidential and to inform stakeholders of the duration of the detection time of the main medications when screening is performed with the HSL. A detection time is the time at which the urinary (or plasma) concentration of a drug, in all horses involved in a trial conducted according to the EHSLC guidance rules, is shown to be lower than the HSL when controls are performed using routine screening methods. These detection time, as issued by the EHSLC (and adopted by the Fédération Equestre Internationale or FEI) provide guidance to veterinarians enabling them to determine a withdrawal time for a given horse under treatment. A
withdrawal time should always be longer than a detection time because the withdrawal time takes into account the impact of all sources of animal variability as well as the variability associated with the medicinal product actually administered in order to avoid a positive test. The major current scientific challenges faced in horse doping control are those instances of the administration of recombinant biological substances (EPO, GH, growth factors etc.) having putative long-lasting effects while being difficult or impossible to detect for more than a few days. Innovative bioanalytical approaches are now addressing these challenges. Using molecular tools, it is expected in the near future that transcriptional profiling analysis will be able to identify some molecular "signatures" of exposure to doping substances. The application of proteomic (i.e. the large scale investigation of protein biomarkers) and metabolomic (i.e. the study of metabolite profiling in biological samples) techniques also deserve attention for establishing possible unique fingerprints of drug abuse [10293].

It was reviewed drug and medication control in equestrian sports and addressed the rules of racing, the technological advances that have been made in drug detection and the importance of metabolism studies in the development of effective drug surveillance programmes. Typical approaches to screening and confirmatory analysis are discussed, as are the quality processes that underpin these procedures. It was also addressed four specific topics relevant to equestrian sports: substances controlled by threshold values, the approach adopted recently by European racing authorities to control some therapeutic substances, anabolic steroids in the horse and LC-MS analysis in drug testing in animal sports and metabolism studies. It was emphasised the importance of research and development and collaboration to further global harmonisation and the development and support of international rules [10294].

**Drug metabolism in horses**

A detailed understanding of equine drug metabolism is important for detection of drug abuse in horseracing and also in veterinary drug development and practice. To date, however, no comprehensive review of equine drug metabolism has been published. The majority of literature regarding equine drug metabolite profiles is derived from sports drug detection research and is generally targeted at detecting marker metabolites of drug abuse. However, the bulk of the literature on equine drug metabolism enzymology is derived from veterinary studies aimed at determining the molecular basis of metabolism. In one article, the phase 1 and 2 metabolisms of seven of the most important classes of drugs monitored in horseracing were reviewed, including: anabolic-androgenic steroids (AAS), beta₂-agonists, stimulants, sedatives/tranquilizers, local anesthetics, non-steroidal anti-inflammatory analgesics (NSAIDS)/cyclooxygenase-2 (COX-2) inhibitors, and opioid analgesics. A summary of the literature relating to the enzymology of drug metabolism in this species is also be presented. The future of equine drug metabolism in the area of doping research will be influenced by several factors, including: a possible move towards the increased use of blood and other alternative testing matrices; the development of assays based on intact drug conjugates; the increasing threat of 'designer' and herbal-based products; advances in the use of in vitro technologies; the increased use of liquid-chromatography/high-resolution mass spectrometry; and the possibility of screening using 'omics' approaches. Also, the recent cloning of a range of equine cytochrome P450 (CYP) enzymes opens up the potential for carrying out more detailed mechanistic pharmacological and toxicological veterinary studies [11310].

