- users of AAS often demonstrate unfavorable measurements of vascular reactivity involving endothelial-dependent or endothelial-independent vasodilatation. A degree of reversibility seems to be consistent, though
- there is a comprehensive body of evidence documenting that AAS induce various alterations of lipid metabolism. The most prominent changes are concomitant elevations of LDL and decreases of HDL, effects that increase the risk of coronary artery disease
- the use of AAS appears to confer an increased risk of life-threatening arrhythmia leading to sudden death, although the underlying mechanisms are still far from being elucidated
Taken together, various lines of evidence involving a variety of pathophysiologic mechanisms suggest an increased risk for cardiovascular disease in users of anabolic androgenic steroids [10064].

Athletes use androgenic-anabolic steroids but it may lead to dilated cardiomyopathy. It was report a case of a 41-year-old bodybuilder with severe systolic dysfunction and Class IV heart failure despite maximal medical therapy. He used anabolic steroids and insulin growth factor, and did not have any other risk factors for cardiomyopathy. It was briefly reviewed the literature and summarize other reported cases with similar scenarios. In most of them cardiomyopathy was at least partially reversible after discontinuation of anabolics. Abuse of anabolic steroids may be an uncommon cause of cardiomyopathy in young and otherwise healthy individuals [09057].

Chronic heart failure (CHF) involves derangements in multiple neurohormonal axes leading to a procatabolic state and wasting syndrome associated with significant mortality. Catabolic abnormalities include excess catecholamines and glucocorticoids. Anabolic defects include deficiencies of sex steroids, insulin resistance, and growth hormone (GH) resistance. These abnormalities are also correlated with increased morbidity and mortality in CHF. Anabolic axes have been augmented in pilot studies in CHF with testosterone, GH, insulin-like growth factor-1, and GH secretagogues. Results have been varied although some treatments have been associated with improved surrogate endpoints. One review article explores the current understanding of metabolic derangements in CHF and highlights potential neuroendocrine treatment strategies [09058].

Recent surveys and reports suggest that many athletes and bodybuilders abuse anabolic-androgenic steroids (AAS). However, scientific data on the cardiac and metabolic complications of AAS abuse are divergent and often conflicting. A total of 49 studies describing 1,467 athletes were reviewed to investigate the cardiovascular effects of the abuse of AAS. Although studies were typically small and retrospective, some associated AAS abuse with unfavorable effects. Otherwise healthy young athletes abusing AAS may show elevated levels of low-density lipoprotein and low levels of high-density lipoprotein. Although data are conflicting, AAS have also been linked with elevated systolic and diastolic blood pressure and with left ventricular hypertrophy that may persist after AAS cessation. Finally, in small case studies, AAS abuse has been linked with acute myocardial infarction and fatal ventricular arrhythmias. In conclusion, recognition of these adverse effects may improve the education of athletes and increase vigilance when evaluating young athletes with cardiovascular abnormalities [10431].

The most common cardiovascular consequences of AAS include atherosclerosis (secondary to changes in cholesterol metabolism and platelet function), hypertension, cardiac hypertrophy, impaired cardiac function, and sudden death. AAS use causes metabolic derangements that increase the risk for atherosclerosis and thrombus formation. Studies using animal models and various steroid regimens have demonstrated changes in serum cholesterol levels with decreased high-density lipoprotein and increased low-density lipoprotein, both promoting atherosclerotic and peripheral vascular disease. Cholesterol alterations vary among different AASs; alkylated agents (e.g. stanozolol) cause greater changes than testosterone [07058].

AAS use also increases platelet reactivity without an associated thrombocytosis; this has been proposed as an etiology for some of the myocardial infarctions, strokes, and peripheral vascular disease events reported in otherwise healthy individuals. AAS use also increases serum C-reactive protein (CRP), reflecting an inflammatory state that may contribute to atheroma formation and peripheral vascular disease. Conversely, changes in lipid
metabolism may be protective from atheroma formation because of a reduction in lipoprotein A. Many studies show that AASs cause abnormal cholesterol profiles, increased CRP, and increased platelet reactivity. It is difficult to quantify the change in risk, but one study estimates AASs triple the cardiovascular risk [07058].

Recent evidence suggests that low, rather than high, testosterone (T) is associated with increased male morbidity and mortality. It was reviewed relationships between hypogonadism, metabolic syndrome (MetS) and cardiovascular (CV) disease (CVD), along with erectile dysfunction (ED), a common condition in the three diseases. Although several experimental data indicate that T exerts a protective effect on vascular function, epidemiological studies do not support a link between hypogonadism and CVD and three meta-analyses found no significant effect of testosterone replacement therapy (TRT) on CV events. Low T is associated with increased risk of CV death in community-dwelling men, and in men with ED. It is possible that both low T and CVD are associated with another, still unknown (or not assessed) factor, thus explaining the association, in the absence of any causal relationship. A meta-analysis on the effect of TRT in MetS-associated hypogonadism demonstrated positive effects of T on some of the components of MetS. Large-scale interventional studies with TRT are therefore advisable [11092].

Cardiovascular disorders are known to be the most common cause of sudden death during exercise. In younger athletes (below 45 years) this is due in the majority of cases to congenital heart diseases, while in older people atherosclerosis is the primary cause. There is, however, a non-negligible percentage of disorders of the cardiovascular system, even sudden cardiac death (SCD), that are attributable to the use of performance-enhancing drugs, either prohibited (doping) or legal. The users can be athletes, professional or amateur, or just people engaging in exercise in gyms or fitness and leisure centres, while both sexes and all age groups are involved. Seeking to improve their performance, according to the event in which they participate, most athletes use a combination of prohibited substances and methods, or of prohibited and non-prohibited drugs, so as to alleviate the complications and/or to avoid being detected by screening. The most common and serious consequences of almost all illicit drugs in sport concern the cardiovascular system. These disorders, such as hypertension, cardiac arrhythmias, and acute myocardial infarction, may be manifested either directly, or as the result of long-term use. Frequent complications may also occur in other organs. Specifically, anabolic steroids have been implicated in liver cirrhosis and liver or kidney cancer, growth hormone in diabetes mellitus, erythropoietin in thromboembolic episodes, central nervous system stimulants in psychotic syndromes, and so on. Apart from the prohibited substances, however, cardiovascular disorders may be caused by other substances commonly used in sports, such as dietary supplements [12126].

A search of the English-language scientific literature from 1976 through March 2012 was performed primarily by searching the MEDLINE, Embase, and Google databases. The key words used in the search included androgens, anabolic, androgenic, steroids, exercise, athlete, cardiovascular, effects. The bibliographies of articles from the above search also were searched for relevant articles; links on Web sites containing published articles were searched for pertinent information [12119].

Potential adverse effects of AAS on the cardiovascular system include atherogenesis, thrombosis, vasospasm, myocarditis, concentric left ventricular hypertrophy, myocardial fibrosis, hypertrophic cardiomyopathy with ventricular dysrhythmias, and direct myocardial injury. However, the contribution of AAS use to these potential adverse cardiovascular effects remains unclear. Chronic AAS use enhances hepatic triglyceride lipase activity, resulting in reduction of high-density lipoproteins and elevation of low-density lipoproteins. Although these changes are reversible within several months of cessation of AAS use,
chronic AAS use theoretically increases the risk of cardiac disease. Potentially, the chronic abuse of AAS enhances coagulability and thrombosis, but the clinical importance of this potential adverse effect also remains unclear. Studies of chronic AAS abuse in weight lifters suggest that some anabolic-androgenic steroid using weight lifters have accelerated activation of their hemostatic system as evidenced by increased generation of both thrombin and plasmin. A study of AAS-positive steroid using weight lifters indicated that these individuals had a higher percentage of abnormally high plasma thrombin-antithrombin complexes along with elevated plasma concentrations of prothrombin fragment 1, antithrombin II, and protein S, when compared with non-AAS using controls. Additionally, the plasma concentrations of tissue plasminogen activator and its inhibit or were lower in AAS users than in controls. Clinical studies on body builders suggest that chronic AAS use impairs vascular eactivity independent of the smooth muscle hypertrophy and vascular stiffness associated with bodybuilding. Anabolic-androgenic steroids decrease the production of cyclic guanosine monophosphate (cGMP) by inhibiting guanylyltransferase. As a result, AAS spottetently inhibit the ability of nitric oxide store lax smooth muscles in the coronary arteries resulting in coronary artery vasospasm and potentially sensitizing AAS users to sudden death. Case reports associate the chronic use of anabolic steroids with sudden death and contraction band necrosis in the myocardium. In these cases, no other cause of death was apparent, but the role of chronic, high-dose anabolic steroid use in these deaths remains unclear. Athletes with certain genetic mutations and structural abnormalities may be particularly vulnerable to the use of anabolic steroids including athletes with accessory AV pathways, latent structural heart diseases (dilated cardiomyopathy, arrhythmogenic right ventricular dysplasia type II, myocarditis, segmental arrhythmogenic ventricular cardiomyopathy, and coronary artery anomalies), latent Brugada syndrome, mutations of the long QT syndrome genes, and other genetic mutations of ion channels (cardia cryanodine receptor gene defects and calsequestrin gene defects). Pathologic evidence of some of these abnormalities may not appear on postmort emexamination. The use of diuretics to mask the use of anabolic steroids may predispose these athletes to serious ventricular dysrhythmias from hypokalemia and dehydration [13003].

Experimental
The aim of one study was the investigation of effects of the metenolone enanthate (ME) that is used among athletes as doping and muscle amplifier, on hearts of male and female rats that are in puberty using morphometrical methods. A total of 36 rats which were divided into three separate groups (Experiment, ME; vehicle, PO; control, C) each consisting of 6 male and 6 female rats were used. 0.5mg/kg metenolone enanthate was applied intraperitoneally into experiment subjects 5 times a week over a period of 4 weeks. At the end of experiment, rats were euthanized and their hearts were cut at the level of musculus papillaris after the fixation in formalin. Hearts were taken out and embedded in paraffin wax. Photos were taken at cut surfaces, and thickness, diameters and surface area levels were measured. Left ventriculus mass (LVM) and left ventriculus mass index (LVMI) were calculated. In the study LVM and LVMI were found to be significantly higher in the ME group in females whereas left ventricular lumen diameter (LVLD) were found to be significantly lower. Thus left ventricular hypertrophy development was observed. LVM and LVMI were found to be similar in ME and C groups among male rats and the highest level of these data were found in the group. LVM and LVMI were higher among females. In conclusion, it has been shown that the adverse effects of ME on heart were developing starting from puberty and resulting with the enlargement of the heart and left ventricular hypertrophy and especially among females this condition was more evident. It has also been discussed that the continuous use of drugs may further enhance this condition [12127].

Cardiac aldosterone might be involved in nandrolone decanoate (ND) deleterious effects on the heart. Therefore, we investigated the involvement of cardiac aldosterone, by the
pharmacological block of AT1 or mineralocorticoid receptors, on cardiac hypertrophy and fibrosis. Male Wistar rats were randomized into 8 groups (n=14/group). Nandrolone (10 mg/kg/week), was administered during 10 weeks of swimming training (5 times/wk). Losartan (20 mg/kg/day) and spironolactone (10mg/kg/day) were administered in drinking water. Cardiac hypertrophy was increased 10 percent by using nandrolone and 17 percent by nandrolone plus training. In both groups, there was a significant increase in the collagen volumetric fraction (CVF) and cardiac collagen type III expression. The nandrolone treatment increased: LV-ACE activity, AT1 receptor expression, aldosterone synthase (CYP11B2) and 11-beta hydroxysteroid dehydrogenase 2 (11betaHSD2) gene expression and inflammatory markers, TGFbeta and osteopontin. Both losartan and spironolactone inhibited the increase of CVF and collagen type III. In addition, both treatments inhibited the increase in LV-ACE activity, CYP11B2, 11betaHSD2, TGFbeta and osteopontin induce by the nandrolone treatment. The results suggest that these effects may be associated to TGFbeta and osteopontin. Thus, it was conclude that the cardiac aldosterone has an important role on the deleterious effects on the heart induced by nandrolone [11065].

To investigate the effects of exercise training and anabolic androgenic steroids (AAS) on hemodynamics, glycogen content, angiogenesis, apoptosis and histology of cardiac muscle. Forty rats were divided into 4 groups; control, steroid, exercise-trained and exercise-trained plus steroid groups. The exercise-trained and trained plus steroid groups, after one week of water adaptation, were exercised by jumping into water for 5 weeks. The steroid and trained plus steroid groups received nandrolone decanoate, for 5 weeks. Systolic blood pressure and heart rate (HR) were monitored weekly. Heart weight/body weight ratio (HW/BW ratio) was determined. Serum testosterone, vascular endothelial growth factor (VEGF), cardiac caspase-3 activity and glycogen content were measured. Compared with control, the steroid group had significantly higher blood pressure, HR, sympathetic nerve activity, testosterone level, HW/BW and cardiac caspase-3 activity. Histological examination revealed apoptotic changes and hypertrophy of cardiomyocytes. In exercise-trained group, cardiac glycogen, VEGF and testosterone levels were significantly higher while HR was significantly lower than control. HW/BW was more than control confirmed by hypertrophy of cardiomyocytes with angiogenesis on histological examination. Trained plus steroid group, had no change in HR, with higher blood pressure and HW/BW than control, cardiac glycogen and serum VEGF were higher than control but lower than exercise-trained group. Histological examination showed hypertrophy of cardiomyocytes with mild angiogenesis rather than apoptosis. Thus, when exercise is augmented with AAS, exercise-associated cardiac benefits may not be fully gained with potential cardiac risk from AAS if used alone or combined with exercise [13129].

One study focused on the short term effects of repeated low level administration of turinabol and methanabol on cardiac function in young rabbits (4 months). The experimental scheme consisted of two oral administration periods, lasting 1 month each, interrupted by 1 month wash-out period. Serial echocardiographic evaluation at the end of all three experimental periods was performed in all animals. Oxidative stress markers have also been monitored at the end of each administration period. Treated animals originally showed significantly increased myocardial mass and systolic cardiac output, which normalized at the end of the wash out period. Re-administration led to increased cardiac output, at the cost though of a progressive myocardial mass reduction. A dose-dependent trend towards impaired longitudinal systolic, diastolic and global myocardial function was also observed. The adverse effects were more pronounced in the methanabol group. For both anabolic steroids studied, the low dose had no significant effects on oxidative stress markers monitored, while the high dose created a hostile oxidative environment. In conclusion, anabolic administration has been found to create a possible deleterious long term effect on the growth of the immature heart and should be strongly discouraged especially in young human subjects [13130].
High doses of anabolic androgenic steroids (AAS) impair the cardioprotective effects of exercise against ischemia/reperfusion (I/R) insult, possibly through cellular redox imbalance. Here, the effect of nandrolone decanoate (DECA) treatment on heart redox metabolism was investigated during I/R in sedentary and exercised rats. DECA treatment significantly reduced superoxide dismutase and glutathione reductase activities in exercised rats after heart reperfusion. Catalase and glutathione peroxidase activities were not affected by DECA in both sedentary and trained rats, regardless the I/R period. DECA also induced myocardial oxidative stress, as evidenced by the reduced levels of total reduced thiols after heart reperfusion in exercised rats treated with the anabolic steroid. These results indicate that cardiotoxic effects of supraphysiological doses of AAS involve reduced heart antioxidant capacity [13131].

One study focuses on the short term effects of repeated low level administration of turinabol and methanabol on cardiac function in young rabbits (4 months-old). The experimental scheme consisted of two oral administration periods, lasting 1 month each, interrupted by 1-month wash-out period. Serial echocardiographic evaluation at the end of all three experimental periods was performed in all animals. Oxidative stress markers have also been monitored at the end of each administration period. Treated animals originally showed significantly increased myocardial mass and systolic cardiac output, which normalized at the end of the wash out period. Re-administration led to increased cardiac output, at the cost though of a progressive myocardial mass reduction. A dose-dependent trend towards impaired longitudinal systolic, diastolic and global myocardial function was also observed. The adverse effects were more pronounced in the methanabol group. For both anabolic steroids studied, the low dose had no significant effects on oxidative stress markers monitored, while the high dose created a hostile oxidative environment. In conclusion, anabolic administration has been found to create a possible deleterious long term effect on the growth of the immature heart and should be strongly discouraged especially in young human subjects [13133].

Metabolic syndrome

Obesity is one of the constellations of factors that make up the definition of the metabolic syndrome. Metabolic syndrome is also associated with insulin resistance, dyslipidemia, hypertriglyceridemia, and type 2 diabetes mellitus. The presence of obesity and metabolic syndrome in men and women is also associated with increased risk of cardiovascular disease and hypertension. In men, obesity and metabolic syndrome are associated with reductions in testosterone levels. In women, obesity and metabolic syndrome are associated with increases in androgen levels. In men, reductions in androgen levels are associated with inflammation, and androgen supplements reduce inflammation. In women, increases in androgens are associated with increases in inflammatory cytokines, and reducing androgens reduces inflammation [11093].

Coronary artery calcifications

The authors measured coronary artery calcification as a means of examining the impact of anabolic steroids on the development of atherosclerotic disease in body builders using anabolic steroids over an extended period of time. Fourteen male professional body builders with no history of cardiovascular disease were evaluated for coronary artery calcium, serum lipids, left ventricular function, and exercise-induced myocardial ischemia. Seven subjects had coronary artery calcium, with a much higher than expected mean score of 98. Six of the 7 calcium scores were >90th percentile. Mean total cholesterol was 192 mg/dL, while mean
high-density lipoprotein was 23 mg/dL and the mean ratio of total cholesterol to high-density lipoprotein was 8.3. Left ventricular ejection fraction ranged between 49 percent and 68 percent, with a mean of 59 percent. No subject had evidence of myocardial ischemia. This small group of professional body builders with a long history of steroid abuse had high levels of coronary artery calcium for age. The authors conclude that in this small pilot study there is an association between early coronary artery calcium and long-term steroid abuse. Large-scale studies are warranted to further explore this association [06069].

Myocardial infarction

Anabolic-androgenic steroids are associated with numerous side effects, including acute myocardial infarction. It was reported a case of myocardial infarction in a young 31-year-old bodybuilder. Because of the serious cardiovascular complications of anabolic steroids, physicians should be aware of their abuse and consequences [08142].

Sudden cardiac deaths secondary to myocardial infarction and related to AAS use in previously healthy athletes have been reported; however, it must be pointed out that these effects are reported in individual case reports and no large, randomized study has been conducted to verify these results. Exposure to AAS alters endothelial cell growth with a strong antiproliferative effect, induces apoptosis, and modifies intracellular levels of calcium. These observed endothelial alterations may be considered events that predispose to serious damage at the cell vasculature level. Androgens impair arterial vasomotor response and consequently increase collagen and other fibrous proteins in arterial vascular tissue and they impair flow-mediated, endothelium-dependent vasodilation. This effect may improve after the discontinuation of agents. Moreover, experimental studies have shown that androgens potentiate platelet aggregation in vitro and in vivo. Androgens may exert their effect on platelets through an effect on the prostaglandin system and lead to increasing platelet production of thromboxane A2 (a potent platelet aggregator), decreasing the production of prostacycline (prostaglandin I2, an inhibitor of platelet aggregation) and increasing fibrinogen levels. They also increase human platelet thromboxane A2 receptor density and their aggregation responses. The above-mentioned physiological changes may predispose individuals to be at higher risk for myocardial infarction. It also has been shown that aortic distensibility decreases in athletes who use AAS. This went against previously reported increases in aortic distensibility in athletes in comparison with age-matched sedentary volunteers. Aortic stiffness by increasing ventricular load predisposes to the development of LVH, progressing to left ventricular dysfunction and cardiac failure, and creating an unfavorable oxygen supply/demand ratio. It also causes a reduction in arterial pressure during diastole, which decreases the coronary perfusion pressure and contributes to myocardial ischemia even in the absence of coronary artery atherosclerotic narrowing [12119].

Cardiac arrhythmias

Sudden cardiac arrhythmia resulting from inflammatory process and myocardial fibrosis has been suggested to be the cause of death in athletes using AAS. AAS cause the deepest and most prolonged depression of stimulation threshold in the heart muscles. Long-term use may be responsible for an alteration in the electrophysiology of the myocardium that may predispose to reentry mechanism. It also has been shown that QTc interval and dispersion are increased in individuals who abuse androgens, suggesting the presence of ventricular repolarization abnormalities that could increase the risk of cardiac arrhythmias and sudden cardiac death. Atrial fibrillation secondary to high-dose steroids was reported in two cases of athletes who were using AAS and had no other known cause of atrial fibrillation [12119].
In an electrophysiological study power athletes taking AAS were found to have increased QT dispersion and short QT intervals. The authors associated these changes with the manifestation of arrhythmias. In addition, in an experimental study it was found that the administration of nandrolone decanoate to rats led to a disturbance of cardiac autonomic nervous system function. It was also found analogous results in a study of athletes who used anabolic steroids, who presented a reduction in baroreflex sensitivity and maintained that anabolic steroids lead to degenerative changes in endomyocardial sympathetic neurons, resulting in the appearance of malignant arrhythmias. This degenerative mechanism is referred to as catecholamine myotoxicity [12126].

Cardiac arrhythmias are associated with AAS abuse. Most commonly, atrial fibrillation but also ventricular tachycardia and ventricular fibrillation has been described secondary to AAS abuse in human case reports. In a study on rats treated with high-dose nandrolone for 10 weeks, heart rate variability measurements revealed a reduction in parasympathetic activity compared with the vehicle-treated group. Sympathetic indices were also higher in the AAS-treated group. It was also shown that AAS-treated animals show prolonged action potentials as a result of reduced density of transient potassium outward current in the left ventricle [12125].

The current management of athletes with cardiac arrhythmias has become complicated by the widespread use of illicit drugs, which can be arrhythmogenic. The World Anti-Doping Agency annually updates a list of prohibited substances and methods banned by the International Olympic Committee that includes different classes of substances namely, anabolic androgenic steroids, hormones and related substances, beta2-agonists, diuretics, stimulants, narcotics, cannabinoids, glucocorticosteroids, alcohol, beta-blockers and others. Almost all illicit drugs may cause, through a direct or indirect arrhythmogenic effect, a wide range of cardiac arrhythmias (focal or reentry type, supraventricular and/or ventricular) that can even be lethal and which are frequently sport activity related. A large use of illicit drugs has been documented in competitive athletes, but the arrhythmogenic effect of specific substances is not precisely known. Precipitation of cardiac arrhythmias, particularly in the presence of a latent electrophysiologic substrate including some inherited cardiomyopathies, at risk of sudden death or due to long-term consumption of the substances, should raise the suspicion that illicit drugs may be a possible cause and lead cardiologists to investigate carefully this relationship and appropriately prevent the clinical consequences [07063].

**QT-interval**

The association between physiologic levels of sex hormones and QT-interval duration in humans was evaluated using data from 727 men enrolled in the Third National Health and Nutrition Examination Survey and 2,942 men and 1,885 postmenopausal women enrolled in the Multi-Ethnic Study of Atherosclerosis. Testosterone, estradiol, and sex hormone-binding globulin levels were measured in serum and free testosterone was calculated from those values. QT interval was measured using a standard 12-lead electrocardiogram. In men from the Third National Health and Nutrition Survey, the multivariate adjusted differences in average QT-interval duration comparing the highest quartiles with the lowest quartiles of total testosterone and free testosterone were -8.5 ms (95% confidence interval: -15.5 to -1.4) and -8.0 ms (95% confidence interval -13.2, -2.8), respectively. The corresponding differences were -1.8 ms and -4.7 ms, respectively. Estradiol levels were not associated with QT-interval duration in men, but there was a marginally significant positive association in postmenopausal women. The findings suggest that testosterone levels may explain differences in QT-interval duration between men and women and could be a contributor to population variability in QT-interval duration among men [11330].

**Maximal heart rate**
Previous study showed that muscle sympathetic nerve activity (MSNA) was augmented in anabolic steroids users (AASU). In one study, it was tested the hypothesis that the heart rate (HR) responses after maximal exercise testing would be reduced in AASU. Ten male AASU and 10 AAS nonusers (AASNU) were studied. Cardiopulmonary exercise was performed to assess the functional capacity and heart rate recovery. MSNA was recorded directly from the peroneal nerve by microneurography technique. Peak oxygen consumption (VO₂) was lower in AASU compared to AASNU (44 ± 2 vs 53 ± 2 mL/kg/min). HR recovery (HRR) at first and second minute was lower in AASU than AASNU (21 vs 27 bpm, and 37 vs 45 bpm, respectively). MSNA was higher in AASU than AASNU (29 vs 20 bursts/min). Further analysis showed a correlation between HRR and MSNA, HRR at first minute and peak VO₂ and HRR at second minute and peak VO₂. The exacerbated sympathetic outflow associated with a lower parasympathetic activation after maximal exercise, which impairs heart rate recovery, strengthens the idea of autonomic imbalance in AASU [13132].

Heart rate recovery

Previous study showed that muscle sympathetic nerve activity (MSNA) was augmented in anabolic steroids users (AASU). In the present study, we tested the hypothesis that the heart rate (HR) responses after maximal exercise testing would be reduced in AASU. Ten male AASU and 10 AAS nonusers (AASNU) were studied. Cardiopulmonary exercise was performed to assess the functional capacity and heart rate recovery. MSNA was recorded directly from the peroneal nerve by microneurography technique. Peak oxygen consumption (VO₂) was significantly lower in AASU compared to AASNU. HR recovery (HRR) at first and second minute was significantly lower in AASU than AASNU. MSNA was higher in AASU than AASNU. Further analysis showed a correlation between HRR and MSNA, HRR at first minute and peak VO₂ and HRR at second minute and peak VO₂. The exacerbated sympathetic outflow associated with a lower parasympathetic activation after maximal exercise, which impairs heart rate recovery, strengthens the idea of autonomic imbalance in AASU [13136].

Myocardial fibrosis caused of anabolic steroids

Experimental studies have demonstrated that AAS abuse leads to skeletal muscle hypertrophy and increased collagen accumulation; changes that are similarly detected in the myocardium. Studies in rats and mice have shown that AAS abuse leads to both myocardial hypertrophy and fibrosis, destruction of the mitochondria and other elements of the cardiomyocytes, disturbances of the microcirculation, and to a deterioration in systolic function and to diastolic dysfunction. Post-mortem studies of athletes who used AAS have found infiltration of eosinophils into myocardial cells, as well as destruction of myofibrils. Endothelial dysfunction was also observed [12126].

A 2005 study reported two cases of sudden cardiac death in young male athletes related to AAS abuse. Both cases involved healthy individuals without any history of coronary artery disease (CAD) and with no evidence of significant abnormality in arterial microscopic examination. Autopsy of both hearts showed focal myocardial fibrosis suggestive of prior myocardial injury. In a study of a sudden unexpected death in a female fitness athlete using steroids and ephedrine, the only pathological finding was a few small foci of granulation tissue, which was interpreted as evidence of earlier myocardial necrosis. Sudden cardiac arrhythmia resulting from inflammatory process and myocardial fibrosis was suggested to be the cause of death in these cases. Other researchers have reported sudden cardiac deaths related to steroids that also showed myocardial fibrosis in the absence of CAD [12119].
**Left ventricular myocardial dysfunction and cardiac hypertrophy**

Chronic anabolic steroid use suppresses left ventricular functions. However, there is no information regarding the chronic effects of anabolic steroids on right ventricular function which also plays a key role in global cardiac function. The main objective of one study was to investigate the effects of androgenic anabolic steroids usage among athletes on remodeling the right part of the heart. Androgenic-anabolic steroids-using bodybuilders had smaller diastolic velocities of both ventricles than drug-free bodybuilders and sedentary counterparts. This study shows that androgenic anabolic steroids-using bodybuilders exhibited depressed diastolic functions of both ventricles [08141].

Anabolic steroids cause a variety of side effects, among them a slight concentric left ventricular hypertrophy. The objective of the present study was to clarify if they also induce alterations in left ventricular function. Fourteen male body builders with substantial intake of anabolic steroids (users) were examined by standard echocardiography and cardiac tissue Doppler imaging. They were compared to 11 steroid-free strength athletes (non-users) and 15 sedentary control subjects. Users showed an increased left ventricular muscle mass index. The ratio of peak transmitral blood flow velocities during early diastolic filling and atrial contraction did not differ between groups. In contrast an analogous tissue Doppler parameter, the ratio of myocardial velocities during early and late ventricular filling in the basal septum, was significantly lower in users when compared to non-users or controls. The velocity gradient during myocardial E-wave in the posterior wall showed significantly lower values in users as compared to controls. There were no differences in systolic function. Summarizing strength athletes abusing anabolic steroids show negative alterations in diastolic function [07064].

Recent echocardiographic studies of AAS users demonstrate an increase in septal and left ventricular posterior wall thickness. This hypertrophy is greater in weight-trained individuals using AASs than in weight-trained individuals provided placebo or not using AASs and persists for years among former AAS users. Cardiac wall hypertrophy may not occur after short-term ASA use. AAS use impairs measures of diastolic function (e.g. isovolumetric relaxation time and altered tissue Doppler imaging of the left ventricle) that reflect impaired relaxation and altered filling during diastole. Possible etiologies for impaired diastolic function include increased collagen content or areas of focal necrosis, seen at autopsy of AAS users. Cardiovascular performance also can be assessed by way of formal exercise testing; although AASs may increase bulk and strength, they do not improve endurance. Despite having similar aerobic and weight-training schedules as control subjects, AAS users had a significantly decreased maximum oxygen consumption (VO₂max; an index of metabolic and cardiovascular endurance ability). Impaired diastolic function could contribute to decreased VO₂max [07058].

Biopptic data have shown that in athletes under the pharmacological effects of AAS, a focal increase in myocardial collagen content might occur as a repair mechanism against myocardial damage. To investigate the potential underlying left ventricular myocardial dysfunction after chronic misuse of AAS in athletes by use of Doppler myocardial imaging (DMI) and strain rate imaging (SRI). Standard Doppler echocardiography, DMI, SRI and ECG treadmill test were undertaken by 45 bodybuilders, including 20 athletes misusing AAS for at least 5 years (users), by 25 anabolic-free bodybuilders (non-users) and by 25 age-matched healthy sedentary controls, all men. The mean number of weeks of AAS use per year was 31 in users, compared with 9 years in non-users, and the mean weekly dosage of AAS was 525 mg. The groups were matched for age. Systolic blood pressure was higher in athletes (145 vs 130 mm Hg) than in controls. Left ventricular mass index did not significantly differ
between the two groups of athletes. In particular, both users and non-users showed increased wall thickness and relative wall thickness compared with controls, whereas left ventricular ejection fraction, left ventricular end-diastolic diameter and transmitral Doppler indexes were comparable for the three groups. Colour DMI analysis showed significantly lower myocardial early: myocardial atrial diastolic wave ratios in users at the level of the basal interventricular septum (IVS) and left ventricular lateral wall, in comparison with both non-users and controls. In addition, in users, peak systolic left ventricular strain rate and strain were both reduced in the middle IVS and in the left ventricular lateral free wall. By stepwise forward multivariate analyses, the sum of the left ventricular wall thickness, the number of weeks of AAS use per year and the weekly dosage of AAS were the only independent determinants of middle IVS strain rate. In addition, impaired left ventricular strain in users was associated with a reduced performance during physical effort. Several years after chronic misuse of AAS, power athletes show a subclinical impairment of both systolic and diastolic myocardial function, strongly associated with mean dosage and duration of AAS use. The combined use of DMI and SRI may therefore be useful for the early identification of patients with more diffused cardiac involvement, and eventually for investigation of the reversibility of such myocardial effects after discontinuation of the drug [07065].

Anabolic androgenic steroids (AAS) are used by some athletes to enhance performance despite the health risk they may pose in some persons. This work was carried out to evaluate the possible structural and functional alterations in the heart using two-dimensional, M-mode, tissue Doppler imaging (TDI) and strain rate imaging (SRI) in athletes using supraphysiological doses of AAS. Additionally, the histological and ultrastructural changes in cardiac muscles of adult albino rats after injection of sustanon, as an example of AAS, were studied. Fifteen male bodybuilders using anabolic steroids constituted group 1, five male bodybuilders who are not using anabolic steroids constituted group 2, and five nonathletic males constituted negative control group (group 3). They were investigated by two-dimensional, M-mode, TDI and SRI. Moreover, a study was performed on 30 adult albino rats. They were divided into two groups. Group I (Control group) (n=10) was subdivided into negative control, subgroup 1a (n=5), and subgroup 1b (n=5), which received 0.8 ml olive oil intramuscular once a week for 8 weeks. Group II (Experimental group) (n=20) received sustanon 10 mg/kg intramuscularly once a week for 8 weeks. The heart specimens were prepared for light microscopy and transmission electron microscopy. Echocardiographic results showed that bodybuilders who use steroids have smaller left ventricular dimension with thicker walls, impaired diastolic function, as well as higher peak systolic strain rate in steroid-using bodybuilders as compared to the other two groups. Light microscopy examination of cardiac muscle fibers showed focal areas of degeneration with loss of striations and vacuolation in the experimental group. Ultrastructural examination showed disturbance of the banding pattern of the cardiac muscle fiber with disintegration, loss of striations, dehiscent intercalated disc, and interrupted Z-bands. Administration of supraphysiological doses of AAS caused severe deleterious effects in the myocardium both in athletes and in experimental animals. The SRI shows promise in the early detection of systolic dysfunction in those athletes who use steroids [09056].

Anabolic androgenic steroids (AAS) are sometimes used by power athletes to improve performance by increasing muscle mass and strength. Recent bioptical data have shown that in athletes under the pharmacological effects of AAS, a focal increase in myocardial collagen content might occur as a repair mechanism against myocardial damage. To investigate the potential underlying left ventricular myocardial dysfunction after chronic misuse of AAS in athletes by use of Doppler myocardial imaging (DMI) and strain rate imaging (SRI). Standard Doppler echocardiography, DMI, SRI and ECG treadmill test were undertaken by 45 bodybuilders, including 20 athletes misusing AAS for at least 5 years (users), by 25 anabolic-
The effects of anabolic androgenic steroids (AASs) on left ventricular (LV) diastolic function in strength-trained athletes are controversial. The main objective of this study was to evaluate the effects of regular AAS administration in bodybuilders using pulsed tissue Doppler imaging (TDI) to evaluate LV relaxation properties. Fifteen male bodybuilders with a history of intensive, long-term strength training and 16 age-matched sedentary controls were recruited. Six of the bodybuilders reported regular use of AASs, and 9 were drug free. To assess LV diastolic function, each subject underwent standard Doppler echocardiography and pulsed TDI. Drug-using bodybuilders exhibited altered LV diastolic filling characterized by a smaller contribution of passive filling to LV filling compared with their drug-free counterparts. TDI measurements indicated that drug-using bodybuilders had smaller peak E(m) than drug-free bodybuilders and sedentary controls, except at the level of the anterior wall, at which peak E(m) was significantly smaller than in drug-free bodybuilders only. The E/E(m) ratio, an index of LV filling pressures, was not affected by strength training or by AAS use. Drug-using bodybuilders exhibited larger LV end-diastolic diameters, volumes, and masses than their drug-free counterparts. However, no difference was found in LV wall thickness between the groups. In conclusion, drug-using bodybuilders showed a decrease in the contribution in LV passive filling to LV filling associated with a decrease in LV relaxation properties. Because no wall thickening was obtained in drug-using bodybuilders, the decrease in LV relaxation properties might have been due to an alteration in the active properties of the myocardium, but that has yet to be confirmed [06067].

It was compared cardiac parameters in weightlifters reporting long-term AAS use to those in otherwise similar weightlifters without prior AAS exposure. It was performed 2D tissue-Doppler and speckle-tracking echocardiography to assess left ventricular (LV) ejection fraction, LV systolic strain, and conventional indices of diastolic function in long-term AAS users (n=12) and otherwise similar AAS nonusers (n=7). AAS users (median [quartile 1, quartile 3] cumulative lifetime AAS exposure, 468 [169, 520] weeks) closely resembled nonusers in age, prior duration of weightlifting, and current intensity of weight training. LV structural parameters were similar between the two groups; however, AAS users had significantly lower LV ejection fraction (51 % [48, 54] versus 59 % [58 %, 62 %]), longitudinal...
strain (17 % [14 %, 19 %] vs 21 % [20 %, 23 %]), and radial strain (38 % [29 %, 44 %] vs 50 % [44 %, 62 %]). Ten of the 12 AAS users showed LV ejection fractions below the accepted limit of normal (>55 %). AAS users also demonstrated decreased diastolic function compared to nonusers as evidenced by a markedly lower early peak tissue velocity (7.4 [6.8, 7.9] cm/s vs 9.9 [8.3, 10.5] cm/s) and early-to-late diastolic filling ratio (0.93 [0.88, 1.39] vs 1.80 [1.48, 2.00]). It was concluded that cardiac dysfunction in long-term AAS users appears to be more severe than previously reported and may be sufficient to increase the risk of heart failure [10327].

An increase in LV mass is an independent risk factor for CV disease. AS use has been associated with an increase in LV mass, but there is conflicting data. There are some data in AS users that suggest a reduction in systolic cardiac function although this is not a consistent finding between studies. A reduction in diastolic function has been observed more frequently and it has been suggested that a reduction in myocardial relaxation/elastance is associated with AS use [12114].

Left ventricular hypertrophy (LVH) has been reported in androgen abusers. Several groups have shown that athletes using AAS have reduced end diastolic dimension, a thicker posterior wall and interventricular septum, and a larger left ventricular mass than athletes not using AAS. Cardiac muscle cells have receptors for androgens, and both testosterone and dihydrotestosterone produce a hypertrophic response by acting directly on cardiac muscle cells, increasing amino acid incorporation into protein. The problem is that LVH may persist after discontinuation of AAS [12119].

In athletes who are mainly involved in bodybuilding, echocardiographic studies have derived conflicting results regarding the effects of AAS on left ventricular mass and function. Most studies compared the echocardiographic results between AAS users and nonusers or healthy controls. It has been found significant left ventricular wall thickening in elite power athletes using AAS compared to non AAS-users. Indeed, in one case the wall thickness was 16 mm. However, none of them demonstrated diastolic dysfunction. In contrast, a number of studies found no significant difference in left ventricular hypertrophy between AAS users and non-users. In most cases, the hypertrophy observed was concentric, as would be expected after long-term static exercise training, while only a few showed eccentric hypertrophy due to dilatation of the cardiac cavities. It is noteworthy that studies until early 2000 found no particular evidence for systolic and diastolic dysfunction in athletes using AAS. However, with the use of the latest echocardiographic techniques, such as tissue Doppler, some researchers detected left ventricular diastolic dysfunction in athletes who are AAS users. In a study of ours the use of pulsed tissue Doppler was helpful in the early detection of diastolic dysfunction caused by AAS abuse, which was not detectable using the classical estimation of transmural flow. Moreover, the diastolic dysfunction was found to be correlated with the dosage and the duration of use. Apart from left ventricular diastolic dysfunction, it was found using Doppler myocardial imaging and strain rate imaging, also recorded early findings of deteriorated systolic function in drug users. It is likely that studies using the latest non-invasive diagnostic techniques will confirm the possibility that AAS lead to cardiomyopathy in athletes, mainly due to a direct toxic effect on the myocardium. There are reports of athletes with dilated cardiomyopathy and heart failure after AAS abuse [12126].

The use of anabolic androgenic steroids (AASs) has been associated with hypertrophy of the left cardiac ventricle (LVH) as diagnosed by echocardiography. Case reports suggest that AAS-related LVH may lead to sudden death. It was performed an investigation of the gross cardiac pathological findings in deceased male AAS users in order to further elucidate the proposed role of AAS in cardiac hypertrophy. Eighty-seven deceased males who tested positive for AAS at autopsy and 173 age-adjusted control deceased males without suspected
AAS use were studied for cardiac hypertrophy. The AAS-positive subjects had been examined at any of the six departments of forensic medicine in Sweden during the period from 1989 to 2009. Data were assessed employing multivariate analyses controlling for body weight, height, age, bleeding after trauma, and the impact of weight training. The analysis of the logarithm of heart mass by multivariate statistics implied that strong correlations existed between body mass and heart mass, height and heart mass, age and heart mass, and trauma (bleeding) and heart mass. After controlling for these factors, a significantly higher heart mass was found among the AAS-positive males. The findings suggest that use of AAS may lead to cardiac hypertrophy with a direct cardiotropic effect [12128].

The role of AAS abuse in myocardial hypertrophy has been shown in animal and human studies. In a recent investigation on rats treated with high-dose nandrolone for 8 weeks, electrical remodelling and increasing myocytes nuclei diameter in the AAS group suggested early stages of myocardial hypertrophy. Significant increase in left ventricular mass index, ranging from 7 to 24 percent, has been shown in studies on rats treated with low-dose and high-dose AAS for 8-10 weeks. Another study on the AAS treatment for 3 weeks in mice subjected to aerobic training and sedentary mice showed that high-dose AAS treatment in sedentary mice results in increased ventricular mass index by 25 percent. Also, many case reports of sudden cardiac death in athletes who abused AAS have shown clinically important left ventricular hypertrophy. Association between AAS abuse and echocardiographical detected myocardial hypertrophy has been shown in a study on athletes who chronically abused AAS (median 24 months). In this study, hypertrophic index (interventricular septum plus posterior wall thickness divided by the internal diameter) was significantly higher in AAS (ex-)abusers compared with nonuser athletes. Moreover, the extent of AAS abuse was linearly correlated with mean left ventricular wall thickness. It has been shown that long-term AAS abuse increases peripheral vascular resistance, blood pressure, and myocardial sympathetic nerve activity, which can explain mechanical stress-induced myocardial hypertrophy in AAS abusers. Moreover, androgen receptors which are responsible for AAS-induced hypertrophic effects on skeletal muscles are also present in myocytes and result in increased protein anabolism within myocardial cells and interstitium [12125].

Anabolic androgenic steroids (AAS) abuse for improving physical appearance and performance in body builders is common and has been considered responsible for serious cardiovascular effects. Due to disagreement about cardiovascular side effects of these drugs in published articles, this case control study was designed to evaluate the echocardiographic findings in body builder athletes who are current and chronic abusers of these drugs. Body builder athletes with continuous practice for the preceding two years and were training at least twice weekly were selected and divided into AAS abuser and non user and compared with age and BMI matched non athletic healthy volunteers (15 cases in each group). There was no significant difference in left ventricular size or function either systolic or diastolic in comparison to cases and control groups. The only difference was in diastolic size of septum and free wall but observed differences were only significant between first (athletic with AAS abuser) and third group (non athletic and nonuser). The difference between the above-mentioned indexes was not significant between two groups of athletes. Observed differences in diastolic size of septum and free wall is in favor of that long term abuse of anabolic steroid results in accentuation of physiologic hypertrophy due to long term sport most probably due to higher rate pressure product. Furthermore long term abuse and supra pharmacologic doses do not have significant effect in size and left ventricular function [13798].

Concentric left ventricular myocardial hypertrophy is a common pathologic finding following the chronic use of AAS. A 21-year-old, previously healthy weight lifter collapsed during a benchpress workout, and paramedics found him in ventricular fibrillation. For the preceding several months, he used parenteral AASs (nandrolone, 19-nortestosterone). Postmortem
findings included marked cardiac hypertrophy, regional myocardial fibrosis, and focal myocardial necrosis along with hepatosplenomegaly and renal hypertrophy. There was no evidence of recent myocardial inflammation. Other autopsies of AAS abusers have not demonstrated cardiac hypertrophy, but histologic examination of cardiac tissue also detected focal myocardial necrosis. The postmortem examination of 2 cases of sudden death in 2 previously healthy chronic AAS abusers (i.e. bodybuilders) demonstrated also focal myocardial necrosis (contraction band necrosis) without evidence of significant coronary artery disease or myocardial hypertrophy. Other pathologic changes associated with cardiac arrest in previously healthy athletes following AAS use (e.g. oxymesterone) include hypertrophic cardiomyopathy, acute cellular ecrosis, interstitial fibrosis, and myocarditis. Typically, there is no evidence of coronary artery disease in these cases of sudden death. However, evidence of recent (i.e. 2 weeks) myocardial infarction may occur in these cases of sudden death [13003].

Cardiac (autonomic) dysfunction

To date no published data exist regarding the effects of chronic high-dose anabolic-androgenic steroid administration on tonic cardiac autonomic control. The aim of this study was to evaluate, by power spectral analysis of heart rate variability (HRV), the effects of chronic treatment with supraphysiological doses of nandrolone decanoate (DECA) on tonic cardiac autonomic regulation in sedentary rats. Male Wistar rats were treated weekly with 10 mg/kg of DECA (n=7) or vehicle (CONTROL, n=7) for 10 weeks. At the 8th week of treatment, electrocardiogram was recorded in the conscious state, for time- and frequency-domain HRV analysis. Parasympathetic indexes were reduced in DECA group: high-frequency power, RMSSD, and pNN5. The sympathetic index LF/HF tended to be higher in DECA group. In conclusion, chronic treatment with DECA, in rats, impairs tonic cardiac autonomic regulation, which may provide a key mechanism for anabolic steroid-induced arrhythmia and sudden cardiac death [06068].

Anabolic-androgenic steroids abuse has been shown to affect the cardiomyocyte survival and heart function in cell cultures, animal models and humans. A recent study reported that both diastolic and systolic functional parameters are impaired in AAS abuser athletes comparing with nonabuser athletes. In this study, echocardiography in AAS abusers showed a significantly lower ejection fraction (50 % vs 59 %) and longitudinal strain compared to AAS nonabusers. A similar trend was observed in diastolic functional parameters. The mechanisms of high-dose AAS-associated heart dysfunction are still not thoroughly investigated. However, some studies showed deleterious molecular and cellular effects of high-dose AAS administration on myocardium which overlap early injury pathways of heart failure. It is known that in hypertrophic myocardium, hypertrophy can be linked with any of the heart failure signalling pathways, resulting in heart failure. It has also been shown that AAS indirectly mediates the processes that precede mitochondrial damage, apoptosis and sarcomere disruption. It has also been reported that high-dose AAS treatment in small animal models is associated with interstitial collagen deposition and fibrosis. Fibrosis is assumed to occur initially as an adaptation in myocardial hypertrophy to preserve the function of the ventricles and, thereafter, as a repair mechanism to compensate apoptotic myocardial cell loss [12125].

An echocardiographic study of 47 strength-training individuals (46 male subjects), 28 of whom were regular AAS users, revealed a lower systolic function in AAS users versus nonusers, ejection fractions 58 versus 63 percent, respectively. In addition, there was evidence of reduced diastolic function by tissue Doppler measurement in the AAS users (i.e. their hearts were weaker and stiffer). Another study of 12 long-term AAS users noted that compared with controls, they were noted to have significant systolic cardiac dysfunction as
measured by lower left ventricular ejection fraction (50 % vs 59 %). An Italian Doppler imaging study also showed reduced systolic function but in a regional distribution [12119].

One study aimed to evaluate if androgenic-anabolic steroids (AAS) abuse may induce cardiac autonomic dysfunction in recreational trained subjects. Twenty-two men were volunteered for the study. The AAS group (n=11) utilized AAS at mean dosage of 410 ± 78.6 mg/week. All of them were submitted to submaximal exercise testing using an Astrand-Rhyming protocol. Electrocardiogram (ECG) and expired gas analysis were monitored at rest, during, and post-effort. Mean values of VO2 , VCO2 , and VE were higher in AAS group only at rest. The heart rate variability variables were calculated from ECG using MATLAB-based algorithms. At rest, AAS group showed lower values of the standard deviation of R-R intervals, the proportion of adjacent R-R intervals differing by more than 50 ms (pNN50), the root mean square of successive differences (RMSSD), and the total, the low-frequency (LF) and the high-frequency (HF) spectral power, as compared to Control group. After submaximal exercise testing, pNN50, RMSSD, and HF were lower, and the LF/HF ratio was higher in AAS group when compared to control group. Thus, the use of supraphysiological doses of AAS seems to induce dysfunction in tonic cardiac autonomic regulation in recreational trained subjects [13134].

**Vascular reactivity**

Anabolic androgenic steroids are used by some bodybuilders to enhance performance. While the cardiovascular implications of supraphysiological androgen levels requires further clarification, use is associated with sudden death, left ventricular hypertrophy, thromboembolism and cerebro-vascular events. To further understand the effect of androgenic anabolic steroid abuse on vascular function, this study assessed vascular stiffness (pulse-wave analysis) and cardiovascular risk factors in 28 male, bodybuilding subjects, of whom ten were actively receiving anabolic agents (group A; 26 years) and eight had undergone a 3-month "wash-out" period (group B; 32 years). The remaining ten bodybuilding subjects (group C; 24 years) denied any past use of anabolic steroids or other performance enhancing drugs. Comparisons were made with ten sedentary male controls (group D, 29 years). Endothelial independent dilatation in response to glycerol trinitrate was significantly impaired in the group currently using anabolic steroids (group A) compared with the other three groups, whereas no significant differences in endothelial-dependent dilatation were detected between the groups. Previous studies described a decline in vascular reactivity occurring in bodybuilding subjects which is independent of anabolic steroid use and may result from smooth muscle hypertrophy with increased vascular stiffness. This study revealed impaired vascular reactivity associated with anabolic agents and that improvement in vascular function may occur following their discontinuation [06070].

**Cholesterol changes**

An association between premature cardiovascular events and the misuse of AAS in athletes has been observed. This is believed to be primarily mediated through changes in the lipid profile. Although endurance exercise favorably affects the lipid profile primarily through an antiatherogenic effect of raising high-density lipoprotein (HDL) cholesterol and lowering triglycerides, heavy resistance training alone fails to show a similar effect. This implies that the effect of AAS on lipid profile may confounded by the type of training the athlete pursues. Multiple prospective studies of AAS effects on cholesterol have yielded varied results. The majority of results (studies ranging from 3 to 26 weeks) show no overall change in levels of total serum cholesterol; however, some individual studies show increases and others show a decrease in total cholesterol. Despite the varied results on total cholesterol, the effects on
HDL seem more consistent. Reductions in HDL range from 39 to 70 percent depending on the type of AAS and also appear to be dose dependent. Several studies show reductions of HDL down into the teens, which, based on Framingham data, places these patients at a three times greater risk for coronary artery disease compared with men with HDL above 50 mg/dL. There even appears to be some variation in the dose effect based on gender. In one study of hemodialysis patients, weekly administration of nandrolone resulted in a reduction of HDL-2 and apolipoprotein A-1 levels, complemented by a corresponding increase in apolipoprotein B and triglycerides. The oral 17-alpha alkylated steroids, as opposed to parenteral nandrolone, seem to exert the greatest effects on lipids and lipoproteins, which can be seen as early as the first few days of administration. This reduction often reaches a plateau effect after 8 weeks of use. Although the direct mechanisms of action and impact on cardiovascular disease remain unproven, this negative effect on HDL suggests a higher risk of atherogenesis. The alteration in lipid profile seems completely reversible upon discontinuation, but may take at least 4 to 12 weeks, often depending on dose and duration of steroid use [06031].

In addition to HDL effects, an increase in low-density lipoprotein (LDL) appears to parallel the HDL reduction. Significant LDL increases were appreciated in just 8 weeks of anabolic steroid use in one study, and often had not returned to baseline 6 weeks after cessation of AAS use. Because HDL acts as a primary scavenger of LDL particles, LDL changes possibly reflect a secondary rather than primary effect. These alterations in HDL and LDL cholesterol are more profound in athletes engaged in heavy resistance sports taking AAS as compared with endurance athletes, possibly reflecting the influence of the athlete’s training regimen. In one arm (self-administered, prospective, nonblinded portion) of the study from the Netherlands, reductions in lipoprotein (a), which is an independent risk factor for vascular disease, seem to provide a slightly beneficial effect on the lipid profile. Reductions of as much as 50 percent of lipoprotein (a) were observed in as little as 8 weeks of AAS use, and remained decreased at 6 weeks postcessation. Longer duration of AAS did not correlate directly with further serum reductions, but did demonstrate a more prolonged return to baseline of lipoproteins. In the second phase (randomized controlled trial, double-blinded portion) of the Dutch study, both placebo groups and nandrolone decanoate both demonstrated reductions (19 % and 40 %, respectively) in lipoprotein (a) that was nonsignificant. One explanation for the difference is that the oral 17-alpha alkylated steroids, taken in the first portion, seem to exert the greatest effects on lipids and lipoproteins as opposed to the parenterally administered nandrolone used in the second arm. This is mediated by the first-pass metabolism of the orally administered drugs through the liver. These effects can be seen as early as the first few days of administration, and seem to be more dependant on the type of steroid as opposed to the duration, although no long-term studies exist currently. Concentrations of lipoprotein (a) have been shown to have a close correlation with deposition in vascular walls, are often genetically determined, and seem resistant to current lipid [06031].

**Impaired exercise-induced cardioprotection of antioxidant enzymes**

High doses of anabolic androgenic steroids (AAS) impair the cardioprotective effects of exercise against ischemia/reperfusion (I/R) insult, possibly through cellular redox imbalance. Here, the effect of nandrolone decanoate (DECA) treatment on heart redox metabolism was investigated during I/R in sedentary and exercised rats. DECA treatment significantly reduced superoxide dismutase and glutathione reductase activities in exercised rats after heart reperfusion. Catalase and glutathione peroxidase activities were not affected by DECA in both sedentary and trained rats, regardless of the I/R period. DECA also induced myocardial oxidative stress, as evidenced by the reduced levels of total reduced thiols after heart reperfusion in exercised rats treated with the anabolic steroid. These results indicate that
Cardiotoxic effects of supraphysiological doses of AAS involve reduced heart antioxidant capacity [13126].

Uncertainty remains about possible cardiac adaptation to resistance training. Androgenic anabolic steroids (AAS) use plays a potential role and may have adverse cardiovascular effects. To elucidate the effect of resistance training and of AAS-use on cardiac dimensions and function cardiac magnetic resonance (CMR) were performed in 156 male subjects aged 18-40 years: 52 non-athletes (maximum of 3 exercise hours/week), 52 strength-endurance (high dynamic-high static, HD-HS) athletes and 52 strength (low dynamic-high static, LD-HS) trained athletes (athletes ≥ 6 exercise hours/week). Twenty-eight LD-HS athletes denied and 24 admitted to AAS use for an average duration of 5 years (range 3 months-20 years). No significant differences were found between non-athletes and non-AAS-using LD-HS athletes. AAS-using LD-HS athletes had significantly larger LV and RV volumes and LV wall mass than non-AAS-using LD-HS athletes, but lower than HD-HS athletes. In comparison to all other groups AAS-using LD-HS athletes showed lower ejection fractions of both ventricles (LV/RV EF 51/48 % versus 55-57/51-52 %) and lower E/A ratios (LV/RV 1.5/1.2 versus 1.9-2.0/1.4-1.5) as an indirect measure of diastolic function. Linear regression models demonstrated a significant effect of AAS-use on LV EDV, LV EDM, systolic function and mitral valve E/A ratio. It was concluded that strength athletes who use AAS show significantly different cardiac dimensions and biventricular systolic dysfunction and impaired ventricular inflow as compared to non-athletes and non-AAS-using strength athletes. These findings may help raise awareness of the consequences of AAS use [13127].

The beneficial effects of exercise in reducing the incidence of cardiovascular diseases are well known and the abuse of anabolic androgenic steroids (AAS) has been associated to cardiovascular disorders. Previous studies showed that heart protection to ischemic events would be mediated by increasing the antioxidant enzyme activities. Here, we investigated the impact of exercise and high doses of the AAS nandrolone decanoate (DECA), 10 mg/kg body weight during 8 weeks, in cardiac tolerance to ischemic events as well as on the activity of antioxidant enzymes in rats. After a global ischemic event, hearts of control trained (CT) group recovered about 70 percent of left ventricular developed pressure, whereas DECA trained (DT), control sedentary (CS) and DECA sedentary (DS) animals recovered only about 20 percent. Similarly, heart infarct size was significantly lower in the CT group compared to animals of the three other groups. The activities of the antioxidant enzymes superoxide dismutase (SOD), glutathione peroxidase (GPx) and glutathione reductase (GR) were significantly higher in CT animals than in the other three groups, whereas catalase activity was not affected in any group. Together, these results indicate that chronic treatment with DECA cause an impairment of exercise induction of antioxidant enzyme activities, leading to a reduced cardioprotection upon ischemic events [06071].

**Sudden death**

Among 15,000 forensic post-mortem examinations performed on the coroner's order over a 24-year period (1981-2004) in the area of Lyon, France (population: 2,000,000), 2250 cases of unexpected cardiac sudden death were identified retrospectively according to WHO criteria. Of these, 108 occurred during recreational sport and 12 occurred in athletes. In the latter category, a history of anabolic steroid abuse was found in 6 cases, whereas pre-existing ordinary cardiac lesions were observed in the 6 remaining cases. To shed light on the possible role of anabolic steroids in the induction of cardiac lesions, an experimental study was conducted in rabbits that were treated orally with norethandrolone 8mg/kg/day for 60 days, and sacrificed at day 90. The histopathological examination of the heart from treated animals showed coronary thrombosis associated with left ventricle hypertrophy in 3
cases, and lesions analogous to toxic or adrenergic myocarditis in all other treated animals. These findings were very similar to those observed after cardiac sudden death in the 6 athletes with a history of anabolic steroid abuse. In addition, elevated caspase-3 activity in the heart of treated rabbits as compared to controls suggests that apoptosis is involved in the induction of norethandrolone-induced cardiac lesions. These results confirm the cardiotoxic potential of anabolic steroid abuse [08140].

There have been several cases described of sudden death, SCD, in athletes using AAS. However, the frequency and the pathophysiological mechanism of SCD remain unknown. Some researchers have concluded that AAS have an arrhythmogenic action, while others believe that SCD is a secondary event, resulting from the cardiovascular side effects caused by their abuse. Cases of atrial fibrillation and ventricular tachycardia have also been described in athletes users. It has been suggested that the chronic administration of anabolic agents prolongs and increases the inhomogeneity of repolarisation, thus creating an arrhythmogenic substrate. These disturbances are more apparent in athletes with significant cardiac hypertrophy as an adaptation to long term exercise training (“athlete’s heart”) or to the use of anabolic substances [12126].

Anabolic androgenic steroids (AAS) are the main class of doping agents and their consumption produces adverse effects involving several organs and systems. Three cases of sudden cardiac death (SCD) and one of death due to congestive heart failure of previously healthy athletes who were AAS users are herein reported. Concentric cardiac hypertrophy with focal fibrosis (one case), dilated cardiomyopathy with patchy myocyte death (two cases) and eosinophilic myocarditis (one case) were observed and most probably relate to the final event. Molecular investigation for viral genomes was positive in one case (Ebstein virus). The data confirm previous findings, showing that the most typical cardiac abnormality in AAS abusers is left ventricular hypertrophy, associated with fibrosis and myocytolysis. An exceptional cardiovascular substrate was represented by the case with drug induced eosinophilic myocarditis. These features are at risk of ventricular arrhythmias as well as congestive heart failure. The cause-effect relationship between AAS abuse and cardiac death can be established only by a rigorous methodology with the use of standardized protocols, including precise morphological studies of all target organs to search for chronic toxic effects. Laboratory investigations should focus on AAS searching on a wide range of biological matrices to demonstrate type, magnitude and time of exposure [12129].

Sudden cardiac death related to sports in young patients can have many causes. Hypertrophic cardiomyopathy, congenital coronary abnormalities, and myocarditis make up about half of the causes of sudden cardiac death after sports. Screening for all athletes is important to prevent such episodes. This involves yearly examinations including clinical examinations, stress echocardiograms, echocardiography, and laboratory investigations. Also, behavioral follow up should be addressed, as cocaine administration and doping can both lead to cardiac problems and sudden cardiac death after sports. It was presented a case of a 17-year-old boy who collapsed after an ice hockey competition as a result of an acute myocardial infarction, which was first represented by ventricular fibrillation. It was also reviewed the main causes of sudden cardiac death in such young athletes and the main investigations that have to be performed to reach the proper diagnosis and etiology of the condition [06072].

Sudden death among athletes is very rare (1:50,000-1:100,000 annually) but it is still 2-4 times more frequent than in the age-matched control population and attracts significant media attention. We propose a mechanism underlying sudden cardiac death in athletes that does not relate to myocardial ischemia but is based on repolarization abnormalities due to potassium channel downregulation and can also be best explained by the concurrent...
presence of several factors such as cardiac hypertrophy (athlete's heart), and/or hypertrophic cardiomyopathy, increased sympathetic tone, genetic defects, drugs, doping agents, food, or dietary ingredients. These factors together can increase the repolarization inhomogeneity of the heart ("substrate") and an otherwise harmless extrasystole ("trigger") occurring with a very unfortunate timing may sometimes induce life-threatening arrhythmias. The effective and possible prevention of sudden cardiac death requires the development of novel cost effective cardiac electrophysiological screening methods. Athletes identified by these tests as individuals at higher proarrhythmic risk should then be subjected to more costly genetic tests in order to uncover possible underlying genetic causes for alterations in ionic channel structure and/or function [10066].

It was reported two cases of sudden cardiac death (SCD) involving previously healthy bodybuilders who were chronic androgenic-anabolic steroids users. In both instances, autopsies, histology of the organs, and toxicologic screening were performed. The findings support an emerging consensus that the effects of vigorous weight training, combined with anabolic steroid use and increased androgen sensitivity, may predispose these young men to myocardial injury and even SCD [07066].

Several case reports associate the chronic use of AAS with serious cardiovascular complications including acute myocardial infarction, cardiac arrest, and hypertrophic cardiomyopathy without significant cardiac valvular or coronary artery disease. Case reports associate chronic AAS abuse with myocardial infarctions in young men with and without evidence of coronary artery occlusion; the presence of coronary artery disease in these athletes occurs despite the lack of known risk factors for coronary artery disease. The development of an acute myocardial infarction was associated with high-dose AAS abuse (e.g. 6 weeks daily, years intermittently) by a 44-year-old recreational bodybuilder with diffuse coronary artery disease and multiple myocardial risk factors including polycythemia, smoking, and family history of early coronary artery disease. Left ventricular hypertrophy is a common structural abnormality in bodybuilders with AAS abuse. A study of 21 bodybuilders with reported AAS abuse suggests that concentric hypertrophy of the left ventricular wall and impaired diastolic function are common complications of steroid abuse. Echocardiographic studies of these athletes demonstrated increased left ventricular posterior wall thickness and end-diastolic volumes as well as decreased ratios of ventricular end-diastolic diameter to body mass. A case report of 2 previously healthy bodybuilders associated sudden cardiac death with chronic AAS abuse. There was evidence of focal myocardial necrosis without clinically significant coronary artery disease, but the role of chronic AAS abuse in the cardiac arrest remains unclear. Ventricular dysrythmias are not commonly associated with chronic AAS abuse. Several case reports associate persistent atrial fibrillation with chronic AAS use. A 22-year-old man developed generalized weakness, diaphoresis, anxiety, and dyspnea. The electrocardiogram revealed rapid atrial fibrillation and the echocardiogram indicated an early cardiomyopathy. He had gynecomastia, and he admitted to the recent injection of anabolic steroids. Although there is no direct evidence that AASs are thrombogenic in humans, case reports suggest a possible causal relationship between AAS use and thrombogenic events (e.g. massive pulmonary embolus, cerebral thrombosis, cardiomyopathy with congestive heart failure, biventricular thrombi, and hepatorenal dysfunction). Studies on the association between chronic AAS use and hypertension or left ventricular hypertrophy are inconsistent [13003].

Sudden death is the most frightening consequence of AAS use. The etiology of these events likely is multifactorial, with AAS use contributing to the observed pathology. There are case reports of myocardial infarctions, stroke, and peripheral vascular obstruction from thrombus that likely are related to the changes in platelet function, inflammation, and cholesterol metabolism discussed above. Autopsies of 34 users of AASs found chronic cardiac changes
consisting of cardiac hypertrophy, myocardial fibrosis, and coronary artery atheromatous changes in 12 victims, although these were believed to contribute to the deaths of only 2 victims. Many sudden death events among AAS users have been due to ischemia secondary to coronary artery disease; however, there is a report of ventricular tachycardia during exercise testing of an AAS user who had myocardial fibrosis on biopsy. Other case reports of sudden death demonstrate diffuse, patchy fibrotic changes in the myocardium of AAS users without coronary artery atherosclerosis. The presence of scar or infiltrative processes is commonly believed to be a cause for arrhythmia. The exact cause of sudden death in AAS users is unclear but likely is due to ischemia or arrhythmia [07058].

*Multiple organ failure*

It was a report of a 42 year old male amateur body builder using anabolic androgenic steroids, who developed acute respiratory distress syndrome, acute kidney injury and refractory supraventricular tachycardia. He required extracorporeal membrane oxygenation, continuous veno-venous hemodialysis, and catheter ablation. It was thought that long-term anabolic androgenic steroid abuse predisposed the patient to developing multiple organ dysfunction syndromes from its immunomodulatory effects in an otherwise healthy patient. Anabolic androgenic steroid use should be part of the history taking process since it may complicate patient outcomes [13139].

*Altered lipid profile*

Altered lipid profiles in AAS users are reflected in increased low-density lipoprotein and decreased high-density lipoprotein. The oral C-17 alkylated steroids seem to exert the greatest effects on the lipid profile. Thrombus formation has been postulated by way of these adverse lipid changes and is supported further by findings of AAS-induced increased platelet aggregation, enhanced coagulation enzyme activity, and coronary vasospasm. Hypertension in AAS users has been reported and is likely the result of blood volume increases and fluid retention. This effect, as well as the finding of increased septal thickness and left ventricular mass reported in AAS users, can lead to significant detrimental cardiac remodeling [07008].

*Lipid profiles in rats*

Dietary protein amount and source, hypertrophy resistance training (RT) and anabolic androgenic steroids (AAS) may affect body weight and plasma and hepatic lipid profile. 157 adult male Wistar rats were randomly distributed in 16 experimental groups resulting in: normal-protein (NP) or high-protein (HP) diets, whey or soy-protein diets, with or without RT and with or without AAS, for 3 months. Final body weight was lower in the RT and AAS groups compared to sedentary and non-AAS groups, respectively. Plasma total cholesterol (TC) was lower for the HP compared to the NP diets, for the whey compared to the soy-protein diets and for the AAS compared to the non-AAS groups. Plasma HDL-cholesterol was higher in the RT groups but lower for the AAS groups, the HP and the soy-protein diets. Plasma triglycerides (TAG) were lower for the HP diet, for the RT and the non-AAS groups. Liver TC was lower for the NP, for the soyprotein and for the AAS groups. Liver TAG were lower for the whey-protein diet, RT and non-AAS groups. Some interactions were found, such as the greater effect of AAS on reducing body weight of rats that performed RT or ingested a HP diet. HDL-cholesterol was higher when RT was combined with HP diets or non-AAS and when HP diets were combined with non-AAS. Groups that combined RT with non-AAS administration obtained the lowest hepatic TAG. Among all the interventions tested, AAS was the factor that most negatively affected plasma and hepatic lipid profile, whereas HP diets and RT could benefit lipid profile, especially when combined [13143].

*Abnormal plasma lipoprotein*
Many studies have shown that AAS can cause dyslipidemia by increasing low-density lipoprotein as high as 596 mg/dL and decreasing high-density lipoprotein as low as 5 mg/dL. Alterations in high- and low-density lipoprotein levels occur in a dose-dependent manner within 9 weeks of self-administration of steroids. These changes could accelerate coronary artery atherosclerosis over the long term, resulting in an increased risk of coronary heart disease three to six times that of normal. The effects of androgens on lipid profile have been shown to be reversible after the discontinuation of administration [12119]

AS have been associated with negative alterations in lipid profiles. Changes reported include a decrease in high-density lipoprotein (HDL), an elevation in low-density lipoprotein (LDL) and reduced apolipoprotein levels, possibly through up-regulation of hepatic triglyceride lipase. The changes in lipid profiles indicate an increase in atherosclerotic risk. Increases in homocysteine, a naturally occurring amino-acid thought to have a role in vaso-control, and C-reactive proteins (CRP), an acute-phase protein that rises in response to inflammation, have been implicated as risk factors for CV disease. It has been demonstrated a significant increase in CRP in AS users. It was noted a significant elevation in homocysteine in AS users as well as those who had abstained from AS use for 3 months, indicating a possible effect of AS on vitamin B absorption. Previous studies have also suggested a possible link between AS use and thrombotic risk through alterations in haemoglobin levels [12114].

To evaluate the effects of anabolic androgenic steroids (AAS) on chylomicron metabolism an artificial lipid emulsion labeled with radioactive cholesteryl ester (CE) and triglycerides (TG) mimicking chylomicrons was intravenously injected into individuals who regularly weight trained and made regular use of AAS (WT+AAS group), normolipidemic sedentary individuals (SDT group) and individuals who also regularly weight trained but did not use AAS (WT group). Fractional clearance rates (FCR) were determined by compartmental analysis for emulsion plasma decay curves. FCR-CE for the WT+AAS group was reduced (0.0073 ± 0.0079 per min, 0.0155 ± 0.0100 per min, 0.0149 ± 0.0160 per min, respectively), FCR-TG was similar for both the WT and SDT groups. HDL-C plasma concentrations were lower in the WT+AAS group when compared to the WT and SDT groups (22 ± 13; 41 ± 7; 38 ± 13 mg/dL, respectively). Hepatic triglyceride lipase activity was greater in the WT+AAS group when compared to the WT and SDT groups (7243 ± 1822; 3898 ± 1232; 2058 ± 749, respectively). However, no difference was observed for lipoprotein lipase activity. Data strongly suggest that AAS may reduce the removal from the plasma of chylomicron remnants, which are known atherogenic factors [12130].

**Chylomicron metabolism**

An artificial lipid emulsion labeled with radioactive cholesteryl ester (CE) and triglycerides (TG) mimicking chylomicrons was intravenously injected into individuals who regularly weight trained and made regular use of AAS (WT+AAS group), normolipidemic sedentary individuals (SDT group) and individuals who also regularly weight trained but did not use AAS (WT group). Fractional clearance rates (FCR) were determined by compartmental analysis for emulsion plasma decay curves. FCR-CE for the WT+AAS group was reduced, FCR-TG was similar for both the WT and SDT groups. HDL-C plasma concentrations were lower in the WT+AAS group when compared to the WT and SDT groups. Hepatic triglyceride lipase activity was greater in the WT+AAS group when compared to the WT and SDT groups. However, no difference was observed for lipoprotein lipase activity. Data thus strongly suggest that AAS may reduce the removal from the plasma of chylomicron remnants, which are known atherogenic factors [12146].

**Trombocyte function**
Several mechanisms have been implicated in atherothrombosis of the coronary and other arteries in steroid users: atherogenesis, thrombosis, vasospasm, and direct myocardial damage. Another cause of atherothrombosis may be the increase in erythrocytosis caused by testosterone. A number of studies have demonstrated a significant disturbance of lipid metabolism in athletes who have used anabolic steroids. The beneficial effect of AAS on platelet aggregation and the mechanism of thrombosis, mainly through the activation of prostaglandins and plasminogen, is well known from experimental studies. However, there are conflicting results regarding the effects of anabolic steroids on the mechanism of thrombosis in athletes. In addition, there are only a few reports on the effect of anabolic steroids on vascular function in athletes [12126].

**Adhesion molecules expression and platelets aggregation**

Although therapeutic and physiological dosages of AAS seem to have beneficial effects on platelet aggregation, deleterious effects of supraphysiological AAS dosages in promoting expression of adhesion molecules in vessel walls and facilitating platelet-endothelium binding have been reported as a mechanism that contributes to AAS-induced atherosclerosis. Additionally, the role of AAS abuse in thrombogenicity has been reported in some studies. Detection of adhesion molecules expression as an upstream process leading to binding of platelets to the arterial wall can depict atherosclerotic plaque formation at early stages. Vascular cell adhesion molecule-1 (VCAM-1) and integrins provide suitable targets for molecular imaging of adhesion molecules expression. VCAM-1 is expressed by endothelial cells, macrophages and smooth muscle cells. Integrins, that is, avb3 integrin, are adhesion molecules that are expressed following endothelial cell injury, as well as at more progressed stages of atherosclerotic plaque formation during neo-angiogenesis. avb3 integrin has high binding affinity to arginine-glycine-aspartate amino acid sequence facilitating cell to extracellular matrix interactions [12125].

**Hypercoagulability**

One study evaluated the short-term effects of oxandrolone, an anabolic androgenic synthetic steroid, on blood coagulation and the hemostatic/fibrinolytic system in healthy individuals. Subjects (n=14) were administered oxandrolone (10 mg twice daily) for 14 days. Blood was obtained on days 0, 1, 3, 7, 9, 14, and then at day 42 (28 days after discontinuation of the drug). Samples were analyzed for the plasma plasminogen, plasminogen activator inhibitor (PAI-1), fibrinogen, and coagulation factors (II, V, VII, VIII, and X). After 7 days of administration of oxandrolone, the plasma plasminogen level significantly increased significantly. PAI-1 was significantly decreased at day 3. Coagulation factors II and V significantly increased at day 14, respectively. Factor VII level decreased (not significantly) by day 3, but after 14 days factor VII level returned to baseline. The increase of factor VIII level was not significant. Factor X increased steadily over 14 days of drug treatment and after discontinuation, decreased and returned to baseline by day 42. Fibrinogen decreased by 22 ± 12 percent. Administration of oxandrolone, to healthy young men was thus associated with a significant increase in select blood coagulation factors and plasminogen. These changes create a state of potential hypercoagulability that appears to be counterbalanced by increased fibrinolytic activity to maintain homeostasis [06073].

Suppression of clotting factors II, V, VII, and X and bleeding in patients receiving concomitant anticoagulant therapy have been reported with testosterone. Case reports demonstrated that coadministration of oral anticoagulants and 17-alkylated androgens (fluoxymesterone, oxandrolone, oxymetholone, methyltestosterone, methandrostenolone, stanozolol) resulted
in a prolonged prothrombin time and hemorrhages; AASs may reduce the need for therapeutic anticoagulants by 25 percent [07058].

Anabolic androgenic steroids (AAS) are synthetic derivatives of testosterone with thrombogenic potential in high doses and long-term administration. Taurine, a widely distributed amino-sulfonic acid, is known for its beneficial effects in hypercoagulable states. In order to assess the impact of chronic administration of high doses of AAS and taurine upon haemostasis process in rats, 40 male Wistar rats were divided into four equal groups: control group (group C) – no treatment; androgen group (group A) – received 10 mg/kg per week of nandrolone decanoate (DECA); taurine (group T) – received oral supplementation of 2 percent taurine in drinking water; androgen and taurine group (group AT) – concomitant administration of DECA and taurine. After 12 weeks, blood samples were collected and haemostasis parameters were assessed with the thrombelastographic (TEG) analysis system: reaction time, clot kinetics (K, alpha), final clot strength, coagulation index and the clot lysis (Ly30). Nandrolone significantly decreased reaction time in group A compared with control, whereas taurine significantly increased reaction time, the effect was maintained in group AT compared with group A. Similar differences between groups have been recorded for the clot kinetics parameters K, alpha. The final clot strength and coagulation index were significantly increased in group A versus group C, but not in group AT versus group C. There were no differences in clot lysis, as shown by Ly30. Nandrolone produces an accelerated clot development and an increased clot firmness in Wistar rats. Taurine association ensures a protective effect against this hypercoagulable state, partially restoring the altered parameters of the coagulation profile [12131].

**Altered coagulation profile**

Anabolic androgenic steroids (AAS) are synthetic derivatives of testosterone with thrombogenic potential in high doses and long-term administration. Taurine, a widely distributed amino-sulfonic acid, is known for its beneficial effects in hypercoagulable states. In order to assess the impact of chronic administration of high doses of AAS and taurine upon haemostasis process in rats, 40 male Wistar rats were divided into four equal groups: control group (group C) – no treatment; androgen group (group A) – received 10 mg/kg per week of nandrolone decanoate (DECA); taurine (group T) – received oral supplementation of 2% taurine in drinking water; androgen and taurine group (group AT) – concomitant administration of DECA and taurine. After 12 weeks, blood samples were collected and haemostasis parameters were assessed with the thrombelastographic (TEG) analysis system: reaction time, clot kinetics (K, alpha), final clot strength, coagulation index and the clot lysis (Ly30). Nandrolone significantly decreased reaction time in group A compared with control, whereas taurine significantly increased reaction time, and this effect was maintained in group AT compared with group A. Similar differences between groups have been recorded for the clot kinetics parameters K, alpha. The final clot strength and coagulation index were significantly increased in group A versus group C but not in group AT versus group C. There were no differences in clot lysis, as shown by Ly30. Nandrolone produces an accelerated clot development and an increased clot firmness in Wistar rats. Taurine association ensures a protective effect against this hypercoagulable state, partially restoring the altered parameters of the coagulation profile [13138].

**Arterial thrombosis**

The use of supraphysiological doses of anabolic androgenic steroids can have serious side effects. One article reports the case of a young man who suffered potentially life-threatening arterial thromboses following the use of these drugs [13135].
Thrombosis

It was presented a case of a 19-year-old male athlete with protein C deficiency who developed proximal deep venous thrombosis and pulmonary embolism while abusing anabolic-androgenic steroids. Anabolic-androgenic steroids have been reported to have anticoagulatory and profibrinolytic effects in patients with protein C deficiency. Despite these antithrombotic effects, the patient developed repeated venous thromboembolism during treatment with low-molecular-weight heparin. The net effect of anabolic-androgenic steroids on the haemostatic system may change from antithrombotic to prothrombotic in male abusers of anabolic steroids with protein C deficiency [10065].

Cerebral venous thrombosis

There are only a few reports of patients developing cerebral venous sinus thrombosis (CVST) after androgen therapy. It was presented a young man who developed cortical venous thrombosis after using androgens to increase muscle mass. He was hospitalised for paraesthesia and dyspraxia in the left hand followed by a generalised tonic-clonic seizure. At admission, he was drowsy, not fully orientated, had sensory inattention, pronation drift and a positive extensor response, all on the left side. The patient had been using anabolic steroids (dianabol 20 mg/day) for the last month for bodybuilding. CT angiography showed a right cortical venous thrombosis. Anticoagulation therapy was started with intravenous heparin for 11 days and oral anticoagulation (warfarin) thereafter. A control CT angiography 4 months later showed resolution of the thrombosis. He recovered fully [13148].

Pulmonary embolism

It was presented case of a 56-year-old man with deep vein thrombosis (DVT) and pulmonary embolism (PE). He had been given intramuscular injections of testosterone and the anabolic-androgenic steroid nandrolone, due to a muscle injury, a total of three times prior to manifestation of the symptoms. An ultrasonographic examination of the right leg revealed a DVT and computed tomography of the pulmonary arteries showed PE. The thromboembolic episodes in this previously healthy patient were in all probability associated with intramuscular injections of testosterone and nandrolone, to which there is a clear correlation in time [07070].

Endothelial cells

The aim of one study was to investigate the effects in vitro induced by androgenic anabolic steroids (AAS) (testosterone, nandrolone, androstenedione, norandrostenedione, and norandrostenediol) used illicitly in sport competitions, on the proliferation ability, apoptosis and the intracellular calcium concentration ([Ca\(^{2+}\)]\(_i\)) in human umbilical vein endothelial cells (HUVECs), selected as a prototype of a biological target system whose structure and function can be affected by steroids. For this purpose, it was evaluated the proliferation inhibition by cytotoxic assay expressed as the concentration of drug inducing a 50 percent decrease in growth (IC\(_{50}\)). The IC\(_{50}\) was reached for testosterone at 100 microM, androstenedione at 375 microM, nandrolone at 9 microM, norandrostenedione at 500 microM. The IC\(_{50}\) value for norandrostenediol was not reached until a concentration of 6000 microM. The apoptotic effect was evaluated by flow cytometry at IC\(_{50}\) for each drug. It was observed that testosterone induced 31 percent of apoptotic cells, norandrostenedione 25 percent, androstenedione 15 percent and nandrolone 18 percent. It was analyzed the effects of these drugs on [Ca\(^{2+}\)]\(_i\) both in the immediate and long-term continuous presence of each compound. The data show a statistically significant increase of [Ca\(^{2+}\)]\(_i\) in the acute condition and in long-term treated cultures, suggesting that androgen steroids modulate intracellular
levels of calcium independent of incubation time or compound identity. As a whole, the study demonstrates that AAS might alter endothelial homeostasis, predisposing to the early endothelial cell activation that is responsible for vascular complications observed frequently in AAS users [07067].

Atherothrombotic markers and endothelial dysfunction
The use of androgenic anabolic steroids (AAS) may be associated with changes in atherothrombotic markers and endothelial function. The purpose of one study was to compare atherothrombotic markers and endothelial function of AAS users and non-users. Ten athletes who were users of AAS (confirmed by urine analysis) and 12 non-user athletes were evaluated. Body weight, blood pressure, exercise load (hours/week), complete blood count (CBC), platelets, fibrinogen, lipids, high-sensitivity C-reactive protein (hs-CRP), follicle-stimulating hormone, testosterone and estradiol were measured. Endothelium-dependent and independent functions were assessed by brachial artery ultrasound. AAS users had significantly higher body mass and blood pressure. Platelet count was higher whereas HDL-cholesterol was lower in AAS users compared with non-users. Levels of hs-CRP were higher in AAS users. Follicle-stimulating hormone was suppressed in all users and not suppressed in non-users. Compared with non-users, flow-mediated dilation was significantly reduced in AAS users, whereas endothelium-independent function was similar in both groups. Additionally, flow-mediated dilation was positively associated with levels of HDL-cholesterol. AAS users present important changes in blood lipids as well as in inflammatory markers, which are compatible with increased cardiovascular risk. Furthermore, this profile is accompanied by a reduction in the endothelial function [13137].

Increased intima-media thickness
AS use has also been associated with reduced endothelial function in conduit arteries. It was noted a reduced flow-mediated dilation in AS users as well as a reduced vasodilator response to glyceryl-trinitrate [12114].

It has been measured carotid intima-media thickness and radial and brachial artery reactivity in bodybuilders using AAS. It was found a non-significant increase in the thickness and diameter of the arteries in users compared to non-users, which was attributed mainly to fluid retention. A small degree of endothelial dysfunction was also reported by other investigators. It was also found changes of aortic wall elasticity in athletes who used steroids. Moreover, using an electron beam tomography system, it was found increased calcium deposition in the coronary arteries of bodybuilders using AAS. The authors hypothesised that this was due to a direct toxic or inflammatory effect of steroids on the vascular endothelium [12126].

Aortic elasticity
The use of anabolic-androgenic steroids (AAS) has been linked to acute cardiovascular events in athletes. The purpose of the present study was to investigate the aortic elastic properties in athletes who had been self-administering AAS compared with a group of athletes not using these drugs. Fourteen male bodybuilders using AAS and 27 male wrestlers (non-users) volunteered to the study. All subjects were placed in a mild recumbent position and the ascending aorta was recorded in the two-dimensional guided M-mode tracings. The aortic distensibility was found to be reduced in user athletes. The results of this study indicate that aortic stiffness is increasing in athletes using AAS [07068].

Arterial hypertension
Significant research attention has focused on the impact of AS use on cardiovascular (CV) disease risk factors namely blood pressure, lipid profile, left ventricular (LV) mass, cardiac function and arterial function. Elevated systemic arterial blood pressure is associated with an increased CV disease risk. Compared to healthy controls, AS users have increased resting and exercise systolic blood pressure. Conversely, other studies have not observed increased blood pressure in AS user. Differences in the training level of the participants along with age could be responsible for the differences seen in these studies [12114].

Although not shown in all studies, an association between elevated blood pressure and AAS abuse has been reported. Enhanced reactivity of the vasculature to norepinephrine, increased plasma renin activity, stimulation of aldosterone production by testosterone, and sodium retention by the kidneys are suggested mechanisms for high blood pressure following AAS use in athletes. Blood pressure response to androgen use typically shows a dose-response relation. The effects of AAS abuse on blood pressure may persist for long periods; some studies have shown persistent elevations for 5 to 12 months after discontinuing steroids [12119].

In experimental studies it has been found that the administration of AAS leads to hypertension. An increase in the secretion of 11-deoxycorticosterone, norepinephrine, renin, or aldosterone has been implicated as a possible mechanism, while others have noted an increase in cardiac output and peripheral resistances. However, clinical studies in athletes have led to conflicting results. Some observed a significant increase in both systolic and diastolic blood pressure, whereas others noted only the latter. It has been attributed the increase in blood pressure in steroid-using athletes to an increase in plasma volume. In contrast, other authors found no significant increase in blood pressure at rest or during exercise in athletes who used steroids compared to non-users [12126].

Systemic hypertension is a side effect of medical steroid administration and may require antihypertensive therapy; therefore, high-dose ASA use also should result in systemic hypertension. This is found in some reports, but not consistently. AAS-induced hypertension may be related to vascular endothelial response, increased responsiveness to catecholamines, and increased renin production. The magnitude and incidence of hypertension likely are related to dosage and to the specific AAS [07058].

Other vascular effects

Reported severe adverse effects of anabolic-androgenic steroid use include cerebral venous sinus thrombosis, ischemic cerebral stroke, and cardiovascular events in the absence of risk factors. Two cases of limb-threatening arterial thrombosis were reported with the use of danazol (Danocrine®), an antigonadotropin steroid-like compound with weak anabolic properties [07031].

Lipid profile influence early atherogenesis. Therapeutic use of AAS has been shown in many studies to affect the individuals’ lipid profile. A meta-analysis including 19 studies and comprising 272 hypogonadal men showed that substitution therapy with intramuscularly administered testosterone results in a decrease in plasma HDL cholesterol levels. The same results were also demonstrated in a recent meta-analysis including 51 studies on men with low or low-to-normal plasma testosterone levels who received testosterone in different doses as therapy. Moreover, high-dose AAS abuse has been demonstrated to exert unfavourable direct and indirect effects, through AAS-associated hyperhomocysteinaemia, on plasma lipid levels. In a nonblinded investigation on 19 bodybuilders, short-term (8 weeks) and long-term (> 14 weeks) high dosages of AAS administration markedly reduced HDL cholesterol. The
suppressive effects of AAS administration on HDL plasma levels are dose dependent and depending on the type of AAS and route of administration can result in decrement of 40-70 percent. The adverse effects of high AAS dosages on plasma levels of LDL cholesterol have been shown in animal and human studies. Lipid profile impairment is causally implicated in vascular wall injury by promoting inflammatory processes in the arterial wall, macrophage recruitment, and uptake of LDL and oxidized LDL by macrophages which results in foam cell formation. The aforementioned processes, which contribute to establishment and progression of atherosclerotic plaques, can be depicted by molecular imaging techniques. $^{18}$F-fluorodeoxyglucose ($^{18}$F-FDG) positron emission tomography (PET) has been studied in a notable number of investigations and has been shown to correlate with the macrophage density in atherosclerotic plaques in humans and in animal models. Additionally, $^{18}$F-FDG PET depicts MI subsequent to coronary atherosclerosis. Molecular targeting of oxidized LDL and macrophage uptake of radiolabelled LDL has verified promising targets for visualizing vulnerable atherosclerotic plaques. Moreover, a recent pilot study reported feasibility of ultrasmall superparamagnetic particles of iron oxide (USPIO) in detecting inflammation in endothelial cells during atherogenesis with magnetic resonance imaging (MRI) [12125].

**Impaired vasodilatation**

Although endogenous testosterone has been shown to exert vasodilatory effects, AAS use in hypogonadal men has been shown to result in paradoxical pro-atherogenic vasoconstrictive effects. It was shown that testosterone therapy in hypogonadal men is correlated with impaired vasodilation, independently from lipid profile measures. Supraphysiological doses of AAS have also shown to exert similar effects on vasoreactivity in human and animal studies. In a study on male bodybuilders who abused AAS for 3-4 years, vasodilatation was significantly lower than that of ex-abusers and controls. AAS abuse in bodybuilders independently of the other factors impaired endothelium-independent vasodilator pathways. It was also shown that a 3-month period of abstinence results in a degree of improvement in vascular function. Moreover, longterm therapy with supraphysiological doses of AAS in female-to-male transsexuals has shown to result in decreased vasodilation independent of the effects of age, lipid profile and vessel size. The mechanisms through which AAS induces deleterious effects on vasodilatation are not sufficiently investigated. However, endothelial injury as a result of lipid profile alterations and establishment of atherosclerosis could explain the impairment in endothelium-dependent pathway through decreased NO production [12125].

**Stroke**

Anabolic-androgenic steroids are synthetic substances derived from testosterone that are employed for their trophic effect on muscle tissue, among other uses. Their consumption can give trigger a series of adverse side effects on the body, including the suppression of the hypothalamus-pituitary-gonadal axis as well as liver, psychiatric and cardiovascular disorders. The most common effects are altered fat profiles and blood pressure values, cardiac remodelling, arrhythmias or myocardial infarcts. It was reported a case of a young male, with a background of anabolic-androgenic steroids abuse, who visited because of an acute neurological focus in the right hemisphere related with an ischaemic stroke. The aetiological study, including cardiac monitoring, echocardiograph and imaging studies (magnetic resonance and arteriography) and lab findings (thrombophilia, serology, autoimmunity, tumour markers) showed no alterations. Thus, the association between consumption of anabolic-androgenic steroids and cardiovascular pathologies is known, but its relation with cerebrovascular disease has not received so much attention from researchers [13128].

**Summary of metabolic and vascular effects of anabolic steroids**

In summary, metabolic and vascular adverse effects of AAS abuse can be classified as
alterations in the lipid profile, especially decreased serum HDL levels and hyperhomocysteinaemia contributing to endothelial damage
- increased platelets adhesion to vascular wall
- vasospastic effects and impaired vasodilatation

**Experimental**

The objectives of one study were to investigate the time-course and the cellular, ionic and molecular processes underlying ventricular repolarization in rats chronically treated with AAS. Male Wistar rats were treated weekly for 8 weeks with 10 mg/kg of nandrolone decanoate (n=21) or vehicle (n=20). ECG was recorded weekly. Action potential and transient outward potassium current (I_{to}) were recorded in rat hearts. Expression of KChIP2, Kv1.4, Kv4.2, and Kv4.3 was assessed by real-time PCR. Hematoxylin/eosin and Picrosirius red staining were used for histological analysis. QTc was greater in the DECA group. After nandrolone treatment the left, but not right, ventricle showed a longer AP duration than did the control. I_{to} current densities were 48 percent lower in the left but not in the right ventricle after nandrolone. In the right ventricle the I_{to} inactivation time-course was slower than in the control group. After nandrolone the left ventricle showed lower KChIP2 (approximately 26 %), Kv1.4 (approximately 23 %) and 4.3 (approximately 70 %) expression while the Kv 4.2 increased in 4 (approximately 250 %) and diminished in 3 (approximately 30 %) animals of this group. In the right ventricle the expression of I_{to} subunits was similar between the treatment and control groups. Nandrolone-treated hearts had 25 percent fewer nuclei and greater nuclei diameters in both ventricles. The results strongly suggest that supra-physiological doses of AAS induce morphological remodeling in both ventricles. However, the electrical remodeling was mainly observed in the left ventricle [10328].

**Cardiovascular effects of low androgens**

Interestingly, if androgen levels are too low, cardiac risk may increase. Androgen-deprivation therapy (ADT) is a widely used treatment for prostate cancer, and several studies have reported an association between ADT and an increased risk of myocardial infarction and cardiovascular mortality. Antiandrogens (e.g. flutamide, bicalutamide) block the binding of androgen to its receptor, and they are often coupled with gonadotropin-releasing hormone (GnRH) agonists (e.g. leuprolide, goserelin, triptorelin). In one population-based Medicare study, the use of a GnRH agonist in men with prostate cancer for at least 1 to 4 months was associated with an increased risk of incident coronary heart disease (adjusted hazard ratio, HR, 1.16), myocardial infarction (adjusted HR), and sudden cardiac death or life-threatening ventricular arrhythmia (adjusted HR 1.16). Another population based study noted that the use of ADT was associated with a 20 percent higher risk of cardiovascular morbidity (HR 1.20) during 5 years of follow-up. In addition, androgen deficiency has been associated with cardiovascular risk factors by causing increased serum total cholesterol, low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, and triglycerides. There is also an association between low androgen levels and an adverse metabolic profile (insulin resistance, metabolic syndrome, and diabetes) [12119].

**Summaries of effects of anabolic steroids on the heart**

To sum up, the myocardial effects of AAS abuse can be summarized in three different categories including [125]:

[12125]:

- alterations in the lipid profile, especially decreased serum HDL levels and hyperhomocysteinaemia contributing to endothelial damage
- increased platelets adhesion to vascular wall
- vasospastic effects and impaired vasodilatation
- myocardial hypertrophy as result of
  o elevated muscle sympathetic nerve activity
  o direct anabolic effects of AAS
  o renin-angiotensin system activity induced collagen deposition and interstitial fibrosis
- left ventricular dysfunction as result of
  o AAS-induced myocardial hypertrophy
  o mitochondrial damage and apoptosis as consequences of Ca\(^{2+}\) signaling
  o rennin-angiotensin system activity and fibrosis
- cardiac arrhythmias as result of increased myocardial mass and reduction

Some physiological effects of anabolic-androgen steroids were summarized [12119]:

**Increased risk of diabetes**

Anabolic steroids decrease glucose tolerance and increase insulin resistance, which lead to hyperinsulinism and secondary diabetes mellitus with type II symptoms [07058].

The case of a 36-year-old male professional bodybuilder was reported. He presented to the accident and emergency department with right upper quadrant pain. This was on the background of a 15-year history of anabolic steroid and growth hormone misuse. Examination revealed mild hepatomegaly and a random blood sugar of 30.2 mmol/L. There was no evidence of ketonuria or acidosis. Biochemical evidence of hepatitis was found, and the patient was in acute renal failure. He was given a sliding scale of insulin and an intravenous infusion of crystalloid. The hepatitis and hyperglycaemia settled with conservative treatment. It is believed that this is the first reported case of frank diabetes precipitated by supraphysiological recreational growth hormone misuse [07069].

A 33-year-old male presented to the emergency department with complaints of polydipsia, polyuria, nausea, headaches, blurry vision and malaise. Lab work revealed a serum glucose level of 1166 mg/dl (64.8 mmol/L). The patient admitted to completing a cycle of androgenic anabolic steroids (AASs) for bodybuilding. His regimen consisted of supraphysiologic intramuscular injections of a bovine growth hormone, trenbolone acetate and testosterone. The patient received intravenous fluids and insulin to restore metabolic balance. Previously healthy with a non-contributory family history, he was diagnosed with new onset diabetes.
Discussion: It has been demonstrated that AAS use, specifically growth hormone, can affect glucose homeostasis through increasing cellular insulin resistance and reducing glucose uptake. Excess growth hormone has been shown to cause symptoms of acromegaly which predisposes up to 40% of patients to diabetes. As trenbolone acetate is not indicated for human use and athletes are known to use supraphysiologic doses of this underground, performance enhancing drug, the correlation of the timing of events and the use of this veterinary growth hormone likely exacerbated an underlying condition or caused this new onset diabetes. It was reported a case of a young bodybuilder with no significant past medical history who was diagnosed with new onset diabetes associated with supraphysiologic self-injections of the bovine growth hormone, trenbolone acetate, combined with testosterone. AAS have the potential to induce or exacerbate diabetic conditions due to decreased glucose tolerance and increased insulin resistance [11094].

Effects on the brain

The misuse of anabolic androgenic steroids has in several reports been associated with effects resulting in altered behavior. One study used the Morris water maze task to investigate the effect of high doses of the anabolic androgenic steroid nandrolone on spatial learning and memory in male rats. During the experiment, it was observed a significantly impaired Morris water maze performance in the nandrolone-treated rats compared with controls. The hippocampus, a brain region associated with cognitive function, was analyzed for mRNA expression of prodynorphin, the precursor of dynorphinergic peptides. The results indicated that the transcription levels of prodynorphin were significantly elevated in the animals treated with nandrolone compared with controls. Thus, the findings suggest that administration of nandrolone to male rats impairs memory function, possibly via dynorphinergic actions [09059].

Anabolic androgenic steroids and high testosterone doses have been reported to induce impulsive behavior in man and behavioral disinhibition in rats. The purpose of the present study was to investigate whether aromatization of testosterone to estradiol is of importance for the behavioral disinhibiting effect of a high testosterone dose in adult male rats. Testosterone administered via five testosterone-filled silastic capsules implanted subcutaneously to non-castrated, group-housed rats for six days induced behavioral disinhibition in a modified Vogel's drinking conflict model and yielded supraphysiological serum levels of testosterone and increased accessory sex organ weights. Moreover, concurrent administration of the aromatase inhibitor 1,4,6-androstatriene-3,17-dione (ATD; 60 mg/kg/day s.c.) decreased behavioral disinhibition in testosterone-treated rats (without affecting accessory sex organ weights) while behavior was not significantly affected in sham-treated animals. Since some reports indicate that ATD, in addition to inhibit aromatase, also may affect the binding of testosterone to the androgen receptor, the effect of the non-steroidal androgen receptor antagonist flutamide was investigated. Flutamide treatment did not affect disinhibited behavior in testosterone-treated rats. However, in sham-treated animals, flutamide (50 mg/kg/day) produced behavioral disinhibition. These results suggest that estradiol is of importance in the mechanisms underlying behavioral disinhibition in non-castrated rats treated with a high testosterone dose. Speculatively, aromatization may be involved in pro-impulsive effects of high testosterone doses in humans [09060].

Several case reports associated chronic AAS abuse with the development of seizures, ischemic midbrain lesions with residual dysfunction (hemiparesis, aphasia, and dysarthria), and thrombotic strokes, but the causal link between cerebrovascular accidents and chronic AAS abuse is unproven. A 34-year old bodybuilder developed an acute right hemiparesis is a dysarthria after using various AASs for 4 years. He had a simple partial seizure. At discharge,
he had mild motor weakness in the right upper extremity with no sensory changes. A 21-year old man developed a generalized tonic-clonic seizure, left-sided hemiparesis after using 6-8 mg ethylestrenol daily for 6 weeks. Angiography demonstrated an occlusion of the right anterior cerebral and right middle cerebral arteries. In a retrospective cohort study of 248 patients who tested positive for the presence of AAS in connection with receiving medical care, the incidence of unspecified convulsions was increased in the AAS-positive group (RR 54) when compared with controls (i.e. patients testing negative for AAS at the same institution). One of the AAS-positive patients with seizures died. However, there are few data from cohort or case-control studies to confirm the causal link between AAS abuse and seizures [13003].