**Report from Iran**

One survey evaluated the use of prohibited substances cases in the first 2 years of
medication regulation in horseracing in Iran so that the impact of these regulations on the level of positive cases over the period could be assessed. A total of 656 horses that were winners or second in races were tested during the 2 year study. In the first year 354 horses (209 males and 145 females) and in the second year 302 horses (155 males and 147 females) were tested. In the 2 years, 306 were found to be positive. Urine samples were taken from candidate horses and sent to the Central Doping Laboratory. Blood samples were taken from those horses where a urine sample could not be taken within one hour. Detection and measurement of prohibited substances were carried out by ELISA, GC and HPLC using standard methods. Thirty-two percent of males were positive for prohibited substances, which was not significantly different from the percentage of females (26 %). In the second year, of the 302 horses tested for prohibited substances, 33.5% of males were positive, again similar to females (33 %). Almost 83 percent of horses tested positive for prohibited substances once in the first year, 15 percent tested positive twice and 2 percent tested positive 3 times. In the second year 78 percent tested positive once, 15 percent tested positive twice and 7 percent tested positive 3 times. Morphine was the most used prohibited substance and was detected 42 times during the survey, followed by caffeine and phenylbutazone. Morphine was also the most used drug in combination with other drugs in both years. It was concluded that in Iran morphine and caffeine were the most popular prohibited substances found in the measurements. As these substances were found in the environment and food stuffs, their presence in the samples may be due to unintentional feeding of contaminated materials (bread, hay and chocolate) [10295].

**Live stock**

In contrast to the use of hormonal doping agents in sports to enhance the performance of athletes, in the livestock industry hormonal growth promoters ("anabolics") are used to increase the production of muscle meat. This leads to international disputes about the safety of meat originating from animals treated with such anabolics. As a consequence of the total ban in the EU of all hormonal active growth promoters ("hormones") in livestock production, in contrast to their legal use [e.g. of five such hormones (17beta-estradiol, testosterone, progesterone, trenbolone and zeranol) as small solid ear implants and two hormones as feed additives for feedlot heifers (melengestrol acetate) and for swine (ractopamine) in the USA], the regulatory controls also differ sharply between the EU and the USA. In the EU the treatment of slaughter animals is the regulatory offence that has to be controlled in inspection programs. In the USA testing for compliance of a regulatory maximum residue level in the edible product (muscle, fat, liver or kidney) is the purpose of the inspection program (if any). The EU inspection programs focus on sample materials that are more suitable for testing for banned substances, especially if the animals are still on the farm, such as urine and feces or hair. In the case of slaughtered animals, the more favored sample materials are bile, blood, eyes and sometimes liver. Only in rare occasions is muscle meat sampled. This happens only in the case of import controls or in monitoring programs of meat sampled in butcher shops or supermarkets. As a result, data on hormone concentrations in muscle meat samples from the EU market are very rare and are obtained in most cases from small programs on an ad hoc basis. EU data for natural hormones in meat are even rarer because of the absence of "legal natural levels" for these hormones in compliance testing. With the exception of samples from the application sites – in the EU the site of injection of liquid hormone preparations or the site of application of "pour on" preparations – the hormone concentrations observed in meat samples of illegally treated animals are typically in the range of a few micrograms per kilogram (ppb) down to a few tenths of a microgram per kilogram. In the EU dozens of illegal hormones are used and the number of active compounds is still expanding. Besides estrogenic, androgenic and progestagenic
compounds also thyreostatic, corticosteroidal and beta-adrenergic compounds are used alone or in "smart" combinations. An overview is given of the compounds identified on the EU black market. An estimate is also given of the probability of consumption in the EU of "highly" contaminated meat from the application sites in cattle. Finally some data are presented on the concentration of estradiol in bovine meat from animals treated and not treated with hormone implants. These data are compared with the recent findings for estradiol concentrations in hen's eggs. From this comparison, the preliminary conclusion is that hen's eggs are the major source of 17alpha- and 17beta-estradiol in the consumer's daily "normal" diet [10299].

Proper identification of racehorses competing in an official race and maintenance of defensible chain of custody are important in doping control regulations. The purpose of one study was to develop a reliable multiplex PCR method for providing genetic evidence for matching donors to test samples by using short tandem repeat (STR) loci. Amplification of 21 STR loci from blood, urine or hair root was achieved in a single tube and STR length polymorphism was analyzed using fluorescent labeled capillary electrophoresis. This novel approach showed an allele confidence interval of 0.19-0.43 bp and size estimation error of 0-0.48 bp. In 90 thoroughbred (TB) and 171 standardbred (STB) horses, the method was highly discriminating and reproducible with probability of false identification of 1 in 10^{11} (TB) and 1 in 10^{13} (STB). All loci were highly polymorphic with an average probability of identity of 0.18 (TB) and 0.13 (STB), heterozygosity of 0.65 (TB) and 0.68 (STB), and polymorphism information content (PIC) of 0.62 (TB) and 0.69 (STB). The highest allele frequency also reflected the degree of polymorphism due to high correlation with PIC. To obtain evidence of sample tampering with human material, three human specific STR markers were included in the panel. This method is the first in the horseracing industry, specifically designed for racehorse identification and detection of equine sample contamination by human DNA [10300].