**Brain development**

Puberty is a critical period for brain maturation that is highly dependent on gonadal sex hormones. Modifications in the gonadal steroid environment, via the use of anabolic androgenic steroids (AAS), have been shown to affect brain development and behavior. Studies in both humans and animal models indicate that AAS exposure during adolescence alters normal brain remodeling, including structural changes and neurotransmitter function. The most commonly reported behavioral effect is an increase in aggression. Evidence has been presented to identify factors that influence the effect of AAS on the expression of aggression. The chemical composition of the AAS plays a major role in determining whether aggression is displayed, with testosterone being the most effective. The hormonal context, the environmental context, physical provocation and the perceived threat during the social encounter have all been found to influence the expression of aggression and sexual behavior. All of these factors point toward an altered behavioral state that includes an increased readiness to respond to a social encounter with heightened vigilance, and enhanced motivation. This AAS-induced state may be defined as emboldenment. The evidence suggests that the use of AAS during this critical period of development may increase the risk for maladaptive behaviors along with neurological disorders [12133].

**Cerebral infarction**

Anabolic androgenic steroid (AAS) abuse has increased among athletes in recent years. However, AAS abuse can increase hypercoagulopathy and cause cerebrovascular disease. We report a case of a 27-year-old man who had right hemiparesis, hemianopia, dysarthria, and double vision in the middle of muscle training. He suspected acute disseminated encephalomyelitis at first, because of a preceding respiratory infection. However, extensive work-up was performed, including brain magnetic resonance imaging, transcranial Doppler and transesophageal echocardiography, confirming the final diagnosis of cardioembolic stroke. Physicians should be aware that cerebrovascular disease may be a side effect of AAS, even in younger populations [12134].

**Brain nerve growth factor**

Anabolic androgenic steroids (AASs) are synthetic androgen-like compounds which are abused in sport communities despite their side effects. Nerve growth factor (NGF) influences neuronal differentiation and survival, and also mediates higher brain functions such as learning and memory. Changes in NGF expression have been implicated in neurodegenerative disorders, including Alzheimer's disease. Hence, we decided to study the effect of chronic AASs exposure on brain NGF profile, NGF-dependent cholinergic function and related behavioral performance. Male Wistar rats were injected for 4 weeks with either nandrolone or stanozolol at daily doses (5.0 mg/kg, s.c.) that are considered equivalent to
those abused by humans. NGF levels and NGF receptor (TrkA and p75NTR) expression were measured in the hippocampus and in the basal forebrain. Choline acetyltransferase expression was evaluated in basal forebrain. Spatial learning and memory were assessed using the Morris water maze. AASs treatment caused region-specific changes in the expression of NGF and its receptors. Both nandrolone and stanozolol increased NGF levels in the hippocampus and reduced NGF levels in the basal forebrain, reduced p75NTR expression in the hippocampus, and failed to affect TrkA expression in the basal forebrain. Finally, AASs treatment reduced the expression of choline acetyltransferase in the basal forebrain and impaired the behavioral performance in the Morris water maze. The evidence that supraphysiologic doses of AASs cause neurotrophic unbalance and related behavioral disturbances, raises the concern that AASs abuse in humans may affect mechanisms that lie at the core of neuronal plasticity [12132].

Decreased memory

Chronic exposure to the anabolic androgenic steroids (AAS) nandrolone decanoate (ND) in supra-physiological doses is associated with learning and memory impairments. Given the well-known beneficial effects of voluntary exercise on cognitive functions, it was examined whether voluntary exercise would improve the cognitive deficits induced by chronic administration of ND. It was also investigated the effects of ND and voluntary exercise on hippocampal BDNF levels. The rats were randomly distributed into 4 experimental groups: the vehicle-sedentary group, the ND-sedentary group, the vehicle-exercise group, and the ND-exercise group. The vehicle-exercise and the ND-exercise groups were allowed to freely exercise in a running wheel for 15 days. The vehicle-sedentary and the ND-sedentary groups were kept sedentary for the same period. Vehicle or ND injections were started 14 days prior to the voluntary exercise and continued throughout the 15 days of voluntary exercise. After the 15-day period, the rats were trained and tested on a water maze spatial task using four trials per day for 5 consecutive days followed by a probe trial two days later. Exercise significantly improved performance during both the training and retention of the water maze task, and enhanced hippocampal BDNF. ND impaired spatial learning and memory, and this effect was not rescued by exercise. ND also potentiated the exercise-induced increase in hippocampal BDNF levels. These results seem to indicate that voluntary exercise is unable to improve the disruption of cognitive functions by chronic ND. Moreover, increased levels of BDNF may play a role in ND-induced impairments in learning and memory. The harmful effects of ND and other AAS on learning and memory should be taken into account when athletes decide to use AAS for performance or body image improvement [12135].

Anabolic-androgenic steroids (AAS) are used in the medical treatment of many disorders. Erythropoietin (EPO) is a hematopoietic cytokine that has anti-apoptotic, anti-oxidative, and anti-inflammatory effects. The aim of one study was to investigate the neuroprotective effects of EPO in the hippocampus, parietal cortex and prefrontal cortex, in brain damage due to nandrolone decanoate. Thirty-five Wistar male rats were randomly divided into: (1) control group, (2) sham group, (3) nandrolone decanoate group (ND, intramuscular, 10mg/(kg week), 8 weeks), (4) ND+low dose EPO treated group (ND+L-EPO) and (5) ND+high dose EPO treated group (ND+H-EPO). EPO was administrated by intraperitoneal injection at a dose of 100U/(kg day) for L-EPO treatment and at a dose of 500 U/(kg day) for H-EPO treatment during 8 weeks. The number of neurons of CA1, CA2, CA3 and dentate gyrus of hippocampus, parietal cortex and prefrontal cortex were significantly less in the ND group compared with the control group. Treatment with H-EPO significantly preserved the number of neurons in hippocampus when compared with ND administrated. Besides, H-EPO treatment decreased the number of TUNEL-positive and active caspase-3 positive cells and MDA levels and increased GPx levels when compared to ND group. In conclusion, abuse of AAS causes reduction in the number of neurons in hippocampus, parietal cortex and
prefrontal cortex regions and increases oxidative damage and therefore H-EPO may be useful as a neuroprotective agent in brain injury [12136].

Mania

Anabolic androgenic steroids (AASs have been associated with several major psychiatric symptoms and disorders such as violence, aggression, suicidal tendency, psychotic deterioration, cognitive impairment, depression, and mania. Among these, manic symptoms were considered to be the most frequent, as shown by a clinical trial with testosterone cypionate and a controlled study that analyzed a population of AAS-using athletes. The synthetic male sex hormone mesterolone has even been tested as an antidepressant in clinical studies in the 1980s. These studies, however, yielded inconsistent results. Here it was reported the development of a manic episode subsequent to oral intake of mesterolone in a previously mentally healthy person. The 38-year-old white patient was admitted to a psychiatric ward because of a maniform syndrome that was present for approximately 2 weeks. On admission, he demonstrated with disturbed contact behavior, logorrhea, incoherent thinking with flight of ideas, reduced attention and appetite, increase of impulse, euphoric mood, and reduced need to sleep. There were no overt psychotic phenomena in terms of megalomania or delusion. Physical examination was unremarkable (body weight, 96 kg; height, 178 cm; body mass index, 30.3 kg/m²) apart from hypertrophic upper body musculature. Evidence for previous psychiatric disorders, especially history of an addictive disorder or abuse of psychotropic substances, was absent. Family history revealed major depressive disorder of the patient’s sister, mother, and aunt on the mother’s side. The patient was working as a car mechanic and had a stable partnership without children. On admission, routine blood examination including thyroid tests and urine drug screening (amphetamines, benzodiazepines, cannabinoids, cocaine, 3,4-methylenedioxymethamphetamine, opiates, tricyclic antidepressants) were unremarkable. Blood glucose levels as well as glycated hemoglobin (HbA₁₀) were within reference limits. Four days later, the patient suddenly reported to have used Proviron (mesterolone 25 mg/d) for muscle gain during the last 21 days before admission until the day of admission. He reported that he had been bodybuilding for more than 15 years and that he had never used any illicit substances, that is, from the group of AAS to enhance training effects before the use of mesterolone. As the initial urine samples were already discarded, urine was collected again (4 days after the last self-reported mesterolone intake) and analyzed for mesterolone metabolites (1alpha-methyl androsterone, 1alpha-methyl-5alpha-androstane-3alpha, 17beta-diol), but as expected in view of the short window for drug detection, these substances could no longer be detected by means of gas chromatography combined with high-resolution mass spectroscopy and liquid chromatography combined with mass spectroscopy. In addition, pituitary hormones were measured normal. To rule out an underlying somatic disease affecting the central nervous system (eg, encephalitis), electroencephalogram, magnetic resonance imaging of the brain, and examination of the cerebrospinal fluid were performed without pathological findings. Hence, a diagnosis of (putative) mesterolone-induced mania was made. Initially, the patient was treated with olanzapine that was gradually increased up to 30 mg/d. Because of a remarkable increase in liver enzymes, olanzapine was discontinued, and amisulpride was administered. Because the patient developed parkinsonism under amisulpride at a dosage of 800 mg/d and the antimanic effect was still insufficient, it was reduced amisulpride and administered lithium carbonate. Under treatment with lithium carbonate (lithium carbonate 1800 mg/d) and amisulpride (400 mg/d), the patient developed complete remission within 2 months of in-patient treatment. At follow-up 6 months after discharge, the patient was still without psychopathological findings. Mesterolone (1-methyl-dihydrotestosterone) is a relatively weak androgen with only partial androgenicity. Thus, it is rarely used for oral testosterone replacement therapy in male patients with hypogonadism associated with androgen deficiency. Although its application in medicine is rather infrequent, mesterolone is
still used in professional as well as in amateur sports to enhance training success, particularly regarding muscle hypertrophy, and thus, it can require medical treatment for the development of adverse effects, as in the case presented. To our knowledge, this is the first case report that describes the development of a manic episode related to the use of mesterolone. Considering the absence of other conclusive etiologic factors and the chronological coherence between the onset of AAS use and the development of psychiatric symptoms, mesterolone is the most plausible causal agent in the development of the manic episode. Taking into account the short elimination half-life of mesterolone (drug levels in serum decrease with a terminal half-life of 12-13 hours and 50 % of the orally applied dose is excreted in urine within 24 hours), absent proof of metabolites in the urine 4 days after the last intake does not speak against the use of mesterolone, rather being in full agreement with the patient’s reports. He was also able to show the Proviron medicine box in detail. He maintained his statements after remission of mania and came from the bodybuilding scene, so we had no reasons to believe that the patient had not told the truth about taking mesterolone; although, unfortunately, we were not able to prove its use. Apart from that, the patient’s positive family history of mood disorders certainly has posed an additional individual risk factor for the development of mania related to mesterolone use. Another aspect is the comparatively low dosage of mesterolone (175 mg/wk) and its short duration of use that was associated with the development of mania in our case, especially when compared to clinical and field studies that described effects of AAS on mood after significantly higher dosages (up to 600 mg testosterone cypionate per week or even up to 1000 mg testosterone per week) and longer application intervals (up to 6 weeks) [12137].

**Effects on GABA**

Anabolic androgenic steroids are synthetic derivatives of testosterone designed for therapeutic purposes, but now taken predominantly as drugs of abuse. The most common behavioral effects associated with anabolic androgenic steroid use are changes in anxiety, aggression and reproductive behaviors, including the onset of puberty and sexual receptivity. GABAergic circuits in the forebrain underlie these behaviors and are regulated by gonadal steroids. Work from one laboratories has shown that the expression and function of GABA_A receptors in the rat and mouse forebrain varies between the sexes and across the estrous cycle. It was also shown that there are significant changes in GABA_A receptor expression that occur with the progression through puberty to adulthood. Because GABAergic systems are both steroid-sensitive and critical for the expression of behaviors altered with anabolic androgenic steroid use, forebrain GABA(A) receptors are an attractive candidate to assess how molecular actions of anabolic androgenic steroids may be translated to known behavioral outcomes. The studies demonstrate that anabolic androgenic steroids elicit both acute modulation of GABA_A receptor-mediated currents, as well as chronic regulation of GABA_A receptor expression and forebrain GABAergic transmission. Because anabolic androgenic steroid use has now become prevalent not only among adolescent boys, but in an increasing number of adolescent girls, we have also been particularly interested in determining age- and sex-specific effects of anabolic androgenic steroids. The data show that the effects of chronic anabolic androgenic steroid exposure can be greater for adolescent than adult animals and are more marked in females than in males. These data have particularly important implications with respect to studies we have done demonstrating that chronic anabolic androgenic steroid exposure alters the onset of puberty, estrous cyclicity and sexual receptivity [06076].

**GABAergic neuroactive steroids**

Neurosteroids are synthesized in the brain and modulate brain excitability. There is increasing evidence of their sedative, anesthetic and antiseizure properties, as well as their
influence on mood. Currently neurosteroids are classified as pregnane neurosteroids (allopregnanolone and allotetrahydrodeoxycorticosterone), androstane neurosteroids (androstanediol and etiocholanone) or sulfated neurosteroids (pregnenolone sulfate and dehydroepiandrosterone sulfate). Both preclinical and clinical findings indicate that progesterone derivative neurosteroids such as allopregnanolone and allotetrahydrodeoxycorticosterone play a role in mood disorders. Clozapine and olanzapine, which were shown to be effective in stabilizing bipolar disorder, elevate pregnenolone levels in rat hippocampus, cerebral cortex, and serum. In lithium-treated mice, the blood levels of allopregnanolone and pregnenolone were elevated compared to control levels. Women diagnosed with bipolar disorder typically show symptomatic exacerbation in relation to the menstrual cycle, and show vulnerability to the onset or recurrence of mood disorders immediately after giving birth, when the levels of neurosteroid derivatives of progesterone drop. Whereas in women who had recovered from bipolar disorder, the plasma concentration of allopregnanolone was elevated compared to either healthy controls or women with major depressive disorder during the premenstrual period. During depressive episodes, blood level of allopregnanolone is low. Treatment with fluoxetine tends to stabilize the levels of neurosteroids in depression. These findings converge to suggest that these steroids have significant mood-stabilizing effect. This hypothesis is consistent with the observation that a number of anticonvulsants are effective therapies for bipolar disorder, a finding also consistent with the antiseizure properties of neurosteroids. Further exploration of action of neuroactive steroids is likely to open new frontiers in the investigation of the etiology and treatment of mood disorders, particularly bipolar disorders [12140].

**Rewarding systems**

Research findings regarding androgen abuse in people and hedonic effects of androgens in laboratory rats are reviewed. Androgens, like other steroids, can have traditional actions via cognate intracellular steroid receptors, as well as other substrates. Results indicate that testosterone (T) metabolites may have actions in part via gamma-aminobutyric acid (GABA_A)/benzodiazepine receptor complexes (GBRs) and/or dopaminergic neurons in the nucleus accumbens, to mediate T's positive hedonic states. This may provide the basis for positive reinforcing effects of androgen seeking and use behavior. Following a comprehensive review of the background literature, findings are presented that have explored the extent to which metabolites of T mediate euphorogenic effects of androgens by acting in the nucleus accumbens. Then results regarding whether GBRs are necessary substrates for androgens' positive hedonic effects are discussed. Lastly, research that addresses if dopaminergic neurons in the nucleus accumbens are necessary for these effects of androgens are discussed. This review provides a comprehensive examination of the hedonic properties and abuse/addiction potential of androgens and the putative mechanisms underlying these effects [06077].

**Monoygotic twins**

Anabolic androgenic steroids (AAS) are derived by chemical manipulation of the testosterone molecule. The specified category of drugs produces anabolic, androgenic and psycho-active effects including elevated aggressive, hostile, violent and anti social behavior. The objective of this case report observational study was to evaluate the possible psychological consequences of AS use in the twin user of each pair, compared with the non-user twin. It was studied two pairs of male monозygotic twins: one pair 24 years old and the other 31 years old, with absolute genome and phenotype similarity. One of the twins of each pair used AAS while the other did not. Both pairs lived in Hellenic provincial towns and followed a common training and nutrition regime. The psychometric instruments used were the
Symptoms Check List-90 (SCL-90) and the Hostility and Direction of Hostility Questionnaire (HDHQ). The psychometric evaluations took place within a time interval of 6 months. The study found high levels of aggressiveness, hostility, anxiety and paranoid ideation in the twins who used AS. The non-user twins showed no deviation from their initial status. The use of AAS induced several important psychiatric changes in monozygotic twins which were not present in the twin who did not use AAS [06078].

**Sleeping pattern**

Anabolic androgenic steroid (AAS) abuse has become a public health problem in many countries, and is associated with many psychiatric disorders. Epidemiological studies have also found increasing numbers of sleep disorders reported by individuals using AASs. The purpose of this study was to evaluate sleep patterns and disorders in anabolic androgenic users who practice resistance exercise. The sample comprised 58 males divided into three groups: 20 current AAS users aged 26, and 21 controls with no history of AAS use, aged 26, and 17 sedentary men with no sleep disorders aged 27. The volunteers spent a night in the sleep laboratory for polysomnography. Comparing the three groups, the user group showed significantly reduced sleep efficiency and more wakings after sleep onset than the sedentary group. The sedentary group showed a higher percentage of stage 4 than the non-users group. It was suggested that using of anabolic steroids reduced sleep efficiency and alters sleep architecture [07075].

**Psychologic and psychiatric effects**

*Human*

The objective of one study was to evaluate the psychological consequences of real-world AAS use in athletes abusing such agents, in comparison with a placebo and control group of comparable athletes, while correlating the severity of abuse with the side effects observed. The hypothesis tested by the study was that the use of AAS induces a wide range of psychological side effects whose impact and emergence is dependent upon the severity of the abuse. The study includes a substantial group of AAS abusing athletes and two more groups demographically similar to the first, one composed of athletes not using any substance and a placebo group. All athletes were stratified according to the severity of AAS abuse. Psychometric instruments were applied to all athletes in specific time intervals, dependent to the AAS abusers’ regimens, providing us with a final psychological profile that was to be compared to the pre-study profile. All results were comparable (within and between groups) for statistically significant differences and correlated to the severity of the abuse. Homogeneity of all groups was safeguarded by random doping controls, monitoring of drug levels and analysis of all self obtained drugs by method of liquid chromatography/mass spectrometry. All athletes were provided with a common exercise and dietary regime, so common training and nutritional conditions were achieved. It was studied a cohort of 320 body-building, amateur and recreational athletes, of whom 160 were active users of AAS (group C), 80 users administering placebo drugs (group B) and 80 not abusing any substance (Group A). Group C athletes were stratified according to AAS abuse parameters, thus providing us with three subgroups of "light, medium and heavy abuse". Athletes of groups A and B were included in a "no abuse" subgroup. The psychometric instruments used were the Symptoms Check List-90 (SCL-90) and the Hostility and Direction of Hostility Questionnaire (HDHQ). The psychometric evaluations took place within a time interval of 13 months. Statistical analysis was performed by using the Mann-Whitney/Wilcoxon two-sample non-parametric test (Kruskal-Wallis test for two groups) for data that were not normally distributed and Linear regression analysis was used to ascertain the correlation between severity of use and escalation of side effects. The study showed a statistically significant
increase in all psychometric subscales recorded in group C, and no statistically significant difference in group C and A. There was a significant increase in the scorings of group C for all subscales of SCL-90 and HDHQ. Correlation of abuse severity and side effects showed that there was a statistical significant increase in Delta values of all SCL-90 and HDHQ subscales that escalated from light abuse to medium and heavy abuse/consumption patterns. The results of the study suggest that the wide range of psychiatric side effects induced by the use of AAS is correlated to the severity of abuse and the force of these side effects intensifies as the abuse escalates [06075].

Muscle dysmorphia has been described as a disorder in which individuals are pathologically preoccupied with their muscularity. One study was designed to further investigate the symptom characteristics and psychiatric conditions associated with the disorder. Weight lifting males meeting current criteria for muscle dysmorphia (n=15), past muscle dysmorphia (n=8), and no history of muscle dysmorphia (n=28) responded to advertisements placed in gymnasium and nutrition stores. Structured and semistructured interviews were administered, as well as survey measures. Relative to controls, males with current muscle dysmorphia experienced more aversive symptoms related to the appearance of their bodies, including more often thinking about their muscularity, dissatisfaction with appearance, appearance checking, bodybuilding dependence, and functional impairment. Higher rates of mood and anxiety disorders were found among individuals with a history of muscle dysmorphia relative to individuals with no history of muscle dysmorphia. The findings suggest that muscle dysmorphia can be distinguished from normal weight lifting on a number of clinical dimensions. Muscle dysmorphia appears to be comorbid with other psychiatric conditions [08127].

The risks from chronic administration of anabolic steroids may appear relatively low when compared with the use of socially acceptable drugs such as tobacco and alcohol. The literature tends to rely heavily on specific case reports, identifying psychiatric or psychological disorder, because of the private and personal nature of the abuse of this class of drug [08128, 08129]. Anabolic androgen steroids self-administration have increased over the last decade, in the wake of the demonstration that steroids increase muscle mass and strength in healthy adult males, over and above resistance training [08130]. However, there may be other reasons why individuals abuse anabolic substances. Thirteen percent of 75 female weightlifters, who admitted to abusing androgenic anabolic steroids to gain muscle mass, had increased their weightlifting activities to be better able to defend themselves against men and also reported that they were previously sexually abused [08131]. It is believed that compulsive weightlifting and steroid abuse may represent a form of response to the trauma of sexual assault and also may assist in raising self-esteem. The psychiatric evaluation of dedicated female athletes also demonstrated the exhibition of ergogenic polysubstance dependence, often with significant co-morbidity [08132]. Fifty six percent demonstrated hypomania during the “administration-phase” and 40 percent reported depressive symptoms during withdrawal. These athletes also displayed several psychiatric syndromes, previously ill-defined, such as obsessive compulsive disorder, rigid dietary practice, nontraditional gender roles, and chronic dissatisfaction and preoccupation with their physiques (muscle dysmorphia) [08133].

Pagonis et al [08134] has shown in a study of 160 steroid-abusing athletes compared with 160 placebo and controls that the wide range of psychiatric side effects induced by the abuse of anabolic steroids is correlated to the severity of abuse. The force of these side effects intensifies as the abuse escalates. They have a distorted body image and reported the condition of “reverse anorexia”, where they believed they were small and weak, despite being large and muscular [08135]. The reasons for use of these anabolic agents appear to be based not only on peer review, but also scientific research [08042]. Low self-esteem and
unrealistic, muscular male body ideals, puts individuals at risk for negative body images and unhealthy eating and exercise habits. These individuals resort to drug-taking to counteract their altered body images [08133].

The psychiatric effects of anabolic-androgenic steroids (i.e. testosterone and its derivatives) have been less well studied than their physical effects but are reported to include depression, mania, psychosis, and aggression. Dependence can also occur, with withdrawal involving psychiatric and physical symptoms [07031].

The psychiatric effects of anabolic-androgenic steroids are hard to study, for several reasons. Many of the available studies are, by necessity, observational. But because the substances are illicit, users have no way to verify their exact nature or amounts taken. Moreover, many steroid users concomitantly take a multitude of other performance-enhancing drugs and dietary supplements that also may have psychiatric effects. Prospective studies are hard to carry out because of the ethical issues inherent in testing a potentially dangerous substance. Because many users belong to a subculture of bodybuilders, weightlifters, or elite athletes, study results are hard to extrapolate to the general public. Most studies to date have evaluated dosages lower than most users report taking. Further, users of anabolic-androgenic steroids tend to use them for prolonged and repeated cycles over many years, which is hard to recreate in clinical trials. More studies are needed on a larger scale with dosing that is compatible with the supraphysiologic dosages used in the community. In addition, pre-existing personality traits that might predispose people to use steroids may significantly confound assessing any psychiatric effects of drug use. Suspected risk factors for men include antisocial personality traits, low self-esteem, and poor body image (body dysmorphia). It was found that weightlifters and bodybuilders who used anabolic steroids had significantly higher scores on dimensions of pathologic narcissism and lower scores on ratings of empathy. Another study found that up to 50 percent of steroid users had worked as bouncers and described themselves as aggressive regardless of their drug use [07031].

Uncontrolled, observational trials in the 1930s and 1940s found that men with refractory depression responded favorably to testosterone treatment. However, randomized, placebo-controlled studies conducted in the 1980s were equivocal. Observational studies show hypomania, mania, and depression. It was retrospectively studied 164 weightlifters and bodybuilders who used anabolic-androgenic steroids and found that about 10 percent had hypomania. Depression occurred when steroids were stopped in about 10 percent. In another study it was interviewed 41 bodybuilders and football players taking anabolic-androgenic steroids and found that 9 displayed full affective syndromes and 5 showed psychotic symptoms. In a later study, it was compared 88 athletes who were using anabolic-androgenic steroids with 68 nonusers and found that 23 percent of the steroid users reported major mood symptoms (including mania, hypomania, and depression) versus only 6 percent of the nonusers, and several users reported aggressive thoughts. The higher the steroid dosage, the more severe were the psychiatric symptoms. It was conducted a similar study of weightlifters and found more symptoms of depression and mania among users of anabolic-androgenic steroids, although formal diagnoses were not made. In controlled studies, high dosages led to mood changes in some users. Studies with supraphysiologic doses of anabolic-androgenic steroids found minimal or no changes in mood in most users, but a minority of users had significant mood changes. In another randomized, placebo-controlled crossover trial, it was given injections of testosterone cypionate (Depotest®) to 56 men, gradually increasing the dosage to 600 mg/week. Most of the men showed no significant manic symptoms, but 6 (12 %) had mild hypomania and 2 (4 %) had marked hypomania. In yet another placebo-controlled, crossover prospective trial, oral methyltestosterone (Virilon®) 40 or 240 mg/day was given to 20 normal men. Those on the high dose had increased
positive mood changes (euphoria, increased energy, and sexual arousal) as well as negative mood changes (irritability, violent feelings, hostility, and distractibility). One man developed mania at the high dosage, and another developed hypomania. Physiologic doses have minimal mood effects. Studies of the effects of low or near-physiologic doses of anabolic-androgenic steroids found minimal effects on mood [07031].

Studies in mice have found aggressive behavior correlating with increasing dosages and duration of anabolic-androgenic steroid treatment, culminating in females killing their offspring. Observational studies of aggressive behavior changes in people taking steroids have been equivocal. Placebo-controlled studies using supraphysiologic doses of anabolic-androgenic steroids have also been equivocal. Physiologic doses do not enhance aggression. However, serum testosterone level correlates with aggressiveness [07031].

AAS use has been associated with self-reported changes in mood and behavior. One study identified psychiatric syndromes in weightlifters using AASs. Twenty-three percent of AAS users experienced major mood changes of mania, hypomania, or major depression. Also common in AAS users was aggressive behavior resulting in fights, domestic disturbances, assaults, and arrests. Data from the National Household Survey on Drug Abuse have demonstrated a strong association between AAS use and self-acknowledged acts of violence against people and crimes against property. In general, the behavioral effects of AASs are variable, short-lived on discontinuation, and seem to be related to the type and dosage of AAS. The potential for physical dependence upon AASs does exist. In one study of AAS users, 50 percent of them met the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition criteria for dependence or abuse of steroids. Deeply entrenched body dissatisfaction and body dysmorphic disorder may underlie a psychologic dependence. Clearly, the addictive potential of AASs cannot be [07008].

AASs induce a state of euphoria and diminished fatigue that enables prolongation of training sessions by users. Recent data may explain how AASs exert these psychoactive effects on the brain. It has been proposed that AAS-mediated acute and chronic changes in the gamma-aminobutyric acid (GABA) receptor system cause many of the known behavioral effects. For instance, the immediate effects of decreased anxiety and enhanced sense of well-being that are experienced by AAS users likely arise from enhancement of forebrain GABAergic circuits. In contrast, anxiety and aggression are the result of a down-regulation of GABA receptor expression secondary to chronic AAS exposure. Further study may reveal that expression of these behaviors is influenced by the age and gender of the AAS user and the particular chemical composition of the AAS administered [07008].

In a study in middle and high school students, 5 percent of boys and 3 percent of girls had used steroids in the previous year. Use in boys was associated with higher rates of depressed mood, prior suicide attempts, greater substance abuse, and lower self-esteem. Another study of adolescents suggested that steroid use was associated with other high-risk behaviors and was less likely to be an isolated behavior. Many case reports describe psychiatric symptoms in patients using AASs. Reports of suicide include at least one patient who did not have a personal or family history of depression or suicidal behaviors. In one series of eight suicides in AAS users from Sweden, collateral information was sought, and when possible, “psychologic autopsies” were performed. Retrospectively, psychiatric symptoms, such as irritability, aggressiveness (“roid rage”), mood swings, decreased impulse control, and increased energy were noted during AAS use; however, the series included men who had prior psychiatric syndromes, personality disorders, and other substance abuse. Another report showed homicidal or near homicidal behavior in three men during AAS use. None had a history of psychiatric illness or violence before AAS use, and all met the Diagnostic and Statistical Manual of Mental Disorders, Revised Third Edition criteria for
manic episode during use. Two of the three men experienced depression and suicidal ideation upon the abrupt discontinuation of use. Although it is tempting to attribute this behavior to AAS use, this is a small set of case studies and as the investigators note, legal ramifications for the patients may have led to exaggeration in their reports. A series of 34 deaths of AAS users revealed nine victims of homicide, 11 suicides, 12 accidental deaths, and 2 deaths of indeterminate cause. The homicide victims showed high levels of aggression; in most of the suicide and accidental deaths, impulsive and violent behaviors had been noted by family or physicians. Most of the cases of accidental death were related to polysubstance overdose; four of the victims were heroin addicts who had histories of only sporadic or moderate AAS use. One study identified seven AAS users and evaluated them every 2 weeks for as long as 44 weeks. During clinic visits, subjects reported their AAS use, and assessments, including the Beck Depression Inventory (BDI), Profile of Mood States Questionnaire, and Buss-Durkee Hostility Scale, were administered. Scores fluctuated over time, but the fluctuations were not associated with AAS use. Additionally, most of the subjects had a history of major depression, and five reported abusing other substances. A larger study (n=160) comparing AAS-using athletes with nonusing athletes revealed that far more AAS users displayed mood disorders compared with nonusers and AAS users during periods of no use. Another study describing 41 AAS-using athletes reported that 22 percent displayed mood syndromes during use, which was significantly higher than the rate observed during periods of no exposure. Additionally, this study reported that 12 percent displayed psychotic symptoms during use compared with 0 percent during AAS-free periods. Yet another naturalistic study comparing weight-lifting AAS users with nonusers correlated supranormal testosterone levels with subjective and objective measures of aggression. Cluster B personality traits, including antisocial, borderline, and histrionic, were more prominent in AAS users [07058].

Attempts have been made to study the effects of AASs in humans in prospective laboratory-controlled settings. One double-blind study administered placebo followed by low-dose (40 mg/d) and then high-dose (240 mg/d) methyltestosterone to 20 normal healthy men without psychiatric disease or history of AAS use. During the high-dose period (3 days), distractibility, irritability, and energy level increased significantly, and there was a trend for an increase in anger and violent feelings. One subject developed acute mania, and another developed hypomania. Subtle, but significant, elevations in the BDI, Hamilton Depression Rating Scale, Brief Psychiatric Rating Scale, and hostility, anxiety and somatization on the Symptom Checklist (SCL-90) were observed. In follow-up studies, an increase in aggressiveness correlated with an increase in free T4, an increase in forgetfulness and distractibility correlated with total testosterone levels, and an increase in activation symptoms (energy, sexual arousal, and diminished sleep) correlated with cerebrospinal fluid 5-hydroxyindole acetic acid levels. In another placebo-controlled cross-over study of 50 men free of substance abuse or psychiatric illness, increasing levels of testosterone cypionate were administered over 6 weeks. Aggressive responses on the Point Subtraction Aggression Paradigm and increased manic scores on the Young Mania Rating Scale were demonstrated; 84 percent showed minimal psychiatric symptoms, 12 percent became mildly hypomanic, and 4 percent became markedly hypomanic. An additional study evaluated testosterone cypionate over 14 weeks at levels up to 500 mg/week in healthy men free of psychiatric illnesses and personality disorders; it found minimal psychologic effects in most men, but one adverse psychiatric effect resembled mania. Additionally, some studies showed no changes in psychometric measures in healthy men who were administered AASs. All of these studies used doses lower than those typical in AAS use, so they likely underestimated the psychiatric consequences of AAS [07058].

Several case reports and survey studies have indicated that abuse of anabolic androgenic steroids (AAS) often leads to increased aggressiveness and feelings of hostility that may
occasionally trigger violent behaviour. Other observations indicate that many users of AAS also abuse alcohol and/or various illegal substances. Since substance abuse is a well-known risk factor for violent behaviour, it could be that violence committed by AAS users might, at least in many cases, actually be caused by abuse of other drugs. In order to examine this possibility further here, the criminal histories (in terms of incidences of convictions) of deceased users of AAS with (AASpos-subst.pos) and without (AASpos-subst.neg) signs of abuse of other illegal substances were compared to the corresponding histories of deceased users of illicit substances testing negatively for AAS (subst.pos-AASneg) at the time of autopsy. The risk of being convicted for a crime against property was significantly higher in the subst.pos-AASneg group than in either the AASpos-subst.neg or AASpos-subst.pos groups (RR=0.048 versus 0.408). At the same time, the risk of being convicted for a crime of violence was at least as high for the two AAS-positive groups as for the AAS-negative group. Furthermore, when compared with the first 3 years after the first criminal conviction, a pronounced increase in the proportion of incidence of violent crimes and a marked reduction in the proportion of incidence of crime against property was observed during the 3-year period immediately preceding death only among the AASpos-subst.neg subjects. In conclusion, the incidence of violent crime among users of AAS without signs of other drug abuse was comparable to the corresponding incidences for drug addicts without AAS use. This observation suggests that the violent criminality observed among AAS users is not confounded in any systematic fashion by abuse of other drugs. The findings also indicate that use of AAS in certain predisposed individuals might cause a high rate of violent crimes, especially if the use of AAS is combined with the use of other illegal substances [07076].

**Long-term effects on mental health**

The knowledge concerning the long-term effect of former anabolic androgenic steroids (AAS)-use on mental health is sparse. One study aims to investigate whether previous AAS-use affects mental health, present sociodemographic data, sport activity and substance abuse in a retrospective 30-year follow-up study of former elite athletes. Swedish male-elite power sport athletes (n=683) on the top 10 national ranking lists during any of the years 1960-1979 in wrestling, Olympic lifting, powerlifting and the throwing events in track and field answered a questionnaire. At least 20 percent of the former athletes admitted previous AAS-use. They had more often sought professional expertise for mental problems and had used illicit drugs compared to those not having used AAS. The AAS-users also differed in former sport activity pattern compared to non AAS-users. It is clear that a relationship exists between use of AAS and mental-health problems. Further studies need to be done in order to clarify this relationship [13149].

**Rat**

It was previously showed that 14 days of daily intramuscular injections of the anabolic androgenic steroid nandrolone decanoate (15 mg/kg) reduced the extracellular levels of the dopaminergic metabolites 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) in the nucleus accumbens shell using microdialysis. The aim of one study was to investigate whether the same dose regimen of nandrolone decanoate may affect the activities of the dopamine-metabolizing enzymes monoamine oxidases A and B (MAO-A and MAO-B). A radiometric assay was used to determine the activities of MAO-A and MAO-B in rat brain tissues after 14 days of daily i.m. nandrolone decanoate injections at the doses 3 and 15 mg/kg. Gene transcript contents of MAO-A, MAO-B and cathecol-O-methyltransferase (COMT) were measured with quantitative real-time reverse transcription PCR. 3 mg/kg of nandrolone decanoate significantly reduced the activity of both MAO-A and -B in the caudate putamen. 15 mg/kg of nandrolone decanoate significantly reduced the activity of MAO-A in the amygdala and increased the gene transcript level of MAO-B in the substantia nigra. In conclusion, imbalanced MAO activities may contribute to explain the impulsive and aggressive behaviour often described in AAS abusers. The reduced MAO
activities observed are in line with previously presented findings of decreased extracellular levels of DOPAC and HVA in the rat brain, indicating decreased monoaminergic activity following repeated AAS administration [08136].

It has been shown that male rats pubertally exposed to anabolic androgenic steroids (AAS) displayed aggression towards females in response to physical provocation. This experiment examined two factors that may modulate AAS-induced behavior towards females: olfactory cues and frustration. Gonadally intact males began one of three AAS treatments at puberty (D40): testosterone propionate (T), stanozolol (S), T+S, or vehicle control. To test for the relevance of olfactory cues in the elicitation of behavior toward females, a hidden neighbor paradigm was used. The proximal stimulus was an ovariectomized (OVX) female, estrogen plus progesterone (E+P) female, or an E+P female with tape-obstructed vagina (OBS). Distal olfactory cues from a hidden neighbor were delivered from a separate cage connected to the testing arena. The vaginally obstructed, sexually receptive female (OBS) was used to determine the effects of frustration on behavior by AAS males. Both sexual and aggressive behaviors were measured. The presence of distal olfactory cues had no effect on either sexual or aggressive behavior. In the presence of E+P and OBS females, all males displayed sex behaviors, not aggression. However, AAS males displayed significantly more aggression towards proximal OVX females than controls. AAS males mounted OBS females significantly more than controls, indicating a persistence of once rewarded behavior. These results suggest that proximal cues of the conspecific female are more salient than distal olfactory cues in determining behavior and that AAS males display frustration-induced persistence in response to vaginally obstructed receptive females [06081].

Human studies suggest that anabolic androgenic steroid (AAS) users are aggressive towards women. This study used a rat model to evaluate whether AAS potentiated aggression towards females and the conditions under which this occurs. Gonadally intact pubertal male rats received one of the following AAS treatments (5 mg/kg s.c. 5 days/week for nine weeks): testosterone (T), stanozolol (S), testosterone + stanozolol (T + S), or vehicle control. Each rat was tested with 3 conspecific stimuli: ovariectomized females (OVX), estrogen only females (E), and estrogen + progesterone females (E + P). The response to physical provocation was tested under three conditions: without physical provocation, provocation of the experimental male, and provocation of the conspecific female. Provocation was a mild tail pinch. Both aggressive and sexual behaviors were measured during each test. In the absence of physical provocation, AAS males were not aggressive towards females. However, provocation significantly increased aggression in males treated with testosterone but only towards OVX females. In the presence of E or E + P females, all animals displayed sex behavior, not aggression. Thus, factors such as the nature of the AAS and the hormonal status of the females are important in determining whether male rats will be aggressive towards females. However, the most salient factor determining aggression towards females is the presence of provocation in combination with high levels of testosterone [06082].

Illicit use of anabolic androgenic steroids (AAS) has become a prevalent health concern not only among male professional athletes, but, disturbingly, among a growing number of women and adolescent girls. Despite the increasing use of AAS among women and adolescents, few studies have focused on the effects of these steroids in females, and female adolescent subjects are particularly underrepresented. Among the hallmarks of AAS abuse are changes in reproductive behaviors. Here, it was discussed work from laboratories on the actions of AAS on the onset of puberty and sexual behaviors in female rodents, AAS interactions and sex- and age-specific effects of these steroids on neural transmission mediated by gamma-aminobutyric acid receptors within forebrain neuroendocrine control regions that may underlie AAS-induced changes in these behaviors [06083].
Anabolic androgenic steroid (AAS) abuse is increasing in teenagers. It was examined the effects of stacked AAS in adolescent male rats. Stacking, in which multiple AAS are taken simultaneously, is commonly employed by humans. Beginning at puberty gonadally intact male rats received testosterone, nandrolone, or stanozolol. Additional groups received stacked AAS: testosterone + stanozolol, nandrolone + stanozolol, or nandrolone + testosterone. Injections continued during tests for sexual behavior, vocalizations, scent marking, partner preference, aggression and fertility. Body and reproductive tissue weights were taken. Sexual and aggressive behaviors were increased by testosterone yet inhibited by stanozolol; nandrolone had no effect. Stacking testosterone with stanozolol prevented the inhibitory effects of stanozolol. Body weight was decreased by testosterone and all stacked AAS. Cell nuclear androgen receptor binding in brain was significantly increased in nandrolone males and decreased in stanozolol males; testosterone males were slightly higher than controls. Androgen receptors in stacked groups were intermediate between individual AAS suggesting that stanozolol competed with other AAS for androgen receptors despite its low affinity. The results indicate that stacking AAS influences the effects of individual AAS on behavioral and endocrine measures, and levels of androgen receptor occupation are not directly correlated with AAS effects on behavior [06084].

**Mouse**

Anabolic androgenic steroid abuse triggers impulsive aggression, anxiety, and depression, which suggests a dysfunction of GABAergic neurotransmission. Socially isolated female mice that have received testosterone propionate (1.45 micromol/kg) treatment for 3 weeks during social isolation express aggression, neurosteroid downregulation, and changes in the cortical mRNA expression of several gamma-aminobutyric acid type A receptor subunits (alpha1, alpha2, gamma2 are decreased by 30-40 %, and alpha4 and alpha5 are increased by 50 %). Administration of allopregnanolone or the potent selective brain steroidogenic stimulant S-norfluoxetine, in doses (1.8-3.6 micromol/kg) that fail to inhibit 5-hydroxytryptamine reuptake, normalizes olfactory bulb neurosteroid level downregulation and abolishes aggression. This work underscores the role of neurosteroids in the regulation of aggression elicited by testosterone propionate in socially isolated female mice [06080].

Anabolic androgenic steroids effects vary according to chemical structure and metabolism, route of administration, and AAS regimen. In one study, male mice were systemically exposed to testosterone propionate, nandrolone or 17alpha-methyltestosterone, type I, type II and type III AAS, respectively, in order to determine the hedonic or aversive properties of each drug. For this purpose, the conditioned place preference test was employed at three different AAS doses (0.075, 0.75 and 7.5 mg/kg). Other behavioral domains monitored were light-dark transitions (side changes) and general activity. Testosterone propionate shifted place preference at all doses tested, and nandrolone shifted place preference at 0.75 and 7.5 mg/kg, but not at 0.075 mg/kg, the lower dose tested. Conversely, mice receiving 17alpha-methyltestosterone did not show alteration in the preference score. The lower dose of nandrolone did modify exploratory-based anxiety showing a decrease in light-dark transitions if compared to vehicle-treated animals, while mice treated with testosterone propionate 17alpha-methyltestosteronewere not affected. The data suggest that when studying hedonic and rewarding properties of synthetic androgens, distinction has to be made based on type of AAS and metabolism [08137].

**Hamster**

Repeated exposure to anabolic/androgenic steroids (AAS) during adolescence stimulates high levels of offensive aggression in Syrian hamsters. The current study investigated whether adolescent AAS exposure activated neurons in areas of hamster forebrain implicated in aggressive behavior by examining the expression of FOS, i.e., the protein product of the immediate early gene c-fos shown to be a reliably sensitive marker of neuronal
activation. Adolescent AAS-treated hamsters and sesame oil-treated littermates were scored for offensive aggression and then sacrificed 1 day later and examined for the number of FOS immunoreactive (FOS-ir) cells in regions of the hamster forebrain important for aggression control. When compared with non-aggressive, oil-treated controls, aggressive AAS-treated hamsters showed persistent increases in the number of FOS-ir cells in select aggression regions, namely the anterior hypothalamus and lateral septum. However, no differences in FOS-ir cells were found in other areas implicated in aggression such as the ventrolateral hypothalamus, bed nucleus of the stria terminals, central and/or medial amygdala or in non-aggression areas, such as the somatosensory cortex and the suprachiasmatic nucleus. These results suggest that adolescent AAS exposure may constitutively activate neurons in select forebrain areas critical for the regulation of aggression in hamsters. A model for how persistent activation of neurons in one of these brain regions (i.e., the anterior hypothalamus) may facilitate the development of the aggressive phenotype in adolescent-AAS exposed animals is presented [06079].

Chronic treatment with anabolic-androgenic steroids during adolescence alters the activity of various neurotransmitter systems in male Syrian hamsters (Mesocricetus auratus). One study was conducted to determine whether glutamatergic cells in the lateral anterior hypothalamus, a sub-region of the anterior hypothalamus, have lasting activation following adolescent AAS exposure, and to examine AAS-induced alterations in the connections between the lateral anterior hypothalamus and the ventrolateral hypothalamus governed by glutamate. Hamsters were administered AAS during adolescence and then examined for changes in FOS (protein product of the immediate early gene c-fos) and phosphate activated glutaminase (PAG; the rate-limiting enzyme in the synthesis of glutamate) immunoreactivity (FOS/PAG-IR) using double-label immunohistochemistry. In a second experiment, a retrograde tracing study was conducted using a red fluorescent tracer microinjected into the ventrolateral hypothalamus. Then brains were processed for PAG immunofluorescence and examined for AAS-induced changes in the number of PAG positive cells containing the tracer (PAG/Tracer) in the lateral anterior hypothalamus. When compared to oil-treated controls, AAS-treated hamsters showed significant increases in PAG-IR and FOS/PAG-IR in the lateral anterior hypothalamus, decreases in afferent innervation from the lateral anterior hypothalamus to the ventrolateral hypothalamus and decreases in the total number of glutamate cells in the lateral anterior hypothalamus projecting to the ventrolateral hypothalamus. Together with previous research from our lab showing increased AAS-induced expression of PAG in the AH and increased glutamate receptor expression in the ventrolateral hypothalamus, the current results suggest that adolescent AAS exposure leads to alterations in the function and expression of the glutamatergic system as well as changes in hypothalamic neural connections. In addition, the current results further strengthen the notion that a specific nucleus in the lateral anterior hypothalamus is a critical hypothalamic sub-region particularly sensitive to AAS-induced neurodevelopmental effects [08138].

Influence on serotonin in the brain
The goal of this study was to assess the interactive effects of chronic anabolic androgenic steroid (AAS) exposure and brain serotonin (5-hydroxytryptamine, 5-HT) depletion on behavior of pubertal male rats. Serotonin was depleted beginning on postnatal day 26 with parachlorophenylalanine (PCPA 100 mg/kg, every other day); controls received saline. At puberty (P40), half the PCPA-treated rats and half the saline-treated rats began treatment with testosterone (T, 5 mg/kg, 5 days/week). Behavioral measures included locomotion, irritability, copulation, partner preference, and aggression. Animals were tested for aggression in their home cage, both with and without physical provocation (mild tail pinch). Brain levels of 5-HT and its metabolite, 5-hydroxyindoleacetic acid (5-HIAA), were determined using HPLC. PCPA significantly and substantially depleted 5-HT and 5-HIAA in all brain regions examined. Chronic T treatment significantly decreased 5-HT and 5-HIAA in
certain brain areas, but to a much lesser extent than PCPA. Chronic exposure to PCPA alone significantly decreased locomotor activity and increased irritability but had no effect on sexual behavior, partner preference, or aggression. T alone had no effect on locomotion, irritability, or sexual behavior but increased partner preference and aggression. The most striking effect of combining T+PCPA was a significant increase in attack frequency as well as a significant decrease in the latency to attack, particularly following physical provocation. Based on these data, it can be speculated that pubertal AAS users with low central 5-HT may be especially prone to exhibit aggressive behavior [06085].

Agression and violence

It was examined the effects of anabolic-androgenic steroid use on serious violent behavior. Multivariate models based on data from the National Longitudinal Study of Adolescent Health in the US (n=6823) were used to examine the association between lifetime and past-year self-reported anabolic-androgenic steroid use and involvement in violent acts. Compared with individuals who did not use steroids, young adult males who used anabolic-androgenic steroids reported greater involvement in violent behaviors after it was controlled for the effects of key demographic variables, previous violent behavior, and polydrug use [08147].

In humans and animals, anabolic-androgenic steroids (AAS) increase aggression, but the underlying behavioral mechanisms are unclear. AAS may increase the motivation to fight. Alternatively, AAS may increase impulsive behavior, consistent with the popular image of ‘roid rage. To test this, adolescent male rats were treated chronically with testosterone (7.5 mg/kg) or vehicle and tested for aggressive motivation and impulsivity. Rats were trained to respond on a nose-poke on a 10min fixed-interval schedule for the opportunity to fight in their home cage with an unfamiliar rat. Although testosterone increased aggression (6.3 ± 1.3 fights/5 min vs 2.4 ± 0.8 for controls), there was no difference in operant responding (28.4 ± 1.6 nose-pokes/10 min for testosterone, 32.4 ± 7.0 for vehicle). This suggests that testosterone does not enhance motivation for aggression. To test for impulsivity, rats were trained to respond for food in a delay-discounting procedure. In an operant chamber, one lever delivered one food pellet immediately, the other lever gave 4 pellets after a delay (0, 15, 30 or 45s). In testosterone- and vehicle-treated rats, body weights and food intake did not differ. However, testosterone-treated rats chose the larger, delayed reward more often (4.5 ± 0.7 times in 10 trials with 45s delay) than vehicle controls (2.5 ± 0.5 times), consistent with a reduction in impulsive choice. Thus, although chronic high-dose testosterone enhances aggression, this does not include an increase in impulsive behavior or motivation to fight. This is further supported by measurement of tyrosine hydroxylase (TH) by Western immunoblot analysis in brain regions important for motivation (nucleus accumbens, Acb) and executive function (medial prefrontal cortex, PFC). There were no differences in TH between testosterone- and vehicle-treated rats in Acb or PFC. However, testosterone significantly reduced TH (to 76.9 ± 3.1 % of controls) in the caudate-putamen, a brain area important for behavioral inhibition, motor control and habit learning [12138].

Millions of individuals worldwide have used anabolic-androgenic steroids (AAS) to gain muscle or improve athletic performance. Recently, in vitro investigations have suggested that supraphysiologic AAS doses cause apoptosis of neuronal cells. These findings raise the possibility, apparently still untested, that humans using high-dose AAS might eventually develop cognitive deficits. It was administered five cognitive tests from the computerized CANTAB battery (Pattern Recognition Memory, Verbal Recognition Memory, Paired Associates Learning, Choice Reaction Time, and Rapid Visual Information Processing) to 31 male AAS users and 13 non-AAS-using weightlifters age 29-55, recruited and studied in 2012 in Middlesbrough, UK. Testers were blinded to participants' AAS status and other historical data. Long-term AAS users showed no significant differences from nonusers on
measures of response speed, sustained attention, and verbal memory. On visuospatial memory, however, AAS users performed significantly more poorly than nonusers, and within the user group, visuospatial performance showed a significant negative correlation with total lifetime AAS dose. These were large effects: on Pattern Recognition Memory, long-term AAS users underperformed nonusers by almost one standard deviation, based on normative population scores (adjusted mean difference in z-scores=0.89; p=0.036), and performance on this test declined markedly with increasing lifetime AAS dose. These results remained stable in sensitivity analyses addressing potential confounding factors. These preliminary findings raise the ominous possibility that long-term high-dose AAS exposure may cause cognitive deficits, notably in visuospatial memory [12139].

The association between substance abuse, particularly alcohol abuse, and violence has been well established. However, since substance abuse co-occurs with several other risk factors for violence, the causal link between substance abuse and violence and the extent to which the acute influence of alcohol, illicit drugs, benzodiazepines, and anabolic androgenic steroids have a triggering effect on violent behavior are more uncertain. Case-crossover design was used based on data from structured face to face interviews with remand prisoners (n=194; 172 men, 22 women) suspected of violent crimes. Main outcome measure: odds ratio (OR) for a violent crime, 24h after exposure to different substances, compared to periods of no exposure was calculated using conditional logistic regression and a Mantel-Haenszel estimator with confidence intervals for sparse data. Intake of alcohol (OR 6) and large doses of benzodiazepines (OR 36) triggered interpersonal violence. Stratified analyses of possible effect modifiers were sex, conduct/behavioral problems, trauma experiences; psychiatric vulnerability did not reveal any substantial differences. Influences of alcohol and unusually high doses of benzodiazepines are proximal risk factors for violent crime. Improved knowledge of short-term (and dose-related) risk factors may contribute to treatment planning and risk assessment of violence [13160].

In humans and animals, anabolic-androgenic steroids (AAS) increase aggression, but the underlying behavioral mechanisms are unclear. AAS may increase the motivation to fight. Alternatively, AAS may increase impulsive behavior, consistent with the popular image of 'roid rage. To test this, adolescent male rats were treated chronically with testosterone (7.5 mg/kg) or vehicle and tested for aggressive motivation and impulsivity. Rats were trained to respond on a nose-poke on a 10 min fixed-interval schedule for the opportunity to fight in their home cage with an unfamiliar rat. Although testosterone increased aggression (6.3 ± 1.3 fights/5 min vs 2.4 ± 0.8 for controls), there was no difference in operant responding (28.4 ± 1.6 nose-pokes/10 min for testosterone, 32.4 ± 7.0 for vehicle). This suggests that testosterone does not increase motivation for aggression. To test for impulsivity, rats were trained to respond for food in a delay-discounting procedure. In an operant chamber, one lever delivered one food pellet immediately, the other lever gave 4 pellets after a delay (0, 15, 30 or 45 s). In testosterone- and vehicle-treated rats, body weights and food intake did not differ. However, testosterone-treated rats chose the larger, delayed reward more often (4.5 ± 0.7 times in 10 trials with 45 s delay) than vehicle controls (2.5 ± 0.5 times), consistent with a reduction in impulsive choice. Thus, although chronic high-dose testosterone enhances aggression, this does not include an increase in impulsive behavior or motivation to fight. This is further supported by measurement of tyrosine hydroxylase (TH) by Western immunoblot analysis in brain regions important for motivation (nucleus accumbens, Acb) and executive function (medial prefrontal cortex, PFC). There were no differences in TH between testosterone- and vehicle-treated rats in Acb or PFC. However, testosterone significantly reduced TH (to 76.9 ± 3.1 % of controls) in the caudate-putamen, a brain area important for behavioral inhibition, motor control and habit learning [13206].

Twin studies

598
Individual behavioral and psychiatric responses to chronic AAS abuse are extremely variable, depending on pre-existing psychiatric conditions, personality, and type and dose of AAS. Case reports and some epidemiology studies associate chronic AAS use with changes in behavior, mood, and somatic perceptions in a small subset of chronic AAS abusers. Psychiatric complications associated with chronic AAS use include mania, aggression, and agitation, but no large-scale epidemiologic studies have confirmed a causal relationship between chronic AAS abuse and severe psychiatric complications (e.g. psychosis). Depression may occur, particularly in the immediate period after cessation of use, along with fatigue, decreased libido, insomnia, anorexia, and headaches. Studies suggest that male AAS users have more frequent and prolonged periods of anger, aggression, irritability, and hostility than nonusers. Multivariate models based on data from the National Longitudinal Study of Adolescent Health (n=6823) indicate that young men using anabolic-androgenic steroids report greater involvement in violent behaviors than non-users after control for the effects of key demographic variables, previous violent behavior, and polydrug use. In a study of 2 sets of male monozygotic twins with only 1 twin using AASs, the use of AASs was associated with anxiety, hostility, aggressiveness, and paranoid ideations as determined by comparing responses to a Symptoms Checklist-90 and the Hostility and Direction of Hostility Questionnaire. Behavioral abnormalities included are tractibility, delirium, delusions, irritability, paranoia, impulsivity, insomnia, hostility, anxiety, agitation, aggression, violence, and mood lability. These behavioral effects are dose dependent with effects ranging from mild effects (increased confidence, enhanced self-esteem, and euphoria) to serious behavioral abnormalities (mood swings, grandiose thinking, paranoia, impulsivity, hostility, violence, and antisocial behavior) [13003].

Experimental
In the US and worldwide anabolic/androgenic steroid use remains high in the adolescent population. This is concerning given that anabolic/androgenic steroid use is associated with a higher incidence of aggressive behavior during exposure and anxiety during withdrawal. This study uses pubertal Syrian hamsters (Mesocricetus auratus) to investigate the hypothesis that an inverse behavioral relationship exists between anabolic/androgenic steroid-induced aggression and anxiety across adolescent exposure and withdrawal. In the first experiment, it was examined aggression and anxiety during adolescent anabolic/androgenic steroid exposure and withdrawal. Adolescent anabolic/androgenic steroid administration produced significant increases in aggression and decreases in anxiety during the exposure period followed by significant decreases in aggression and increases in anxiety during anabolic/androgenic steroid withdrawal. In a second experiment, anabolic/androgenic steroid exposed animals were separated into groups based on their aggressive response during the exposure period and then tested for anxiety during exposure and then for both aggression and anxiety during withdrawal. Data were analyzed using a within-subjects repeated measures predictive analysis. Linear regression analysis revealed that the difference in aggressive responding between the anabolic/androgenic steroid exposure and withdrawal periods was a significant predictor of differences in anxiety for both days of testing. Moreover, the combined data suggest that the decrease in aggressive behavior from exposure to withdrawal predicts an increase in anxiety-like responding within these same animals during this time span. Together these findings indicate that early anabolic/androgenic steroid exposure has potent aggression- and anxiety-eliciting effects and that these behavioral changes occur alongside a predictive relationship that exists between these two behaviors over time [13150].

Association with criminality

Sweden
Observations suggest that the use of anabolic androgenic steroids (AAS) may trigger uncontrolled, violent rage. Other observations indicate that certain groups of criminals may
use AAS with the intention of being capable of committing crime more efficiently. To examine the proposed association between the use of AAS and criminality a controlled retrospective cohort study of registered criminal activity among individuals tested for AAS use during the period of 1995 to 2001 was performed. All individuals in Sweden who were tested for AAS use during this period were included. These individuals were referred for testing from both inpatient and outpatient clinics as well as from centers for treatment of substance abuse: individuals testing positive for AAS (n=241), with those testing negative for AAS during the same period (n=1199) serving as the control group. The risk of having been convicted for a weapons offense or fraud was higher among individuals testing positive for AAS than among those testing negative (RR, 2.090 and 1.511, respectively) whereas there were no significant differences with respect to violent crimes (RR, 1.116) or crimes against property (RR, 0.942). When patients referred from substance abuse centers were excluded, a lower risk for crimes against property was observed for the individuals who tested positive for AAS (RR, 0.761) and the risk for fraud in the 2 groups was equalized (RR, 1.117). The increased risk for a weapons offense among the individuals testing positive for AAS remained virtually unchanged. It was concluded that in addition to the impulsive violent behavior previously shown to be related to AAS use, such use might also be associated with an antisocial lifestyle involving various types of criminality. However, the existence and nature of this possible association remain unclear and call for further investigation [06086].

**Suicide risk**

It was studied 62 professional weightlifters in Finland who were strongly suspected of using anabolic-androgenic steroids. They were compared them with 1,094 population controls. Over a 12-year period, 8 (13 %) of the weightlifters died versus 34 (3 %) of the controls, which was a statistical significant difference. The causes of death in the weightlifters were suicide (3 subjects), acute myocardial infarction (3), hepatic coma (1), and non-Hodgkin lymphoma (1) [07031].

**Addiction**

An estimated 14 to 57 percent of anabolic-androgenic steroid users develop dependence. How addiction develops is unknown, but psychological dependence is believed to play a large role. Different substance abuse patterns exist in different populations that use anabolic-androgenic steroids. In one study it was found that steroid-using weightlifters almost always previously tried other illicit substances. On the other hand, others found that elite athletes, weightlifters, and bodybuilders rarely abuse illicit drugs, reflecting their interest in optimizing their physique and performance. Adolescents who abuse steroids are more likely to smoke and use other illicit substances than are older users [07031]

**Withdrawal effects**

Users of high-dose AAS regimens report a withdrawal syndrome, including steroid craving, depression, suicidality, irritability, muscle aches, and autonomic instability including hot flashes, nausea and vomiting, tachycardia, and hypertension [07058].

Physical symptoms of withdrawal are similar to those seen during alcohol and opioid withdrawal, including diaphoresis, myalgias, nausea, and increases in blood pressure and heart rate. Withdrawal may also be characterized by depressive symptoms [07008].

**Treating psychiatric effects of steroid use**
Steroid abusers rarely seek help, and many regard the psychiatric effects as beneficial, especially for athletes in certain sports. Illicit use is compounded by mistrust of doctors, a perception that medical people lack knowledge about these drugs, and fear of stigma or negative consequences that may result from drug use being exposed. Adverse effects of steroid abuse should be managed by discontinuing the drugs by tapering if necessary and by treating the symptoms. Steroid abusers typically take doses 10 to 100 times higher than physiologic doses, in cycles lasting 6 to 14 weeks, consisting of daily oral doses plus weekly or monthly intramuscular injections. Treatment of psychiatric effects starts with stopping the steroids. It is reasonable to substitute testosterone enanthate (Andro-Estro) and gradually taper the dose. The short-term use of antipsychotic medications may help treat steroid-induced mania and psychosis. Benzodiazepines may help control panic or anxiety in the short term. Selective serotonin reuptake inhibitors or tricyclic antidepressants should be used if long-term treatment is needed. Depression sometimes occurs when use is stopped. Fluoxetine (Prozac®) can be used in this situation. Anabolic-androgenic steroid abuse is no longer confined to professional athletes; therefore physicians should be aware of its signs and symptoms in order to address adverse effects and provide treatment [07031].

**Cognitive deficits**

Millions of individuals worldwide have used anabolic-androgenic steroids (AAS) to gain muscle or improve athletic performance. Recently, in vitro investigations have suggested that supraphysiologic AAS doses cause apoptosis of neuronal cells. These findings raise the possibility, apparently still untested, that humans using high-dose AAS might eventually develop cognitive deficits. It was administered five cognitive tests from the computerized CANTAB battery (Pattern Recognition Memory, Verbal Recognition Memory, Paired Associates Learning, Choice Reaction Time, and Rapid Visual Information Processing) to 31 male AAS users and 13 non-AAS-using weightlifters age 29-55, recruited and studied in May 2012 in the UK. Testers were blinded to participants’ AAS status and other historical data. Long-term AAS users showed no significant differences from nonusers on measures of response speed, sustained attention, and verbal memory. On visuospatial memory, however, AAS users performed significantly more poorly than nonusers, and within the user group, visuospatial performance showed a significant negative correlation with total lifetime AAS dose. These were large effects: on Pattern Recognition Memory, long-term AAS users underperformed nonusers by almost one standard deviation, based on normative population scores, and performance on this test declined markedly with increasing lifetime AAS dose. These results remained stable in sensitivity analyses addressing potential confounding factors. These preliminary findings raise the ominous possibility that long-term high-dose AAS exposure may cause cognitive deficits, notably in visuospatial memory [13144].

**Effects on learning**

The illicit use of anabolic androgenic steroids (AAS) has gained popularity among adolescents in the last decade. However, although it is known that exposure to AAS impairs cognition in adult animal models, the cognitive effects during adolescence remain undetermined. An inhibitory avoidance task (IAT) was used to assess the effect of AAS (17alpha-methyltestosterone; 17alpha-meT-7.5 mg/kg) in male and female periadolescent rats. A single injection of 17alpha-meT immediately before the footshock produced significant impairment of inhibitory avoidance learning in males but not females. Generalized anxiety, locomotion, and risk assessment behaviors (RAB) were not affected. The results show that exposure to a single pharmacological dose of 17alpha-meT during periadolescence exerts sex-specific cognitive effects without affecting anxiety. Thus, disruption of the hormonal milieu during this early developmental period might have negative impact on learning and memory [13145].
Mood disorders
The knowledge concerning the long-term effect of former anabolic androgenic steroids (AAS)-use on mental health is sparse. One study aimed to investigate whether previous AAS-use affects mental health, present sociodemographic data, sport activity and substance abuse in a retrospective 30-year follow-up study of former elite athletes. Swedish male-elite power sport athletes (n=683) on the top 10 national ranking lists during any of the years 1960-1979 in wrestling, Olympic lifting, powerlifting and the throwing events in track and field answered a questionnaire. At least 20 percent of the former athletes admitted previous AAS-use. They had more often sought professional expertise for mental problems and had used illicit drugs compared to those not having used AAS. The AAS-users also differed in former sport activity pattern compared to non AAS-users. It is clear that a relationship exists between use of AAS and mental-health problems. Further studies need to be done in order to clarify this relationship [13146].

The true prevalence of these neuropsychiatric disorders is difficult to determine, but relatively few individuals develop these adverse effects; they are found primarily in high-dose chronic AAS abusers. In a study of 88 AAS-using athletes and 68 non-users, the incidence of major mood disorders (mania, hypomania, and major depression) was significantly more frequent in steroid users compared with non-users. Additionally, these mood disorders were more frequent in current AAS users than in abstinent AAS users [13003].

Effects on the brain's neurotrophyanabolic androgenic steroids (AAS) are synthetic androgen-like compounds that are abused in sport communities despite their adverse effects. Nerve growth factor (NGF) influences neuronal differentiation and survival, and it also mediates higher brain functions such as learning and memory. Changes in NGF expression have been implicated in neurodegenerative disorders, including Alzheimer disease. Hence, we decided to study the effect of chronic AAS exposure on brain NGF profile, NGF-dependent cholinergic function, and related behavioral performance. Male Wistar rats were injected for 4 weeks with either nandrolone or stanozolol at daily doses (5.0 mg/kg, s.c.) that are considered equivalent to those abused by humans. NGF levels and NGF receptor (TrkA and p75NTR) expression were measured in the hippocampus and in the basal forebrain. Choline acetyltransferase expression was evaluated in basal forebrain. Spatial learning and memory were assessed using the Morris water maze. AAS treatment caused region-specific changes in the expression of NGF and its receptors. Both nandrolone and stanozolol increased NGF levels in the hippocampus and reduced NGF levels in the basal forebrain, reduced p75NTR expression in the hippocampus, and failed to affect TrkA expression in the basal forebrain. Finally, AAS treatment reduced the expression of choline acetyltransferase in the basal forebrain and impaired the behavioral performance in the Morris water maze. It was concluded that the evidence that supraphysiological doses of AAS cause neurotrophic unbalance and related behavioral disturbances raises the concern that AAS abuse in humans may affect mechanisms that lie at the core of neuronal plasticity [13147].

Liver changes due to sex hormones (anabolic steroids and oral contraceptives)

Overview
The liver is a hormone-sensitive organ, and in fact both normal liver and hepatocellular carcinoma (HCC) tissues from male and female mammals have been shown to express specific estrogen receptors (ERs). Experimentally, estrogens may act as liver tumor inducers or promoters in vivo, and are involved in stimulating hepatocyte proliferation in vitro.
Moreover, anti-estrogens like tamoxifen have been shown to reduce levels of ERs and to inhibit hepatocyte proliferation following partial hepatectomy. As regards the role of androgens, it has also been observed that androgen receptors (ARs), specifically activated by testosterone, are present in normal liver tissue from both males and females and that their expression is increased in tumor tissue and in the surrounding liver of individuals with HCC. In addition, observations from clinical and epidemiological studies have highlighted that the long-term use of OCs and anabolic androgenic steroids (AASs) can induce benign and malignant hepatocellular tumors. One study provided definite and quantitative evidence that OC use was significantly, although modestly associated with FNH. The time-risk relation gave convincing support to the existence of a real association, given that there was a direct trend in risk with duration and an inverse trend with age at first use. Benign tumors of the liver are often discovered incidentally in asymptomatic individuals during diagnostic imaging or exploratory laparotomy performed for other reasons. Hemangiomas are the most common benign liver tumors, followed in prevalence by focal nodular hyperplasia (FNH) and the rarer condition of adenoma; their growth and development have been linked to hormonal stimulation. Long-term use of oral contraceptives (OCs) and anabolic androgenic steroids (AASs) can induce both benign (hemangioma, adenoma, and focal nodular hyperplasia, FNH) and malignant (hepatocellular carcinoma, HCC) hepatocellular tumors. Hepatic adenomas (HAs) are rare, benign neoplasms usually occurring in young women, the development and the complications of which have been related to the strength of OCs and the duration of their use. HA incidence has fallen since the introduction of pills containing smaller amounts of estrogens. In recent times AASs have also been proven to be involved in the development of hepatic adenoma. Apparently, androgen-induced HAs are relatively rare. However, the possibility that an oral AAS can induce liver cell proliferation must be taken into account and sportsmen taking AASs over a long period should be considered a group at risk for developing hepatic sex tumors. FNH is a benign lesion, most commonly seen in young women, which is thought to represent a local hyperplastic response of hepatocytes to a vascular abnormality. Because of the female predominance and the young age at onset, a role of female hormones has been suggested. Furthermore, a large proportion of women with FNH (50-75%) are OC users. Liver hemangiomas (LHs) are the most common benign liver tumors and are seen more commonly in young adult females. The female predilection and clinical observations of LH growth under conditions of estrogenic exposure suggest a possible role for estrogen in the pathogenesis of LHs. HA has been strongly associated with the use of OCs; in fact, it has been calculated that about 320 new cases are diagnosed each year, mostly attributable to OC use. Consequently, in contrast with what happens for LH and FNH, at least for HA there is an agreement among authors about the fact that the association between OCs and HA is strong and depends on the duration of use. Furthermore, unresected lesions may decrease in size in young women once they stop OC use. All these data taken together suggest that the association between HA and OC use is one of cause and effect. HCC has become one of the most widespread tumors in the world in recent years, representing the sixth leading cancer and the third most common cause of death from cancer. Apart from liver cirrhosis, numerous other factors responsible for its onset have been proposed: hepatitis infections from virus B (HBV) and C (HCV), alcohol, smoking, and aflatoxin. However, regardless of etiology, chronic liver diseases progress at unequal rates in the two sexes, with the major sequelae, such as cirrhosis and HCC, being more frequent in men than in women. These epidemiological data have prompted researchers to investigate the relationship between sex hormones and liver tumors. The human liver expresses estrogen and androgen receptors and experimentally both androgens and estrogens have been implicated in stimulating hepatocyte proliferation and may act as liver tumor inducers or promoters. As regards the role of estrogens in HCC, it seems that in the physiological status of premenopausal women, in the absence of other risk factors for liver disease, they have a somewhat protective role against the development of HCC [06074].
Athletes and nonathletes have been using anabolic-androgenic steroids (AAS) for a long time, in an inadequate and unsupervised manner, with the aim of improving sports performance or for cosmetic purposes. AAS consumption is becoming more widespread and involving younger people, and there is a trend for self-administration of higher doses and for combining AAS with other potentially harmful drugs. Almost any subject abusing AAS will experience adverse effects. Therefore, adverse effects from these exposures, including liver toxicity, are expected to increase in the years to come. It was described a representative case of intrahepatic cholestasis with the intention to discuss AAS-related liver toxicity (including the potential therapeutic role of ursodeoxycholic acid) and to comment on several aspects of the clinical scenario the gastroenterologist should be aware of [07061].

Cholestatic jaundice with intrahepatic cholestasis and variable degrees of hepatocellular necrosis on liver biopsy is the most commonly reported serious pathologic abnormality of the liver associated with AASs abuse. Rarely, case reports associate the presence of multiple, dilated liver cysts filled with blood in the liver (peliosis hepatitis) with chronic use of AASs. The pathogenesis of peliosis hepatitis is unknown. Other pathologic abnormalities of the liver detected in the autopsy of AAS abusers include focal nodular hyperplasia and adenomas. Rarely, the abuse of androgenic-anabolic steroids are associated with the development of blood-filled cysts (peliosis) involving the liver, spleen, bone marrow, lymph nodes, and lung. A 9-year-old bodybuilder was found dead at home; an autopsy demonstrated peliosis of the lung with the left pleural cavity filled with blood [13003].

**Metabolism of anabolic steroids in the liver**

Anabolic androgenic steroids are the xenobiotic substrates that are metabolized in the body by the protective enzyme systems. Mixed function oxygenase enzymes include a group of enzymes which play an essential role in the metabolism of a broad range of xenobiotics including endogenous and exogenous substrates. Cytochrome P-450, a member of mixed function oxygenase enzymes, plays an important role in oxidative metabolism of drugs and xenobiotics entering human body. Various anabolic steroids are found either to increase or decrease the activity of cytochrome P-450. However, effect of nandrolone decanoate, most commonly abused anabolic steroid, on cytochrome P-450 activity is still fragmentary. In one study, albino mice were administered intramuscular 2.5 mg of nandrolone decanoate injection at 15 days interval. Investigation shows a significant increase of cytochrome P-450 (nmol/mg) activity in liver tissue as compared to that of kidney tissues. A tissue specific and dose specific increase of cytochrome P-450 activity is observed. Mean cytochrome P-450 is found highest in liver tissue on 45th day whereas the activity in kidney tissue is noticed on 90th day of treatment. From the above observation, nandrolone decanoate can be suggested as a potent inducer of cytochrome P-450 activity like other anabolic steroids [09061].

**Enzyme elevations**

Various studies have demonstrated transient elevations of liver function tests (elevated plasma alkaline phosphates, aminotransferases, conjugated bilirubin, and plasma proteins) with and without significant hepatic injury. The orally 17-alpha alkylated steroids have a higher incidence of hepatotoxicity than other preparations. The mechanism of action is most likely from a direct toxic effect due to the brief period of time between exposure and liver damage and a dose-related effect. The most common used measures of hepatotoxicity are aspartate aminotransferase (AST), alanine aminotransferase (ALT), and lactate dehydrogenase (LDH). Values are usually in the range of two to three times normal. These changes often mimic the effects seen with oral contraceptives. Elevations in AST, ALT, and gamma-glutamyl-transferase (GGT) tend to peak within 2 to 3 weeks of consumption even at
relatively low doses, and will usually return to baseline within several weeks upon discontinuation. GGT was the most sensitive enzyme to detect hepatic dysfunction. However, physicians must be careful in evaluating serum elevations of these enzymes, because strenuous exercise alone can cause muscle breakdown, leading to transaminase elevations. In addition, with the exception of LDH, the enzymes can be found in other body tissues confounding the picture even more [06031].

**Cholestatic liver disease**

In the face of increasing societal pressure to achieve bodily perfection, young men in particular sometimes turn to anabolic steroids to help them achieve the body they want. The health consequences of this choice are often overlooked. It was described two cases of severe cholestatic liver disease in young men who had taken anabolic steroids with the aim of enhancing their body image. Both patients needed a prolonged stay in hospital for treatment resistant pruritus. The second case was associated with considerable psychological morbidity, so much so that the patient felt he had to leave school. The agent implicated in both the cases of severe cholestatic liver injury was methandrostenolone. This is a weak androgen receptor agonist and has long been recognised as a cause of liver damage. This fact seems to be well known among users of anabolic steroids as many internet steroid forums recommend taking the drugs for no more than four weeks to avoid going “yellow” [12025].

Many different formulations and types of anabolic steroids are available to users. However, it is the 17alpha alkylated steroids, such as methandrostenolone and methyltestosterone that have the most capacity to be hepatotoxic – 17alpha alkylation slows down metabolism of the steroids in the liver, thereby exposing hepatocytes and cholangiocytes to the drug for longer. Fewer of the injectable anabolic steroids are 17alpha alkylated, so use of oral anabolic steroids is more commonly associated with abnormal liver function. Anabolic steroids vary in their androgenic and anabolic properties, and body builders often use several steroids with the intent of producing differing results. Most of these drugs are sourced either illegally or via the internet. The actual anabolic steroids used, and the true dosage, are often unknown to the user. Anabolic steroids are freely available online and there seems to be no regulation of the quality or quantity of drugs dispensed in the various formulations. Several “dietary supplements” have been found to contain substantial amounts of anabolic steroids. A report from Portugal described a case in which cardiomyopathy induced by anabolic steroids had caused fulminant liver failure in a bodybuilder who took large doses of anabolic steroids. A further, Canadian case report has described the simultaneous occurrence of cholestatic jaundice, acute kidney injury, and acute pancreatitis [12025].

Steroids induce a wide range of hepatic disorders ranging from impaired excretion, cellular hepatocyte changes, cholestasis, peliosis hepatitis, and hepatocellular hyperplasia to carcinomas. Androgen-related cholestasis has been observed in varying frequency from a few cases to 17 percent in some studies. The cholestasis results from the reduced bile transport and disruption of intrahepatic microfilaments. This jaundice appears to be transient in nature and is secondary to biliary stasis in the biliary canaliculi without any structural hepatic injury. This is in contrast to the associated inflammation and necrosis seen with other forms of hepatitis. There may also be a relationship between cholestasis and hypercholesteremia [06031].

Cholestasis is common, but often is asymptomatic or associated with subclinical elevation of hepatic transaminases. Hepatocellular hyperplasia and elevations of transaminases, conjugated bilirubin, alkaline phosphatase, and lactate dehydrogenase occur. Early elevation
of transaminases without increasing gamma-glutamyl transpeptidase may represent muscle damage; serum creatine phosphokinase should be measured. Dose-dependent jaundice is common after several months of AAS use and usually resolves after discontinuing AAS use. Steroid “cycling” is believed to reduce cholestasis and jaundice. Benign hepatic adenomas and rarer hepatocellular carcinoma have been reported in association with AAS use. Regression of adenomas after avoidance of AAS has occurred; death from carcinoma also has occurred. Peliosis hepatis is the presence of blood-filled cavities in the liver; this has occurred with iatrogenic AAS use and with AAS abuse. Sometimes reversible, peliosis hepatitis can cause liver failure, and the rupture of these cysts can cause fatal internal hemorrhage [07058].

Though possession of androgenic anabolic steroids (AAS) is illegal, non-prescription use of AAS persists. It was described two Caucasian males (aged 25 and 45 years) with cholestatic hepatitis following ingestion of the dietary supplement Mass-Drol (“Celtic Dragon”) containing the AAS 2alpha-17alpha-dimethyl-etochohan-3-one,17beta-ol. Despite substantial hyperbilirubinaemia peak gamma-glutamyl transferase (GGT) remained normal. Besides bland intralobular cholestasis, liver biopsy in both found deficiency of canalicular expression of ectoenzymes as seen in ATP8B1 disease. In the older patient, bile salt export pump marking (encoded by ABCB11) was focally diminished. It was hypothesized that AAS had either induced inhibition of normal ATP8B1/ABCB11 expression or triggered initial episodes of benign recurrent intrahepatic cholestasis (BRIC) type 1/or 2. On sequencing, ATP8B1 was normal in both patients although the younger was heterozygous for the c.2093G>A mutation in ABCB11, a polymorphism previously encountered in drug-induced liver injury. Thus, AAS marketed as dietary supplements continue to cause hepatotoxicity in the UK; underlying mechanisms may include unmasking of genetic cholestatic syndromes [13140].

It was describde two Caucasian males (aged 25 and 45 years) with cholestatic hepatitis following ingestion of the dietary supplement Mass-Drol (“Celtic Dragon”) containing the AAS 2alpha-17alpha-dimethyl-etochohan-3-one,17beta-ol. Despite substantial hyperbilirubinaemia peak gamma-glutamyl transferase (GGT) remained normal. Besides bland intralobular cholestasis, liver biopsy in both found deficiency of canalicular expression of ectoenzymes as seen in ATP8B1 disease. In the older patient, bile salt export pump marking (encoded by ABCB11) was focally diminished. We hypothesized that AAS had either induced inhibition of normal ATP8B1/ABCB11 expression or triggered initial episodes of benign recurrent intrahepatic cholestasis (BRIC) type 1/or 2. On sequencing, ATP8B1 was normal in both patients although the younger was heterozygous for the c.2093G>A mutation in ABCB11, a polymorphism previously encountered in drug-induced liver injury. It was concluded that AAS marketed as dietary supplements continue to cause hepatotoxicity in the UK; underlying mechanisms may include unmasking of genetic cholestatic syndromes [13142].

**Combination herbal and designer drugs**

It was reported a case of cholestatic jaundice as a result of combination herbal and designer supplement use. A 50-year-old Hispanic male presented to the hospital with a 1-week history of significant painless jaundice; total bilirubin on admission was 29.4 mg/dL. He reported use of both herbal (creatine and whey protein) and designer (Incredible Bulk and Spartan 45) supplements concurrently for approximately 2 months. Upon admission, all supplements were discontinued and multiple laboratory and diagnostic tests were ordered. On day 6 of his hospital admission, a liver biopsy was performed, the results of which indicated drug-induced hepato toxicity. On day 9 he was discharged with prescriptions for ursodeoxycholic acid and hydroxyzine. Three months post hospital discharge, the patient continued to be supplement-free and bilirubin had decreased substantially. Anabolic-androgenic steroids are capable of causing hepatotoxicity, and multiple cases reported in the literature support this. A case report described hepatotoxicity secondary to both creatine and whey protein consumption, and several reports have described liver damage secondary to designer supplement use. To
our knowledge, this is the first case to describe hepatotoxicity as a result of combination herbal and designer supplement use. The Roussel Uclaf Causality Assessment Method (RUCAM) score for drug-induced hepatotoxicity indicated a highly probable correlation between the use of combination supplements and cholestatic jaundice [13141].

Non-alcoholic fatty liver disease (NAFLD)

Industrial toxin and drugs have been associated with non-alcoholic fatty liver disease (NAFLD); in these cases, the disease has been termed toxicant-associated steatohepatitis (TASH). One study hypothesized that the use of anabolic-androgenic steroids (AAS) could also be a risk factor to TASH or better toxicant-associated fatty liver disease (TAFLD) development. A case-control study including 180 non-competitive recreational male bodybuilders from 2007 to 2009 was performed. Ninety-five had a history of intramuscular AAS use (cases; G1) and 85 were non-users (controls; G2). They underwent a clinical evaluation and abdominal ultrasound, and their blood levels of aminotransferases, creatine phosphokinase (CPK), lipids, glucose and insulin were measured. TAFLD criteria: history of AAS use >2 years; presence of hepatic steatosis on ultrasound and/or aminotransferase alterations with normal CPK levels; exclusion of ethanol intake ≥20 g/day or use of other drugs; and exclusion of obesity, dyslipidaemia, diabetes and other liver diseases. Homeostasis model assessment for insulin resistance ≥3 was considered insulin resistant. All cases were asymptomatic. Clinical and laboratorial data were similar in G1 and G2. TAFLD criteria were observed in 13 percent of the G1 cases and 2 percent of controls had criteria compliant with non-alcoholic fatty liver related to metabolic conditions. Odds ratio was 6.0 (95 % confidence interval 1.3 to 27.6). These results suggest that AAS could be a possible new risk factor for TAFLD. In this type of fatty liver disease, the individuals had a low body fat mass and they did not present insulin resistance [11066].

Peliosis

Other rare hepatic lesions include some potentially life-threatening lesions. Peliosis hepatis is a blood-filled cyst seen in many case reports in patients taking oral androgens, and is often correlated with more prolonged use. In the majority of these cases, the lesions were identified incidentally, most on autopsy, and the patients were completely symptom free. Several case reports of patients show direct mortality from internal hemorrhage or hepatic failure secondary to these lesions. Both cholestasis and peliosis hepatis are believed to be explained by similar processes. Oral 17-alpha alkylated androgens produce hepatocyte hyperplasia, with enlarged hepatocytes occluding both hepatic venous return and sinusoids. Sinusoidal dilatation at the peripheral zone of the hepatic lobule is a common finding with anabolic steroid use [06031].

Hepatocellular adenoma and carcinoma

Medical literature documents isolated cases of androgen- associated hepatic tumors. Many of these reports were in patients with known hereditary anemias being treated with long-term androgens. Most of these tumors are benign adenomas, but early detection may lead to prevention of life-threatening complications associated with these tumors. Hepatic adenomas are usually found in young women taking oral contraceptives, and are still relatively uncommon. These adenomas are hypervascular tumors with relatively thin-walled capsules [. They rarely transform to malignant tumors, but have risks of sudden rupture and bleeding, leading to hemoperitoneum which is a life-threatening condition. A particular problem is differentiating adenomas from hepatocellular carcinomas by ultrasound. If the differentiation is not obvious by clinical and histologic findings, a surgical resection is recommended.
Treatment protocols for these lesions are difficult to formulate secondary to their varied prognosis, their difficult resection, and their unknown potential for malignancy. However, regression of the majority of these lesions after discontinuation of the steroids raises the question if there is truly malignant potential attributable to AAS use. Most of these lesions are linked to usage of the orally administered 17-alpha alkylated AAS. Sources recommend repeat ultrasound every 6 months with consideration of excision if late diagnosis is made. Nonsurgical options should be the optimal approach because many of the tumors will regress after discontinuation of the AAS, especially if detected early. Prompt detection of these lesions prevents important, potentially life-threatening sequelae and possible malignant deterioration [06031].

In a case report a 35-year-old male bodybuilder was found to have a hepatocellular carcinoma (HCC) arising in a pre-existing hepatic adenoma following recreational anabolic steroid use. Malignant transformation to HCC from a pre-existing hepatic adenoma confirmed by immunohistochemical study has previously not been reported in athletes taking anabolic steroids [08146].

**Hepatocellular necrosis.**

Case reports associate AAS abuse with hepatic enlargement, peliosis hepatitis, serious cholestatic jaundice [2,17-dimethylidihydrotestosterone(methasterone)], and hepatorenal failure, particularly following the use of oral 17alpha-alkylated AAS (e.g. methandrostenolone, methyltestosterone, oxymetholone, oxandrolone, and stanozolol). Typically, non-17-alkylated anabolic steroids are not associated with hepatocellular damage. Jaundice typically resolves several months after cessation of AAS use, and liver transplantation is not usually necessary. Case reports also associate the use of high doses of AAS with the development of hepatocellular necrosis. A 26-year old male bodybuilder reportedly used testosterone enanthate (500 mg intramuscularly twice weekly), stanozolol (40 mg orally/day), and methylandrostenediol (30 mg/day orally for 5 weeks). He subsequently developed evidence of severe hepatitis with hepatic dysfunction that required a prolonged hospitalization. Peliosis hepatitis is a rare illness characterized by blood-filled spaces within the hepatic parenchyma that typically occurs in association with a variety of chronic wasting diseases (e.g. tuberculosis and malignancy). This condition has been associated with both the chronic use of pharmacologic doses of AAS and the chronic, intermittent abuse of AAS by bodybuilders. The appearance of peliosis hepatitis is not related to the dose of AAS or duration of use. Some athletes using AAS take polyunsaturated phospholipids and vitamin complex to reduce the elevation of hepatic aminotransferases often associated with the use of AAS; however, there are inadequate data to determine the efficacy of this combination supplement [13003].

**Spontaneous hepatic rupture**

Anabolic androgenic steroids are commonly used at high doses by bodybuilders and athletes to enhance physique and improve performance levels. It was reported a case of spontaneous hepatic rupture with life-threatening haemorrhage associated with a past history of anabolic steroid use [07062].

**Anabolic steroids and reproductive system and male infertility**

There is no doubt that lifestyle factors can be detrimental to fertility. The aim of one pilot study was to identify initial prevalence rates for behaviour-related fertility disorders in a clinical sample of couples wanting a child. Between February and August 2010, all patients
coming for the first time to Heidelberg University's Women's Hospital for consultation on involuntary childlessness were asked to fill out a questionnaire designed by the authors of this article. The questionnaire was based on a review of the relevant literature, with special reference to the latest research findings on behaviour detrimental to fertility. Of the 156 couples addressed, 110 women and 100 men took part in the study. For behaviour-related infertility, 9 percent of the women and 3 percent of the men in our sample were classified on the basis of BMI <18.5, sexual disorders, or abuse of anabolic steroids. If it was included smokers, these figures increase: 11 percent female smokers and 18 percent male smokers. A further 19 percent of the women practised sport to an excessive degree; and 26 percent of the women and 53 percent of the men had a BMI ≥25. The prevalence of behaviour-related fertility disorders should not be underestimated. For the prevention of behaviour-related fertility disorders, it is important to inform the population about lifestyle-mediated fertility risks [12144].

One-third of infertile couples may have a male factor present. Illicit drug use can be an important cause of male factor infertility and includes use of anabolic-androgenic steroids, marijuana, opioid narcotics, cocaine, and methamphetamine. The use of these illicit drugs is common in the United States, with a yearly prevalence rate for any drug consistently higher in males compared with females. The aim of one study was to provide a review of recent literature on the prevalence and effects of illicit drug use on male fertility and to aid health professionals when counseling infertile men whose social history suggests illicit drug use. Anabolic-androgenic steroids, marijuana, cocaine, methamphetamine, and opioid narcotics all negatively impact male fertility, and adverse effects have been reported on the hypothalamic-pituitary-testicular axis, sperm function, and testicular structure. The use of illicit drugs is prevalent in our society and likely adversely impacting the fertility of men who abuse drugs [12145].

AAS abuse inhibits gonadotropins secretion, endogenous testosterone production and spermatogenesis. AAS-induced sperm alterations include oligozoospermia, azoospermia, decreased sperm motility, and abnormal sperm morphology. These often result in decreased fertility in males. After AAS withdrawal the inhibited HPT axis functions will restore, but not always, within several months. In bodybuilders with a history of long-term AAS abuse, at least 6/12 months are needed for a full recovery of testicular functions. Clomiphene may successfully restore AAS-induced male HPG dysfunction and gonadotropins have been used to recover from AAS-linked azoospermia [12094].

The negative impact of AAS abuse on male fertility is well known by urologists. The secondary hypogonadotrophic hypogonadism is often highlighted when AAS and fertility are being discussed. On the other hand, the patterns of use, mechanisms of action and direct effects over the testicle are usually overseen. One study reviews the vast formal and "underground" culture of AAS, as well as their overall implications. Specific considerations about their impact on the male reproductive system are made, with special attention to the recent data on direct damage to the testicle. This kind of overview is absolutely unique, offering a distinguished set of information to the day-by-day urologists. For several decades, testosterone and its synthetic derivatives have been used with anabolic and androgenic purposes. Initially, these substances were restricted to professional bodybuilders, becoming gradually more popular among recreational power athletes. Currently, as many as 3 million anabolic-androgenic steroids (AAS) users have been reported in the United States, and considering its increasing prevalence, it has become an issue of major concern. Infertility is defined as the failure to achieve a successful pregnancy after 12 months or more of regular unprotected intercourse, with male factor being present in up to 50 percent of all infertile couples. Several conditions may be related to male infertility. Substance abuse, including AAS, is commonly associated to transient or persistent impairment on male reproductive
function, through different pathways. Herein, a brief overview on AAS, specially oriented to urologists, is offered. Steroids biochemistry, patterns of use, physiological and clinical issues are enlightened. A further review about fertility outcomes among male AAS abusers was also presented, including the classic reports on transient axial inhibition, and the more recent experimental reports on structural and genetic sperm damage [11571].

Infertility is generally defined as the inability to conceive a pregnancy or the failure to do so within a reasonable period (typically 12 months). Approximately 85 percent of couples conceive a first pregnancy within 12 months. The prevalence of infertility has increased over the past 10 years, with approximately 10 million affected couples in the United States. Roughly 40-50 percent of infertility is either due to, or is contributed by, a male factor. Given how common the condition is, men and their partners are understandably concerned and interested in identifying and eliminating risk factors for male infertility. One article reviewed the available literature on various aspects of male infertility related to athletic pursuits. These include the effects of exercise on semen parameters, hormonal axes, and testicular health. Due to the prevalence and particular relevance of anabolic steroid use by athletes and the impact of steroid use on fertility, this topic was also reviewed [10448].

In a case report of primary gonadal failure due to the chronic abuse of anabolic steroids used for bodybuilding the clinical symptoms, levels of serum T, FSH, and LH were given. It was a case of initially secondary gonadal failure resulting from anabolic steroid use with subsequent primary gonadal failure and infertility. It adds to the current literature and illustrates that the side effects of anabolic steroids can be prolonged and irreversible [11324].

Long-term side effects of high doses of anabolic androgenic steroids self-administration were evaluated in this study. Twenty male bodybuilders, voluntarily starting steroid self-administration, were followed every 6 months over 2 years. Physical examination, haematological, metabolic and endocrine variables, semen analysis, hepatic and prostate ultrasound and echocardiographic evaluations were performed. LH values were suppressed at 18 and 24 months and FSH at 6, 12, 18, and 24 months and SHBG values significantly lowered at 12, 18, and 24 months. A significant decrease in spermatozoa count and fertility index occurred. HDL-cholesterol was reduced at 18 and 24 months and Apo A-1 at 12, 18, and 24 months. The most important long-term adverse effects were lower fertility and the impairment of lipid profile associated with an increased cardiovascular risk [07071].

Although the same androgen receptor mediates both the anabolic and androgenic effects of steroids, the specific structural characteristics of individual AASs determine the balance between the anabolic and androgenic effects. Masculinization results from the presence of high doses of AASs in women. The aromatase cytochrome P450 (CYP19) enzyme complex converts testosterone to estradiol, which binds to the estrogen receptor. Although this conversion usually accounts for a small percentage of testosterone biotransformation at physiologic doses, excess amounts of testosterone increase the formation of estradiol. Gynecomastia is a consequence of excessive estradiol concentrations in chronic male AAS abusers that result from the peripheral conversion of excess testosterone to estradiol. Drug used by male AAS abusers to prevent the feminizing effects of estradiol include the use of aromatase inhibitors (e.g. anastrozole, and aminoglutethimide) and drugs that block estrogen receptor (clomiphene and tamoxifen) [13003].

All AASs suppress gonadotropin secretion and therefore suppress endogenous testicular function. Adverse effects of AASs on the male reproductive system include reduced hormone levels (gonadotrophic hormones, endogenous testosterone, and sex-hormone-binding globulin), impotence (erectile dysfunction), alterations in sperm morphology, and reductions in sperm count, sperm motility, and the size of the testicles. These changes are not
responsive to the administration of human chorionic gonadotropin, and resolution of the alterations in sperm count occurs several months after cessation of AAS use with some individuals requiring up to 30 weeks of abstinence. Although chronic AAS abuse produces hypogonadism, decreased serum testosterone, and impaired spermatogenesis, these changes are reversible within a few months to 1 year following cessation of AAS use. Abnormalities of the female reproductive system following chronic AAS abuse include menstrual irregularity, deep voice, increased libido, and increased clitoris size along with elevated sex-hormone-binding globulin. Anabolic-androgenic steroids are contraindicated in pregnant women with potential effects including masculinization of the female fetus, clitoral hypertrophy of the female fetus, decreased birth weight, and premature bone maturation [13003].

**Physiology of reproduction-endocrinology**

Exogenous steroids exert their affect on adrenal hormones by negative feedback on the hypothalamic-pituitary-gonadal axis. Large doses of exogenous AAS lead to a decrease in both follicle-stimulating hormone and luteinizing hormone serum concentrations. There is some controversial evidence to show that high doses of exogenous steroids lead to spontaneous increases in growth hormone (GH) production. In one study of men with hypogonadotropic hypogonadism, testosterone enanthate administration resulted in marked increases in spontaneous GH secretion. This elevation of GH provides the negative feedback that leads to decreased endogenous testosterone and gonadotropin release. Suppression of gonadotropin release leads to oligospermia and hypogonadism. This is reflected by decreased levels of testicular precursors of testosterone, namely serum pregnenolone, progesterone, 17-hydroxyprogesterone, and 17-hydroxypregnenolone. Supraphysiologic doses of AAS may lead to infertility due to decrease in both quantity and quality of sperm after several months of use. The return of normal levels of FSH and LH concentrations after discontinuation of AAS can take 6 to 12 weeks, whereas normalization of endogenous serum testosterone levels requires several additional weeks even after the return of normal gonadotropin levels. The amount of time needed for full recovery of normal reproductive function varies both on dose and duration of steroid use and can range from 4 to 5 months to several years. Many athletes turn to human chorionic gonadotrophin or clomiphene to reverse or even maintain spermatogenesis following or during courses of AAS [06031].

Since its isolation and characterization in 1935, there have been further studies on testosterone which have led to the synthesis of numerous derivatives with properties different from the original molecule. It is in 2011 estimated that there are as many as three million AAS users in the USA. Interestingly, two thirds of US users are non-competitive bodybuilders, or even non-athletes, who use these substances for aesthetic purposes only. The negative impact of AAS abuse on male fertility is well known by urologists. Infertility is defined as the failure to achieve a successful pregnancy after 12 months or more of regular unprotected intercourse, and male-factor infertility is the cause in about 50 percent of all infertile couples. Several conditions may explain male-factor infertility. Some are identifiable, but not reversible; others may be identified and also reversed. Hypogonadotrophic hypogonadism is a typical example of a reversible condition, whereas primary testicular impairment is often related to a less reversible one. The secondary hypogonadotropic hypogonadism is often highlighted when AAS and fertility are being discussed. On the other hand, the patterns of use, mechanisms of action and direct effects over the testicle are usually overseen. One review studied the vast formal and "underground" culture of AAS, as well as their overall implications. Specific considerations about their impact on the male reproductive system are made, with special attention to the recent data on direct damage to the testicle. For several decades, testosterone and its synthetic derivatives have been used with anabolic and androgenic purposes. Initially, these substances were restricted to
professional bodybuilders, becoming gradually more popular among recreational power athletes. Currently, as many as 3 million anabolic-androgenic steroids (AAS) users have been reported in the United States, and considering its increasing prevalence, it has become an issue of major concern. Infertility is defined as the failure to achieve a successful pregnancy after 12 months or more of regular unprotected intercourse, with male factor being present in up to 50 percent of all infertile couples. Several conditions may be related to male infertility. Substance abuse, including AAS, is commonly associated with transient or persistent impairment on male reproductive function, through different pathways. Infertility after AAS abuse commonly presents as oligozoospermia or azoospermia, associated with abnormalities in sperm motility and morphology. According to most reports, sperm quality tends to recover spontaneously within 4-12 months after discontinuation. However, the negative effect on semen quality may persist for longer periods. A hypogonadotrophic hypogonadism state is induced, characterized by decreased serum testosterone concentrations, testicular atrophy and impaired spermatogenesis. These effects result from the negative feedback of androgens on the hypothalamic-pituitary axis, and possibly from local suppressive effects of exogenous androgens on the testes. FSH and luteinizing hormone (LH) concentrations are typically low. In addition, during AAS use, serum androgen concentrations may be supraphysiological high, but the hypogonadotrophic state lowers the intratesticular testosterone concentrations required to maintain normal spermatogenesis. The management of AAS-induced male infertility has also been extensively reported. Simple discontinuation of AAS use may lead to fertility recovery in a certain proportion of male users, but there is little literature and considerable disagreement regarding the management of such cases. Patients may also be actively treated, in a manner similar to that used for other forms of hypogonadotrophic hypogonadism infertility, requiring the induction of spermatogenesis with gonadotropins or gonadotropin analogues, including i.m. injections of hCG, human menopausal gonadotropin (hMG) or even recombinant FSH. The use of hCG alone, or in combination with hMG, has been reported to be a successful treatment for this group of patients. Fertility restoration has been reported, even in situations of persistent azoospermia up to 5 years after AAS discontinuation so AAS-associated male infertility may be treatable because of its endocrine nature. Considering the prevalence of AAS abuse and the favourable results after treatment, it is reasonable to consider it during the infertility consultation [11028].