Recombinant human erythropoietin (rhEPO), darbepoetin alfa (DPO) and methoxy polyethylene glycol-epoetin beta (PEG-EPO) are synthetic analogues of the endogenous hormone erythropoietin (EPO). These erythropoiesis-stimulating agents have the ability to stimulate the production of red blood cells and are commercially available for the treatment of anaemia in humans. These drugs are understood to have performance-enhancing effects on human athletes due to their stimulation of red blood cell production, thereby improving delivery of oxygen to the muscle tissues. Although their effect on horses has not been proven, these substances were thought to be similarly performance enhancing and have indeed been applied covertly to horses. As such, these protein-based drugs are prohibited by authorities in both human and equine sports. The method officially adopted by the International Olympic Committee (IOC) and World Anti Doping Agency (WADA) for the confirmation of rhEPO and/or DPO (rhEPO/DPO) in human urine is based on electrophoresis in combination with Western blotting. A shortcoming of the WADA method is the lack of definitive mass spectral data for the confirmation of a positive finding. Recently, a liquid chromatography-tandem mass spectrometry (LC/MS/MS) method for the detection and confirmation of rhEPO/DPO in equine plasma was reported. However, we have not been successful in achieving the reported sensitivity. One paper presented a method for the detection and confirmation of rhEPO/DPO, as well as the newly released PEG-EPO, in equine plasma. The procedures involve immunoaffinity extraction using anti-rhEPO antibody-coated Dynabeads followed by trypsin digestion. The injected extract was further purified and concentrated using an on-line trap column in the nano-LC system. Detection and confirmation were achieved by monitoring a unique peptide segment of rhEPO/DPO/PEG-EPO using nano-liquid chromatography-tandem mass spectrometry equipped with a nanospray ionisation source operated in the selected reaction monitoring mode. rhEPO, DPO and PEG-EPO can be confirmed at 0.1, 0.2 and 1.0 ng/mL, respectively, in equine
Intersex conditions

Two standardbred racehorses that had been winning races while competing as mares underwent postrace drug testing and had serum testosterone concentrations above the acceptable limit for female racehorses. Initial physical examinations by the referring veterinarian revealed ambiguous external genitalia and suspected intra-abdominally located testes leading to a preliminary diagnosis of male pseudohermaphroditism. Horses were referred for further evaluation of sex. Physical examination of the external genitalia confirmed the findings of the referring veterinarian. Transrectal palpation and ultrasonography revealed gonads with an ultrasonographic appearance of testes. On cytogenetic analysis, both horses were determined to have a 64,XY karyotype and 8 intact Y chromosome markers and 5 SRY gene markers, which were indicative of a genetic male and confirmed an intersex condition. Additionally, both horses had some male-type behavior and endocrinologic findings consistent with those of sexually intact males. Taken together, these findings confirmed that both horses were male pseudohermaphrodites. Both horses returned to racing competition as males. This raises the possibility that intersex conditions may be more common in racing standardbreds than was previously suspected [11323].
FUTURUM

Sport celebrates differences in competitors that lead to the often razor-thin margins between victory and defeat. The source of this variation is the interaction between the environment in which the athletes develop and compete and their genetic make-up. However, a darker side of sports may also be genetically influenced: some anti-doping tests are affected by the athlete’s genotype. Genetic variation is an issue that anti-doping authorities must address as more is learned about the interaction between genotype and the responses to prohibited practices. To differentiate between naturally occurring deviations in indirect blood and urine markers from those potentially caused by doping, the "biological-passport" program uses intra-individual variability rather than population values to establish an athlete’s expected physiological range. The next step in "personalized" doping control may be the inclusion of genetic data, both for the purposes of documenting an athlete’s responses to doping agents and doping-control assays as well facilitating athlete and sample identification. Such applications could benefit “clean” athletes but will come at the expense of risks to privacy. One article reviewed the instances where genetics has intersected with doping control, and briefly discusses the potential role, and ethical implications, of genotyping in the struggle to eliminate illicit ergogenic practices [12508].