In men, chronic AAS use can lead to decreased endogenous testosterone production and hypogonadotrophic hypogonadism associated with testicular atrophy. Chronic AAS abuse causes a decrease in gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) as part of the negative feedback system of the hypothalamic-pituitary-gonadal axis. LH and FSH are needed for spermatogenesis so when these hormones are decreased, there is a decrease in sperm count and mobility as well as an increase in the number of morphologically abnormal sperm. One study found a 73 percent overall decrease in sperm count; three individuals had azoospermia with chronic use of high-dose AASs. In individuals who did not experience azoospermia, there was a 10 percent increase in the number of immotile sperm and a 30 percent decrease in the number of motile sperm. Overall, fertility was severely reduced. Decreases in gonadotropins can be seen within 24 hours of beginning AASs. Infertility may result within months. After cessation of use, gonadotropin and testosterone secretion are suppressed for months to years. Usually, the infertility is spontaneously reversible, typically within 1 year of cessation of AAS abuse, but it may take longer in long-term users. At least one user of multiple AASs did not recover fertility spontaneously and required treatment with LH-releasing hormone to regain normal levels of testosterone and fertility. Men also may experience priapism, impotence, prostatic hypertrophy, difficulty/pain with urination, and a possible increased risk for prostate cancer. The risk for these consequences increases with dose and duration of use [07058].
Exogenous steroid administration thus provides feedback inhibition of luteinizing and follicle-stimulating hormones, which leads to testicular atrophy and decreased spermatogenesis. This testicular impairment is reversed upon cessation of AAS use. Excess steroids undergo peripheral aromatization to estrogens, which results in feminizing changes of high voice pitch and male gynecomastia. In long-term AAS abuse, this gynecomastia is irreversible, leaving surgical correction as the only solution. In addition to the female side effects of decreased menstruation and breast tissue atrophy, virilizing effects also occur and include deepened voice, clitoromegaly, and hirsutism. Sometimes these effects are irreversible, even after discontinuation of AAS use [07008].

**Anabolic steroid-induced hypogonadism in young men**

Use of anabolic androgenic steroids (AAS) has not been traditionally discussed in mainstream medicine. With the increased diagnosis of hypogonadism, a very heterogeneous population of men is now being evaluated. Within this larger population of patients, the existence of anabolic steroid-induced hypogonadism (ASIH), whether transient or permanent, should now be considered. An initial retrospective database analysis of all patients (2005-2010, n=6033) seeking treatment for hypogonadism was conducted. Subsequently, an anonymous survey was distributed in 2012 to established patients undergoing testosterone replacement therapy (TRT). Profound hypogonadism, defined as a testosterone ≤50 ng/dL, was identified in 1.6 percent (n=97) of the large retrospective cohort initially reviewed. The most common etiology was prior AAS exposure, identified in 43 percent (42/97) of men. Because of this surprising data, a follow-up anonymous survey of our current hypogonadal patient population (n=382; mean age 49 ± 13 years) was then performed which identified 21 percent of patients (n=80; mean age 40 ± 8 years) with prior AAS exposure. Hypogonadal men <50 years old were greater than 10 times more likely to have prior AAS exposure than men >50 (OR 10). Prior AAS use was significantly negatively correlated with education level and number of children. Prior AAS use is common in young men seeking treatment for symptomatic hypogonadism, and ASIH is the most common etiology of profound hypogonadism. These findings suggest a necessary refocused approach in the evaluation and treatment paradigms of young hypogonadal men [13152].

The use of anabolic androgenic steroids has not been traditionally discussed in mainstream medicine. With the increased diagnosis of hypogonadism a heterogeneous population of men is now being evaluated. In this larger patient population the existence of anabolic steroid induced hypogonadism, whether transient or permanent, should now be considered. It was performed an initial retrospective database analysis of all 6,033 patients who sought treatment for hypogonadism from 2005 to 2010. An anonymous survey was subsequently distributed in 2012 to established patients undergoing testosterone replacement therapy. Profound hypogonadism, defined as testosterone 50 ng/dL or less, was identified in 97 men (1.6 %) in the large retrospective cohort initially reviewed. The most common etiology was prior anabolic androgenic steroid exposure, which was identified in 42 men (43 %). Because of this surprising data, it was performed an anonymous follow-up survey of our current hypogonadal population of 382 men with a mean ± SD age of 49 ± 13 years. This identified 80 patients (21 %) with a mean age of 40 ± 8 years who had prior anabolic androgenic steroid exposure. Hypogonadal men younger than 50 years were greater than 10 times more likely to have prior anabolic androgenic steroid exposure than men older than 50 years (OR 10). Prior anabolic androgenic steroid use significantly correlated negatively with education level and number of children. It was concluded that prior anabolic androgenic steroid use is common in young men who seek treatment for symptomatic hypogonadism and anabolic steroid induced hypogonadism is the most common etiology of profound hypogonadism. These findings suggest that it is necessary to refocus the approach to evaluation and treatment paradigms in young hypogonadal men [13153].

**Azospermi**

Azoospermia may sometimes be related to the use of androgenic anabolic steroids. It was reported a case of an azoospermic man who had abused androgenic anabolic steroids and who recovered spermatogenesis six months after cessation of abuse and the administration of hormonal therapy. An azoospermic 34-year-old man came to Regional Referral Center for Male Infertility. The recovery of spermatogenesis was observed after the cessation of abuse of steroids and the administration of hormonal therapy. Ultrastructural analysis of sperm was carried out by transmission electron microscopy, and the meiotic segregation of chromosomes 1, 9, 18, X, Y was investigated. Mathematically elaborated transmission electron microscopy data highlighted seminal features close to normal fertility. Fluorescence in situ hybridisation showed a high frequency of XY disomy in sperm. The findings confirm the recovery of spermatogenesis but suggest a possible relationship between altered meiotic segregation and the abuse of androgenic anabolic steroids [07072].

**Spermatogenesis**

It was reviewed the current literature for the effect of hormones used in rejuvenation clinics on the maintenance of spermatogenesis. Exogenous testosterone and anabolic androgenic steroids suppress intratesticular testosterone production, which may lead to azoospermia or severe oligozoospermia. Therapies that protect spermatogenesis involve human chorionic gonadotropin (hCG) therapy and selective estrogen receptor modulators (SERMs). The studies examining the effect of human growth hormone (HGH) on infertile men are uncontrolled and unconvincing, but they do not appear to negatively impact spermatogenesis. At present, routine use of aromatase inhibitors is not recommended based on a lack of long-term data. The use of hormones for rejuvenation is increasing with the aging of the Baby Boomer population. Men desiring children at a later age may be unaware of the side-effect profile of hormones used at rejuvenation centers. Testosterone and anabolic androgenic steroids have well-established detrimental effects on spermatogenesis, but recovery may be possible with cessation. Clomiphene citrate, human growth hormone (HGH)/insulin-like growth factor-1 (IGF-1), human chorionic gonadotropin (hCG), and aromatase inhibitors do not appear to have significant negative effects on sperm production, but quality data are lacking [13151].

**Histopathology**

Experiments in animal models mainly report AAS-induced Leydig cell alterations, but cellular morphology anomalies have also been reported. The decrease in this population of cells is accompanied by low testosterone and LH levels in all papers reviewed, especially in those papers reporting on adult animal models. Immunohistochemical findings have suggested decreased steroidogenesis in testicular tissue, hence spermatogenesis was considered unchanged by some other authors. Nethertheless, specific end-stage spermatogenesis impairment, with a lack of advanced forms of spermatids, has been described. After AAS discontinuation, Leydig cells tend to proliferate but remain below the regular counts, even after longer periods. Clearly, long-lasting, or possibly persistent effects of AAS use cannot be ruled out [11028].

**Impact on semen quality**

The use of a combination of hCG and steroids is a common practice among AAS users. The goal is to avoid the impact of LH suppression after long-term AAS administration, which may lead to a persistent state of hypogonadism and low-quality semen. Restoration of
Spermatogenesis has been described; however, more abnormal and hypokinetic spermatozoa are found, even after hCG “post-cycle” use, showing a potential for persistent alterations after the discontinuation of AAS use [11028].

Aneuploidies and ultrastructural changes in spermatozoa

The innovative use of both transmission electron microscopy and fluorescence in situ hybridization (FISH) has recently been reported in an AAS user sperm sample, searching for genetic and ultrastructural consequences of steroid abuse. Immaturity, necrosis and apoptosis were assessed, and a high percentage of structurally normal spermatozoa were found, which showed the absence of a correlation between AAS and ultrastructural sperm changes. In contrast to these findings, FISH sperm analysis revealed XY and chromosomes 1 and 9 disomies, suggesting anomalies in the meiotic process and genetic damage among AAS users [01128].

Case report

A 32-year-old man complained about a reduction of testicular volume and loss of libido. He had been abusing androgenic anabolic steroids for 7 years. Genital examination revealed that both testicular volumes were reduced to 13 ml. Endocrinological investigations showed luteinizing hormone, follicle-stimulating hormone and total testosterone levels to be low. The level of free testosterone was documented to be high. Later, sex hormone-binding globulin (SHBG) and calculated bioavailable testosterone (cBAT) levels were found to be low. Based on these features, it was diagnosed hypogonadotrophic hypogonadism caused by AAS abuse. Treatment with injections of human chorionic gonadotropin (hCG) was started. About one month after treatment with hCG started, his symptoms and endocrinological features were not improved. It is also reported that normal hormonal function usually recovers after AAS are discontinued, but sometimes the condition is not reversible [08144].

Reproductive-endocrine effects in women

The sexual and reproductive effects of AAS are more dramatic in women. Although AASs have been developed to try to minimize androgen effects, all AASs exert some degree of virilizing effects if given for long enough and in sufficiently large doses. Virilization occurs with AAS use by women, regardless of the type used. Early effects include acne, deepening of the voice, and changes in libido. Deepening of the voice occurs as a result of laryngeal hypertrophy. Long-term use can lead to clitoral enlargement, male-pattern baldness, and alterations in pubic hair. Other virilizing effects include decreased body fat, breast atrophy, amenorrhea or oligomenorrhea, uterine atrophy, and hirsutism. The changes in menses are due to suppression of the hypothalamic-pituitary-gonadal axis. Some of these effects may be irreversible with chronic use. AASs may act as a teratogen [07058].

Skin

Cutaneous manifestations develop early in the use of anabolic-androgenic steroids, placing dermatologists in a unique position to make an early diagnosis of AAS abuse in patients who engage in competitive sports. One review of the literature focuses on dermatologic presentations of anabolic-androgenic steroids use [09055].

The most common dermatologic effects of AAS abuse are alopecia, male pattern baldness,
and hirsutism, particularly in women. Other adverse dermatologic effects include keloid formation, sebaceous cysts, comedones, seborrheic furunculosis, folliculitis, striae, and acne. A common triad of chronic AAS abuse is the combination of acne, striae, and gynecomastia. Hyperplasia of the pilosebaceous glands and increased sebum production cause a high incidence of acne in chronic AAS abusers. These effects become prominent about 1 month after initiation of AAS abuse, depending on the dose and frequency of use [13003].

**Acne**

A 22-year-old male amateur bodybuilder presented with a 3-month history of severe acne lesions on his upper trunk and face, accompanied by arthralgia of several joints. He reported the use of anabolic androgenic steroids (AAS) (testosterone enanthate, trenbolone acetate, drostanolone propionate, and methandrostenolone) for 3 months to increase his muscle mass. Shortly after he discontinued AAS intake, he developed severe inflammatory acne with painful rupturing and draining inflammatory nodules, pustules, and hemorrhagic ulcerations on his upper trunk and face. Moreover, he described an immobilizing arthralgia of his right ankle and both shoulder joints, as well as general symptoms including fatigue and a 15-kg weight loss over the 6 weeks prior to presentation. As derivatives of the hormone testosterone, AAS lead to hypertrophy of the sebaceous glands, increased sebum production, and increased density of the *Propionibacterium acnes* population. The patient developed AAS-induced acne fulminans with the typical unresponsiveness to systemic antibiotics. After initial therapy with oral prednisolone, 0.5 mg/kg, and debridements, a clinical response was achieved with isotretinoin, 0.75 mg/kg. In conclusion, it is important for health care providers to keep in mind that androgen-induced acne is one of the most frequent symptoms of AAS abuse. The most important measure is the immediate termination of AAS administration [12141].

Severe cases of acne, especially on the face and back of AAS users, are common dermatologic findings. Premature baldness is noted as well. It has been reported multiple cases of serious muscular abscesses resulting from the common practice of shared needles and shared steroid vials among adolescent AAS users. A limited knowledge of sterile injection technique, as well as limited access to sterile needles and syringes are likely additional causative factors in these infections [07008].

Abuse of anabolic-androgenic steroids (AAS) by members of fitness centers and others in Germany has reached alarming dimensions. Besides health-threatening cardiovascular, hepatotoxic and psychiatric long-term side effects of AAS, acne occurs in about 50 percent of AAS abusers and is an important clinical indicator of AAS abuse, especially in young men 18-26 years of age. Both acne conglobata and acne fulminans can be induced by AAS abuse. The dermatologist should recognize bodybuilding acne, address the AAS abuse, and warn the patient about other potential hazards [07074].

Men experience male-pattern baldness, acne (mostly on the trunk), which likely is due to the effects of DHT. Acne is the result of androgenic stimulation of sebaceous glands [07058].

**Hirsutism**

Hirsutism is a symptom or sign, which may have more serious associations than cosmetic and psychological concern alone, such as adrenal hyperplasia and ovarian tumor, particularly if it develops well after puberty. Some medicines having androgenic activity may also cause this problem. It was presented a case of a young unmarried girl who was given anabolic steroid for the treatment of dysmenorrhoea which resulted in hirsutism [06092].
Androgenic alopecia (baldness)

Adolescent androgenic alopecia is pattern hair loss occurring in boys and girls younger than 18 years, whereas early-onset androgenic alopecia refers to pattern hair loss before 35 years of age. A number of studies published in the last decade have helped to elucidate the prevalence of adolescent androgenic alopecia, have clarified the genetic as well as physiologic mechanisms underlying hair loss, and have revealed the associated psychologic and systemic morbidities. One article provides an overview of the pathophysiology, diagnosis, and treatment of adolescent androgenic alopecia [11448].

Effects on the immune system

Anabolic-androgenic steroids are potentially immunosuppressive based on a study suggesting that chronic AAS abuse reduces immunoglobulins (i.e. IgA), increases natural killer cell activity, and increases mitogen response to staphylococca lantigens. There were no significant differences in T-cell subsets among steroid users and non-users in this study. However, the clinical relevance of these potential immunosuppressive effects is unclear. Sporadic case reports associated infectious complications from the parenteral use of AASs including local abscess at the site of injection, septic arthritis, HIV, and hepatitis, usually as a result of sharing contaminated needles [13003].

Infection risks after injections of anabolic steroids

To describe drug use, sexual risks and the prevalence of blood-borne viral infections among men who inject image and performance enhancing drugs (IPEDs), 19 needle and syringe programmes with 395 men who had injected PEDs were investigated Of the participants (median age 28 years), 36 percent had used IPEDs for <5 years. Anabolic steroids (86 %), growth hormone (32 %) and human chorionic gonadotropin (16 %) were most frequently injected, with 88 percent injecting intramuscularly and 39 percent subcutaneously. Two-thirds also used IPEDs orally. Recent psychoactive drug use was common (46 % cocaine, 12 % amphetamine), 5 percent had ever injected a psychoactive drug and 9 percent had shared injecting equipment. Viagra/Cialis was used by 7 percent, with 89 percent reporting anal/vaginal sex in the preceding year (20 % had 5+ female-partners, 3 % male-partners) and 13 percent always using condoms. Overall, 1.5 percent had HIV, 9 percent had antibodies to the hepatitis B core antigen (anti-HBc) and 5 percent to hepatitis C (anti-HCV). In multivariate analysis, having HIV was associated with: seeking advice from a sexual health clinic; having had an injection site abscess/wound; and having male partners. After excluding those reporting male partners or injecting psychoactive drugs, 0.8 percent had HIV, 8 percent anti-HBc and 5 percent anti-HCV. Only 23 percent reported uptake of the hepatitis B vaccine, and diagnostic testing uptake was poor (31 % for HIV, 22 % for hepatitis C) [13026].

Despite intensive information on possible side effects and complications of performance-enhancing substances in sports, the use of AAS (anabolic androgenic steroids) is far common. Particularly in sports like bodybuilding or weight lifting AAS are used for setting up muscle mass and increasing muscle power. It was presented a case of a 27 year old bodybuilder, who was transferred due to suspected malignant expansion of the upper limb to a department of orthopaedic surgery, not knowing that the patient had injected AAS. At biopsy the tumor was found to be an abscess formation, that had to be treated surgically with curettage. The microbiological analysis detected an infection with Pseudomonas fluorescens
and Erwinia species. Erwinia species are associated with plants. Pseudomonas fluorescens is found in feces, sewage and soil. It is obvious, that the infection is caused by an inappropriate injection of AAS or by the contamination of the injected substances [07077].

Detailed data on performance- and image-enhancing drug injections are difficult to obtain because of the illicit and unsupervised way in which many these drugs are used, and the hidden nature of the group. One study examined the patterns of use, risk behaviours and related harm associated with injections. Data were obtained via a structured questionnaire administered in face-to-face interviews with 60 men who used performance- and image-enhancing drugs (primarily anabolic androgenic steroids) for non-medical purposes. Although the rates of needle sharing were low (5 %), the men more frequently reported re-use of needles/equipment, injecting from a shared container (bladders, vials, etc.), injecting other illicit drugs, injecting insulin and targeting small muscle groups. Self-reports of being hepatitis C antibody positive were associated with lifetime use of heroin and injection of other illicit drugs. All HIV positive participants were gay or bisexual men. Participants reported a range of other injection-related injuries and diseases such as fevers, scarring and abscesses. “Risky injectors” (38 % of participants) were more likely to initiate performance- and image-enhancing drugs use at a younger age, use these drugs in a larger number of cycles per year and report involvement in a violent/aggressive incident than “low risk” injectors and report involvement in a violent/aggressive incident than “low risk” injectors. Participants mainly reported seeking information about performance- and image-enhancing drugs from internet sites (62 %) and friends (55 %). It was concluded that over-reliance on personal networks and internet forums limits this groups' access to objective harm reduction advice and primary care services [08148].

Injection policies

High-performance sporting organizations should have strict policies in place around injection therapy. Injection therapy in high-performance sport should be limited to the treatment of illness or injury by the medical practitioner. There is no role for injection therapy as part of a supplementation programme. If routine injection therapy is taking place as part of a supplementation programme, one of the two things occurs:

1. The person doing the injecting is misleading the athlete and the sporting organisation by injecting substances such as vitamins or other substances, for which there is no scientific basis in the preparation of elite athletes.
2. The person doing the injecting is committing a doping violation.

No member of the support staff should be permitted to administer injections apart from the medical practitioner. No one in a sporting organisation should be permitted to possess injection equipment (syringes and hypodermic needles) other than the team doctor, the only exception being those athletes who have certified medical conditions such as diabetes, anaphylactoid reactions, etc [13027].

Gynecomastia

Drugs are estimated to cause about 10-25 percent of all cases of gynecomastia. Over the course of several decades, multiple medications have been implicated in the development of gynecomastia mostly in the form of case reports and case series. However, these reports suffer from a multitude of deficiencies, including poor quality of evidence. Studies were selected for this review by performing an extensive electronic and hand-search using

618
BIOSIS, EMBASE and Medline, from 1940 to present, for all reported drug associations of gynecomastia and their possible pathophysiology. Quality of evidence was assessed on a three-point scale: good, fair and poor, and each of the drugs reported to cause gynecomastia was assigned a level of strength. The pathophysiology of gynecomastia is also discussed in detail for each of the drugs found to have a good or fair evidence of association with gynecomastia. Most of the reported drug-gynecomastia associations were based on poor quality evidence. The drugs definitively associated with the onset of gynecomastia are spironolactone, cimetidine, ketoconazole, hGH, estrogens, hCG, anti-androgens, GnRH analogs and 5-α reductase inhibitors. Medications probably associated with gynecomastia include risperidone, verapamil, nifedipine, omeprazole, alkylating agents, HIV medications (Efavirenz), anabolic steroids, alcohol and opioids [12143].

Testosterone is broken down to form estradiol in the peripheral tissues of the body. In supratherapeutic doses of testosterone and its metabolites, the peripheral aromatization will lead to a major increase in estradiol. Serum levels of estradiol are often seven times the levels prior to onset of AAS use and approach medium levels of hormones found in normal women. In male athletes these levels of estradiol will often lead to gynecomastia and a heightened voice. Gynecomastia may cause breast pain and undesirable cosmetic affects for athletes. Some athletes even resort to taking estrogen-blocking medications such as tamoxifen to prevent these effects, although no scientific data support this practice. In most cases, gynecomastia will remit upon discontinuation of the steroids. However, in more prolonged use of AAS, gynecomastia can be permanent and thus require surgical resection for cosmesis [06031].

Testosterone is converted to estrogens by aromatase and to DHT by way of 5-alpha reductase. The estrogens lead to feminizing effects in men, such as gynecomastia and an increase in voice pitch. Although the breast tissue that develops becomes softer and less prominent after cessation of AAS use, this effect may be irreversible and require surgical correction [07058].

Gynecomastia in males is a common adverse effect of chronic AAS abuse. These effects are not readily reversible, particularly in adolescents. Adverse effects in women following chronic AAS use include masculinization (male pattern baldness and hirsutism), acne, oily skin, and breast atrophy. The virilizing effects of AAS use by women are similar to the clinical features of the virilizing syndrome associated with congenital adrenal hyperplasia and adrenal carcinoma [13003].

**Bone**

Testosterone is the major gonadal sex steroid produced by the testes in men. Androgens induce male sexual differentiation before birth and sexual maturation during puberty; in adult men, they maintain the function of the male genital system, including spermatogenesis. Testosterone is also produced in smaller amounts by the ovaries in women. The adrenal glands produce the weaker androgens dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione. Because testosterone can be metabolized to estradiol by the aromatase enzyme, there has been controversy as to which gonadal sex steroid has the greater skeletal effect. In this respect, there is increasing evidence that at least part of the effects of androgens in men can be explained by their aromatization into estrogens. The current evidence suggests that estradiol plays a greater role in maintenance of skeletal health than testosterone, but that androgens also have direct beneficial effects on bone [12142].
The definition of bone quality is evolving particularly from the perspective of anabolic agents that can enhance not only bone mineral density but also bone microarchitecture, composition, morphology, amount of microdamage, and remodeling dynamics. From a MEDLINE search (1996-2010), articles were identified by the search terms “bone quality” (1851 articles), “anabolic agent” (5044 articles), “PTH or parathyroid hormone” (32,229 articles), “strontium” or “strontium ranelate” (283 articles), “prostaglandin” (77,539 articles), and “statin” or “statins” (14,233 articles). The search strategy included combining each with the phrase “bone quality.” Another more limited search aimed at finding more novel potential agents. Parathyroid hormone is the only US Food and Drug Administration-approved bone anabolic agent in the United States and has been the most extensively studied in in vitro animal and human trials. Strontium ranelate is approved in Europe but has not undergone Food and Drug Administration trials in the United States. All the studies on prostaglandin agonists have used in vivo animal models and there are no human trials examining prostaglandin agonist effects. The advantages of statins include the long-established advantages and safety profile, but they are limited by their bioavailability in bone. Other potential pathways include proline-rich tyrosine kinase 2 (PYK2) and sclerostin (SOST) inhibition, among others. The ongoing research to enhance the anabolic potential of current agents, identify new agents, and develop better delivery systems will greatly enhance the management of bone quality-related injuries and diseases in the future [11325].

**Effect on bone density**

One study evaluated the relationship between anabolic androgenic steroid (AAS) use and body constitution. Dual-energy x-ray absorptiometry was used to measure bone mineral density (BMD, g/cm²) of the total body, arms, and legs. Total gynoid and android fat mass (grams) and total lean mass (grams) were measured in 10 strength trained athletes (41 ± 8 years) who had used AASs for 5-15 years (Doped) and 7 strength trained athletes (29 ± 6 years) who had never used AASs (Clean). Seventeen sedentary men (30 ± 2 years) served as controls. Doped athletes had significantly more lean body mass and a greater index of fat-free/fat mass compared with Clean athletes and controls. Doped athletes also had significantly less gynoid fat mass compared with that of Clean athletes. There were no differences in BMD between the athletes but both groups had significantly higher BMDs at all sites compared with that of controls. Thus, long-term AAS use seems to alter body constitution, favoring higher muscle mass and reduced gynoid fat mass without affecting BMD [12148].

**Influence on muscle and tendon injury and injury healing**

In the past 20 years, there has been an increase in the incidence of upper extremity tendinous injuries, especially in sports including strong physical activity, such as in weight lifting, as well as with the concurrent use of anabolic steroids. Today, there are more than 200 cases describing rupture of the pectoralis major muscle in athletes. Twenty athletes with pectoralis major muscle (PMM) rupture were studied; 10 had surgical treatment, and the other 10 were treated nonoperatively. The average follow-up was 36 months (range, 48-72 months). Injuries were diagnosed by history, physical examination, and subsidiary tests. Functional evaluation and isokinetic evaluation were performed on all 20 patients. It was concluded that total pectoralis major muscle rupture in athletes showed a better functional result after surgical treatment than after nonsurgical treatment [10058].
The indiscriminate use of anabolic-androgenic steroids has been shown to induce pathologic changes in the Achilles tendon in several situations. To study tendon remodeling in rats treated with anabolic-androgenic steroids combined with an exercise program Wistar rats were grouped as follows: sedentary (group I), injected with anabolic-androgenic steroids only (group II), trained only (group III), and trained and injected with anabolic-androgenic steroids (group IV). The trained groups performed jumps in water: 4 series of 10 jumps each, with an overload of 50 to 70 percent of the animal's body weight and a 30-second rest interval between series, for 6 weeks. Anabolic-androgenic steroids (5 mg/kg) were injected subcutaneously. Activity of matrix metalloproteinases, a marker for tendon remodeling, was analyzed in tissue extracts by zymography on gelatin-sodium dodecyl sulfate-polycrylamide gel electrophoresis. Morphological analyses of tendons showed that in group II, the most external layer that covers the tendon was thicker with aggregation of the collagen fibers, suggesting an increase in collagen synthesis. In group IV, an inflammatory infiltrate and fibrosis in tendons as well as a pronounced increase of the serum corticosterone level were observed. This training protocol upregulated matrix metalloproteinase activity, whereas anabolic-androgenic steroid treatment strongly inhibited this activity. The appearance of lytic bands with molecular masses of approximately 62 and 58 kDa suggests the activation of matrix metalloproteinase-2. It was concluded that anabolic-androgenic steroid treatment can impair tissue remodeling in the tendons of animals undergoing physical exercise by down-regulating matrix metalloproteinase activity, thus increasing the potential for tendon injury. Since the AAS abuse is so widespread, a better comprehension of the pathological effects induced by these drugs may be helpful for the development of new forms of therapy of AAS-induced lesions [06089].

Although testosterone administration elicits well documented anabolic effects on skeletal muscle mass, the enhancement of muscle regeneration after injury has not been widely examined. The purpose of one study was to determine if anabolic steroid administration improves skeletal muscle regeneration from bupivacaine-induced injury. Male C57BL/6 mice were castrated 2 weeks prior to muscle injury induced by an intramuscular bupivacaine injection into the tibialis anterior muscle. Control mice received an intramuscular PBS injection. Anabolic steroid (nandrolone decanoate, 6 mg/kg) or sesame seed oil was administered at the time of initial injury and continued every 7 days for the study's duration. Mice were randomly assigned to one of 4 treatment groups for 5, 14 or 42 days of recovery as follows: 1) Control (uninjured); 2) nandrolone decanoate only (uninjured + nandrolone); 3) Bupivacaine only (Injured); or 4) Bupivacaine + nandrolone. Tibialis anterior morphology, protein and gene expression was analyzed at 14 and 42 days after injury, protein expression was analyzed at 5 days after injury. After 14 days of recovery the Injury and Injury + nandrolone treatments induced small diameter myofiber incidence, and also decreased mean myofiber area. The increase in small myofiber incidence was 65 percent greater in Injury + nandrolone muscle when compared to Injury alone. At 14 days, Injury + nandrolone induced a 5-fold increased in muscle IGF-1 mRNA expression, which was greater than injury alone. Muscle Akt activity and GSK3beta activity were also induced by Injury + nandrolone at 14 days of recovery, but not by Injury alone. Nandrolone had a main effect for increasing muscle MyoD and Cyclin D1 mRNA expression at 14 days. After 42 days of recovery, Injury + nandrolone increased large diameter myofiber incidence compared to Injury only. It was concluded that nandrolone decanoate administration can enhance castrated mouse muscle regeneration during the recovery from bupivacaine-induced injury [09063].

Experimental evidence exists that the use of AASs combined with intense exercise can cause structural and biomechanical alterations of tendons resulting in rupture. Structurally, the collagen fibril alignment is highly disorganized. From a biomechanical perspective, when muscle strength is increased with AAS use, the tendon becomes stiffer, absorbs less energy, and is more likely to fail during physical activity. Premature growth cessation due to physeal...
closures in younger users has not been studied systematically. Such case reports of the resultant permanent short stature have been described for several decades [07008].

Muscle mass seems to be affected greatly by AAS dosing. Higher doses have been shown to garner increases in muscle mass. Muscle mass gains are larger when AAS use is combined with strength training compared with AAS use alone. AASs increase the number of myonuclei. Strenuous exercise seems to increase the number of androgen receptor sites on the muscle. Body weight increases can be in the range of 2 to 5 kg after 10 weeks of AAS use. With more androgen receptors present in the upper regions of the body, the neck, shoulders, thorax, and upper arms gain the most new bulk. The thigh muscles require higher doses to show measurable increases in mass and are not as likely to show increases in the number of androgen receptors. Upon discontinuation, muscles shrink and strength declines over a period of 6 to 12 weeks. Androgens stimulate osteoblast proliferation and differentiation and inhibit the osteoclast. At the start of puberty, androgens stimulate bone formation. At the end of puberty, they induce epiphyseal closure. In adulthood, the sex hormones slow the rate of bone remodeling, protect against bone loss, encourage bone formation, and increase bone density. The adolescent AAS user risks an increased rate of muscle strains or ruptures. Unlike muscles, tendons do not increase in strength so with more intense training, they have a greater risk for rupture. In a developing adolescent, the growth plate cartilage is considered the “weakest link,” and generally is more prone to injury compared with ligaments. A rapid increase in the intensity, frequency, or volume of training is noted consistently in athletes who present with overuse injuries. Injury to the growth plate from weight training has long been a subject of controversy; power lifting may increase the risk for injury, even in adolescents not taking AAS [07058].

Long-standing rotator cuff tendon tearing is associated with retraction, loss of work capacity, irreversible fatty infiltration, and atrophy of the rotator cuff muscles. Although continuous musculotendinous relengthening can experimentally restore muscular architecture, restoration of atrophy and fatty infiltration is hitherto impossible. Continuous relengthening with pharmacological stimulation of muscle growth using an anabolic steroid or insulin-like growth factor (IGF) can reverse atrophy and fatty infiltration as well as improve the work capacity of chronically retracted rotator cuff muscles in sheep. Sixteen weeks after tenotomy of the infraspinatus (ISP) tendon, atrophy and fatty infiltration had developed in the retracted ISP muscle. The musculotendinous unit was continuously relengthened in 14 sheep during 6 weeks: Four sheep were treated without pharmacological stimulation, 4 with intramuscular administration of an anabolic steroid, and 6 with IGF before final repair and rehabilitation (12 weeks). Changes were documented by intraoperative measurements of muscle work capacity, histology, and computed tomography/magnetic resonance imaging. Musculotendinous relengthening by continuous traction resulted in gains of length ranging from 0.7 cm in the IGF group to 1.3 cm in the control group. Fatty infiltration progressed in all groups, and the muscle’s cross-sectional area ranged from 71 to 74 percent of the contralateral side at sacrifice and did not show any differences between groups in weight, volume, histological composition, or work capacity of the muscle. The contralateral muscles in the anabolic steroid group, however, showed significantly higher (mean ± standard deviation) muscle work capacity of 10 ± 0.9 N·m than the contralateral muscles of the control group (6.8 ± 2.4 N·m). This was accompanied by an increased mean muscle fiber area as well as by an unusual gain in the animals’ weight after injection of the anabolic steroid. It was concluded that subcutaneous continuous relengthening of a chronically retracted musculotendinous unit is feasible and advances the retracted musculotendinous junction toward its original position. This does not change the muscle work capacity. Whereas anabolic steroids have been shown to be effective in preventing classic degenerative muscle changes after tendon tears, neither an anabolic steroid nor IGF contributes to regeneration of the muscle once degenerative changes are established. Thus, the findings demonstrate that
muscle cells lose Reactiveness to an anabolic steroid and IGF once retraction has led to fatty infiltration and atrophy of the muscle. Retraction of the muscle after tendon tears must be avoided by early repair, particularly in an athlete, as no regeneration can be achieved by mechanical or pharmacological means at this time [12147].

Muscle healing in power-lifters

Power-lifters have hypertrophic muscle fibers with fissures seen in cross-sections, called as fiber splitting. Whether this phenomenon is due to real splitting or defective regeneration has not been settled. To elucidate this matter, we have examined biopsies from the trapezius and vastus lateralis of power lifters (P group) and power lifters self-administrating anabolic steroids (PAS group). For this purpose, immunohistochemical staining of serial cross-sections was used. The PAS group had significantly more fibers with fissures than the P group in the vastus lateralis but not in the trapezius muscle (1.7 % in both groups). Serial sections revealed that the fibers with fissures changed their profile profoundly over short distances. Some such fibers had a mature staining profile, whereas other fibers indicated recent degeneration and/or regeneration. Activation of satellite cells and formation of aberrant segments were also evident. It was concluded that the so-called split fibers are due to defect regeneration. Some fibers with fissures are the results of old events of segmental muscle fiber damage, whereas the others reflect an ongoing process. The normal regenerative process is most likely disturbed in power-lifters by their continuous training with repeated high mechanical stress on the muscles [06090].

Tendon adaptation

Combined androgenic-anabolic steroids (AAS) and overloading affects tendon collagen metabolism and ultrastructure and is often associated with a higher risk of injury. The aim of this prospective study was to investigate whether such effects would be reflected in the patellar tendon properties of individuals with a history of long-term resistance training and AAS abuse (RTS group), compared with trained (RT) and untrained (CTRL) nonsteroids users. Tendon cross-sectional area (CSA), stiffness, Young's modulus, and toe limit strain were measured in vivo, from synchronized ultrasonography and dynamometry data. The patellar tendon of RT and RTS subjects was much stiffer and larger than in the CTRL group. However, stiffness and modulus were higher in the RTS group (26 % and 30 %, respectively) than in the RT group. Conversely, tendon CSA was 15 percent larger in the RT group than in RTS, although differences disappeared when this variable was normalized to quadriceps maximal isometric torque. Yet maximal tendon stress was higher in RTS than in RT (15 %), without any statistical difference in maximal strain and toe limit strain between groups. The present lack of difference in toe limit strain does not substantiate the hypothesis of changes in collagen crimp pattern associated with AAS abuse. However, these findings indicate that tendon adaptations from years of heavy resistance training are different in AAS users, suggesting differences in collagen remodeling. Some of these adaptations (e.g., higher stress) could be linked to a higher risk of tendon injury [13121].

Compartment syndrome in upper limb

Acute compartment syndrome, a surgical emergency, is defined as increased pressure in an osseofascial space. The resulting reduction of capillary perfusion to that compartment requires prompt fasciotomy. Treatment delay has a poor prognosis, and is associated with muscle and nerve ischemia, resultant infarction, and late-onset contractures. It was reported a case of traumatic bilateral upper limb acute compartment syndrome associated with anabolic steroids, requiring bilateral emergency fasciotomies. A 25-year-old male
bodybuilder taking anabolic steroids, with no past medical history, presented to the Emergency Department 25 min after a road traffic accident. Secondary survey confirmed injuries to both upper limbs with no distal neurovascular deficit. Plain radiographs demonstrated bilateral metaphyseal fractures of the distal humeri. Within 2 h of the accident, the patient developed clinical features that were consistent with bilateral upper arm compartment syndrome. Bilateral fasciotomies of both anterior and posterior compartments were performed, confirming clinical suspicion [13122].

**Rhabdomyolysis**

A 34-year-old bodybuilder presented at the emergency room with fever, vomiting and muscle cramps that had started during a bodybuilding session. Several days before he started training he had used tablets and intramuscular injections containing the anabolic steroids: dehydro-chloro-methyltestosterone, boldenone and trenbolone. In addition, he had taken clenbuterol tablets, liothyronine tablets and subcutaneous injections of phosphatidylcholine. Laboratory investigations revealed massive rhabdomyolysis. The patient was treated with intravenous fluid replacement and sodium bicarbonate to alkalinize the urine. He recovered quickly and his renal function remained unaffected. Doping among amateur athletes in the Netherlands occurs frequently. Apart from long term side-effects, doping can also cause acute health problems. Therefore it is important to ask about doping use during history taking in amateur athletes [06091].

The use of supraphysiologic doses of testosterone increases muscle mass and maximal voluntary strength in a dose-dependent manner, but there is no definitive evidence that testosterone improves performance in endurance events. Rare case reports associate a general necrotizing myopathy with the chronic use of AAS. A 23-year old man developed diffuse myalgias and severe rhabdomyolysis with anuria. Although he developed a viral upper respiratory tract infection 1 week prior to the development of rhabdomyolysis, muscle biopsy and serum testing revealed no evidence of inflammation or immune disease. He had a history of chronic AAS abuse. Other case reports associate localized rhabdomyolysis of the deltoid muscles with chronic AAS injections in the same location. There are few data in the medical literature regarding the effect of chronic AAS abuse on the function of connective tissue. Several case reports associate the chronic abuse of AAS with disruption of connective tissues including spontaneous rupture of ligaments and muscles [13003].

Rhabdomyolysis (breakdown of skeletal muscle tissue) may be caused by mechanical, physical, chemical, or biological factors. It was presented the unique case of a bodybuilder who developed localized rhabdomyolysis of the deltoid muscle after injection of steroids into the shoulder region. Polymyositis and dermatomyositis, mild injury, infectious myositis without phlegmon or abscess formation, radiation therapy, subacute denervation, compartment syndrome, early myositis ossificans, rhabdomyolysis, and sickle cell crisis were differential diagnoses. The patient was treated with intravenous fluid replacement and sodium bicarbonate to alkalinize the urine. Four days after admission, his pain had decreased, he had regained range of motion, and his renal function remained unaffected. This was the first description of localized rhabdomyolysis in the area of an AAS injection [09062].

AAS users also are at risk for rhabdomyolysis or acute skeletal muscle destruction. Rhabdomyolysis has been reported after vigorous weight lifting and may be more likely in patients escalating and supplementing weight training with AASs. Physicians should consider the creatine phosphokinase and gamma-glutamyl transpeptidase levels as essential
elements in distinguishing muscle damage from liver damage when evaluating enzyme elevations in patients who use anabolic steroids [07058].

Renal effects

Renal side effects of AAS are uncommon and have been documented in a few isolated case reports. These reports noted a minimal effect of AAS use on renal function with a mild elevation in serum creatinine. The combination of AAS and creatine supplementation, commonly abused by weightlifters, may increase renal damage. One case of membranoproliferative glomerulonephritis has been cited in an athlete with prolonged AAS abuse. An unusual cancer in adults, Wilms' tumor, has been seen in a few athletes who were self-administering AAS over several years. In one case report, a 23-year-old bodybuilder on cycles of 8 weeks of oral stanozolol and oxymetholone and parenteral nandrolone, testosterone, and boldenone, along with a high-protein diet, developed profound symptoms after only 6 months of use. Of note, the patient was also limiting sodium and water intake and taking the diuretic torasemide. The patient presented with acute confusion, asthenia, and anorexia of 1 month's duration [06031].

Other side effects

Anabolic-androgenic steroids (AAS) are synthetic drugs derived from testosterone. Illegally, these drugs are regularly self-administered by bodybuilders and powerlifters to enhance their sporting performance. Adverse side effects of AAS include sexual dysfunction, alterations of the cardiovascular system, psyche and behavior, and liver toxicity. However, severe side effects appear only following prolonged use of AAS at high dose and their occurrence is limited. Occasionally, AAS abuse may be linked to certain social and psychological traits of the user, like low self-esteem, low self-confidence, suffered hostility, childhood conduct disorder, and tendency to high-risk behavior. The overwhelming stereotype about AAS is that these compounds cause aggressive behavior in males. However, the underlying personality traits of a specific subgroup of the AAS abusers, who show aggression and hostility, may be relevant, as well. Use of AAS in combination with alcohol largely increases the risk of violence and aggression. The dependence liability of AAS is very low, and withdrawal effects are relatively mild. Based on the scores for acute and chronic adverse health effects, the prevalence of use, social harm and criminality, AAS were ranked among 19 illicit drugs as a group of drugs with a relatively low harm [10059].

Side effects of anabolic steroids with relevance in forensic medicine are mainly due to life-threatening health risks with potential fatal outcome and cases of uncertain limitations of criminal liability after steroid administration. Both problems are typically associated with long-term abuse and excessive overdose of anabolic steroids. Side effects may be due to direct genomic or nongenomic activities (myotrophic, hepatotoxic), can result from down-regulation of endogenous biosynthesis (antiandrogenic) or be indirect consequence of steroid biotransformation (estrogenic). Logically, there are no systematic clinical studies available and the number of causally determined fatalities is fairly limited. A compilation reviews typical abundant observations in cases where nonnatural deaths (mostly liver failure and sudden cardiac death) were concurrent with steroid abuse. Moreover, frequent associations between structural characteristics and typical side effects may be explained [10060].

Regarding the health risks associated with the abuse of performance-enhancing drugs in sport data from randomized clinical trials may not be sufficient to identify the complete range
of adverse effects possible with the abuse; more specific studies are necessary to assess their actual and full toxic potential [08139].

**Thyroidal effects**

The most prominent effect on human thyroid function of anabolic steroids is reduction of thyroxine binding globulin (TBG), with consequent reductions of total serum T3 and T4, depending however on the susceptibility of the drug to aromatization and subsequent transformation into estrogen. In rats, anabolic steroids also act in the peripheral metabolism of thyroid hormones and seem to exert an important proliferative effect on thyroid cells [08145].

The use of anabolic steroids to increase physical performance and for aesthetic ends has reached alarming indices in the last three decades. Besides the desired actions, several collateral effects have been described in the literature, such as the development of some types of cancer, gynecomastia, peliosis hepatis, renal insufficiency, virilization, amongst others. The most prominent effect on human thyroid function is the reduction of thyroxine binding globulin (TBG), with consequent reductions of total serum T3 and T4, depending however on the susceptibility of the drug to aromatization and subsequent transformation into estrogen. In rats, anabolic steroids also act in the peripheral metabolism of thyroid hormones and seem to exert an important proliferative effect on thyroid cells. Thus, the aim of the present paper was to review data on the effect of supraphysiological doses of anabolic steroids on thyroid function, showing the danger that indiscriminate use of these drugs can cause to health [07073].

Thyroid cells have androgen receptors, and AASs may directly influence thyroid function. Some studies have shown effects on thyroid function, including a decrease in total triiodothyronine, thyroxine (T₄), and thyroid-binding globulin. Some studies have shown an increase in thyrotropin and free T₄, whereas others have shown no change in these concentrations. It is unclear if this relative impairment in thyroid function leads to a clinical effect. These changes may be due to direct block of thyroid hormone release or synthesis or some other mechanism [07058].

**Hematological**

AASs increase renal synthesis of erythropoietin. They also promote erythropoietic stem cell differentiation. Subsequently, hemoglobin and hematocrit may become elevated, which could result in erythrocytosis or sludging. Two adult cases of intramuscular testosterone-induced polycythemia were reportedly reversed by switching to transdermal testosterone; however, a 65-year-old man developed hypertension and polycythemia during daily testosterone application to his scrotum for 5 years (estimated dose 10 mg/d). Polycythemia and hypertension resolved when testosterone was discontinued. Mild, but significant, increases in mean red blood cell, hematocrit, hemoglobin, and white blood cell concentrations in 33 men were reported following intramuscular testosterone enanthate, 200 mg every 3 or four weeks for 24 weeks. The men remained asymptomatic. Increased platelet count and aggregation also may occur. AASs may potentiate platelet aggregation and be thrombogenic in humans; however, another study found only non-significant trends, including thrombocytosis and increased aggregation [07058].

**Hypercalcemia**
A 26-year-old male bodybuilder was admitted to the surgical department of a Danish community hospital for hematemesis. During the clinical interview, he revealed that he had recently finished a course of anabolic steroids and erythropoietin. The patient also had a previous history of infections and chronic ulcers due to paraffin-oil injections in both upper arms one year before. Over the course of the next few hours, the patient developed signs of multi-organ dysfunction, including pancreatitis, hemorrhagic gastritis, nephropathy with temporary anuria, and respiratory insufficiency, and was transferred to the ICU. After manometric monitoring on the patient's upper arms proved difficult, invasive blood pressure monitoring was used and revealed that the patient was in a state of hypertensive crisis. This case of multi-organ dysfunction was possibly caused by multi-substance-induced hypercalcemia [11067].

Effect on gingival tissues

Anabolic androgenic steroid (AAS) is the familiar name for synthetic derivatives of the male sex hormone, testosterone. A large number of young adults abuse AAS to enhance performance and physical appearance. The aim of one study was to evaluate the effects of AAS abuse on the gingival tissues in a group of bodybuilders and weight lifters. The test group was composed of 24 athletes aged between 17 and 29 years who had been using AAS for >1 year. All subjects were clinically examined for plaque levels (plaque index), gingival inflammation (gingival index), and gingival enlargement. The results were compared to a control group of 20 bodybuilders who had never used AAS drugs and who matched for age, educational level, and oral habits according to the data obtained from the test group. Although there were no statistical differences between the plaque index and gingival index scores of the study group and the control group, the AAS abusers had statistically higher scores of gingival thickness, extent of gingival encroachment, and total gingival enlargement scores compared to non-users. It was concluded that the results of this study have revealed that the prolonged use of AAS is closely associated with significant levels of gingival enlargement. Because recreational abuse and abuse in non-competitive sports seem to increase despite legislation, dentists and periodontists should be familiar with the adverse effects of these synthetic derivatives of testosterone on the gingival tissues [06087].

Peridontit

One study aimed to evaluate periodontal microbiological differences between systemically healthy nonsmoker males taking anabolic androgenic steroids (AASs) and non-AAS users and to find associations between disease severity and AAS use. Ninety-two men practicing bodybuilding were included in the study. They were divided into AAS users and a matched control nonuser group and subgrouped based on their most severe periodontal condition. Pooled subgingival samples from each individual were cultured to evaluate specific periodontopathogen infection. AAS users had significantly higher prevalence of severe periodontitis. AAS users had greater gingival inflammation and clinical attachment loss of ≥3 mm than nonusers (odds ratio 2.4;). AAS users were 4.9 times more likely to be infected with Prevotella intermedia than AAS nonusers (OR 4.9). The OR of presenting subgingival Aggregatibacter actinomycetemcomitans was 8.2 times higher in AAS users (OR 8.2). AAS users were 5.6 times more likely to present subgingival Candida spp. than nonusers (OR 5.6). AAS users were 14.8 times more likely to present subgingival Candida parapsilosis than nonusers (OR 14.8). The likelihood of AAS users presenting subgingival Candida tropicalis was 4.3 times higher than nonusers. A. actinomycetemcomitans was mostly isolated in individuals with severe periodontitis and was associated with subgingival Porphyromonas gingivalis, P. intermedia, and Candida spp. It was concluded that AAS use may increase the risk for severe periodontitis and may cause a subgingival selection of certain Candida species. Specific periodontopathogens, such as Candida dubliniensis and
Candida albicans, seem to be negatively affected by AAS use. The higher risk for disease progression in AAS users may be explained by the significantly higher proportions of A. actinomycetemcomitans, P. gingivalis, P. intermedia, and Candida species as compared to controls. Data on the influence of AAS on subgingival periodontopathogens and disease progression are scarce. Higher proportions of specific periodontopathogens are plausible in AAS users. AAS users had a higher prevalence of severe periodontitis, gingival inflammation, and clinical attachment loss. Men taking AAS are at greater risk of periodontitis and specific periodontopathogen infection [13155].