Besides "conventional" misuse of drugs such as erythropoietin and insulins, experts fear that therapeutics that are currently undergoing clinical trials might be part of current or future doping regimens, which aim for an increased functionality and performance or organs and tissues. The number of compounds and doping methods in sports is in a state of constant flux. In addition to “traditional” doping agents, such as anabolic androgenic steroids or erythropoietin, new therapeutics and emerging drugs have considerable potential for misuse in elite sport. Such compounds are commonly based on new chemical structures, and the mechanisms underlying their modes of action represent new therapeutic approaches arising from recent advances in medical research; therefore, sports drug testing procedures need to be continuously modified and complementary methods developed, preferably based on mass spectrometry, to enable comprehensive doping controls. It may be discussed not only emerging drugs that can be categorized as anabolic agents (selective androgen receptor modulators, SARMs), modulators of muscle fiber calcium channels, gene doping such as hypoxia-inducible factor (HIF) stabilizers and peroxisome-proliferator-activated receptor (PPAR)delta-agonists, and erythropoietin-mimetics (Hematide) but also compounds with potentially performance-enhancing properties that are not classified in the current list of the World Anti-Doping Agency. Compounds such as ryanodine-calstabin-complex modulators (benzothiazepines) may also be included [09404, 09405].

The number of compounds and doping methods in sports is in a state of constant flux. In addition to traditional doping agents, such as anabolic androgenic steroids or erythropoietin, new therapeutics and emerging drugs have considerable potential for misuse in elite sport. Such compounds are commonly based on new chemical structures, and the mechanisms underlying their modes of action represent new therapeutic approaches arising from recent advances in medical research; therefore, sports drug testing procedures need to be continuously modified and complementary methods developed, preferably based on mass spectrometry, to enable comprehensive doping controls. It was thus not only discussed emerging drugs that can be categorized as anabolic agents (selective androgen receptor modulators, SARMs), gene doping (hypoxia-inducible factor stabilizers, peroxisome-proliferator-activated receptor (PPAR)delta-agonists) and erythropoietin-mimetics (Hematide) but also compounds with potentially performance-enhancing properties that are not classified in the current list of the World Anti-Doping Agency. Compounds such as ryanodine-calstabin-complex modulators (benzothiazepines) may also be included [09404, 09405].
complex modulators (benzothiazepines) were also included, their mass spectrometric properties discussed, and current approaches in sports drug testing outlined [10302].

The practice of using prohibited substances to enhance sports performance (typically referred to as “doping”) is a very old practice that has been with us for centuries. To ensure harmonized, coordinated, and effective antidoping programs, the World Anti-Doping Agency (WADA) was created as an independent agency. Over the years, testing programs have continued to expand, and WADA-accredited laboratory testing has increased 40 percent over the last 3 years. The issue of sports doping has gained widespread attention, and the public seems to be continually reminded of athletes who dope and the potential growing problem of doping at all levels of competition. According to WADA statistics, only a small percentage of athletes who are tested test positive for prohibited substances. Establishing the prevalence of prohibited substances use by results of drug testing would be similar to establishing the prevalence of driving under the influence of alcohol by the number of arrests for drinking and driving. A common goal of all drug-testing programs is to level the playing field so that athletes do not feel they have to use performance-enhancing drugs or prohibited substances to be competitive. Drug-testing programs serve the dual purpose of identifying those who attempt to gain an advantage over their competitors by using prohibited substances or techniques, and deterring their use by athletes by increasing the risk with disciplinary actions. However, statistics are somewhat misleading, since they combine all sports and it is known that some sports have a higher incidence of performance-enhancing drug abuse than others. The statistics also combine in- and out-of-competition test results, and it is known that some drugs are not easily detected in competition. WADA figures reveal that 278 000 samples were tested in 2009, with the figures increasing marginally over the years. It is needed more-intelligent testing to target those athletes at risk for drug misuse. Obviously, more research into the use of surrogates as evidence for the use of prohibited substances, as well as the use of individual rather than population reference ranges, will aid detection. It is needed to fine-tune the perceived deterrence model to make it more effective. This is particularly challenging given the history of certain sports and the different sociological and cultural factors involved in international competition. Identification of the endogenous substances that control muscle development and function is important for the treatment of those who suffer from muscular dystrophies and other, similar conditions. As these substances are developed for therapeutic uses, they may also be used by athletes to enhance performance. Endogenous substances also present a challenge for drug-testing laboratories and programs. From a scientific viewpoint, the next two biggest challenges are hormone receptor modulators and protein pharmaceutical agents. There are dozens of structures for hormone receptor modulators that can affect a single biological pathway. The difficulty with protein therapeutics is their relatively short half-lives, making collection of a representative sample and assay sensitivity a challenge [11426].

**Continuing research**

Since 2001, USD 53 million has been spent on research that has successfully discovered detection methods for a new range of substances and doping methods. This investment will continue [12034].

**Criminals**

Doping substances are big business and the criminal underworld (often the same shady characters involved in illegal gambling and corruption) has created networks of supply, just
as they do for other illegal drugs. This is known from the partnerships World Anti-Doping Agency (WADA) has with Interpol and the World Customs Organization [12034].

Economy and techniques

Testing is – and always has been – the bedrock of the fight against doping in sport; science being used against science, with the hope that the science – that of the anti-doping community – one day becomes too sophisticated for athletes to risk doping. The anti-doping community accepts this is not the case right now. Analysis has its limitations and far too many athletes are able to weigh up the risk of getting caught against the financial rewards and glory that can be gained through doping, and come down on the wrong side. When that is allied to unscrupulous members of the athlete entourage, and with financial backing from the underworld, it can be seen the extent of the ill. Doping analysis faces an uphill struggle on many fronts. It is expensive, substances to be tested keep being added to the list and the costs involved in running a comprehensive testing program are getting greater, not smaller. Many anti-doping organizations are operating on small budgets (especially in relation to the size of the problem), having had them frozen or even cut in 2012, which obviously limits the ability to develop effective programs. Consideration must also be given to the sophistication of the doping substances and methods now available and used by the cheaters [12034].

Beyond the 2012 London Olympic Games researchers face two important additional challenges. First, it will be helpful to devise ways of reducing the cost of testing. More cost-efficient methods for detecting banned performance-enhancing drugs and other prohibited strategies would free up resources for more tests or other strategies to foster drug-free sport. Second, fresh ideas would be welcome for developing novel strategies for detecting efforts to tinker with human physiology, including techniques aimed at altering gene expression. There are many good reasons to want to keep performance-enhancing drugs out of sport: to protect the health of athletes, to promote fair competition so that honest athletes are not disadvantaged and to preserve what is good and valuable in sport. Everyone who participates in the effort to deter cheating, through education, research or the process of collection, testing and adjudication, is in a position to support honorable athletes in their pursuit of excellence. These are jobs worth doing well [12482].

Intelligens

While the anti-doping scientists are becoming more sophisticated, so too is the intelligence that exists within the testing community. This intelligence allows for more target testing, so that the money spent is better spent [12034].

What if current zero-tolerance anti-doping policy continues?