*Effect on inflammation*

Aging can alter the skeletal muscle growth response induced by overload. The initiation of overload induces muscle extracellular matrix expansion, increased cellularity, and inflammatory gene expression, which are all related to processes important for myofiber growth. These remodeling processes are also biological targets of testosterone. It is not certain how aging affects the inflammatory response to functional overload and whether anabolic steroid administration can alter this response. The effect of anabolic steroid administration on inflammatory processes during functional overload is not known. The purpose of this study was to determine if age altered the skeletal muscle inflammatory response at the onset of functional overload and whether anabolic steroid administration would modulate this response in young or older animals. Five-month and 25 month F344 x BRN rats were given nandrolone decanoate (ND) (6 mg/kg bw/wk) or sham injections for 3 weeks, and then the soleus muscle was overloaded (OV) for 3 days by synergist ablation. ND alone induced a 230% increase in ED1(+) cells in 5 month muscle. Three days of OV had no effect on ED1(+) cell number at either age. OV combined with ND induced a 90% increase in ED2(+) cells in 5 month muscle, while there was no effect of either treatment alone at this age. In 25 month muscle, OV induced a 40 percent increase in ED2(+) cells. Regardless of age, OV induced muscle TNF-alpha mRNA expression (300%) and IL-6 mRNA expression (900 %). ND attenuated OV-induced IL-6 mRNA but not TNF-alpha expression in both age groups. The overload induction of IL-1beta mRNA was 3-fold greater in 25 month muscle (1400 %), compared to 5 month muscle (400 %). ND administration ablated the overload IL-1beta mRNA induction in 25 month muscle. Anabolic steroid administration can suppress inflammatory cytokine gene expression at the onset of overload and this effect is age dependent [06088].

*In basket ball players*

It was analyze the outcome on testosterone (T) and cortisol (C) responses in 12 professional basketball players during a season of competition. Serum adrenocorticotropic hormone (ACTH), C, total testosterone (TT), and free testosterone (FT) levels were analyzed in October, December, March, and April. A day after the games, blood samples were taken. Serum ACTH levels were maintained at the initial levels during the season. However, basal C significantly changed during the season, with lower levels in December and in April. Basal serum TT levels increased during the season until a maximum in March. No differences were presented in the TT values in December, March, and April. Basal FT presented high levels in October and December, followed by a low level in March, remaining low in April. The T/C increased during the season, attaining a maximum level in December, followed by a significant decrease in March. Free T/C ratio decreased during the season (lower level in March). In conclusion, the players maintained a good anabolic-catabolic balance [10062].

*Side effects in elderly*
Testosterone supplementation has been shown to increase muscle mass and strength in healthy older men. The safety and efficacy of testosterone treatment in older men who have limitations in mobility have not been studied. Community-dwelling men, 65 years of age or older, with limitations in mobility and a total serum testosterone level of 100 to 350 ng per deciliter (3.5 to 12.1 nmol per liter) or a free serum testosterone level of less than 50 pg per milliliter (173 pmol per liter) were randomly assigned to receive placebo gel or testosterone gel, to be applied daily for 6 months. Adverse events were categorized with the use of the Medical Dictionary for Regulatory Activities classification. The data and safety monitoring board recommended that the trial be discontinued early because there was a significantly higher rate of adverse cardiovascular events in the testosterone group than in the placebo group. A total of 209 men (mean age, 74 years) were enrolled at the time the trial was terminated. At baseline, there was a high prevalence of hypertension, diabetes, hyperlipidemia, and obesity among the participants. During the course of the study, the testosterone group had higher rates of cardiac, respiratory, and dermatologic events than did the placebo group. A total of 23 subjects in the testosterone group, as compared with 5 in the placebo group, had cardiovascular-related adverse events. The relative risk of a cardiovascular-related adverse event remained constant throughout the 6-month treatment period. As compared with the placebo group, the testosterone group had significantly greater improvements in leg-press and chest-press strength and in stair climbing while carrying a load. It was concluded that in a population of older men with limitations in mobility and a high prevalence of chronic disease, the application of a testosterone gel was associated with an increased risk of cardiovascular adverse events [10329].

Other infections

Pyomyositis

Pyomyositis, a deep bacterial infection of skeletal muscle, is due to the combination of bacteremia and local muscle injury. It most commonly occurs in children and young adults, with a male predominance; the lower extremities and pelvic girdle are typically involved, with the quadriceps muscle being the most common site of infection. Recognized risk factors are muscle trauma (including strenuous exercise), immunosuppression, diabetes mellitus, malignancy, cirrhosis, rheumatologic disorders, and injections such as illicit drug abuse. The infectious agent is S. aureus in 75-90 percent of cases, with group A Streptococcus a distant second. Most patients will have a leukocytosis with neutrophilia and an elevated erythrocyte sedimentation rate, but muscle enzymes such as creatinine kinase are typically normal. Ultrasonography can be used to locate fluid collections within the musculature and assist with needle aspiration, but CT imaging may better show muscle abnormalities such as edema and abscess formation. Magnetic resonance imaging is thought to be even more sensitive and is the preferred modality in early stages of the disease. A case was presented regarding a previously healthy 45-year-old amateur bodybuilder who reported progressive right thigh pain and swelling for 3 days. He admitted injecting anabolic steroids into the lateral aspect of his right thigh 1 week prior. Although both thighs were quite large, the right was clearly swollen; erythema, warmth, and tenderness were present but there was no crepitus or fluctuance. Laboratory studies found an elevated white blood cell count of 19,000/mm³ with 86 percent neutrophils. A computed tomographic (CT) scan of the right thigh revealed a loculated collection involving the vastus lateralis muscle from just below the lesser trochanter to above the knee (17 cm length by 9 cm transverse by 6.5 cm anterior-posterior), with fluid and inflammatory changes of the rectus femoris and tensor fascia lata and overlying subcutaneous edema [13154].

Tuberculosis

It was presented a case report depicting masking of symptoms of intestinal tuberculosis by anabolic androgenic steroids (AAS) causing delay in diagnosis which lead to a major
surgery. Negative tuberculosis skin test (TST) probably due to immunomodulating effects of AAS also contributed to the delay. Patient had early dependence on AAS and rapid growth of scrotal sebaceous cysts, findings of which have not yet been reported. Patient initially did not reveal his AAS abuse to physician. This is in line with previous studies which report that majority of AAS abusers distrust medical professionals and do not disclose it to their treating physicians. During hospitalisation he reported it probably due to seriousness of his condition, impending major surgery and concurrent use of other medicines. The patient had large sebaceous cysts on scrotum with history of rapid growth in last six months. Although this is not a known side effect of AAS use, increase in growth of sebaceous glands and resulting acne have been documented. It is possible that this side effect might have been missed in previous studies as patients are usually reluctant to reveal it unless specifically asked. Further, most studies involved young age group who are more prone to acne, a clearly visible symptom having significant importance in that age. Usually period for development of AAS dependence is 9-12 months but this patient developed dependence in just four months probably because AAS withdrawal symptoms were associated with appearance of symptoms of tuberculosis [12149].

Genotoxicity (cancer risks)

The abuse of anabolic steroids for doping raises concerns. Many of these compounds have never been examined for their toxicological properties. Aside from hormonal (androgenic) activity, anabolic steroids may also exert genotoxic effects. In one study, it was determined the potencies of the "designer steroid" madol and the anabolic prohormone 19-norandrostenedione to induce micronuclei in V79 cells in vitro. CREST analysis was used to differentiate between aneugenic and clastogenic mechanisms of micronucleus induction. Cytotoxicity of the steroids and their influence on the cell cycle were assessed in parallel. In addition, the ability of the drugs to increase production of reactive oxygen species and to induce apoptosis were studied. Both agents caused a concentration-dependent increase in the rates of micronuclei in V79 cells, exceeding a doubling of the background micronucleus rates of untreated controls, which was evident at 27 μM and 29 μM for madol and 19-norandrostenedione, respectively. The steroid-induced micronuclei were predominantly kinetocho (CREST)-negative, pointing to a clastogenic mode of action. As cytotoxicity of both compounds is weak, cytotoxicity was unlikely to contribute to their genotoxicity. The observed genotoxicity of both compounds was due neither to apoptosis induction nor to production of reactive oxygen species. However, the ability of both steroids to induce micronuclei appears related to their lipophilicity. Therefore, a "non-specific" chromosomal genotoxicity of madol and 19-norandrostenedione, based on hydrophobic interactions, appears likely. This could well result in biologically relevant increases in chromosomal damage as soon as critical concentrations of the agents are reached in vivo. Regarding the current misuse of the steroids for doping, the uncontrolled administration of very high doses must be considered. Therefore it cannot be ruled out that these drugs present genotoxic hazards under current misuse conditions by athletes in sports or in body building [08149].

To evaluate genotoxicity of anabolic androgenic steroids (AAS) in male bodybuilders by a micronucleus assay in buccal mucosa cells 11 male bodybuilders volunteered to participate in a study and two groups were formed: group 1 (n=6), without AAS consumption and group 2 (n=5), with AAS consumption. A sample of buccal epithelium was taken from each participant once a week for 6 weeks. Samples were fixed, stained and analysed by a light microscope, and 2000 cells were counted from each slide. Results are expressed as micronucleated cells (MNC) per 1000 cells and were analysed by the Mann-Whitney U test and Wilcoxon's test. A marked increased in MNC was seen in bodybuilders with AAS consumption compared with those without AAS consumption (mean 4.1 MNC/1000 cells vs 0.4 MNC/1000 cells, respectively). Intragroup comparisons showed no differences in the
MNC frequencies during the sampling time in group 1, whereas the MNC frequency in group 2 varied significantly, reaching the highest MNC frequencies in the third and fourth week of sampling; frequency in the first sampled week was 1.1 MNC/1000 cells. Significant differences in all sampled weeks were found between the two groups. It was concluded that AAS consumption increased the frequency of MNC from buccal mucosa in bodybuilders [07078].

**Fatal events**

Anabolic-androgenic steroids (AAS) are widely abused, but the potential for dependence and addiction remains unclear. Recent studies from our laboratory have shown that male and female hamsters will voluntarily self-administer testosterone and other AAS. Furthermore, it was observed fatal androgen overdose during self-administration. This suggests that AAS are potentially addictive, independent of their effects on muscle mass or athletic performance [06093].

**Multiple organ failure**

It was reported a 42-year-old male amateur body builder and user of anabolic androgenic steroids, who developed ARDS, acute kidney injury, and refractory supraventricular tachycardia. He required extracorporeal membrane oxygenation, continuous veno-venous hemodialysis, and catheter ablation. It was believed that long-term anabolic androgenic steroid abuse predisposed the patient to multiple organ dysfunction syndrome, from its immunomodulatory effects in an otherwise healthy patient. Anabolic androgenic steroid use should be part of the history taking process, since it may complicate diagnosis, disease progression, and prognosis [13156].

**Side effects of topical anabolic steroids**

Androstanolone is an androgen with effects and efficacy comparable to dihydrotestosterone. Topical sexual steroid hormones may easily penetrate human skin and cause systemic effects. Topical androgens like testosterone have been used for decades to treat vulvar lichen sclerosus et atrophicus with a doubtful efficacy. Due to systemic absorption of testosterone virilism expressed as hirsutism may develop. Topical application of testosterone causes also systemic effects. Indeed, sexual steroids including androgens may show a significant percutaneous absorption leading to changes in the serum levels. Precursors like pregnenolone or androstendione fail to alter serum levels because of rapid metabolism. In controlled trials carefully monitored low-dose testosterone therapy in women efficiently increased female sexual interest and desire in the postmenopausal period. An up to two years administration in clinical trials did not cause serious side effects. It is, however, recommended that testosterone levels should be carefully monitored. It was reported five cases with different patterns of adverse reaction due to non-critical and/ or unmonitored use of anabolic steroids: deepening of the voice due to topical use of AAS in an anti-cellulite cream; circumscribed hypertrichosis and late onset acneiform eruptions due to testosterone replacement therapy after ovariectomy in women. Homolateral gynecomastia and infertility, acne and striae distensae was noted in males using injectable AAS. Cellulite is frequently observed in middle aged women and is characterized by furrowed and edematous skin on thighs, hips and buttocks. It seems to be caused by weakened muscular septa and a diffuse pattern of extrusion of underlying adipose tissue into thedermis. An increase of hypodermal adipose tissue and weakened fibrous septa extending perpendicularly from the bones to the
skin surface, have been observed. A higher body mass index is associated with an increased grade of cellulite. Life-style drugs may bear a significant risk of adverse effects, some irreversible or fatal [07013].

Long-term effects on social-medicine demography

Swedish data

The acute effects of AAS-use on mental health are well described in the literature, for example, increased aggression and irritability, anxiety and depressive symptoms, cognitive impairment, suicidal behaviours, hypomanic symptoms, enthusiasm and increased self-confidence. There are studies showing minor or no alterations in aggressive behaviours in past AAS-abusers who had been abstinent for a year or longer. On the other hand, one study found that past (abstinent period not defined) AAS-abusers had significantly more psychiatric diagnoses, as diagnosed by DSM-IV, than current abusers. A Finnish study, concerning a 12-year follow-up study of 62 male-elite Finnish powerlifters, where there was a high suspicion of AAS-use, reported a 4.6 times higher death rate compared with the general population. The main causes of death were myocardial infarctions and suicides. The high occurrence of suicide in populations with a strong suspicion of previous AAS-use is in line with preliminary results from our own study group, showing that death risk from suicide was increased by 2-4 times. One study aimed to investigate whether previous AAS-use affects mental health, present sociodemographic data, sport activity and substance abuse in a retrospective 30-year follow-up study of former elite athletes. During 2004, a questionnaire including structured questions concerning sociodemographic variables, previous and past sport activity, lifetime prevalence of seeking professional help for mental-health problems and previous and past substance use was sent to 996 Swedish male-elite power sport athletes on the top 10 national ranking lists during any of the years 1960-1979 in wrestling, Olympic lifting, powerlifting and the throwing events in track and field answered a questionnaire. At least 20 percent of the former athletes admitted previous AAS-use. A reminder to fill in the questionnaire was sent to those athletes who had not answered, and finally 683 (69 %) subjects had answered the questionnaire including the specific questions in the questionnaire concerning whether they had ever used AAS, and if so, when in relation to their sport career. Regarding their past sport activity, the former AAS-users were significantly older when they started training in the sport discipline within which they reached their highest ranking and they spent more hours per week training during their sport active years compared with non-AAS-users. There was no difference in mean age between the groups when they discontinued elite power sports. Compared with non-AAS-users, former AAS-users had significantly more often sought professional help for depression (13 % vs 5 %), anxiety (13% vs 6 %), melancholy (13 % vs 4 %), concentration deficit (4 % vs 1 %) and worry for mental health (8 % vs 3 %). The two groups did not differ regarding frequency of present alcohol consumption. Concerning tobacco use, the former AAS-users were less often present tobacco users compared with the non-AAS-users. Regarding previous tobacco use, the two groups did not differ. The former AAS-users showed higher lifetime prevalence of illicit drug use compared with the non-AAS-users but AAS-users had more often been offered AAS compared with the non-AAS-users (87 % vs 20). All the former AAS-users (n=143) reported having used AAS during their active sports career. The percentage of AAS-users in specific sport disciplines were: powerlifting (57 %), Olympic lifting (47 %), track and field (28 %) and wrestling (6 %). Forty-two percent (n=60) had administrated AAS by tablets, 3 percent (n=5), by injections and 55 percent (n=78) by both tablets and injections. The main reasons for using AAS were: to achieve better sport results (81 %), to train harder (56 %), a suspicion that their competitors used AAS (45 %) and faster recovery (43 %). There were no significant differences between former high and low AAS-users concerning
sociodemographic variables and present and past sport activity. Furthermore, there were no
differences in past and present substance use (tobacco, alcohol and illicit drugs). However,
the former high AAS-users significantly more often combined AAS with the use of illicit drugs
and with the use of alcohol compared with the former low AAS-users. The AAS-users also
differed in former sport activity pattern compared to non AAS-users. It was concluded that a
relationship exists between use of AAS and mental-health problems. Thus, the results from
this study of former male-elite athletes in sport disciplines, where increased muscle strength
has a marked influence on performance, showed that at least 20% admitted AAS-use during
their active sport career. The study indicates that the former AAS-users had a higher
frequency of lifetime prevalence of seeking professional expertise for several mental
problems. Furthermore, former AAS-users more often had used illicit drugs. Former AAS-
users were significantly older when they started training in their sport discipline in which they
had been most successful and they also spent more hours per week training. Furthermore, if
the former AAS-using athletes used AAS for a longer time than 2 years, they had more often
sought professional expertise for anxiety, irritation and anger and they had also more often a
combined use of alcohol and illicit drugs together with AAS. These high-consumers of AAS
reported having experienced more side effects of AAS, compared with those athletes having
used AAS no longer than 2 years. A former use of AAS does not seem to have a negative
long-term effect on either present substance abuse and present sport activity or on whether
they presently lived in a relationship or not. The present results can be compared with
previous results regarding lifetime prevalence of AAS-use among elite athletes active in the
60s and 70s. For example, in 1972, it was estimated that one-third of the Swedish-elite track
and field athletes used AAS. The present study is, however, based on a larger number of
athletes and in four power sports. In the same year’s Olympic Games, 68 percent of the
participants in the track and field events reported prior steroid abuse. The former elite
athletes admitting AAS-use were significantly younger compared with the non-users. This
age difference might explain why the former AAS-users are, to a higher degree, in their
present employment. However, this difference disappeared when the old-age pensioners,
that is, above 65 years of age, were excluded from the analysis [13157].

Increased mortality in former users of anabolic steroids

Physical training has been shown to reduce mortality in normal subjects, and athletes have a
healthier lifestyle after their active career as compared with normal subjects. Since the
1950s, the use of anabolic androgenic steroids (AAS) has been frequent, especially in power
sports. The aim of the present study was to investigate mortality, including causes of death,
in former Swedish male elite athletes, active 1960-1979, in wrestling, powerlifting, Olympic
lifting, and the throwing events in track and field when the suspicion of former AAS use was
high. Results indicate that, during the age period of 20-50 years, there was an excess
mortality of around 45 percent. However, when analyzing the total study period, the mortality
was not increased. Mortality from suicide was increased 2-4 times among the former athletes
during the period of 30-50 years of age compared with the general population of men.
Mortality rate from malignancy was lower among the athletes. As the use of AAS was
marked between 1960 and 1979 and was not doping-listed until 1975, it seems probable that
the effect of AAS use might play a part in the observed increased mortality and suicide rate.
The otherwise healthy lifestyle among the athletes might explain the low malignancy rates
[13158].

Tour de France (1947-2012)

In the context of recent concerns regarding performance enhancing techniques and potential
negative health effects of high-level physical activity, data on the long-term outcomes and
causes of death in elite endurance cyclists are of particular interest. Characteristics and vital status of all French participants in the Tour de France were collected for the 1947-2012 period. Causes of death were obtained from 1968. Overall and disease-specific mortalities were compared with the French male population using overall and specific standardized mortality ratios (SMRs) with their 95 percent confidence intervals (CIs). Among the 786 French cyclists who participated at least once between 1947 and 2012, 208 (26%) died by 1 September 2012. Neoplasms and cardiovascular diseases accounted for 61 percent of deaths. It was observed a 41 percent lower mortality in French cyclists (SMR: 0.59, 95% confidence interval 0.51 to 0.68), which did not change over time. It was observed for main mortality causes: for neoplasms (SMR: 0.56; 95% confidence interval 0.42 to 0.72) and for cardiovascular death (SMR: 0.67; 95% confidence interval 0.50 to 0.88), except mortality related to external causes (SMR: 1.06, 95% confidence interval 0.71 to 1.53). It was observed a substantially and significantly lower mortality in participants in the Tour de France, compared with the general male population. However, the results do not allow us to assess in detail the balance between positive effects of high-level sports activity and selection of healthy elite athletes, versus any potential deleterious effects of excessive physical exercise or alleged doping [13159].
TESTOSTERONE

Testosterone is more than a "male sex hormone". It is an important contributor to the robust metabolic functioning of multiple bodily systems. The abuse of anabolic steroids by athletes over the years has been one of the major detractors from the investigation and treatment of clinical states that could be caused by or related to male hypogonadism. The unwarranted fear that testosterone therapy would induce prostate cancer has also deterred physicians from pursuing more aggressively the possibility of hypogonadism in symptomatic male patients. In addition to these two mythologies, many physicians believe that testosterone is bad for the male heart. The classical anabolic agents, 17-alkylated steroids, are indeed, potentially harmful to the liver, to insulin action, and to lipid metabolism. These substances, however, are not testosterone, which has none of these adverse effects. The current evidence, in fact, strongly suggests that testosterone may be cardioprotective. There is virtually no evidence to implicate testosterone as a cause of prostate cancer. It may exacerbate an existing prostate cancer, although the evidence is flimsy, but it does not likely cause the cancer in the first place. Testosterone has stimulatory effects on bones, muscles, erythropoietin, libido, mood and cognition centres in the brain, penile erection. It is reduced in metabolic syndrome and diabetes and therapy with testosterone in these conditions may provide amelioration by lowering LDL cholesterol, blood sugar, glycated hemoglobin and insulin resistance. The best measure is bio-available testosterone which is the fraction of testosterone not bound to sex hormone binding globulin. Several forms of testosterone administration are available making compliance much less of an issue with testosterone replacement therapy [08063].

Testosterone is the principal male sex hormone. As with all natural steroids, it is biosynthesized from cholesterol. Phase I metabolism employs some very specific enzymes and pathways. Phase II metabolism and excretion follow more general patterns. Synthetic and endogenous steroids differ in this measure. Numerous xenobiotic compounds have been derived from testosterone. The modifications typically aim at a reduction of the androgenic properties while maintaining the anabolic potential. Most of these compounds have been withdrawn from the legal market. However, they are found to be illicitly added to otherwise inefficient nutritional supplements. These products represent a major problem to doping control. Recently, clinical trials with selective androgen receptor modulators have been started [10078].

Testosterone causes the hypertrophy of muscle fibers and an increase in the number of myonuclei and satellite cells. This metabolic action follows from the binding of testosterone to the androgen receptor. Its ability to transduce the binding of testosterone in the cytoplasm of the cell to its anabolic action (altering gene function in the nucleus) is inversely proportional to the number of CAG repeats in the first exon of the androgen receptor, a member of the nuclear transcription factor family of receptors and located in virtually all tissues. There are many reports of muscle hypertrophy and increases in strength in athletes who take anabolic steroids. Virtually none are controlled trials of just testosterone or one of other anabolically-active steroids, for many ingest and inject multiple potentially active drugs [10001].

The primary screening method for the detection of doping by athletes using synthetic versions of endogenous steroids such as testosterone relies on measurement of the ratio of testosterone (T) to epitestosterone (E) in urine. In 2005 the World Anti-Doping Agency (WADA) lowered the T/E value at which samples undergo further investigation from six to four. This has resulted in a large increase in the number of athletes with naturally elevated T/E ratios undergoing investigation without a corresponding increase in the number of proven
doping offences involving testosterone. The objective was to develop a new simple screening protocol that can, with high probability, not only distinguish athletes whose natural T/E values exceed four from those whose T/E values have been elevated by testosterone doping but also detect those athletes with naturally low T/E values that do not exceed four despite being administered testosterone. Testosterone (250 mg Sustanon) was administered weekly to a group of 47 young adult males for five weeks in a double-blind placebo controlled study and urine samples collected. The samples were analysed for steroid concentrations using GC/MS and for luteinizing hormone (LH) by immunoassay. The elevation of T/E that occurred in all subjects was accompanied by a significant reduction in urinary LH concentrations to levels that are rare in normal subjects. The appropriate measurement of urinary LH, with the measurement of T/E values, can markedly improve the efficiency of detection of doping with testosterone by male athletes, particularly those who have low natural T/E ratios [09085].

**Theoretical, overviewing, aspects**

It is suggested that the sex steroid hormones testosterone and estrogen (SSH) provide receptor cells with reliable information on protein synthesis and on the level of oxidative metabolism in the cells of the gonads. The SSH are derived from the oxidation of cholesterol. This oxidation is a side reaction of the oxidative processes in the mitochondria that generate most of the energy to the organism. The amount of SSH that is synthesized is correlated to the partial pressure of oxygen at the synthesizing cells. The amount of free SSH that a cell can hold is checked by the damage that free steroids may cause. This damage is prevented by proteins that bind with SSH. As a result, SSH levels are correlated also with the ability of the SSH synthesizing cell to produce proteins that bind with them. A cell can only synthesize SSH in relation to the oxidative processes within it and to its ability to produce the binding proteins necessary to prevent the damage caused by SSH. As a result, the information conveyed by SSH is reliable. It was examined the specific damage caused by testosterone and estrogen, and suggest why each of them is best suited for its function. Although both SSH can provide similar information on the metabolism in the cells that synthesize them, there are secondary reasons why testosterone and estrogen were selected to serve particular functions. Testosterone improves the efficiency of the proton pump at the mitochondria in producing ATP, but increases oxidative damage. Estrogen on the other hand decreases oxygen damage but also decreases the efficiency of the proton pump. These differences between the two SSH may explain why females use estrogen to inform the body about the activity of the cells in their gonads while males do it by testosterone. The increased oxidative damage may also explain why in males the testosterone that reaches the brain is turned into estrogen. It was also suggested why fish use 11-keto testosterone and why insects do not use these two steroids [11326].

Testosterone is among the oldest drugs in medicine. It has a long efficacy and safety record for its prime role of androgen replacement therapy in men with androgen deficiency. Testosterone and synthetic analogue androgens have also been used in pharmacological androgen therapy (PAT) to produce androgenic effects on marrow, muscle or bone. Although PAT is increasingly being superseded by newer, more expensive drugs, androgens remain cost-effective in many older applications. Androgen misuse is the systematic over-prescribing for unproven medical indications. Misuse is increasingly evident for male ageing ("andropause") and some other clinical conditions. Further trials for new indications for androgens require reliable safety data, but rising costs may make it increasingly attractive to circumvent the need for evidence by promoting off-label mass marketing. Androgen abuse is the illicit self-administration of often massive doses of androgens for non-medical purposes - notably power sports and body building. In parallel with effective detection reducing
androgen abuse in elite sports, more focus is needed on non-sporting cosmetic, recreational and occupational androgen abuse. Despite ongoing androgen misuse and abuse, testosterone remains under-prescribed for younger men with classical androgen deficiency that frequently remains undiagnosed [06050].

Testosterone therapy is prescribed for millions of men each year, and the number is increasing rapidly. Prescription sales of testosterone increased by 500 percent in the United States between 1993 and 2000. Most testosterone prescriptions are written to treat nonspecific symptoms, such as fatigue or sexual dysfunction, when accompanied by testosterone levels below the laboratory reference range. Currently, testosterone levels that are at least 2 SD below the mean value for healthy young adults are classified as low. Although convenient, this classification fails to consider the physiological consequences of specific testosterone levels. More than 80 percent of circulating estradiol in men is derived from the aromatization of testosterone. Thus, as serum testosterone levels decline, there is a concomitant decline in serum estradiol levels. Nevertheless, the consequences of male hypogonadism are routinely attributed solely to androgen deficiency; the potential role of the concomitant decline in estrogens is typically ignored. It has become clear, however, that estrogen deficiency may be important in the pathogenesis of some consequences of male hypogonadism, such as bone loss. The potential role of estrogen deficiency in the pathogenesis of other consequences of hypogonadism, such as alterations in body composition or sexual function, is largely unknown. Information on the role of estrogens in male hypogonadism may help identify men at risk for specific manifestations of the condition and may provide a rationale for novel approaches to its management. We sought to determine the relative degree of testosterone deficiency, estradiol deficiency, or both at which undesirable changes in body composition, strength, and sexual function begin to occur and whether those changes are due to androgen deficiency, estrogen deficiency, or both. It was recruited two cohorts of men who were 20 to 50 years of age and healthy. All the men had normal serum testosterone levels. All participants received goserelin acetate (Zoladex®), at a dose of 3.6 mg subcutaneously at weeks 0, 4, 8, and 12, to suppress endogenous gonadal steroids. Participants were then randomly assigned to receive 0 g (placebo), 1.25 g, 2.5 g, 5 g, or 10 g of a topical 1 percent testosterone gel (AndroGel®) daily for 16 weeks. Participants in cohort 2 also received anastrozole (Arimidex®) at a dose of 1 mg daily to block the aromatization of testosterone to estrogen. Participants were unaware of the study-group assignments. Participants were seen every 4 weeks. At each visit, fasting blood samples were obtained to measure gonadal steroid levels, and questionnaires were administered to assess physical function, health status, vitality, and sexual function. At baseline and week 16, body fat and lean mass were assessed by means of dual-energy x-ray absorptiometry (DXA); subcutaneous- and intraabdominal-fat areas and thigh-muscle area were measured by means of computed tomography (CT); and lower-extremity strength was determined by means of a leg press. Data on bone homeostasis (bone-turnover markers and bone mineral density), risk factors for cardiovascular disease (blood pressure, lipids, and insulin sensitivity), and levels of leptin and prostate-specific antigen were also collected but are not included in the present report. It was enrolled 198 men in cohort 1 and 202 men in cohort 2. There were no significant differences in baseline testosterone levels among dose groups or between cohorts. In the study, it was found that the dose of testosterone required to prevent adverse changes in a variety of measures varies considerably. When aromatization was intact, fat accumulation began with mild gonadal steroid deficiency (a testosterone level of approximately 300 to 350 ng per deciliter), whereas lean mass, thigh-muscle area, and muscle strength were preserved until gonadal steroid deficiency was more marked (a testosterone level ≤200 ng per deciliter). Sexual desire and erectile function, the two major domains of sexual function, showed distinct patterns of change as serum testosterone levels were reduced. The variation in tissue sensitivity to androgens could be due to polymorphisms affecting polyglutamine repeat length in the androgen-receptor gene.
tissue-specific differences in androgen-receptor expression or local hormone metabolism, or, as shown in the study, variation in the roles of androgens and estrogens in the regulation of target-tissue responses. Observational studies have shown that lean mass and strength are reduced and fat mass is increased in men with low testosterone levels. Men with hypogonadism report less sexual activity, fewer sexual thoughts, and fewer spontaneous erections than men with normal testosterone levels. Moreover, testosterone replacement increases lean mass, decreases fat mass, and can improve sexual function in men with hypogonadism. These observations have led to the widespread belief that undesirable changes in body composition and sexual dysfunction in men with hypogonadism are due to androgen deficiency. However, because estradiol is a metabolite of testosterone, it is difficult to distinguish the effects of androgens from those of estrogens in observational studies, or even in randomized, controlled trials if aromatizable androgens are used without the administration of an aromatase inhibitor. By administering a variety of testosterone doses with and without concomitant aromatase inhibition, it was found that changes in lean mass, thigh-muscle area, and leg-press strength were attributable to changes in testosterone levels, whereas changes in fat measures were primarily related to changes in estradiol levels. Both androgens and estrogens contributed to the maintenance of normal libido and erectile function. Although these results may be surprising, they are consistent with studies showing that body fat is increased in humans and male mice with null mutations of the aromatase gene or the estrogen-receptor α gene and that sexual function is markedly impaired in mice and humans with these genetic defects. These observations may have important clinical implications. First, they provide a physiological basis for interpreting testosterone levels in young and middle-aged men and identifying the adverse consequences that are most likely to occur at various gonadal steroid levels. Second, because increases in visceral fat reduce insulin sensitivity and are associated with diabetes and the metabolic syndrome, the marked increase in intraabdominal fat with aromatase inhibition could portend an increase in cardiovascular disease with long-term estrogen deficiency. Finally, because lean mass, thigh-muscle area, and erectile function were reduced at a testosterone dose (1.25 g per day) that elicited a mean serum level of approximately 200 ng per deciliter, testosterone supplementation seems justified in men with testosterone levels in this range. However, some men have alterations in these functional outcomes at lower or higher testosterone levels, and other consequences of hypogonadism, such as increases in body fat and loss of sexual desire, routinely develop at higher mean testosterone levels. Thus, each person's specific clinical scenario should be considered when interpreting the clinical significance of the circulating testosterone level. These findings may also have implications for older men. Serum testosterone levels decline modestly as men age, such that 20 percent of men older than 60 years of age and 50 percent of men older than 80 years of age have testosterone levels at least 2 SD below the mean level in young men. The finding that estrogens have a fundamental role in the regulation of body fat and sexual function, coupled with evidence from prior studies of the crucial role of estrogen in bone metabolism, indicates that estrogen deficiency is largely responsible for some of the key consequences of male hypogonadism and suggests that measuring estradiol might be helpful in assessing the risk of sexual dysfunction, bone loss, or fat accumulation in men with hypogonadism. For example, in men with serum testosterone levels of 200 to 400 ng per deciliter, sexual-desire scores decreased by 13 percent if estradiol levels were 10 pg per milliliter or more and by 31% if estradiol levels were below 10 pg per millilitre. The findings also suggest that treatment with aromatizable androgens would be preferable to treatment with nonaromatizable androgens in most men with hypogonadism [13188].

Normal values
Normal total plasma testosterone levels in males are in the range of 300 to 1,000 ng/dL. Most is bound by sex hormone-binding protein and is inactive; free testosterone, the active form, makes up only 2 to 3 percent of circulating testosterone. Testosterone is metabolized into dihydrotestosterone, which is 10 times more potent than testosterone, and estradiol, which has feminizing effects [07031].

Reference ranges are essential for partitioning testosterone levels into low or normal and making the diagnosis of androgen deficiency. It was established reference ranges for total testosterone (TT) and free testosterone (FT) in a community-based sample of men. TT was measured using liquid chromatography tandem mass spectrometry in nonobese healthy men, 19-40 years old, in the Framingham Heart Study Generation 3; FT was calculated. Values below the 2.5th percentile of reference sample were deemed low. It was determined the association of low TT and FT with physical dysfunction, sexual symptoms (European Male Aging Study, EMAS, only), and diabetes mellitus in three cohorts: Framingham Heart Study generations 2 and 3, EMAS, and the Osteoporotic Fractures in Men Study. In a reference sample of 456 men, mean (SD), median (quartile), and 2.5th percentile values were 724 (221), 699 (297), and 348 ng/dL for TT and 142 (45), 134 (60), and 70 pg/mL for FT, respectively. In all three samples, men with low TT and FT were more likely to have slow walking speed, difficulty climbing stairs, or frailty and diabetes than those with normal levels. In EMAS, men with low TT and FT were more likely to report sexual symptoms than men with normal levels. Men with low TT and FT were more likely to have at least one of the following: sexual symptoms (EMAS only), physical dysfunction, or diabetes. It was concluded that the reference ranges generated in a community-based sample of men provide a rational basis for categorizing testosterone levels as low or normal. Men with low TT or FT by these criteria had higher prevalence of physical dysfunction, sexual dysfunction, and diabetes. These reference limits should be validated prospectively in relation to incident outcomes and in randomized trials [11327].

Problems in evaluating serum testosterone values

Testosterone (T) and other androgens are incorporated into an increasingly wide array of human sexuality research, but there are a number of issues that can affect or confound research outcomes. One review addressed various methodological issues relevant to research design in human studies with T; unaddressed, these issues may introduce unwanted noise, error, or conceptual barriers to interpreting results. Topics covered are (1) social and demographic factors (gender and sex; sexual orientations and sexual diversity; social/familial connections and processes; social location variables), (2) biological rhythms (diurnal variation; seasonality; menstrual cycles; aging and menopause), (3) sample collection, handling, and storage (saliva vs. blood; sialogogues, saliva, and tubes; sampling frequency, timing, and context; shipping samples), (4) health, medical issues, and the body (hormonal contraceptives; medications and nicotine; health conditions and stress; body composition, weight, and exercise), and (5) incorporating multiple hormones. Detailing a comprehensive set of important issues and relevant empirical evidence, the review provided a starting point for best practices in human sexuality research with T and other androgens that may be especially useful for those new to hormone research [13194].

Half life

Designer AAS are altered so as to increase the bioavailability and prolong the desired effects. For example, testosterone’s half-life is measured in minutes, whereas fluoxy-mesterone, a synthetic AAS, has a half-life of 9.2 hours [06031].
Testosterone/epitestosterone concentration ratio (T/E)

Determining the origin of testosterone and other steroids in human urine is a major issue in doping control. According to the latest published laboratory statistics of 2009 from WADA, 65 percent of reported adverse and atypical analytical findings by the accredited anti-doping laboratories belonged to the substance group of anabolic agents. Out of these, testosterone is by far the most common agent reported, constituting as much as 70 percent of the findings. An atypical analytical finding of testosterone, however, must not be confused with an anti-doping rule violation. The detection of the administration of testosterone is primarily based on a population reference interval of a urinary ratio of testosterone to epitestosterone, excreted as glucuronide, referred to as the T/E ratio. Since it is well known that natural outliers of a normal steroid profile exist, a further investigation is mandatory after a finding of an elevated T/E ratio. For this reason, samples with a T/E ratio that equals or exceeds 4 are amongst other parameters recommended to be submitted to isotope ratio mass spectrometric (IRMS) analysis. The IRMS analysis is based on differences in isotope ratio between endogenous and synthetic testosterone and provides the basis for confirmatory analysis. The $^{13}$C/$^{12}$C ratio in natural compounds, such as steroids, is determined by the pathway by which they were produced. Consequently, synthetic testosterone is generally less enriched in $^{13}$C and shows a different $^{13}$C/$^{12}$C ratio than human endogenous testosterone. Out of the samples with T/E ratios above 4 submitted to IRMS analysis in one laboratory, about 8 percent were reported as adverse analytical findings for the application of synthetic testosterone or testosterone prohormones [11574].

The use of biomarkers of doping is not new. For example, the testosterone/epitestosterone concentration ratio (T/E) was introduced by several sports organizations in the 1970s to deter the administration of anabolic steroids. Because epitestosterone is only a minor product of testosterone metabolism and does not increase after exogenous testosterone administration, the net effect of the latter is an increase in T/E. In 1983, a T/E in excess of 6.0 was considered indicative of steroid doping by the International Olympic Committee. The introduction of this rule was mitigated, however, by the discovery a few years later that some individuals may have naturally increased T/E, a phenomenon that has recently been attributed to the discovery of genetic polymorphisms that are associated with the metabolism of anabolic steroids. Currently, in addition to the T/E, a urinary steroid profile that includes multiple testosterone metabolites and precursors is used to detect steroid doping, in addition to doping with other anabolic agents, such as designer steroids, gonadotropins, estrogen antagonists, aromatase inhibitors, androgen precursors, and selective androgen receptor modulators [11426].

T/E in police-seized drugs
One possible explanation for some of the negative findings at IRMA in T/E-positiva cases might be the use of testosterone with endogenous-like delta values. The isotopic ratio depends on the manufacturing process and on the carbon feed stocks of the starting materials. Hence, it could be possible to produce testosterone products with carbon isotope ratios in, or close, to the endogenous range, by using $^{13}$C enriched starting materials. In one study, the content of a number of black market testosterone products collected in Austria were analyzed. Additionally, $^{13}$C/$^{12}$C ratios were measured for testosterone in the products after cleavage of the testosterone ester. The aim was to determine whether some of these products had similar $^{13}$C/$^{12}$C ratios to those normally found for endogenous testosterone, which could prevent a positive isotopic ratio mass spectrometric (IRMS) finding in doping control. Moreover, it was investigated to what extent the preparations contained the masking agent epitestosterone, in order to lower the testosterone/epitestosterone (T/E) ratio in urinary steroid profiles. Out of 30 analyzed products, the declared ingredients differed from the actual content in 10 cases. Epitestosterone, however, could not be found in any of the
products. The products displayed $^{13}CVPDB$ values between 24 and 29 percent. Formore than half of these products, the values were within a range reported for endogenous urinary steroids [11574].

**Androsterone to epitestosterone ratio**
The conspicuous interindividual differences in metabolism and urinary excretion of testosterone and its metabolites make it challenging to reveal testosterone doping. The variation in testosterone glucuronide excretion is strongly associated with a deletion polymorphism in the uridine diphosphate-glucuronosyltranferase (UGT) 2B17 gene. The objective of one study was to identify additional biomarkers to detect testosterone abuse and to elucidate alternative pathways for testosterone elimination in individuals devoid of the UGT2B17 enzyme. For this purpose a new ultraperformance liquid chromatographic tandem mass spectrometric method for simultaneous determination of 10 different sulfo- and glucuronide-conjugated steroids was developed. Fifty-four healthy male volunteers with two, one, or no allele (ins/ins, ins/del, or del/del) of the UGT2B17 gene participated in the study. Intervention included a single im dose of 500 mg testosterone enanthate. Urinary sulfo- and glucuronide-conjugated steroids were measured. Testosterone sulfate levels decreased in all individuals after the dose. The individual differences in the excretion of all sulfated metabolites were large. Thus, these metabolites will not serve as appropriate biomarkers for testosterone abuse. However, androsterone glucuronide excretion increased in all of our study subjects after the testosterone dose. Etiocholanolone sulfate was excreted at significantly higher levels in UGT2B17 del/del individuals. It was proposed that the androsterone glucuronide to epitestosterone glucuronide ratio may serve as a complementary biomarker to reveal testosterone abuse [11575].

**Free testosterone/cortisol ratio**

**In golf**
The purpose of one investigation was to study the effects of 36 continuous holes of competitive golf on salivary testosterone, cortisol, and testosterone-to-cortisol ratio and their relation to performance in eight elite male collegiate golfers (age 20 years). Thirty-six holes of a 54-hole NCAA golf tournament were played on the first day of the competition. A saliva sample was taken 45 minutes prior to the round and immediately following each hole for a total of 37 samples per subject. Time matched baseline samples were collected on a different day to account for circadian variation. Six-hole areas under the curve (AUC) values were calculated for endocrine measures. Significant increases were noted for cortisol during competition, however, testosterone did not change during competition compared to baseline. Testosterone-to-cortisol (T/C) ratio was significantly lower throughout the competition compared to baseline measures. Thirty-six-hole AUC testosterone-to-cortisol ratio response was correlated to 36-hole score. There was a high correlation between pre-round testosterone, T/C ratio response, and 36-hole score. CSAI-2 somatic anxiety was correlated to pre-round cortisol and testosterone response. These results indicate a significant hormonal response during 10 hours of competitive golf. Good golf performance (low golf scores) in this competition was related to low T/C ratio. Additionally, results from this investigation validated CSAI-2 somatic anxiety with physiological measures of anxiety [06059].

**In soccer**
The following up of some hormonal parameters during the professional soccer training process could be one of the indicators of the training effects. On the other hand, overreaching and overtraining as an opposite adaptation of supercompensation could be detected by following up some hormonal changes. The aim of one study was to evaluate the changes in some hormonal parameters in professional soccer players during a half-season
competition. It was included 30 professional soccer players from a soccer club of our National Soccer League in this study. All sport medical examinations were conducted three times: before the preparation phase, before the competition phase (after previous phase) and after finishing the competition phase. There were significant differences in all evaluated hormones between three phases of soccer training process, including significant decrease in T/C of more than 30 percent at the end of the competition phase (phase III). The decrease in muscle mass after the preparation phase and the increase in fat mass at the end of competition phase were insignificant. The hormonal changes indicated that some indices could indicate overreaching and overtraining at the end of professional soccer competition season. Although insignificant, the decrease in muscle mass after the preparation phase and the increase in fat mass at the end of competition phase were undesirable effects for us [06060].

The free testosterone:cortisol ratio (FTCR) is widely used for studying and preventing overtraining syndrome in various sports. The use of FTCR for following overtraining syndrome was proposed originally with two approaches: FTCR lower than $0.35 \times 10^{-3}$, calculated on free testosterone (FT) in nanomoles per liter (nmol/L) and on cortisol (C) in micromoles per liter (mmole/L) or a decrease of the ratio of 30 percent or more in comparison with the previous value. In our experience, the use of an absolute value as a threshold is not useful, whereas the evaluation of the concentrations of hormones and their ratio in comparison with previous ones is more useful. These classical approaches are not, however, sufficient to describe the various possible physiological modifications linked to training excess and/or incomplete recovery. It was collected samples from 32 professional soccer players of an Italian First Division team, during the period 2001-2003. It was analyzed the values of 21 athletes during the season 2001-2002 and of 11 athletes during the season 2002-2003 (6 out of 11 were examined also during the previous one) always present when the 4 (first season) or 5 (second season) blood drawings have been performed. We applied an original, pragmatic and easy-to-use classification of FTCR values, in association with classical interpretations based on decreases of the values in comparison with previous athlete’s result. It was used the traditional approaches in two consecutive seasons in a professional soccer team: the evaluation of the decrease >30% of the parameter in comparison with the previous value or with the basal (preseason) value are shown. The statistical differences between the FTCR values of the six athletes followed in both seasons were not significant. Thus, the classification method that was proposed is advantageous in comparison with traditional interpretative schemes, because identify different risk categories, stratifying the interval between the values 0.35-0.8 [06061].

**Time-course of testosterone action**

The classic model of steroid action is that steroid hormones have a relatively slow time-course of action by acting as transcription factors after binding to intracellular receptors Athletes know that the anabolic gains realized while on a pre-competition steroid “cycle” will persist for weeks after AAS use is discontinued. However, research in animals has demonstrated behavioral effects of testosterone that occur within minutes. In the 1980s, East German scientists developed an androgen nasal spray to enhance aggression and competitiveness without systemic effects. Similarly, intranasal 4,16-androstadien-3-one induces an amphetamine-like “high” in human volunteers [12100].

**Stability in the urine**

The stability of testosterone glucuronide (TG), epitestosterone glucuronide (EG) and the T/E ratio in urine has been studied. Samples were analyzed by gas chromatography coupled to
mass spectrometry (GC/MS). Urine samples were submitted to a solid-liquid cleanup followed by extraction of unconjugated testosterone (T) and epitestosterone (E) with tert-butyl methyl ether (free fraction). The remaining aqueous phase was hydrolyzed with beta-glucuronidase and extracted at alkaline pH with n-pentane. Analytes were analyzed by GC/MS as their enol-trimethylsilyl (TMS) derivatives. The urine for stability testing was obtained from an excretion study after the administration of T to healthy volunteers. The homogeneity of the sample was verified before starting the stability study. The stability of TG and EG was evaluated at different storage conditions. For long-term stability testing, analyte concentration in urine stored at 4 degrees C and -20 degrees C was determined at different time intervals for 22 months. For short-term stability testing, analyte concentration was evaluated in urine stored at 37 degrees C for 3 and 7 days. The effect of repeated freezing (at -20 degrees C) and thawing (at room temperature) was studied for up to three cycles. Data obtained in this work demonstrated the stability of TG, EG and the T/E ratio in sterilized urine samples stored at 4 and -20 degrees C for 22 months and after going through repeated freeze/thaw cycles. Decreases in concentration were observed after 7 days of storage at 37 degrees C due to the partial cleavage of the glucuronide conjugates; however, the T/E ratio was not affected. These results show the feasibility of preparing reference materials containing TG and EG to be used for quality control purposes [06051].

**Testosterone prohormones**

The term prohormone strictly refers to a post-translational peptide that is cleaved into a variety of bioactive hormones. In the supplement context, prohormones refer to androgenic precursors which, when ingested, become enzymatically activated to testosterone derivatives. An understanding of the biochemical pathways emphasises the similarity between testosterone and its precursors. Users see prohormones as a natural means to improve muscle strength, body composition and general well-being with fewer side effects than testosterone or synthetic androgenic steroids and a more practical (capsule) form of intake. The marketing strategy of commercial websites is to promote prohormones as “legal alternatives” to testosterone with similar anabolic effects. Of course, many consumers are unaware that these prohormones are included on the WADA list of prohibited substances as well as being illegal for sale or importation in many countries. Prohormones have another concerning role in sports nutrition as contaminants in other sports supplements which account for a large proportion of inadvertent doping offences. From cholesterol, pregnenolone is produced which converts to testosterone via dihydroepiandrosterone (DHEA). The path via DHEA produces androstenedione (DIONE) and androstenediol (DIOL) which convert to testosterone. Importantly, however, these precursors can also be converted to the estrogens, which may cause effects such as gynaecomastia and liver dysfunction. To counteract this effect, some users of prohormones alternate between 1 month on and 2 months off, allowing restoration of intrinsic function within each cycle. Users also often stack differing prohormones of differing oestrogenicity within each cycle, and take N-acetyl cysteine to prevent liver dysfunction. In addition, selective estrogen receptor modulators or aromatase inhibitors are taken to mitigate oestrogenic effects, and androgenic herbal compounds taken to reduce the low period between cycles. Despite these sophisticated multidrug regimens and marketing claims, research fails to demonstrate any anabolic or ergogenic effects of taking DHEA, DIONE or DIOL, which confirms the risk of adverse side effects for DIONE and DIOL. For example Broeder et al gave 200 mg/day DIONE or DIOL to middle-aged men over a 12-week resistance training programme, and showed a significant 16 percent increase in testosterone levels after 1 month of use which had returned to prestudy levels by 12 weeks. DIOL did not significantly increase blood testosterone levels. The major fate of the ingested DIONE and DIOL appears to be aromatisation, since blood estrogen levels were increased by about 63 percent. There was no enhancement in muscle strength during resistance training above placebo but, conversely, an 11 percent increase in
the LDL-Cholesterol/HDL-Cholesterol lipid ratio, corresponding to a significant increase in the cardiovascular disease risk. Twelve weeks of supplementation reduced blood luteinising hormone levels, which may serve to decrease inherent testicular and adrenal testosterone production. The last major literature review, by Brown et al, confirmed the findings that DIONE, DIOL and DHEA do not augment muscle size and strength gains observed from resistance training alone, and that use of DIONE and DIOL may predispose users to serious health risks [12459].