What can be foreseen over the next decades if the central tenet of the anti-doping movement – eradication of doping – continues to drive a global agenda of surveillance and suppression of doping and doping-like behaviour? It is expected that, in the short term, continued pressure from the WADA and the IOC, backed by the international UNESCO convention, will oblige an increasing number of nations to adopt specific anti-doping legislation, especially those who aspire to organize Olympic Games. There is an international tendency to combat doping and related activities like trafficking through criminal law (e.g. in Italy, France and
Slovenia), quite akin to what happened in the field of psychotropic drugs, thus criminalizing the use, possession, traffic and commerce of doping substances. This development will be accompanied by increasingly repressive measures worldwide. Increasing numbers of citizens will have to comply with compulsory drug testing for an increasingly long list of substances. Still, anti-doping arguments are frequently formulated which explicitly or implicitly ignore the actual practical consequences of actual anti-doping policies in and outside sports. Just as for the “war on drugs” the consequences of the “war on doping” should be fully taken into account when engaging into the debate on how to regulate the use of performance enhancing substances and methods in sports [12012].

The alternative proposed is regulation of drug use, based on human rights and public health principles, with a combination of pragmatic policies taking into account local socio-cultural and economic specificities, and continuously adapted to on-going developments. High on the list of policies proposed are treatment and harm reduction measures. Countries like the Netherlands, Switzerland and lately Portugal, where such policies have been put in place, have shown that these strategies are accompanied by a reduction in the cost to society and the individual, by decreasing drug-related mortality and morbidity, as well as crime and its associated costs, without an increase in the prevalence of illicit drug use. The difficulties of applying a model of regulation and harm reduction to sports are of course huge, but perhaps more in line with anthropological generalizations of a socio-culturally moulded, evolutionary defined ‘human nature’. The choice between fighting doping by all means vs. regulation and harm reduction is difficult, since neither will solve the problem; no ultimate solution exists, it will remain ‘messy’. In our view, regulation and harm reduction may come with less cost to society and the individual, as compared to a zero-tolerance approach, and therefore merits to be considered. There is really no ready-made blueprint to offer; if an easy way existed it would already have been in place [12012]

Social, policy, and public health perspectives on new psychoactive substances

New psychoactive substances pose a particular challenge to those formulating drugs policy and related public health responses. This paper outlines some of the main issues arising from their use, with a particular focus on user perspectives. Such substances are often (at least initially) produced and distributed for different reasons than controlled drugs. They emerge in users' repertoires undetected by most monitoring systems and general population drug surveys. While reasons for use by innovators and early adopters are often in the spirit of self-experimentation, such substances may rapidly diffuse to the recreational arena as a result of enthusiastic user propagation where they act as substitutes or complements to controlled drugs. The majority of substances are believed to be sourced, albeit not exclusively, from manufacturers based in China. They are retailed to consumers through the Internet and physical shops (such as “head” and “smart” shops), as well as traditional “street dealers” (although data on the significance of this latter route of supply are limited). The data required for risk assessment of the harms such substances may pose, as well as information required for accurate user-derived harm reduction advice, are often limited. Moreover, some involved in the commercial supply have deliberately misbranded products, including substituting the active substance, in apparent attempts to circumvent regulatory frameworks. This leaves users susceptible to both health and criminal justice harms. Despite various attempts to restrict the supply, they often continue to be available through the illicit market, although it is not yet possible to predict whether they will join other drugs such as MDMA and LSD as mainstays of the recreational pharmacopedia [11427].
Technology advancement

Recent events in the sporting world have made explicit the moral, political, and cultural characteristics of discussions surrounding the use of enhancement technology in sport. The landscape of sport technologies and policy has changed dramatically and it is reasonable to consider that further innovations are imminent. Elite sports constitute arenas for convergent technological applications where a range of applications demonstrates the embeddedness of sports within technological structures. The prospects for even more radical technologies to influence athletic performance grow continually as progress in nanotechnology, stem cells, and genetics gain strength. This growing role of technology within sport raises questions about its future direction, particularly how biology will relate to the “new biology of machines” [06168].