An area for concern is the abuse of a precursor to AAS known as prohormones, such as androstenediol. Many prohormone synthetic chemicals have been banned, but numerous clones have been made with a minor change in the formulation. These prohormones increase hormone levels within the body leading to many of the same benefits and side effects as the AAS [12119].

The first steroids introduced on the prohormone market were dehydroepiandrosterone (DHEA) and androst-4-ene-3,17-dione in 1996, shortly thereafter followed by androst-4-ene-3beta,17beta-diol, androst-5-ene-3beta,17beta-diol and androst-5-ene-3,17-dione. These steroids can be regarded as prohormones of testosterone as they are claimed to metabolise to testosterone after oral administration. Several studies on the metabolism of DHEA androst-4-ene-3,17-dione, androst-4-ene-3beta,17beta-diol, androst-5-ene-3beta,17beta-diol and androst-5-ene-3,17-dione have indicated the possibilities of using alterations in the steroid profile to detect misuse of these steroids. Based upon these studies, monitoring the concentration and ratios of several steroids can be used for the detection of the administration of a testosterone prohormone. A similar approach was already successfully implemented for testosterone and dihydrotestosterone misuse. Amongst the most powerful indicators, besides the increase in the individual urinary concentrations of the administered steroids, were the ratio of androsterone/etiocholanolone and testosterone/epitestosterone.

These parameters were already well established in doping control analysis to detect the administration of testosterone. Besides these parameters, other steroids have been proposed for the detection of misuse of androst-4-ene-3,17-dione, including 6alpha-OH-androstenedione, 6beta-OH-androsterone, 6beta-OH-etiocholanolone, 6beta-OH epiandrosterone and 4-OH-androstenedione. For the detection of DHEA administration, 7beta-OH-DHEA, 7-keto-androsterone, 16alpha-OH-androsterone and 16alpha-OH-etiocholanolone can be used as indicative parameters. 5alpha-Androstane-3beta,17beta-diol is a prohormone of dihydrotestosterone (DHT) and is marketed as such. Administration of this steroid resulted in elevated urinary levels of endogenous 5alpha-steroids, similarly as after DHT administration as well as in high urinary concentrations of epiaandrosterone sulphate. It was therefore suggested that for the detection of the abuse of 5alpha androstane-3beta,17beta- diol, the same criteria as for DHT-misuse could be applied, in addition to the increase in urinary 5alpha-androstane-3beta,17beta- diol glucuronide concentration [06004].

5alpha-Androstane-3,17-dione is an endogenous steroid and an intermediate in the conversion of androstenedione to androsterone and etiocholanolone and is naturally present in urine in low concentrations. In microbiologically contaminated urine however, the concentration of this steroid might rapidly increase. 5alpha-Androstane-3,17-dione is listed as a controlled substance in the 2004 ASCA but was in spite of that detected as a contaminant in a nutritional supplement [06004].

Seasonal variations

Humans' endogenous testosterone concentrations vary over a number of temporal scales, with little known about variation longer than monthly cycles. Past studies of seasonal or
circannual variation have principally used male participants and have produced inconsistent results. Thus, little is known about how testosterone concentrations fluctuate throughout the year, whether such variation differs between men and women, and whether there are influences of hormonal contraceptive use. The present study collected saliva samples from a large sample (n=718) of men and women, each collected at one time point within a relatively uniform distribution over a full calendar year. Both men and normally-cycling women displayed seasonal variation in salivary testosterone concentrations, such that testosterone concentrations are maximal in the fall and minimal in the summer. Notably, normally-cycling women had testosterone concentrations that were over 100 percent greater at their maximum in fall compared to their minimum in summer. Women using hormonal contraceptives not only had consistently lower endogenous testosterone concentrations, but also showed a flatter seasonal testosterone profile [11577].

**Ethnic differences in steroid-related diseases**

Differences in circulating steroid hormone levels have been hypothesized to explain ethnic differences in steroid-related diseases. The aim of one study was to determine the serum levels of a wide panel of steroid hormones, both androgens and estrogens, in healthy middle-aged African-Caribbean and European men. Serum steroid hormone levels were determined in men participating in a systematic public health study funded by the French National Health Insurance system. Blood was collected in the morning from 304 healthy African-Caribbean and European men aged between 40 and 69 years. Serum steroids were measured by mass spectrometry-gas chromatography, except for DHEAS and sex hormone-binding globulin, which were determined by RIA. Data were analyzed in 10-year age intervals by analysis of covariance, with adjustment for age, body mass index, waist-to-hip ratio, tobacco and alcohol consumption, and season of sampling. Compared with Europeans, African-Caribbean men presented significantly higher serum levels of measured bioavailable testosterone, 4-androstenedione (4-dione), and estrone (E1) regardless of the age group, of 5-androstenediol (5-diol) in those aged 40-49 and 50-59 years, and of testosterone (TT) and dihydrotestosterone in those aged 40-49 years. In contrast, European men aged 40-69 years showed significantly higher serum levels of DHEA and DHEAS. It was concluded that significant differences in serum steroid hormone levels were observed in middle-aged African-Caribbean and European men. Whether such differences could contribute to ethnic differences in disease risk in adult men remains to be investigated. Some steroids, such as bioavailable TT, 4-dione, 5-diol, and E1, deserve particular attention [11578].

It is hypothesised that seemingly disparate and unrelated phenomena clustering in persons of African descent living in the Americas such as outstanding sprinting ability and high prostate cancer incidence and mortality are in fact related and emerge from enhanced testosterone responsiveness in descendants of African slaves surviving the transatlantic trade in Africans. It is postulated that the ability to have survived the middle passage was positively correlated with greater responsiveness of the androgen receptor to its primary ligands dihydrotestosterone and testosterone, and that slaves possessing more responsive androgen receptors experienced a survival advantage engendered by the enhanced anabolic effects which accrued such as increased red cell mass and therefore greater oxygen carrying capacity and tissue oxygen delivery enabling these slaves to tolerate stifling conditions in the hull of the slave ship, increased lean muscle mass and therefore greater surface area to volume ratio resulting in easier ability to dissipate heat and remain cool, and increased skin thickness and sebum production resisting the macerating effect of lying in admixed bodily fluids below deck. These androgen effects as well as others would have produced a survival advantage under the severe selection pressure created by the inhumane and physiologically challenging circumstances under which the slaves were transported from the interior of the African continent and West Africa to the 'New World'. This would result in a population shift...
favouring increased androgen receptor responsiveness in descendants of African slaves populating the Americas and a corresponding geographic and racial distribution of androgen related phenomena such as sprinting prowess and prostate cancer. African-Americans having the highest prostate cancer incidence rate and the Caribbean having the highest prostate cancer mortality rates in the world are consistent with this hypothesis as is the observation that the 10 fastest men and 9 fastest women of all time are exclusively the descendants of West African slaves who survived the middle passage. It is predicted that as yet undiscovered as well as known biological correlates of enhanced androgen receptor responsiveness such as relatively short CAG-repeats in the poly Q tail of exon 1 of the androgen receptor gene will be more prevalent among African-Americans and Afro-Caribbean peoples than among West Africans. It is also predicted that African-Americans and Afro-Caribbean peoples will have relatively shorter CAG-repeats in the androgen receptor gene compared to West Africans [11579].

**Urinary levels of testosterone and epitestosterone in a Korean male population**

Cannabis, or marijuana, the most commonly used illicit drug in the world, has been shown to be responsible for suppressing the production and secretion of androgens, particularly testosterone. However, despite such findings in animals, the chronic effects of marijuana use on human endocrine systems have proved to be inconsistent. Here, it was investigated the reference ranges of urinary levels of testosterone (T) and epitestosterone (E) as well as their metabolic ratio of T/E in a Korean male population (n=337), which would enable an evaluation of abnormal changes in steroid metabolism induced by habitually administered cannabis. The T/E ratio was significantly decreased in the marijuana group (n=18), while the urinary testosterone concentrations were also tended to decrease. This study is the first to provide data for the reference values of two urinary androgens and T/E values among control Korean males, and, furthermore, suggests that the T/E ratio, though not testosterone levels, might be used to understand the suppression of human male gonadal function affected by smoking marijuana [13219].

**Status of lean elite athletes**

It was investigated the endocrine profile, body composition, and state of mood in male Olympic athletes participating in sports that do or do not emphasize leanness. Forty-four Swedish male Olympic athletes participating in 26 different sport disciplines were studied. Body composition was determined by dual-energy x-ray absorptiometry, and blood levels of steroid hormones and biomarkers of nutritional status were analyzed. In addition, states of mood were assessed employing the profile of mood states (POMS) test. The athletes were divided into 2 groups on the basis of whether their sporting discipline emphasized leanness or not. In all subjects, body composition, hormone levels, and POMS scores were within normal ranges. However, the leanness athletes (n=18) displayed significantly lower proportion of body fat, higher spinal bone mineral density, lower serum levels of free testosterone and leptin, and higher serum levels of insulin-like growth factor binding protein 1 than nonleanness athletes (n=26). Leanness athletes also had higher POMS scores for depression and anger, and a higher global POMS score, the latter being positively correlated to the frequency of illness before the Olympic Games. It was concluded that although there were no indications of energy deficiency or endocrine disturbance in the leanness athletes, their higher POMS scores and frequency of illness may indicate the potential harmfulness of their pursuit of outstanding athletic performance [13195].

**Levels in male Olympics**
To investigate the endocrine profile, body composition, and state of mood in male Olympic athletes participating in sports that do or do not emphasize leanness 44 Swedish male Olympic athletes participating in 26 different sport discipline were investigated. Body composition was determined by dual-energy x-ray absorptiometry, and blood levels of steroid hormones and biomarkers of nutritional status were analyzed. In addition, states of mood were assessed employing the Profile of Mood States (POMS) test. The athletes were divided into 2 groups on the basis of whether their sporting discipline emphasized leanness or not. In all subjects, body composition, hormone levels, and POMS scores were within normal ranges. However, the leanness athletes (n=18) displayed significantly lower proportion of body fat higher spinal bone mineral density, lower serum levels of free testosterone and leptin and higher serum levels of insulin-like growth factor binding protein 1 than nonleanness athletes (n=26). Leanness athletes also had higher POMS scores for depression and anger, and a higher global POMS score, the latter being positively correlated to the frequency of illness before the Olympic Games. CONCLUSION:: Although there were no indications of energy deficiency or endocrine disturbance in the leanness athletes, their higher POMS scores and frequency of illness may indicate the potential harmfulness of their pursuit of outstanding athletic performance [12105].

**Older men**

Little information exists about longitudinal changes in body composition and physical function in relation to sex hormone levels in older men. The aim of one study was to determine associations of testosterone, estradiol, and SHBG with changes in body composition and physical function. It was conducted a prospective cohort study within the Osteoporotic Fractures in Men (MrOS) study at six US clinical centers. A total of 5994 ambulatory men aged 65 years or older enrolled in the MrOS. It was examined 1183 men with complete measures of sex steroid hormones, body composition, and some measure of physical function. Intervention: There were no interventions. Sex steroids were measured by mass spectrometry in serum collected at baseline. Measurements of body composition using dual-energy x-ray absorptiometry and physical performance (grip strength, leg power, timed chair stands, narrow walk, and 6-m walk) were performed at baseline and repeated 4.5 years later. Overall, men lost 1.3 kg (± 4.4) weight between study visits. Lean mass, especially appendicular, declined less at higher baseline testosterone levels. These associations were most evident in the 40 percent of men who lost more than 2.0 kg during follow-up. In weight losers, higher testosterone was associated with less decline in timed chair stands. Estradiol was not related to body composition or physical function changes. Higher SHBG was associated with less loss of appendicular lean mass and grip strength. Higher endogenous testosterone is associated with reduced loss of lean mass and lower extremity function in older men losing weight. Endogenous testosterone may contribute to healthy aging [11580].

Cycling androgens has been reported by athletes to improve physical performance by enhancing muscle mass and strength, a paradigm that has not been studied, and may have clinical value in older men being treated with testosterone. It was investigated the efficacy of a monthly cycled testosterone regimen that uses half the testosterone dose as the current standard of care continuous therapy on body composition and muscle strength in older men. Twenty-four community-dwelling older men 70 ± 2 years of age with total testosterone levels below 500 ng/dL were randomized at the Institute for Translational Sciences-Clinical Research Center into a 5-month double-blind placebo-controlled trial. Subjects were dosed weekly for 5 months, receiving continuous testosterone (TE, n=8; 100 mg testosterone enanthate, im injection), monthly cycled testosterone (MO, n=8; alternating months of testosterone and placebo), or placebo (PL, n=8). Main outcomes included body composition by dual-energy x-ray absorptiometry and upper and lower body muscle strength. Secondary
outcomes included body weight, serum hormones, and mixed-muscle protein fractional synthesis rate (FSR). Total lean body mass was increased and percent fat was reduced after 5 months in TE and MO. Upper body muscle strength increased in TE, and lower body muscle strength increased in TE and MO. FSR increased in TE and MO but not in PL. It was concluded that cycled testosterone improved body composition and increased muscle strength compared with placebo and increased FSR similarly to continuous testosterone [11581].

Testosterone in Older Men with Mobility Limitations Trial determined the effects of testosterone on muscle performance and physical function in older men with mobility limitation. Trial's Data and Safety Monitoring Board recommended enrollment cessation due to increased frequency of adverse events in testosterone arm. It was concluded that cycled testosterone improved body composition and increased muscle strength compared with placebo and increased FSR similarly to continuous testosterone [11581].

The measurement of serum testosterone in women is challenging due to lack of trueness, precision, and sensitivity of various available testosterone assays. Accurate assessment of testosterone in women is crucial especially in conditions associated with alleged over- or under-production of testosterone, such as in polycystic ovary syndrome (PCOS) or primary ovarian insufficiency (POI). The aim of this study was to measure and compare androgen concentrations in women with PCOS, POI, and female controls and to evaluate the performance of extraction RIA and liquid chromatography-tandem mass spectrometry (LC-MS/MS) in these women. Carefully phenotyped women with POI (n=208) or PCOS (n=200) and 45 healthy, regularly cyclic female controls were included. Method comparison analyses were performed for total testosterone, androstenedione (AD), and DHEA, as measured by
LC-MS/MS and extraction RIA. All androgen levels were significantly elevated in women with PCOS compared with POI patients and controls. Women with POI presented with similar androgen concentrations as controls, except for AD. Compared with measurements by extraction RIA, testosterone, DHEA, and AD concentrations measured by LC-MS/MS were systematically lower. However, using extraction RIA and LC-MS/MS, testosterone, DHEA, and AD measurements were shown to have good agreement as assessed by Bland-Altman analysis and intraclass correlation coefficient: 0.95, 0.83, and 0.96, respectively. It was concluded that LC-MS/MS, compared with a labor-intensive extraction RIA, shows good precision, sensitivity, and high accuracy for measuring female testosterone, DHEA, and AD concentrations under various clinical conditions. LC-MS/MS, therefore, represents a convenient and reliable assay for both clinical and research purposes, where androgen measurement in women is required [11439].

To evaluate the role of physiologic levels of androgens and their precursors in the regulation of body composition, energy and substrate metabolism and aerobic capacity in healthy, cycling, premenopausal women it was evaluated 30 young (27 ± 1 year) premenopausal, non-obese (23 ± 0.5 kg/m²), normally-cycling women, without clinical or chemical evidence of hyperandrogenism or hyperinsulinemia, for parameters of total and regional body composition, glucose tolerance, aerobic capacity and resting energy expenditure and substrate oxidation. Serum was assayed for androgens and androgen precursors by techniques optimized to assess the low androgen levels in this population. Higher serum testosterone levels correlated with greater fat mass but not abdominal adiposity or other metabolic/physiologic variables. Additionally, dehydroepiandrosterone (DHEA) was negatively related to visceral fat content. Other serum androgens did not correlate with total or regional adiposity, skeletal muscle mass, aerobic capacity, glucose tolerance, or resting energy and substrate metabolism. It was concluded that this group of non-obese, premenopausal women with no clinical or chemical evidence of hyperandrogenemia, serum testosterone levels were positively related with fat mass, but not with abdominal adiposity; whereas, DHEA was negatively related to visceral adiposity. The data suggest that within the normal physiologic range, testosterone is a predictor of overall adiposity, but that this effect does not appear to be associated with concomitant alterations in resting energy or substrate metabolism that could predispose to weight gain [11440].

Androgen therapy is being increasingly used in the management of postmenopausal women. The most common indication is to improve sexual function. The aim of one review was to evaluate current knowledge pertaining to testosterone and sexual function in postmenopausal women. The change of testosterone levels during the menopause transition remains controversial. A correlation of endogenous testosterone levels and sexual function is still inconclusive. A Cochrane Review and recent randomized control trials have, however, consistently demonstrated that short-term testosterone therapy in combination with traditional hormone therapy regimens improves sexual function in postmenopausal women, particularly surgically menopausal women with hypoactive sexual desire disorder. An adverse effect on the lipid profile has been identified which appears to be mostly associated with oral methyltestosterone. Data for other effects of testosterone and long-terms risks are lacking. Testosterone may act in a variety of ways in different tissues. This is, however, an area that requires further investigation. Thus, testosterone therapy is a promising option for treating women with hypoactive sexual desire disorder after surgical menopause. Two remaining questions need to be answer: who is most likely to benefit from testosterone therapy and what are the long-term health risks? [06052].

**Testosterone after use of chlorinated swimming pools**
The goal of one study was to evaluate the associations between testicular hormones at adolescence and the exposure to chlorination by-products when attending chlorinated swimming pools. We obtained serum samples from 361 school male adolescents (aged 14-18 years) who had visited swimming pools disinfected with chlorine or by copper-silver ionization. We analysed serum concentrations of inhibin B (two different assays), total and free testosterone, sex hormone-binding globulin, luteinizing hormone (LH), follicle stimulating hormone (FSH) and dehydroepiandrosterone sulphate (DHEAS). There were strong inverse associations between serum levels of inhibin B (both assays) or of total testosterone, adjusted or unadjusted for gonadotropins and the time adolescents had spent in indoor chlorinated pools, especially during their childhood. Adolescents having attended indoor chlorinated pools for more than 250 h before the age of 10 years or for more than 125 h before the age of 7 years were about three times more likely to have an abnormally low serum inhibin B and/or total testosterone (<10th percentile) than their peers who never visited this type of pool during their childhood (odds ratio 2.83 and 3.67, respectively). Such associations were not seen with free testosterone, LH, FSH and DHEAS or with the attendance of outdoor chlorinated pools or of the copper-silver pool. Swimming in indoor chlorinated pools during childhood is strongly associated with lower levels of serum inhibin B and total testosterone. The absorption of reprotoxic chlorination by-products across the highly permeable scrotum might explain these associations [11441].

**Testosterone prohormones**

Testosterone prohormones such as androstenedione, androstenediol, and dehydroepiandrosterone (DHEA) have been heavily marketed as testosterone-enhancing and muscle-building nutritional supplements for the past decade. Concerns over the safety of prohormone supplement use prompted the United States Food and Drug Administration to call for a ban on androstenedione sales, and Congress passed the Anabolic Steroid Control Act of 2004, which classifies androstenedione and 17 other steroids as controlled substances. As of January 2005, these substances cannot be sold without prescription. Here, we summarize the current scientific knowledge regarding the efficacy and safety of prohormone supplementation in humans. We focus primarily on androstenedione, but we also discuss DHEA, androstenediol, 19-nor androstenedione, and 19-nor androstenediol supplements. Contrary to marketing claims, research to date indicates that the use of prohormone nutritional supplements (DHEA, androstenedione, androstenediol, and other steroid hormone supplements) does not produce either anabolic or ergogenic effects in men. Moreover, the use of prohormone nutritional supplements may raise the risk for negative health consequences [06122].

**Salivary testosterone (and testosterone to cortisol ratio)**

Salivary testosterone (T) and cortisol (C) concentrations were monitored across a sports competition. Data were compared using two enzyme-immunoassay (EIA) methods and two sample preparations to determine their influence on hormone concentrations. A group of male athletes (n=19) provided a saliva sample the morning before and one day after (24h post) an international rugby union match. Following an extraction procedure, the samples were analysed for T and C concentrations using a commercial kit (CM_e) and an in-house method (IH_e). Raw samples (no extraction procedure) were also tested using the commercial kit (CM_r). There were no significant changes in T and C levels from pre to post competition with each EIA method and sample preparation, but significant differences in T (IH_e>CM_e>CM_r) and C (CM_r)>IH_e and CM_e) concentrations were seen when both samples were pooled. Bland-Altman analyses confirmed the presence of fixed and proportional bias. Strong and significant correlations were demonstrated between the IH_e and CM_e measures of
salivary T and C. The T and C values from the raw and extracted samples were also strongly correlated. The measurement of salivary T and C concentrations across an international sports event was influenced by different EIA methods and sample preparations, but all measures were strongly correlated with some bias. Both T and C were unresponsive to the sports event, but within the group results large individual variation was seen [12106].

To prepare efficiently for competition, wrestlers usually train physically for a period of approximately 12-20 weeks. Numerous physical qualities must be developed during this period of preparation: aerobic fitness, maximal strength, muscular endurance, power, and speed. However, numerous studies have concluded that it is difficult to concurrently develop strength and aerobic fitness for several reasons, in particular antagonistic endocrine variations. The study involved 15 elite junior wrestlers who trained at a sports training school for 15 weeks. To investigate the effects of long-term training and to assess the relationships between hormonal concentrations (salivary testosterone [T] and cortisol [C]) and performance changes during simultaneous strength and aerobic fitness training, 6 saliva samples and 3 physical tests and 2 measures of body composition were made during the training period. Wrestlers had a significant increase (+1.5 kg) in body weight without changes in percentage body fat. Apart from the 20-m maximal shuttle speed, all performances increased significantly during the 15 weeks of training: maximum mechanical power output (Pmax: +13 %), mean power during 30 seconds (Pmean: +11 %), bench press (+6 %), squat (+23 %), power clean (+6 %), time to 3,000- and 30-m sprints (-3.6, -1.3 % respectively). During the period that the C increased, there was no significant variation for the T. The T/C ratio followed a variation pattern contrary to that of the C. It was found strong correlations between salivary T, C, and T/C and the variation in explosive strength. The results suggest that data about subjects’ salivary C, T, and T/C may be employed to optimize the training process for sports people who need to develop strength and aerobic fitness simultaneously [12107].

It was developed a simple and sensitive method for the simultaneous determination of testosterone (TES), cortisol (CRT), and dehydroepiandrosterone (DHEA) in saliva by automated online in-tube solid-phase microextraction (SPME) coupled with liquid chromatography-tandem mass spectrometry (LC-MS/MS) using a Discovery HS F5 column. The optimum in-tube SPME conditions were 25 draw/eject cycles of 40 μL of sample at a flow rate of 200 μL/min using a Supel-Q PLOT capillary column as an extraction device. The extracted compounds were easily desorbed from the capillary by passage of the mobile phase, and no carryover was observed. The in-tube SPME LC-MS/MS method showed good linearity with correlation coefficients r ≥ 0.9998 for TES, CRT, and DHEA using their respective stable isotope-labeled internal standards. The intra-day and inter-day precisions (relative standard deviations) were below 4.9 and 8.5 percent (n=5), respectively. This method was successfully utilized to analyze TES, CRT, and DHEA in saliva samples without any other pretreatment or interference peaks, and the quantification limits (S/N = 10) of TES, CRT and DHEA were about 0.01, 0.03 and 0.29 ng/mL saliva, respectively. The recoveries of these compounds spiked into saliva samples were each above 94 percent. This method was applied to analyze changes in salivary TES, CRT, and DHEA levels resulting from stress and fatigue load [12108].

In women
To compare the baseline free testosterone (T) and cortisol (C) concentrations of elite and non-elite female athletes 18 females from different sports (track and field, netball, cycling, swimming, bob skeleton) were monitored over a 12-week period. Baseline measures of salivary free T and C concentrations were taken weekly prior to any training. The elites (n=9) and non-elites (n=9) were classified as international and national level competitors, respectively, with both groups matched by sport. The pooled free T concentrations of the
elites (87 pg/ml) were significantly higher than the non-elites (41 pg/ml) and consistently so across all weekly time points. Pooled free C concentrations were also greater in the elite group (2.90 ng/ml) than the non-elites (2.32 ng/ml). The pooled baseline T and C measures were higher in elite female athletes than non-elites. Higher free T and C concentrations could indicate a greater capacity for physical performance at higher work rates, which is commensurate with the demands of elite sport. Speculatively, the T differences observed could influence female behavior and thereby help to regulate sporting potential [12109].

**Laboratory techniques**

A sensitive and rapid liquid chromatographic (LC) method for the simultaneous determination of testosterone (T) and epitestosterone (E) in human urine samples has been developed and elaborated. The ratio of the both steroids (T/E) in human urine is a widely used as doping control indicator. A sample pretreatment by solid-phase extraction (SPE) after hydrolysis using 36 percent hydrochloric acid for determination of total level of T has been applied. Unconjugated (free) form of the both androgens was determined without hydrolysis steps, what makes novelty of the method, because simplifies the proposed procedure. In turn, the measurements of urinary free T and E provided the diagnostic information for excess adrenal production of steroids. The proposed LC assay was evaluated by analyzing a series of urine samples containing T, E and methyltestosterone (MT) as internal standard at the range of concentration 2-300 ng/mL of both analyzed hormones. The proposed method was fully validated for specificity, linearity, limits of detection and quantitation, precision and trueness according to the current requirements concerning analytical methods. Interestingly, the developed LC method allows to obtain a sensitive enhancement with respect to UV detection with the quantitation limit for T and E equaled 2 ng/mL. The method was selective and reliable for identity and enables to detect changes of endogenous levels of T and E in urine independently of fluctuations characteristic for both analyzed endogenous hormone level in plasma [12110].

**Biological action**

The anabolic hormone testosterone induces muscle hypertrophy, but the intracellular mechanisms involved are poorly known. It was addressed the question whether signal transduction pathways other than the androgen receptor (AR) are necessary to elicit hypertrophy in skeletal muscle myotubes. Cultured rat skeletal muscle myotubes were preincubated with inhibitors for ERK1/2 (PD98059), PI3K/Akt (LY294002 and Akt inhibitor VIII) or mTOR/S6K1 (rapamycin), and then stimulated with 100 nM testosterone. The expression of α-actin and the phosphorylation levels of ERK1/2, Akt and S6K1 (a downstream target for mTOR) were measured by Western blot. mRNA levels were evaluated by real time RT-PCR. Myotube size and sarcomerization were determined by confocal microscopy. Inhibition of AR was assessed by bicalutamide. Testosterone-induced myotube hypertrophy was assessed as increased myotube cross-sectional area (CSA) and increased alpha-actin mRNA and alpha-actin protein levels, with no changes in mRNA expression of atrogenes (MAFbx and MuRF-1). Morphological development of myotube sarcomeres was evident in testosterone-stimulated myotubes. Known hypertrophy signaling pathways were studied at short times: ERK1/2 and Akt showed an increase in phosphorylation status after testosterone stimulus at 5 and 15 min, respectively. S6K1 was phosphorylated at 60 min. This response was abolished by PI3K/Akt and mTOR inhibition but not by ERK1/2 inhibition. Similarly, the CSA increase at 12 h was abolished by inhibitors of the PI3K/Akt pathway as well as by AR inhibition. These results suggest a crosstalk between pathways involving fast intracellular signaling and the AR to explain testosterone-induced skeletal muscle hypertrophy [13189].
Anabolic steroids are performance enhancers, this being particularly apparent in women, although there is a high risk of virilization despite the favourable myotrophic-androgenic dissociation that many xenobiotic steroids confer. Modulation of androgen receptor expression appears to be key to partial dissociation, with consideration of both intracellular steroid metabolism and the topology of the bound androgen receptor interacting with co-activators. An anticatabolic effect, by interfering with glucocorticoid receptor expression, remains an attractive hypothesis. Behavioural changes by non-genomic and genomic pathways probably help motivate training. It is important not to exaggerate the medical risks associated with their administration for sporting or bodybuilding purposes but to emphasize to users that an attitude of personal invulnerability to their adverse effects is certainly misguided [08064].

Androgens are modulators of skeletal muscle adaptation and regeneration processes. The control of satellite cell activity is a key mechanism during this process. In this study, it was analyzed the ability of dihydrotestosterone (DHT) and anabolic steroids to induce and modulate the differentiation of myoblastoma cells toward myotubes. Myoblastoma cells were dose-dependently treated with DHT and anabolic steroids. The time-dependent effects on differentiation were measured and correlated with the expression of genes involved in the regulation of satellite cell activity. The distribution of myoblastoma cells within the cell cycle was measured by flow cytometry and differentiation by creatine kinase (CK) activity. Gene expression was analyzed using quantitative real-time PCR and confocal microscopy. The treatment with DHT and anabolic steroids resulted in a stimulation of myoblastoma cell proliferation and CK activity. The antiandrogen flutamide was able to antagonize this effect. The expression of the androgen receptor, SOX8, SOX9, Delta, Notch, myostatin, and paired box gene7 (Pax7) was modulated by androgens. The treatment with DHT and anabolic steroids resulted in a strong stimulation of myostatin expression not only in undifferentiated cells but also in myotubes. The stimulation could be antagonized by flutamide. The expression of Pax7 was detectable in myoblastoma cells early after treatment with DHT. The results demonstrate that the key mechanisms of satellite cell differentiation are modulated by androgens. Androgens stimulate the proliferation of myoblastoma cells, accelerate the process of differentiation, and increase the expression of myostatin in undifferentiated and differentiated cells [08065].

Important mechanisms behind the myotrophic effects of testosterone were uncovered both in athletes using steroids for several years and in short-term controlled studies. Both long-term and short-term steroid usage accentuates the degree of fibre hypertrophy in human skeletal muscle by enhancing protein synthesis. A mechanism by which testosterone facilitates the hypertrophy of muscle fibres is the activation of satellite cells and the promotion of myonuclear accretion when existing myonuclei become unable to sustain further enhancement of protein synthesis. Interestingly, long-term steroid usage also enhances the frequency of fibres with centrally located myonuclei, which implies the occurrence of a high regenerative activity. Under the action of testosterone, some daughter cells generated by satellite cell proliferation may escape differentiation and return to quiescence, which help to replenish the satellite cell reserve pool. However, whether long-term steroid usage induces adverse effects of satellite cells remains unknown. Testosterone might also favour the commitment of pluripotent precursor cells into myotubes and inhibit adipogenic differentiation. The effects of testosterone on skeletal muscle are thought to be mediated via androgen receptors expressed in myonuclei and satellite cells. Some evidence also suggests the existence of an androgen-receptor-independent pathway. Clearly, testosterone abuse is associated with an intense recruitment of multiple myogenic pathways. This provides an unfair advantage over non-drug users. The long-term consequences on the regenerative capacity of skeletal muscle are unknown [08066].
There is strong evidence that androgen administration in men increases skeletal muscle mass, maximal voluntary strength and muscle power. However, there is no good experimental evidence to support the presumption that androgen administration improves physical function or athletic performance. Androgens do not increase specific force or whole body endurance measures. The anabolic effects of testosterone on the skeletal muscle are mediated through androgen receptor signaling. Testosterone promotes myogenic differentiation of multipotent mesenchymal stem cells and inhibits their differentiation into the adipogenic lineage. Testosterone binding to androgen receptor induces a conformational change in androgen receptor protein, causing it to associate with beta-catenin and TCF-4 and activate downstream Wnt target genes thus promoting myogenic differentiation. The adverse effects of androgens among athletes and recreational bodybuilders are under reported and include acne, deleterious changes in the cardiovascular risk factors, including a marked decrease in plasma high-density lipoproteins (HDL) cholesterol level, suppression of spermatogenesis resulting in infertility, increase in liver enzymes, hepatic neoplasms, mood and behavioral disturbances, and long term suppression of the endogenous hypothalamic-pituitary-gonadal axis. Androgens are often used in combination with other drugs which may have serious adverse events of their own [08067].

One study examined the anabolic-hormone response to carbohydrate (CHO) supplementation at rest and after resistance exercise. Nine recreationally trained men randomly underwent 4 testing conditions: rest with placebo, rest with CHO, resistance exercise with placebo, and resistance exercise with CHO. The resistance-exercise protocol was four sets of Smith machine squats with a 10-repetition-maximum load, with 90-s rests between sets. Participants then consumed either a placebo or CHO (24 % CHO, 1.5 g/kg) drink. Blood was taken before exercise, immediately after testing, and then 15, 30, and 60 min after drink ingestion. Blood was analyzed for cortisol, glucose, insulin, and total testosterone (TTST). Cortisol did not change significantly in any condition. Glucose concentrations increased significantly. Insulin concentrations increased significantly under resistant conditions. There were no significant changes in total testosterone concentrations during rest with or without carbohydrate in contrast to the exercise groups. It was concluded that ingesting carbohydrates after resistance exercise resulted in decreased total testosterone concentrations during recovery, although the mechanism is unclear [00868].

Many hormones (e.g. catecholamines, growth hormone, adrenal steroids, androgens, etc.) influence health status, exercise/sport performances and the physiological adaptation to exercise-related stress in athletes. In addition to classic reproductive and sexual effects (e.g. sexual behaviour, penis growth, erection, secondary sexual characteristics and spermatogenesis), and also depending on the role of CAG repeat polymorphism on androgen receptors biological activity, endogenous testosterone exert a wide spectrum of actions in males. Particularly, testosterone can differently influence body composition (e.g. muscles growth, fat mass, bone density), central nervous system maturation and functions (e.g. behavior characteristics, aggression and cognitive processes), endocrine and metabolic pathways (glucose metabolism, insulin and leptin), muscles physiology and motor behaviour, erythropoiesis, and adaptation to stress. A biologically normal testosterone secretion appears therefore fundamental in males to guarantee both a physiological exercise adaptation and safe sport participation. The reproductive system is highly sensitive to the effects of exercise-related stress and the reproductive hormones may both increase and decrease after different acute or chronic exercises. Exercise and sport participation may positively or negatively influence andrological health status depending on the type, intensity and duration of performed physical activity and on individual health status. In addition, prohibited substances administration (e.g. androgenic-anabolic steroids, and so forth) in competitive and non-competitive athletes represents the main cause of iatrogenic andrological diseases [12094].
Hypothalamic-pituitary-gonadal (HPG) axis

The hypothalamic-pituitary-gonadal (HPG) axis is regulated by a negative feedback mechanism. Testosterone inhibits the frequency and amplitude of gonadotropin-releasing hormone (GnRH) release from the hypothalamus and also the secretion of luteinizing hormone (LH) from the pituitary. The Sertoli cells of the testes, in addition to stimulating spermatogenesis, also secrete the glycoprotein hormone inhibin, which provides negative feedback to the pituitary, inhibiting the secretion of follicle stimulating hormone (FSH).

Testosterone is converted to dihydrotestosterone (DHT) by 5-alpha-reductase enzymes or to estradiol by P450 aromatase in target cells. Testosterone and DHT both bind to the androgen receptor where they exert their biological effects. Approximately 20 percent of the DHT in the circulation is produced directly by testicular secretion, with the remaining 80 percent being derived from conversion of testosterone in peripheral tissues. Target cells that contain 5-alpha-reductase are concentrated in the prostate, reproductive system, and skin. Aromatase containing cells predominate in the liver, adipose tissue, and regions of the brain.

Total serum testosterone is composed of 3 components added together. Roughly half of testosterone is bound to the carrier molecule sex hormone-binding globulin (SHBG), almost all of the remainder is bound to albumin, and 1-2 percent is unbound or free. Testosterone binds so tightly to SHBG that it is functionally unavailable to cells. In contrast, albumin-bound testosterone dissociates readily, meaning that this component and the free component are available to cells. The term “bioavailable testosterone” refers to a combination of the albumin-bound and free portions [12095].

Brain

Sex steroids readily pass the blood-brain barrier, and receptors for them are abundant in brain areas important for the regulation of emotions, cognition and behaviour. The sex steroid receptors are ligand-activated transcription factors that bind to specific hormone response elements in their target genes. There are two subtypes of estrogen receptors: alpha and beta [08069]. In addition, several isoforms of each subtype have been reported [08070]. The two estrogen receptor subtypes have comparable affinities to estradiol, but many other ligands show preferential binding to one or the other of them. The two subtypes also differ with respect to tissue distribution and coregulator interactions [08071, 08072]. The human estrogen receptor α gene (ESR1) is located on chromosome 6q25.1 [08073] and composed of 8 exons. A large number of polymorphisms in this gene have been identified, none of which has as yet been shown beyond doubt to be functional. The human estrogen receptor β gene (ESR2) is located on chromosome 14q22–24. The gene is composed of 8 exons [08074] and has several polymorphisms.

So far, there seems to be only a single subtype of the androgen receptor and the progesterone receptor. Alternative splicing of the amino terminal of androgen receptor and progesterone receptor genes, however, results in different isoforms displaying differences in both expression and function [08075, 08076].

The human progesterone receptor gene (PGR) is located on chromosome 11q22-23 [077] and composed of 8 exons. The receptor exists in 2 molecular forms, PR-A and PR-B; these differ only at the amino terminus, with PR-B containing an additional stretch of amino acids. This domain plays an important role in identifying target genes that can be activated by the PR-B protein but not by the PR-A protein. The expression ratio of the 2 PR isoforms in the brain varies during fetal development and as a result of the estrous cycle and also differs between males and females. Administration of estrogen and progesterone has been shown
to influence the expression ratio, and some of these variations may therefore be induced by these hormones. Notably, PR-A has recently been shown to play a key role in both hormone-dependent and hormone-independent facilitation of female sexual behavior [08078].

The androgen receptor gene (AR) is located on chromosome Xq11-12 and composed of 8 exons [08079, 08080]. Preliminary evidence from several studies also suggests that AR repeat polymorphisms may be of importance for interindividual differences in personality traits.

Coregulators of sex steroid receptors play an important role for tissue-specific actions of sex steroids. Several coregulators of importance for brain function have been identified [08081]; for example, both the steroid receptor coactivator gene and CREB-binding protein have been shown to be involved in estrogen receptor–mediated effects on sexual behavior [08082]. Moreover, the coactivator estrogen receptor–associated protein 140, which interacts with both estrogen receptor α and estrogen receptor β, displays its highest expression in the brain [083]. Another protein expressed in the brain that, among other tasks, serves as coactivator for sex steroid receptors, is E6-associated protein (UBE3A) [08084].

The aromatase enzyme converts androgens into estrogens. The human aromatase gene (CYP19) is located on 15q21.1 and contains several genetic variants [08085, 08086].

Notably, enzymes required for the synthesis of sex steroids, as well as for functionally active sex steroid metabolites, are expressed locally within the brain; some of the sex steroids present in the central nervous system are thus probably produced locally [08087]. For example, within the brain, progesterone is metabolized to allopregnanolone [08088, 08089] that may influence behaviour by interacting with GABA_A receptors. The genes for the 5 alpha-reductase type 1 and type 2 enzymes, which are critical for this conversion, contain functional polymorphisms [08090] that could be relevant for the study of psychiatric disorders for which allopregnanolone has been attributed importance, such as premenstrual dysphoric disorder.

Animal experiments have revealed that sex steroids have both an important early and permanent influence on brain development and an ongoing influence on brain neurotransmission in the adult organism. The influence exerted by sex steroids on animal behaviour, including sexual activity and aggression, is exerted by both these mechanisms [08091-08094]. That sex steroids also influence behavior in humans is shown by the reduction in libido that often follows a decrease in serum sex steroids and by conditions such as premenstrual dysphoric disorder (where the symptoms coincide with sex steroid fluctuations in serum and can be abolished by means of ovariectomy or treatment with ovulation inhibitors), postpartum depression, dysphoria induced by oral contraceptives and changes in behavior induced by anabolic steroids [08094-08097]. The hypothesis that sex hormones play a role in the regulation of mood and behavior also gains support from the fact that a large number of psychiatric conditions, including depression, panic disorder, generalized anxiety disorder, social phobia and eating disorders, are more prevalent in women than in men. In contrast, alcoholism, attention-deficit hyperactivity disorder and autism are more common in men. As well, with respect to normal personality traits, there are subtle but clear differences between women and men at the group level (e.g. with respect to anxiety-related traits). Similarly, certain aspects of cognitive abilities appear to differ slightly between the sexes. Autism is a disorder of particular interest in regard to the possible role of sex steroids; there is evidence suggesting that subjects with autism are characterized by a brain that, in certain aspects, may be regarded as unusually masculinized [08093, 08094].

Anabolic androgenic steroids at supratherapeutic doses seem to improve physical
appearance and the drug user becomes more bold and courageous. Investigations of the possible neurochemical effects of AAS have focused partially on the monoaminergic systems, which are involved in aggressive behaviours and the development of drug dependence. In one study, it was administered nandrolone decanoate (3 or 15 mg/kg/day for 14 days) and measured mRNA expression of dopaminergic and serotonergic receptors, transporters and enzymes in the male rat brain using quantitative real-time polymerase chain reaction. Expression of the dopamine D1-receptor transcript was elevated in the amygdala and decreased in the hippocampus while the transcript level of the dopamine D4-receptor was increased in the nucleus accumbens. No changes in transcriptional levels were detected among the serotonin-related genes examined in this study. The altered mRNA expression of the dopamine receptors may contribute to some of the behavioural changes often reported in abusers of anabolic steroids of increased impulsivity, aggression and drug-seeking [08098].

Heart

The aim of one study was to investigate the effects of anabolic androgenic steroids on the cardiac structure and the plasma lipoprotein profile isolated and in combination with exercise. Transgenic mice with a human lapaemic phenotype (expressing cholesteryl ester transfer protein on the LDL receptor knockout background) were used in this study. Sedentary and exercised mice (treadmill running, five times per week for 6 weeks) were treated with mesterolone (2 microg/g body weight) or vehicle (control-C) in the last 3 weeks. Four groups were compared: (i) exercise + mesterolone (Ex-M), (ii) exercise + vehicle (Ex-C), (iii) sedentary + mesterolone (Sed-M) and (iv) sedentary + vehicle (Sed-C). Arterial blood pressure and body mass increased in all groups along time, but Sed-M reached the highest values and Ex-C the lowest. Treatment with mesterolone increased total cholesterol, triglyceride, low-density lipoprotein cholesterol (LDL-c) and very LDL-c (VLDL-c) plasma levels. However, exercise blunted some of these deleterious effects by increasing high-density lipoprotein cholesterol and decreasing LDL-c, VLDL-c and triglycerides. Exercise training induced beneficial effects, such as physiological cardiomyocyte hypertrophy, increase in myocardial circulation and decrease in cardiac interstitium. However, mesterolone impaired such physiological gains and in addition increased troponin T plasma levels both in sedentary and exercised mice. Thus, while mesterolone induced pro-atherogenic lipoprotein profile and pathogenic cardiac hypertrophy, exercise counteracted these effects and modified favourably both the lipoprotein profile and the cardiac remodelling induced by mesterolone [08099].

Tendon

Matrix metallopeptidases (MMPs) are responsible for degradation of the extracellular matrix components and tissue remodeling. To achieve a better understanding of anabolic steroids effects in rat tendon, MMP-2 activity in the proximal and distal regions of the calcanear tendon and proximal, intermediate and distal region of superficial and deep flexor tendons after mechanical load exercise associated with anabolic androgenic steroids was investigated. In animals both proximal and distal regions of the calcanear tendon showed the lowest MMP-2 concentration and the highest proportion in MMP-2 active form. The intermediate region of the superficial flexor tendons differed significantly from the proximal and distal regions with higher proportion of active MMP-2 in the sedentary group. The proportion of active MMP-2 decreased in the proximal region of the calcanear tendon. The differences in the response to exercise and androgenic anabolic steroid treatment are a result of distinct metabolism and recruitment of these tendon regions in the exercise program employed in this study [08100].
The growing and indiscriminate use of high doses of anabolic androgenic steroid (AAS) among youth and athletes has raised serious concerns about its hepatotoxic effects. Now the influence of AAS in the nuclear phenotype of hepatocytes was investigated in sedentary and trained mice heterozygous for the human CETP (cholesteryl ester transfer protein) transgene and for LDL-receptor null allele (CETP+/−/LDLr+/−) by image analysis. Sedentary blank control mice showed the lowest chromatin condensation and highest Feulgen-DNA content, polyploid nuclei frequency, nuclear area and perimeter, suggesting gene activation. Contrarily, exercised mice showed the highest chromatin condensation, and a significant decrease of Feulgen-DNA content and decreased frequency of polyploid nuclei, which suggest gene silencing. Image analysis of the nuclear phenotype offered a coherent descriptive picture of the changing patterns of chromatin organization, which were shown to be congruent with the levels of Feulgen-DNA content, geometric nuclear parameters and hepatocyte activity. In the study, the image analysis permitted the monitoring of the nuclear response to mesterolone and physical exercise action in liver cells, the molecular mechanism of which is in prospect [08101].

Use of testosterone enanthate has been shown to significantly increase strength within 6-12 weeks of administration, however, it is unclear if the ergogenic benefits are evident in less than 6 weeks. The two objectives of this study were to establish if injection of 3.5 mg/kg testosterone enanthate once per week could increase muscular strength and cycle sprint performance in 3-6 weeks; and if the WADA-imposed urinary T/E ratio of 4:1 could identify all subjects being administered 3.5 mg/kg testosterone enanthate. Sixteen healthy young men were match-paired and were assigned randomly in a double-blind manner to either a testosterone enanthate or a placebo group. All subjects performed a structured heavy resistance training program while receiving either testosterone enanthate (3.5 mg/day) or saline injections once weekly for 6 weeks. One repetition maximum (1RM) strength measures and 10-second cycle sprint performance were monitored at the pre (week 0), mid (week 3), and post (week 6) time points. Body mass and the urinary T/E ratio were measured at the pre (week 0) and post (week 6) time points. When compared with baseline (pre), 1RM bench press strength and total work during the cycle sprint increased significantly at week 3 and week 6 in the testosterone enanthate group, but not in the placebo group. Body mass at week 6 was significantly greater than at baseline in the testosterone enanthate group, but not in the placebo group. Despite the clear ergogenic effects of testosterone enanthate in as little as 3 weeks, 4 of the 9 subjects in the testosterone enanthate group (approximately 44 %) did not test positive to testosterone under current WADA urinary T/E ratio criteria [07087].

In myocytes
In myocytes, testosterone binds to the intracellular androgen receptor (AR), initiating an activation cascade with conformational changes and nuclear translocation of the AR-steroid complex. Binding of the complex to androgen responsive elements (ARE) in the DNA results in specific activation or repression of the transcription in target genes [12096].

Breast
Gynecomastia is a common finding in adolescent men. While gynecomastia has long been attributed to an imbalance between estrogen and androgen concentrations, recent literature has begun to illuminate other potential mechanisms for breast development in adolescent men. Increased leptin levels, as well as human chorionic gonadotropin and luteinizing hormone receptors on male breast tissue, may play a role. Newer treatment strategies, such as the antiestrogen raloxifene, have shown promising results; however, further studies are
needed to determine long-term efficacy. As a result of the limited pharmaceutical treatment options, many more adolescents are seeking surgical intervention. Careful attention should be paid to both the breast and testicular examination. A detailed history should include an inquiry regarding the use of illicit substances, anabolic-androgenic steroids, herbal products, and medications. The impact of gynecomastia on the adolescent's mental health should be assessed. Reassurance remains the standard of care for physiologic gynecomastia [08102].

**Liver**

Anabolic steroid abuse is associated with a number of medical complications. Reported hepatic complications include cholestasis, elevation of aminotransferases, jaundice, benign hepatic adenomas, and rare cases of hepatocellular carcinoma. Histologic findings include peliosis hepatis, a lesion characterized by hepatic sinusoidal dilatation that is often cystic. Rupture of these cysts can cause fatal internal hemorrhage. The risk of androgen-associated liver tumors appears to correlate with the cumulative androgen dose and the potency of the steroid used [08103-08110].

It was described a case of a 27-year-old male bodybuilder with multiple hepatic adenomas induced by anabolic steroids. He initially presented with tumor hemorrhage and was treated with left lateral hepatic segmentectomy. Regression of the remaining tumors was observed with cessation of steroid use. However, 3 years and a half after his initial hepatic segmentectomy, he presented with recurrent tumor enlargement and intraperitoneal hemorrhage in the setting of steroid abuse relapse. This was the first reported case of hepatic adenoma re-growth with recidivistic steroid abuse, complicated by life-threatening hemorrhage [08111].