More complex challenges

In less than 10 years after the implementation of the World Anti-Doping Code and of the International Standard for Laboratories and its related Technical Documents, the analysis of human samples for the purpose of anti-doping testing has undergone a noticeable evolution. The research programs developed by the anti-doping organizations, and in particular the World Anti-Doping Agency (WADA), have created an unprecedented momentum in anti-doping science to strengthen the existing analytical methods, as well as to support the development and implementation of new and more sophisticated methodologies by the WADA-accredited laboratories. The integration of technical novelties into the analytical menus has been stimulated by the never-ending challenges posed by the adoption of more complex doping regimens by some athletes and their entourage. This increased sophistication of doping practices has also been reflected in the addition of new doping substances or methods on the WADA Prohibited Substances and Methods List. The integration of new anti-doping scientific paradigms with the development of the Athlete Biological Passport or the foreseen implementation of genomic- and proteomic-based tests constantly reshapes the environment of anti-doping analysis. It is also true that analysis faces challenges from the law, whereby data protection, the rights of athletes and opposition to aspects of the Code – for example, whereabouts – can hinder efforts to catch the dopers. One article provides a multiangle perspective on some of the key analytical challenges that anti-doping analytical science will face in 2012 and beyond [12509].

New classes of drugs

In 2009 and 2010, the first prohibited selective androgen receptor modulators (SARMs) and the gene doping substances AICAR and GW1516 were detected on the black market. All these substances are still in clinical trials and have not yet been approved as medications. From experience, we may expect that these substances will appear very soon on the dietary supplement market, with advertising that the SARM products will achieve anabolic effects whereas the gene doping substances will enhance endurance. If these substances are added to other supplement products without being declared on the label, new sources of risk for inadvertent doping will be created. The risk of inadvertent doping is predominantly connected to dietary supplements aggressively marketed for their physiological effects, for example, muscle gain and fat loss, but it cannot be confined exclusively to such products. Therefore, athletes should, in general, carefully consider the risks and benefits of dietary supplements. If use seems to be essential, athletes should purchase dietary supplements only from low-risk sources. However, these sources still cannot guarantee that dietary
supplements are free of risk, but they do offer a risk minimisation. Dietary supplements produced by pharmaceutical companies might represent an alternative as such products have not yet been found to be contaminated with doping substances [11425].

An important aspect of preventive doping research is the rapid implementation of tests for emerging drugs with potential for misuse into routine doping control assays. New therapeutics of different classes such as PPARdelta-agonists (e.g. GW501516), ryanodine-calstabin-complex stabilizers (e.g. S-107 and JTV-519), and selective androgen receptor modulators (SARMs, e.g. S-40503) are currently used for the treatment of particular medical conditions such as metabolic syndrome, cardiac arrhythmia, debilitating diseases and osteoporosis, respectively. Due to their being at an early stage of clinical trials and the limited availability of data on the metabolism and possible renal elimination of the active drugs, the development of protocols for doping control analyses of plasma specimens could be an option for the detection of the circulating agents. The mass spectrometric fragmentation of four emerging drug candidates (GW501516, S-107, JTV-519, and S-40503) was elucidated by positive electrospray ionization and collision-induced dissociation using a high resolution/high accuracy mass spectrometer. A screening and confirmation procedure was established based on liquid chromatography/tandem mass spectrometry requiring a volume of 100 microl of plasma. Proteins were precipitated using acetonitrile, the specimens were centrifuged and the supernatant analyzed using a triple-quadrupole mass spectrometer employing multiple reaction monitoring of diagnostic ion transitions. The method was validated with regard to specificity, limits of detection (0.4-8.3 ng/mL), recoveries (72-98 %), intraday and interday precisions (12-21 %), and ion suppression/enhancement effects [09304].

Further challenges have been, and still are, the flood of new medications that the pharmaceutical industry places on the market for good reasons, but that can be misused for doping purposes, the occurrence of food supplements that can be purchased over the counter but may contain doping substances, and truly illegal substances that are produced for doping purposes. The sophisticated doper can be given advice on microdosing at levels that are nearly impossible to detect, and guidance as to how a cocktail of designer drugs can create the desired performance-enhancing effect. The appearance of new potential doping substances has often been accompanied by comments suggesting that they would be impossible to detect at doping controls. Now it is heard the same comments with respect to the potential use of gene transfer for the purpose of doping ("gene doping"). Such comments are too often made by scientists who are not experts in the field, but their statements are taken by the general public as expert opinions. Instead, one should listen to the true experts such as those who came together at the WADA Gene Doping conference in Stockholm, Sweden, in 2005 and stated, “Scientific progress made through research supported by WADA and others suggest that new detection methods are likely to emerge, which will help to keep sport untainted by gene doping methods” [12005].

Synthol

Synthol consists usually of oil, benzyl alcohol and lidocain. It consists of 85 percent of oil (normally it is oil built by medium-length MTC chains because it gives the best effects), 7,5 percent of lidocain (painkiller), 7,5 percent of alcohol (to sterilize the mixture). Synthol is a substance used by body builders as a temporary implant which is injected deeply into the muscle. The enlargement effects are immediate. Synthol is used in small groups of muscles to enlarge their volume (for example triceps, biceps, deltoids, muscles of the calf). Some serious drawbacks can be visible while using synthol. The muscles deform and become unnaturally shaped. The side effects of synthol are manifold and they can also cause a damage of nerves, oil embolic of the pulmonary, occlusion of the pulmonary artery,
myocardial infarction, cerebral stroke and infectious complications [09306].

**Tolperisone**

The rate constants of spontaneous and hydroxide-catalyzed decomposition and the tautomer-specific protonation constants of tolperisone, a classical muscle relaxant were determined. A solution NMR method without any separation techniques was elaborated to quantitate the progress of decomposition. All the rate and equilibrium constants were determined at four different temperatures and the activation parameters were calculated. The molecular mechanism of decomposition is proposed [09307].

**5-hydroxytryptamine (5-HT) agonist**

A possible link between the neurotransmitter, 5-hydroxytryptamine (5-HT), plasma tryptophan, and branched chain amino acids concentration and exercise-induced fatigue is described by the central fatigue hypothesis. 5-HT receptors and neuroendocrine "challenge" tests, using prolactin release as an indirect measure of 5-HT activity were studied by recent investigations. In one study, the original hypothesis about the role of amino acids in increasing brain 5-HT with a neuroendocrine challenge test on elite athletes diagnosed with unexplained, underperformance syndrome (UUPS) was combined. There was an apparent increased sensitivity of 5-HT receptors in athletes with UUPS compared with fit, well-trained controls, as measured via increased prolactin release following a bolus dose of m-chlorophenylpiperazine, a 5-HT agonist. No changes were observed in plasma amino acid concentrations in either group. There is evidence that well-trained athletes have a reduced sensitivity of 5-HT receptors. The present study suggests that this adaptation may be lost in athletes with UUPS: this might explain some of their observed symptoms [10206].

**Prediction of futures anabolic androgenic steroids**
The aim of one work was to develop a flexible in vitro synthesis procedure, which can be applied in order to study and predict the metabolic patterns of new derivatives of anabolic androgenic steroids (AAS) with respect to most prominent target compounds for doping control purposes. Microsomal and S9 fraction of human liver preparations were used as a source of metabolising enzymes and the co-substrates of the synthesis mixture were selected to favour phase-I metabolic reactions and glucuronidation as phase-II conjugation reactions. Model compounds within the study were 4,9,11-trien-3-one steroids, structural derivatives of gestrinone and trenbolone, which both are included in the list of prohibited compounds in sports by the World Anti-Doping Agency (WADA). The correlation between in vitro metabolism of human microsomes and in vivo excretion studies in human was compared with gestrinone and subsequently, the applicability of the in vitro model for prediction of AAS metabolic pathways for new doping agents was evaluated. All the AAS examined within this study were successfully metabolised using the developed in vitro model, hydroxylation, reduction and glucuronide conjugation being the most prominent reaction pathways. Hydroxylated and glucuronide-conjugated metabolites of in vivo experiment with gestrinone were the same metabolites formed in the enzyme-driven process, thus showing good in vitro-in vivo correlation. Liquid chromatographic-mass spectrometric and tandem mass spectrometric methods were developed, relying on the positive polarity of electrospray ionisation, which also allowed the direct detection of intact glucuronide-conjugated AAS metabolites. Due to charge delocalisation and high proton affinity, the developed method was proven effective in the analysis of AAS metabolites bearing extensive conjugated double bond systems in their structures [08195].