**Testosterone deficiency**

Testosterone deficiency (TD) afflicts approximately 30 percent of men aged 40-79 years, with an increase in prevalence strongly associated with aging and common medical conditions including obesity, diabetes, and hypertension. Clinical symptoms of TD include fatigue, decreased libido, ED, and negative mood states. TD also is associated with changes in body composition, including decreased lean body mass, increased fat mass, and decreased bone mineral density. A significant increased risk of TD is noted in association with common medical conditions such as obesity, type 2 diabetes mellitus (T2DM), and hypertension. In addition, a strong relationship was observed between TD and the metabolic syndrom. Further, recent studies in women with complete androgen insensitivity syndrome showed increased body fat, abnormal values of cholesterol, and homeostasis model assessment of insulin resistance (HOMA-IR), suggesting that disruption of androgen signaling in women also is associated with metabolic disorders. Repletion of testosterone (T) in T-deficient men with these co-morbidities may indeed reverse or delay their progression. Studies of testosterone replacement therapy (TRT) on sexual function and performance vary in quality, although findings are generally consistent. Most studies show that TRT increased sexual awareness and arousal, erectile function, and the frequency of spontaneous erections, but is less consistent in enhancing sexual behavior and performance. A number of TRT preparations are currently available. Intramuscular injections of short-acting testosterone derivatives achieve good serum concentrations within 2-3 days, with levels returning to baseline in most men by 2 weeks, resulting in an injection schedule of 1-2 weeks. Topical gels or patches provide a more stable serum-testosterone concentration over time than injections. Patches currently available are associated with a high rate of skin reaction, and their use has been largely supplanted by testosterone gels. The main disadvantages of testosterone gels are cost and a black box warning concerning transfer potential to women and children. A long-acting injection formulation (testosterone undecanoate) is dosed every
10-12 weeks, and is available internationally. Testosterone pellets provide 3-6 months of normal serum testosterone, and are placed subcutaneously in the gluteal region via an in-office surgical implantation procedure under local anesthesia; this formulation also has some disadvantages such as extrusion of pellets post surgical procedure. In addition, the genetic background relating to the patient responsiveness to androgens, hence, androgen receptor polymorphisms, are likely to play an inter-individual role. Adverse events that have been definitively associated with treatment are reversible with cessation of treatment. These include acne, gynecomastia, erythrocytosis, and edema. A number of additional risks have appeared in the literature, but their relationship to TRT is less well established. These include sleep apnea, worsening of urinary voiding symptoms, and prostate cancer. Standard forms of TRT do not appear to adversely affect lipid profiles and does not appear to cause liver toxicity, with the exception of oral alkylated testosterone preparations (e.g. methyltestosterone), which should not be used for testosterone replacement therapy for this reason. A key area of controversy relates to the biochemical determination of TD. There is no defined serum threshold for testosterone. Yet all published guidelines recommend one arbitrary threshold or another, generally ranging from 200 to 350 ng/dL (6.94-12.15 nmol/L)]. Variation in sex hormone-binding globulin levels also confounds the interpretation of bioavailable testosterone levels. There is general agreement that free or bioavailable testosterone provides a better estimation of testosterone status, but there is uncertainty about the reliability of those assays. In addition, genetic variation may influence response to circulating testosterone [11328].

**Opioid-induced androgen deficiency (OPIAD)**

Morphine sulfate, through its binding to opioid receptors, is known to act in several body regions from the gut to the brain. Previous studies have demonstrated that morphine induces a dramatic long-lasting decrease in testosterone, which persists during opioid therapy even if the treatment lasts for months or years, in both males and females. The effect can occur after a few hours, with testosterone concentrations reaching castration levels (< 1 ng/mL). Aloisi and colleagues have also shown that once opioid treatment is interrupted, testosterone levels recover in a few hours/days. Furthermore, spinal (intrathecal or epidural) administration of morphine resulted in a similar reduction in testosterone in both males and females. Opioid therapy is one of the most effective forms of analgesia currently in use. In the past few decades, the use of opioids as a long-term treatment for chronic pain has increased dramatically. Accompanying this upsurge in the use of long-term opioid therapy has been an increase in the occurrence of opioid associated endocrinopathy, most commonly manifested as an androgen deficiency and therefore referred to as opioid associated androgen deficiency (OPIAD). This syndrome is characterized by the presence of inappropriately low levels of gonadotropins (follicle stimulating hormone and luteinizing hormone) leading to inadequate production of sex hormones, particularly testosterone. Symptoms that may manifest in patients with OPIAD include reduced libido, erectile dysfunction, fatigue, hot flashes, and depression. Physical findings may include reduced facial and body hair, anemia, decreased muscle mass, weight gain, and osteopenia or osteoporosis. Additionally, both men and women with OPIAD may suffer from infertility. While the literature regarding OPIAD remains limited, it is apparent that OPIAD is becoming increasingly prevalent among chronic opioid consumers but often goes unrecognized. OPIAD can have a significant negative impact on the the quality of life of opioid users, and clinicians should anticipate the potential for its occurrence whenever long-term opioid prescribing is undertaken. Once diagnosed, treatment for OPIAD may be offered utilizing a number of androgen replacement therapy options including a variety of testosterone preparations and, for female patients with OPIAD, dehydroepiandrosterone (DHEA) supplementation. Follow-up evaluation of patients receiving androgen replacement therapy should include a review of any unresolved symptoms of hypogonadism, laboratory evaluation, and surveillance for
potential adverse effects of androgen replacement therapy including prostate disease in males [12095].

**Testosterone and motivation to compete**

It is possible that high-testosterone individuals have increased motivation to compete in sports. High-testosterone individuals may select into sports as a function of testosterone's positive influence on dominance striving, also known as power motivation. Basal testosterone is positively correlated with power motivation in men, whereas basal estradiol is positively correlated with power motivation in women. High concentrations of testosterone are also positively associated with selection into power-laden careers, e.g., trial law and acting. Knowing that power-motivated individuals are motivated to pursue dominance and find dominance experiences rewarding, the positive association between testosterone and power motivation suggests that high testosterone individuals may be the individuals most motivated to pursue athletic competition. Testosterone is also associated with reduced empathy, reduced perception of negative emotions enhanced attention to social threat, and enhanced amygdala responses to social threat. Additionally, testosterone has been linked to increased risk-taking in economic domains and social domains. Lastly, testosterone is associated with enhanced visuospatial ability, which may provide greater abilities in the perceiving critical targets and navigating the physical sports environment, i.e., field, rink, or court. Thus, high endogenous concentrations of testosterone may confer both psychological and physiological advantage in sports [12100].

It was tested the effects of different post-match recovery interventions on the subsequent hormonal responses to a physical stress-test and game performance in professional rugby union players. On four occasions, participants (n=12) completed a video session (1 h each) with accompanying coach feedback the day after a rugby union match. The interventions showed either video footage of player mistakes with negative coach feedback (NCF1) or player successes with positive feedback (PCF1). Both approaches were repeated (NCF2 and PCF2). In the following week, participants were assessed for their free testosterone (T) and cortisol (C) responses to a physical stress-test, pre-game T and game-ranked performance. The PFC1 and PCF2 approaches were both associated with significantly greater free T (36 % to 42 %) responses to the stress-test when compared to NCF1 and NCF2 (16 % to -3 %), respectively. The PCF interventions were also associated with higher (28 % to 51 %) pre-game T concentrations and superior game-ranked performances than the NCF approaches. In conclusion, the post-game presentation of specific video footage combined with different coach feedbacks appeared to influence the free hormonal state of rugby players and game performance several days later. Therefore, within the sporting context, future behaviour and performance might be modified through the use of simple psychological strategies. These data are applicable to generalised human stress responses and their modifiability by prior exposure to a stressor [12104].

**Effect of magnesium on testosterone levels**

One study was performed to assess how 4 weeks of magnesium supplementation and exercise affect the free and total plasma testosterone levels of sportsmen practicing tae kwon do and sedentary controls at rest and after exhaustion. The testosterone levels were determined at four different periods: resting before supplementation, exhaustion before supplementation, resting after supplementation, and exhaustion after supplementation in three study groups, which are as follows: group 1-sedentary controls supplemented with 10
mg magnesium per kilogram body weight; group 2-tae kwon do athletes practicing 90-120 min/day supplemented with 10 mg magnesium per kilogram body weight; and group 3-tae kwon do athletes practicing 90-120 min/day receiving no magnesium supplements. The free plasma testosterone levels increased at exhaustion before and after supplementation compared to resting levels. Exercise also increased testosterone levels relative to sedentary subjects. Similar increases were observed for total testosterone. The results show that supplementation with magnesium increases free and total testosterone values in sedentary and in athletes. The increases are higher in those who exercise than in sedentary individuals [10080].

**Psychological influence on testosterone levels**

Previous research indicates that testosterone concentrations are highly responsive to human competitive interactions and that winners have elevated testosterone concentrations relative to losers. Also, there is some evidence that simply observing others compete can have a similar effect on the endocrine system. Here, in two studies, it was examined the extent to which elite male hockey players would demonstrate an increase in testosterone concentrations after watching themselves engaged in a previous successful competitive interaction. Results indicated that watching a previous victory produced a significant increase in testosterone concentrations (42-44 % increase), whereas watching a previous defeat or a neutral video did not produce a significant change in testosterone (17 % and 6 %, respectively). Given that natural fluctuations in testosterone have been shown to influence future competitive and aggressive behaviours, the current studies may have important practical implications for individuals involved in competitive sports [09086].

**Influence of psychosocial environment**

The aim of one survey was to provide a literary review of current knowledge of the possible association between the psychosocial working environment and relevant physiological parameters measured in blood and urine. Literature databases (PubMed, Toxline, Biosis and Embase) were screened using the key words job, work-related and stress in combination with selected physiological parameters. In total, 51 work place studies investigated the associations between the psychosocial working environment and physiological changes, of which 20 were longitudinal studies and 12 population-based studies. The studied exposures in work place/population-based studies included: job demands (26/8 studies), job control (24/10 studies), social support and/or leadership behaviour (12/3 studies), effort-reward imbalance (three/one studies), occupational changes (four studies), shift work (eight studies), traumatic events (one study) and other (five studies). The physiological responses were catecholamines (adrenaline, noradrenaline) (14 studies), cortisol (28 studies), cholesterol (23 studies), glycated haemoglobinA(1c) (six studies), testosterone (nine studies), oestrogens (three studies), dehydroepiandrosterone (six studies), prolactin (14 studies), melatonin (one study), thyroxin (one study), immunoglobulin (Ig) A (five studies), IgG (four studies), IgM (one study) and fibrinogen (eight studies). In general, fibrinogen and catabolic indicators, defined as energy releasing, were increased, whereas the anabolic indicators defined as constructive building up energy resources were decreased when the psychosocial working environment was perceived as poor. In conclusion, in this review the association between an adverse psychosocial working environment and HbA(1c), testosterone and fibrinogen in serum was found to be a robust and potential candidate for a physiological effect of the psychosocial working environment. Further, urinary catecholamines appear to reflect the effects of shift work and monotonous work [09087].
**Victory or defeat**

In one study, it was reported evidence from sport competition that is consistent with the biosocial model of status and dominance. Results show that testosterone levels rise and drop following victory and defeat in badminton players of both sexes, although at lower circulating levels in women. After losing the match, peak cortisol levels are observed in both sexes and correlational analyses indicate that defeat leads to rises in cortisol as well as to drops in testosterone, the percent change in hormone levels being almost identical in both sexes. In conclusion, results show the same pattern of hormonal responses to victory and defeat in men and women [12097].

**Home or away game**

The authors examined the extent to which changes in testosterone concentrations before competition would be associated with performance among elite male hockey players. Saliva samples were collected on two noncompetition days (baseline) and before two playoff games (1 home game, 1 away game). Individual performance was assessed by the coaching staff after each game. Results indicated that changes in testosterone before competition predicted performance, but this effect was influenced by game location. Unexpectedly, the authors found a significant negative relationship between a rise in testosterone and performance for the away game and a nonsignificant positive relationship for the home game. These findings indicate that game location should be considered in studies examining the neuroendocrine correlates of athletic competition [12098].

**Spectators**

One field study investigated the release of testosterone and cortisol of a vicarious winning experience in Spanish fans watching the finals between Spain and the Netherlands in the 2010 FIFA World Cup Soccer. Spanish fans (n=50) watched the match with friends or family in a public place or at home and also participated in a control condition. Consistent with hypotheses, results revealed that testosterone and cortisol levels were higher when watching the match than on a control day. However, neither testosterone nor cortisol levels increased after the victory of the Spanish team. Moreover, the increase in testosterone secretion was not related to participants' sex, age or soccer fandom, but the increase in total cortisol secretion during the match was higher among men than among women and among fans that were younger. Also, increases in cortisol secretion were greater to the degree that people were a stronger fan of soccer. Level of fandom further appeared to account for the sex effect, but not for the age effect. Generally, the testosterone data from this study are in line with the challenge hypothesis, as testosterone levels of watchers increased to prepare their organism to defend or enhance their social status. The cortisol data from this study are in line with social self-preservation theory, as higher cortisol secretion among young and greater soccer fans suggests that especially they perceived that a negative outcome of the match would threaten their own social esteem [12099].

**Influence of stress on testosterone (and other anabolics) levels**

To determine whether cycling has an effect on serum PSA, gonadotropins, and uroflowmetric parameters a total of 34 healthy male athletes from the National Cycling Team and 24 healthy male student volunteers from University and medical staff were prospectively enrolled in a study. Blood samples for serum total prostate-specific antigen (tPSA), free PSA (fPSA, fPSA/tPSA, follicle-stimulating hormone (FSH), luteinizing hormone (LH), and
testosterone determinations were obtained before and after cyclists completed 300 km bicycle ride and with each cyclist seated without changing posture and with minimal movement for 10 minutes before blood collection. The athletes and the control group were well matched by age. There was no significant difference between the 2 groups in terms of serum tPSA, fPSA, f/t PSA values, FSH, LH, and testosterone levels and uroflowmetric parameters. The postcycling serum testosterone level was significantly lower than precycling levels (mean, 604 ng/dL vs 425 ng/dL). There was no correlation between body mass index values, postcycling serum FSH, LH levels, age, and testosterone levels [09088].

**Hormone profile in men**

Steroid profiling provides valuable information to detect doping with endogenous steroids. Apart from the traditionally monitored steroids, minor metabolites can play an important role to increase the specificity and efficiency of current detection methods. The applicability of several minor steroid metabolites was tested on administration studies with low doses of oral testosterone (T), T gel, dihydrotestosterone (DHT) gel and oral dehydroepiandrosterone (DHEA). The collected data for all monitored parameters were evaluated with the respective population based reference ranges. Besides the traditional markers T/E, T and DHT, minor metabolites 4-OH-Adion and 6alpha-OH-Adion were found as most sensitive metabolites to detect oral T administration. The most sensitive metabolites for the detection of DHEA were identified as 16alpha-OH-DHEA and 7beta-OH-DHEA but longest detection up to three days (after oral administration of 50 mg) was obtained with non-specific 5β-steroids and its ratios. Steroids applied as a gel had longer effects on the metabolism but were generally not detectable with universal decision criteria. It can be concluded that population based reference ranges show limited overall performance in detecting misuse of small doses of natural androgens. Although some minor metabolites provide additional information for the oral testosterone and DHEA formulations, the topical administered steroids could not be detected for all volunteers using universal reference limits. Application of other population based threshold limits did not lead to longer detection times [10455].
Hormone profile in women

It is unclear whether hormone profiles obtained in two consecutive months are consistent within females. It was prospectively examined month to month consistency in daily, nadir, peak and mean hormone concentrations during the early follicular and luteal phases in recreationally active, young eumenorrheic females. Sixty healthy, non-smoking females who reported normal and consistent menstrual cycles lasting 26-32 days for the past 6 months were followed prospectively to obtain serum samples for the first 6 days of menses, and for 8 days following a positive ovulation test over two consecutive months. Month to month consistency of daily concentrations of estradiol (pg/mL), progesterone (ng/mL), testosterone (ng/dL), SHBG (nmol/L) and FAI were determined using linear mixed models. Month to month consistency in nadir, peak and mean concentrations were then assessed using intraclass correlation coefficients and standard error of the measurement to more precisely examine intra-individual consistency. Linear mixed models revealed stable hormone concentrations across cycles and cycles by day. Reliability estimates for nadir, peak, mean menses and mean postovulatory concentrations range from 0.56-0.86 for estradiol, 0.44-0.91 for progesterone, 0.60-0.86 for testosterone, 0.88-0.97 for SHBG, and 0.78-0.91 for FAI. It was concluded that hormone profiles were reproducible over two consecutive months. In order to reduce month to month intra-individual variations and improve measurement consistency, it was recommended that multiple samples be taken over consecutive days as opposed to a single sample [09102].

Influence of fasting (Ramadan)

The Ramadan fasting period is associated with changes in sleep habits and increased sleepiness, which may affect physical performance in athletes, and may induce metabolic, hormonal, and inflammatory disturbances. In 8 middle-distance athletes (25 ± 1 years), a maximal aerobic velocity (MAV) test was performed 5 days before Ramadan fasting period (day -5), and on days 7 and 21 of Ramadan fasting period. The same days, saliva samples were collected to determine cortisol and testosterone concentrations before and after the MAV test. During Ramadan fasting period, mean body mass and body fat did not statistically change. Compared with day -5, MAV values decreased significantly at days 7 and 21, while testosterone/cortisol ratio values did not change significantly. Nocturnal sleep time and energy intake were significantly lower at day 21 than before Ramadan fasting period. At the end of Ramadan fasting period (day 31), the fatigue score on the Profile of Mood States questionnaire was significantly increased. In conclusion, Ramadan fasting period is accompanied by significant metabolic, hormonal, and inflammatory changes. Sleep disturbances, energy deficiency, and fatigue during Ramadan fasting period may decrease physical performance in Muslim athletes who maintain training. Reduction of work load and (or) daytime napping may represent adequate strategies to counteract Ramadan fasting period effects for Muslim athletes [09089].

Circadian rhythm

The study investigated the effects of circadian rhythm of cortisol (C) and testosterone (T) on maximal force production ($F_{peak}$) and power output ($P_{peak}$). Twenty male university students (mean age 24 years) performed 4 time-of-day testing sessions consisting of countermovement jumps (CMJs), squat jumps (SJ), isometric midthigh pulls (IMTPs), and a 1-repetition maximum (1RM) squat. Saliva samples were collected at 0800, 1200, 1600, and 2000 hours to assess T and C levels on each testing day. Session rate-of-perceived exertion
(RPE) scores were collected after each session. The results showed that $F_{\text{peak}}$ and $P_{\text{peak}}$ presented a clear circadian rhythm in CMJ and IMTP but not in SJ. One repetition maximum squat did not display a clear circadian rhythm. Session RPE scores collected at 0800 and 2000 hours were significantly higher than those obtained at 1200 and 1600 hours. Salivary T and C displayed a clear circadian rhythm with highest values at 0800 hours and lowest at 2000 hours; however, no significant correlation was found between T and C with $F_{\text{peak}}$ and $P_{\text{peak}}$. A very strong correlation was found between $T_{\text{aural}}$ with $F_{\text{peak}}$ of CMJ and IMTP and $P_{\text{peak}}$ of CMJ. Thus, the study showed the existence of a circadian rhythm in $F_{\text{peak}}$ and $P_{\text{peak}}$ in CMJ and IMTP. The evidence suggests that strength and power training or testing should be scheduled later during the day. The use of $T_{\text{aural}}$ seemed to be a more effective indicator of physical performance than hormonal measures, and the use of session RPE should also be closely monitored because it may present a circadian rhythm [11095].

Genetic influence (polymorphism)

Doping with anabolic agents is regulated within a number of sports. Testosterone and its functional analogs are popular compounds for increasing muscle mass, physical performance, recovery, and reducing body fat. While routine tests for anabolic drugs exist (e.g. hair, urine, and blood analysis), the aim of the present study is to determine specific gene expression profiles (induced by testosterone and exercise) which may be used as effective biomarkers to determine the use of anabolic drugs. In one study, whole blood samples of 19 male volunteers were analyzed by semi-quantitative real-time polymerase chain reaction (RT-PCR) for gene expression profiles in the context of exercise and transdermal testosterone application (1.5 mg/kg body weight). The hormone application was monitored by urine and saliva analysis for testosterone. Both urinary and saliva levels indicate that transdermal testosterone application leads to an increase of testosterone, especially after exercise. RT-PCR results showed a clear variation in the expression of target genes as well as established housekeeping genes. Only one of the nine common housekeeping genes, cyclophilin b (PPIB), appears to be independent of both exercise and testosterone. Out of 14 candidate genes, five are unregulated; all others were more or less influenced by the mentioned variables. Only interleukin-6 appeared to be exclusively dependent on long-term testosterone application. This study indicates that many genes are not influenced by testosterone alone while exercise modulates gene expression in whole blood samples. As such, exercise must be considered when validating gene expression techniques for doping analysis [11442].

The ability to identify anabolic steroid use continues to improve. A sudden elevation of the testosterone–epitestosterone ratio typically indicates illegitimate use of an anabolic steroid. However, it is well known that some individuals may have naturally elevated ratios, and it has recently been recognized that 40 percent of those with a certain genotype found in two-thirds of people of Asian ancestry may not reach the threshold elevation of the ratio after administration of testosterone [08112].

The heritability of most behavioural traits, including personality, cognitive abilities and susceptibility to psychiatric illness, is considerable, but as yet, only few genes of definite importance in this context have been identified. Given the important role of sex steroids for brain function, it is unfortunate that relatively few studies so far have addressed the possible influence of sex steroid-related genes on interindividual differences with respect to personality, cognition and susceptibility to psychiatric disorders [08113].

Testosterone is excreted mainly as glucuronide conjugates after metabolism by uridine diphospho (UDP)-glucuronosyl transferases (UGT). It is well established that UGT2B7,
UGT2B15 and UGT2B17 are the principal catalysts of the glucuronidation of androgens and their metabolites in the human [08114]. Testosterone is mainly conjugated by UGT2B17 and, to a minor extent, by UGT2B15. The main androgen substrate of UGT2B15 is androstan-3α,17β-diol [115]. UGT2B17 shares 96 percent homology with UGT2B15 [08116], but its substrate specificity is broader [08115]. UGT2B7 has been shown to have the capacity to conjugate epitestosterone [08117] while testosterone is a poor substrate for this enzyme [08115].

Testosterone abuse is conventionally assessed by the urinary testosterone/epitestosterone (T/E) ratio, levels above 4.0 being considered suspicious. An alternative is determination of the $^{13}$C/$^{12}$C ratio of selected steroids (IRMS analysis) provides the possibility to distinguish between pharmaceutical and natural testosterone because exogenous compounds contain less $^{13}$C than their endogenous homologues [08118].

The large variation in testosterone glucuronide excretion and its strong association with a deletion polymorphism in the UGT2B17 gene challenge the accuracy of the T/E ratio test. Therefore, it was investigated in an open 3-armed comparative study whether genotype based cut-off values will improve the sensitivity and specificity of the test. Fifty-five healthy male volunteers with either two, one or no allele of the UGT2B17 gene were investigated after a single intramuscular dose of 500 mg testosterone enanthate. It was found that the degree and rate of increase in testosterone glucuronide excretion rate was highly dependent on the UGT2B17 genotype with a 20-fold average maximum difference. Forty percent of the subjects with deletions never reached the T/E ratio of 4.0 on any of the 15 days after the dose. This means that consideration of the genetic variation in disposition of androgens will improve the sensitivity and specificity of the testosterone doping test [203]. The polymorphism was considerably more common in a Korean Asian than in a Swedish Caucasian population, with 67 and 9 percent deletion/deletion homozygotes respectively [286, 287]. Continued experience of testing for anabolic steroids indicated that Asian individuals excrete lower amounts of testosterone glucuronide and hence have lower T/E ratios, thus increasing the risk of false-negative doping test results [08119]. This means that there are possible genetic differences between groups of individuals.

Testosterone is excreted in urine as water soluble glucuronidated and sulphatated conjugates. The ability to glucuronidate testosterone and other steroids depends on a number of different glucuronidases (UGT) of which UGT2B17 is essential. A clinical study of 116 healthy boys aged 8 to 19 years had UGT2B17 genotyping performed using quantitative PCR. Serum FSH, LH, T, estradiol (E$_2$) and SHBG were analysed by immunoassays, and urinary levels of androgen metabolites were quantitated by gas chromatography/mass spectrometry in all subjects. Ten out of 116 subjects (9 %) presented with a homozygote deletion of the UGT2B17 gene (del/del), while 52 and 54 boys were hetero- or homozygous carriers of the UGT2B17 gene (del/ins and ins/ins), respectively. None of the reproductive hormones were affected by UGT2B17 genotype. In all subjects, mean urinary T/E ratio was 1.56 ± 1.14 and unaffected by age or pubertal stage. Subjects with homozygous deletions of UGT2B17 had significantly lower urinary levels of T, and 5alpha- and 5beta-androstanediol. Mean urinary T/E was significantly reduced in del/del subjects (0.29 ± 0.30). It was concluded that in pubertal boys, a common homozygous deletion in the UGT2B17 gene strongly affected urinary excretion pattern of androgen metabolites, but did not influence circulating androgen levels [08120].

It has been known for more than a decade that urinary T/E ratios are significantly lower in certain ethnic groups. This observation has limited the effectiveness of a population-based T/E ratio as a screening test for testosterone use. Recent evidence has demonstrated that a deletion polymorphism in the UGT2B17 gene is responsible for reduced urinary testosterone
levels. UGT2B17 deletion polymorphism testing would be difficult to perform on every athlete at this time, and GC/C/IRMS is not a practical screening test for testosterone use [08016].

T/E ratio testing provided a solution for detecting synthetic testosterone use until Asian men were found to have a lower urinary T/E ratio (compared with Caucasians) more than a decade ago. Circulating concentrations of steroid hormones are controlled by the UDP-glucuronosyl transferase 2B (UGT2B) subfamily of uridine diphospho-glucuronosyl transferases, which facilitate urinary excretion by glucuronidation reactions that make steroid molecules more hydrophilic. UGT2B17 is the major enzyme in the UGT2B subfamily that conjugates glucuronide to testosterone, dihydrotestosterone, and androsterone in the liver and tissues. A common deletion polymorphism in the UGT2B17 gene was recently shown to differ among ethnic groups, being more common in whites than in African Americans. Further studies revealed that large differences in urinary testosterone concentrations are associated with a deletion polymorphism in the UGT2B17 gene. Men homozygous for the UGT2B17 deletion polymorphism have extremely low or undetectable urinary testosterone concentrations, and this genotype is 7 times more common in Korean men (67 %) than Swedish men (9 %). Epitestosterone concentrations are similar in the 2 ethnic groups, regardless of whether they have low or high urinary testosterone concentrations [08016].

The strong association of the UGT2B17 deletion polymorphism with testosterone excretion brings into question the ability of a population-based T/E ratio to detect testosterone use. Unfortunately, it would be difficult at this time for laboratories to incorporate genetic testing into their routine test menu and screen each athlete for UGT2B17 deletions. An alternative would be to use a low urinary T/E ratio (<0.2) as evidence for the del/del polymorphism. However, this would be problematic since it would incorrectly classify athletes that are doping with a combination of testosterone and epitestosterone (to lower their T/E ratio) as having the del/del polymorphism. In these cases, either genotyping or other tests to detect doping with epitestosterone would be required, such as the epitestosterone to 5-androstene-3β,17α-diol ratio or 13C/12C ratio of epitestosterone [08016].

Testosterone abuse is conventionally disclosed by urinary assay of the testosterone/epitestosterone (T/E) glucuronide ratio, which should not exceed 4. A noteworthy number of athletes, however, have higher natural ratios than 4, most likely because of decreased excretion of epitestosterone glucuronide. Urine from different study populations was analysed for androgen glucuronides by gas chromatography-mass spectrometry. All men were genotyped for the uridine diphospho-glucuronosyltransferase (UGT) 2B17 deletion polymorphism and single nucleotide polymorphisms in the cytochrome P-450c17alpha (CYP17), UGT2B15 and UGT2B7 genes. Expression of UGT2B15 mRNA in human liver samples was analysed using real-time PCR. A T>C (A1>A2) promoter polymorphism in the CYP17 gene was associated with the urinary glucuronide levels of epitestosterone and its putative precursor androstene-3beta, 17alpha-diol, resulting in 64 percent higher T/E ratios in A1/A1 homozygotes. Individuals devoid of UGT2B17 had significantly higher UGT2B15 mRNA levels in liver than individuals carrying two functional UGT2B17 alleles. The CYP17 promoter polymorphism may partly explain high natural (>4) T/E ratios. The data indicate that 5-androstene-3beta, 17alpha-diol is an important precursor of epitestosterone and that CYP17 is involved in its production. In addition, it was found that lack of the UGT2B17 enzyme may be compensated for by increase in UGT2B15 transcription [08121].

Testosterone and epitestosterone are endogenous steroids that differ in the configuration of the hydroxyl-bearing carbon at the C-17. Testosterone is the predominant male sex hormone while the role of epitestosterone is largely unclear. In humans, both androgens are mainly excreted as glucuronide conjugates and the urinary ratio of testosterone to epitestosterone
(T/E), used to expose illicit testosterone abuse by male athletes, indicates the relative concentrations of the respective glucuronides. Some male athletes have T/E above the accepted threshold value, 4.0, even without testosterone abuse. It was therefore analyzed athletes urine samples and found that the main reason for such "false positives" in doping tests was low epitestosterone glucuronide concentration, not high level of testosterone glucuronide. Sulfate conjugates of both testosterone and epitestosterone were also detected in the different urine samples. Glucuronidation assays with the 19 human UDP-glucuronosyltransferases (UGTs) of subfamilies UGT1A, UGT2A and UGT2B revealed that UGT2B17 is the most active enzyme in testosterone glucuronidation. UGT2B17 does not glucuronidate epitestosterone, but inhibition studies revealed that it binds epitestosterone with similar affinity as testosterone. Epitestosterone glucuronidation is mainly catalyzed by UGT2B7 and the Km of this reaction is significantly lower than the Km of UGT2B17 for testosterone. While UGT2B7 and UGT2B17 exhibited high, although converse, stereoselectivity in testosterone and epitestosterone glucuronidation, UGT2A1, an extrahepatic enzyme that is mainly expressed in the nasal epithelium, catalyzed the glucuronidation of both steroids at considerable rates and similar kinetics [08122].

To study the disposition of serum testosterone and seven of its metabolites before and after 2 days of an intramuscular dose (500 mg) of testosterone enanthate in relation to the phosphodiesterase (PDE7B) and the uridine 5'-diphospho-glucuronosyltransferase (UGT2B17) genotypes patients were genotyped for UGT2B17 deletion polymorphism and single nucleotide polymorphisms in the PDE7B gene. The involvement of PDE7B in hydrolysis of enanthate was assessed in human liver homogenates. Genetic variation in the PDE7B gene was found to be associated with the serum level of testosterone. Individuals homozygous for PDE7B rs7774640 G allele had a smaller increase (2.5-fold) in the serum testosterone levels compared with carriers of the A allele (3.9-fold). In addition, genetic variation in the PDE7B gene significantly influences the testosterone/epitestosterone ratio, a biomarker of testosterone doping. An in-vitro incubation studies confirmed that PDE7B serves as a catalyst of the hydrolysis of testosterone enanthate. The UGT2B17 deletion polymorphism did not show any significant association with serum testosterone levels or the other androgen metabolites investigated. It was concluded that it was found that PDE7B is involved in the hydrolysis of testosterone enanthate and that genetic variation in the PDE7B gene is a determinant of the systemic levels of testosterone after administration of testosterone enanthate. It is reasonable to believe that the genetic variation in testosterone bioavailability may be correlated to varying effects of this androgen, whether it is used for replacement therapy or abused in doping. Thus the results may be important to consider in doping test programmes and in therapeutics with androgens and other esterified drugs [11091].

The deletion polymorphism of the enzyme UGT2B17 is known to correlate with the level of the testosterone to epitestosterone (T/E) ratio in urine specimen. Due to the importance of the T/E ratio to detect testosterone abuse in doping analysis, a PCR-ELISA system was established to identify the UGT2B17 phenotype in urine samples. Epidemiological investigations in a set of 674 routine doping controls (in- and out-of-competition) resulted in 23 percent homozygote gene-deleted and 75 percent UGT2B17-positive athletes. The validated test system has shown to be robust and sensitive: in only 18 cases (3 %) isolation of cell material from urine failed. Following hydrolysis of glucuronidated conjugates, steroids were analyzed as bis-TMS derivatives by gas chromatography-mass spectrometry (GC-MS), for example, testosterone (T) and epitestosterone (E). Additionally, isotope ration mass spectrometry (IRMS) analysis and luteinizing hormone (LH) measurement were applied. Mean T/E ratios significantly correlated with the UGT2B17 phenotype (del: T/E 0.9; pos: 1.7), however the values did not differ as distinctive as reported in previous studies. Additionally, the T/E ratios in the gene-deleted group did not show a normal curve of distribution (median
of T/E 0.5). Obviously, beside the UGT2B17 deletion further influences have to be taken into account, for example, polymorphisms or induction of other metabolizing enzymes. The results indicate that the UGT2B17 polymorphism might be insufficient when utilized solely as a crucial parameter for individual interpretation of T/E in urine. Nevertheless, the detection of the UGT2B17-gene deletion in urine samples would provide additional information important for gathering evidence in analysis of steroids in doping control [11444].

The conspicuous interindividual differences in metabolism and urinary excretion of testosterone and its metabolites make it challenging to reveal testosterone doping. The variation in testosterone glucuronide excretion is strongly associated with a deletion polymorphism in the uridine diphosphate-glucuronosyltranferase (UGT) 2B17 gene. The objective of one study was to identify additional biomarkers to detect testosterone abuse and to elucidate alternative pathways for testosterone elimination in individuals devoid of the UGT2B17 enzyme. For this purpose a new ultraperformance liquid chromatographic tandem mass spectrometric method for simultaneous determination of 10 different sulfo- and glucuronide-conjugated steroids was developed. Fifty-four healthy male volunteers with two, one, or no allele (ins/ins, ins/del, or del/del) of the UGT2B17 gene participated in the study. Intervention included a single im dose of 500 mg testosterone enanthate. Urinary sulfo- and glucuronide-conjugated steroids were measured. Testosterone sulfate levels decreased in all individuals after the dose. The individual differences in the excretion of all sulfated metabolites were large. Thus, these metabolites will not serve as appropriate biomarkers for testosterone abuse. However, androsterone glucuronide excretion increased in all of our study subjects after the testosterone dose. Etiocholanolone sulfate was excreted at significantly higher levels in UGT2B17 del/del individuals. It was proposed that the androsterone glucuronide to epitestosterone glucuronide ratio may serve as a complementary biomarker to reveal testosterone abuse [11445].

**Influence of exercise on testosterone levels**

The purpose of one study was to explore the mechanisms for increased exercise performance in conditions of competition. Endurance trained subjects (n=14) performed incremental treadmill running to exhaustion in control laboratory conditions (non-competition) and in conditions of simulated competition to assess performance (running duration). Heart rate and respiration gases were monitored continuously through each exercise condition. Blood lactate, cortisol, growth hormone and testosterone concentrations were also determined at pre- (rest) and postexercise in each condition. Results indicated competition exercise performance was significantly increased as was peak VO$_2$ response versus non-competition. No significant differences were found in peak measurements of minute ventilation, respiratory exchange ratio, ventilation threshold, post-exercise lactate, heart rate, or the ventilation equivalent for O$_2$ between the exercise conditions. In both conditions growth hormone and testosterone concentrations increased significantly in response to exercise, whereas cortisol responses post-exercise were significantly elevated in the competition but not in the control condition. These findings support that in competitive situations the affective state (motivation) experienced by athletes can enhance performance in exercise events, and lead to an increased peak oxygen uptake. The magnitude of the improvement is of a substantial nature and of a level seen with some training programs. Competitive conditions also augment the cortisol response to exercise, suggesting that enhanced sympatho-adrenal system activation occur in such situations which may be one of the key "driving forces" to performance improvement [10081].

Although adaptations to water-based resistance exercise and conventional water-based
exercise have been investigated, little is known regarding acute anabolic and catabolic hormonal responses to these two types of exercise. The purpose of this study was to investigate the acute responses of salivary testosterone and cortisol to two water-based exercise protocols in which the different intensities were determined using Borg’s perceived exertion scale. Ten young (24 ± 3 yr) and 7 elderly men (65 ± 6 yr) who were familiar with exercise in water were subjects of the study. Salivary samples were collected at rest and 5 minutes after the 2 water-based exercise protocols. One session involved intermittent water resistance training at a Borg-scale intensity of 19 (W19), whereas the other involved continuous water aerobic training at an intensity of 13 (W13). The samples were used to determine salivary levels of free testosterone and cortisol. There was a significant increase on salivary testosterone in both groups after the W19 protocol, but no such alteration was observed after W13. The testosterone response to the W19 protocol was significantly higher in young than in elderly men. Although no modification on salivary cortisol was observed after either protocol, in young men, the cortisol response to W19 was higher than in elderly men. Water-based exercise with emphasis on strength development was found to stimulate a more acute increase on salivary testosterone than water-based aerobic exercise, probably as a result of the higher intensity used in that training protocol. Given the known relationship between acute hormonal responses and chronic neuromuscular adaptations, the testosterone response after W19 should be considered when prescribing water-based exercise, especially to older populations [09090].

It was investigated whether the myosin heavy chain (MyHC) proportion and androgen receptor (AR) concentration in skeletal muscle differ following 21 weeks of strength, endurance and combined training in untrained older men. Strength (S) and endurance (E) groups trained twice per week and combined (S+E) group trained four times per week (two strength and two endurance). Muscle biopsies were obtained before and after the training period from m. vastus lateralis (VL) and AR mRNA and protein concentration and MyHC proportion were determined. 1RM increased during the training period in S, S+E and E but the changes were greater in S and S+E than in E. Statistically significant increases were observed only in S and S+E in maximal isometric force as well as in VL thickness. VO$_{2\text{max}}$ increased significantly only in E. MyHCIIa proportion increased in S, while MyHCIIa proportion decreased and MyHCI increased significantly in the endurance group. No statistically significant changes were observed in serum testosterone and in AR mRNA or protein concentrations. The present results indicate that 21 weeks of strength, endurance or combined training changed MyHC proportion according to the training method but did not have an effect on androgen mRNA or protein expression in skeletal muscle at rest [09091].

One study compared the neuromuscular performance (speed, power, strength) of elite rugby union players, by position, and examined the relationship between player performance and salivary hormones, by squad and position. Thirty-four professional male rugby players were assessed for running speed (10-, 20- or 30-m sprints), concentric mean and peak power during a 70-kg squat jump and 50-kg bench press throw, and estimated 1 repetition maximum (1RM) strength for a box squat and bench press. Tests were performed on separate days with absolute and normalized (power and strength only) values computed. Saliva was collected before each test and assayed for testosterone and cortisol. The testosterone and/or cortisol concentrations of players correlated significantly to speed, power, and strength, especially for the backs, thereby confirming relationships between neuromuscular performance and hormone secretion patterns. Based on these findings, it was suggested that training to increase whole-body and muscle mass might facilitate general performance improvements. Training prescription might also benefit from acute and chronic hormone monitoring to identify those individuals likely to respond more to hormonal change [09092].
The effect of a single exercise as well as exercise training on the growth hormone (GH)-insulin-like growth factor (IGF-I) axis and inflammatory cytokines was studied mainly in adults participating in individualized endurance-type sports. The gender-specific effect of exercise on these systems in adolescents is unknown. Therefore, the purpose of one study was to evaluate the effect of a typical volleyball practice on anabolic (GH, IGF-I, and testosterone) and catabolic hormones (cortisol) and inflammatory mediators (interleukin-6) in elite, national team level, male (n=14) and female (n=13) adolescent volleyball players (13-18 years, Tanner stage 4-5). Exercise consisted of a typical 1-hour volleyball practice. Blood samples were collected before and immediately after the practice. Exercise led to significant increases in GH in men and women, testosterone (6.1 ± 0.9 to 7.3 ± 1.0 and 2.4 ± 0.6 to 3.3 ± 0.7 ng x mL, in men and women, respectively), and interleukin-6. There were no gender differences in the hormonal response to training. Changes in GH and testosterone after the volleyball practice suggest exercise-related anabolic adaptations [09093].

In trained and in not-trained

It is a common view that strength and sprint trained athletes are characterized by high plasma/serum testosterone (T) concentration, which is believed to be partly responsible for their performance level. This opinion, however, has poor scientific background. The aim of one study was to give evidence-based information on this issue. It was examined gonadal hormone status at rest after overnight fasting in high and top-class track and field sprinters (n=16) and in untrained men (n=15). It was shown that basal T, free testosterone (fT), bioavailable testosterone (bio-T), and sex hormone-binding globulin concentrations were not significantly different in sprinters versus untrained subjects. Further comparison of the results of the basal serum T concentration in 8 sprinters showed its significant changes during an annual training period. Significantly higher T concentration during a low-intensity training period (beginning of December) than during heavy sprint specific training period (end of March) was observed in these athletes. It was concluded that basal gonadal hormone concentration in high and top-class athletes (sprinters and jumpers) did not appear to be significantly different when compared with untrained subjects. Moreover, basal T concentration in sprinters can differ significantly during an annual training period. This fact should be taken into consideration when interpreting the results of gonadal hormone status in athletes at varied training stages [11082].

Effects of hard exercise

In the last years, mainly 2 high-intensity-training (HIT) protocols became common: First, a Wingate-based “all-out” protocol and second, a 4×4 min protocol. However, no direct comparison between these protocols exists, and also a comparison with high-volume-training (HVT) is missing. Therefore, the aim of the present study was to compare these 3 endurance training protocols on metabolic, hormonal, and psychological responses. Twelve subjects performed: 1) HVT [130 min at 55 % peak power output (PPO)]; 2) 4×4 min at 95 % PPO; 3) 4×30 s all-out. Human growth hormone (hGH), testosterone, and cortisol were determined before (pre) and 0', 30', 60', 180' after each intervention. Metabolic stimuli and perturbations were characterized by lactate, blood gas (pH, BE, HCO₃⁻, pO₂, PCO₂), and spirometric analysis. Furthermore, changes of the person’s perceived physical state were determined. The 4×30 s training caused the highest increases in cortisol and hGH, followed by 4 × 4 min and HVT. Testosterone levels were significantly increased by all 3 exercise protocols. Metabolic stress was highest during and after 4×30 s, followed by 4×4 min and HVT. The 4×30 s training was also the most demanding intervention from an athlete’s point of view. In conclusion, the results suggest that 4×30 s and 4×4 min promote anabolic processes more than HVT, due to higher increases of hGH, testosterone, and the T/C ratio. It can be
speculated that the acute hormonal increase and the metabolic perturbations might play a positive role in optimizing training adaptation and in eliciting health benefits as it has been shown by previous long term training studies using similar exercise protocols [13197].

**Effect of endurance training**

The aim of one study was to compare the levels of serum immunoglobulin (IgA, IgM, IgG), testosterone and cortisol in semi-endurance elite runners during general preparation and competition phase of training. Thirteen semi-endurance elite male runners with an average age of 19 years volunteered to take part in this study. The runners participated in the selected training for a period of 14 weeks and 12 sessions per week (in the morning and afternoon). Blood samples were collected during the three phases of training (before-preparation phase, after-preparation phase and before-competition phase). The levels of serum IgM in semi-endurance elite runners after preparation phase reduced significantly, while these levels during the competition phase increased even though significantly. The levels of serum IgG and IgA also reduced, however not significantly, during both phases. Moreover, after preparation phase, there was no significant change in serum IgA levels; though, these levels reduced, however not significantly, before competition phase. Cortisol levels significantly decrease after preparation phase; although, it increased before competition phase. Testosterone/cortisol ratio increases significantly after preparation phase, and it decreased before competition phase. Testosterone levels intangibility increased and decreased respectively after preparation and before competition phases. Findings indicated that long and intensive exercises weaken the immune system, while moderate and short drills strengthened this system [12101].

Acute exercise, depending on its characteristics, demands a physiological increase in testosterone. In fact, the majority of investigations showed that total and/or free testosterone acutely increased immediately after acute strenuous and/or prolonged sub-maximal endurance and resistance exercises. Unfortunately, the mechanisms responsible for testosterone increase after acute exercise are still unknown. Probably due to exercise standardization and/or to individual variability gonadotropins levels have been reported unchanged, increased or, rarely, decreased after both sub-maximal and maximal acute exercise. Consequently, other mechanisms, such as a possible adaptation of secretory capacity of the Leydig cells, adrenergic and/or lactate stimulation, modifications of clearance rate, plasma volume reductions and changes in testicular blood flow should be investigated. Studies on the effects of chronic exercise (e.g. training) frequently showed a reduction of free and total testosterone concentrations in endurance-trained men, and the few prospective studies showed contradictory results probably due to the features of the training period, the magnitude of training stimulus and the volume of training load employed. In addition, modifications of androgen receptors status have also been described [12094].

Generally, cardiovascular exercise and resistance training transiently increase testosterone concentrations in men although a few studies report null effects. Testosterone concentrations also vary both before and after competition in a systematic and consistent manner. Wingfield et al. in 1990) proposed the “challenge hypothesis”, which posits that during mating seasons and times of resource scarcity testosterone concentrations rise to facilitate competition, particularly amongst males. The challenge hypothesis is relevant to human competition in the world of sports. As predicted by the challenge hypothesis, pre-competition concentrations of testosterone rise in male and female athletes in anticipation of the impending competition. In men, testosterone commonly increases following victory and decreases following loss. However, this main effect of winning or losing on changes in men's testosterone is not always observed. Several studies have shown that other factors like context, individual
differences, e.g. power motivation, social anxiety, and motivation to win (Suay et al., 1999), as well as cognitive appraisal can play an important role in predicting post-competition testosterone changes. Dominance-motivated individuals, who positively value interpersonal dominance and dislike submission, are those most likely to experience outcome-dependent changes in testosterone. Competitors’ level of engagement is also relevant to testosterone changes, such that men’s testosterone increases are greatest when one’s opponents feel more confident. An elite athlete in an international competition is likely to be more engaged and to value victory and defeat much more significantly than a participant in laboratory manipulations with cognitive games. Accordingly, testosterone changes in situations of high value and importance are likely to be of greater magnitude. A winner will likely benefit from continued victory and increased access to resources, whereas a loser, who may be injured or still in the presence of the victory-primed winner, will likely benefit from disengagement. Several animal studies have elucidated the mediating effects of testosterone in the winner and loser effect, which have been subsequently studied in humans. A single sample collected at the peak of endogenous testosterone production has potential to produce a false positive result, when compared against a population-based average. There is a notable sexual dimorphism in testosterone responses to competition in humans. Testosterone responses to winning and losing appear to principally apply to men. Only a single study has reported an effect winning/losing on differential testosterone changes in women, whereas many more studies have failed to find an effect. This is likely a function of the different source glands for testosterone between the sexes, which include the testes and adrenals in men and ovaries and adrenals in women [12100].

One study examined the predictive relationships between the salivary free testosterone (T) concentrations of elite athletes and the expression of force and power. A group of elite male rugby players (n=64) were assessed for peak force (PF), peak rate of force development (PRFD), force at 100 milliseconds (F100 ms) and 250 milliseconds (F250 ms) during an isometric mid-thigh pull (IMTP), and/or peak power (PP) and height during a counter-movement jump (CMJ). Saliva samples were collected before testing and assayed for free T. Relationships between individual T concentrations and performance were assessed as a pooled group and 4 sub-groups of equal size. As pooled data sets, none of the IMTP and CMJ performance variables were significantly correlated with free T in either the PF or PP groups. The PF and PP abilities of the 4 sub-groups were significantly different, so that PF1>PF2>PF3>PF4 and PP1>PP2>PP3>PP4. When the 4 sub-groups were analysed, the T concentrations of the PF4 group were significantly correlated to PRFD and F100 ms during the IMTP, as was F100 ms in the PF1 group. In the PP1 group, free T also correlated to CMJ height. The key conclusion is that the expression of force and power in an elite athletic group may be dependent, to some extent, on individual variation in salivary free T concentrations and existing strength or power levels. The current results also confirm that the grouping of elite athletes of mixed strength or power ability may bias predictive results in a manner not reflective of sub-groups within this population [12102].

Responses to intensive interval versus steady-state endurance exercise
Free testosterone (FT) hormonal responses were compared between high-intensity interval exercise (IE) and steadystate endurance exercise (SSE) in endurance trained males (n=15). IE session was repeated periods of 90-sec treadmill running at 100-110 percent maximal oxygen uptake (VO\textsubscript{2max}) and 90-sec active recovery at 40 percent VO\textsubscript{2max} for 42-47 min. The SSE session consisted of a continuous 45-min run at 60-65 percent VO\textsubscript{2max}. Total work output was equal for each exercise session. A 45-min supine rest control session (CON) was also performed. All three sessions were on separate days. Pre-session (PRE), immediate post-session (POST), and 12-h post-session (12POST) blood samples were collected and used to determine FT, SHBG, LH, 3- alpha-androstenediol glucuronide (3-alphaDiol G) and cortisol. Analysis of variance compared IE and SSE biomarker responses to the reference
CON session. IE and SSE each caused an increase in FT, but IE more so than SSE. The 5alpha-reductase marker 3-alpha Diol G response at 12POST IE was elevated while FT was reduced; no such change occurred following SSE. These findings suggest IE might produce a more pronounced turnover of FT by androgen sensitive tissue than the SSE form of exercise [12103].

Effect of resistance training

One study assessed the effect of different resistance exercise scheme (RES) designs of similar total of load lifted on the responses of testosterone, cortisol, and creatine kinase (CK). Twenty-seven healthy males performed 1 of 4 bench press workouts described by the 1 repetition maximum (1RM) load: 4 sets of maximum repetitions at 50 percent-1RM (50%-1RM RES), 5 sets of maximum repetitions at 75 percent-1RM (75%-1RM RES), 10 sets of maximum repetitions at 90 percent-1RM (90%-1RM RES), or 8 sets of maximum repetitions at 110 percent-1RM (110%-1RM RES). Each RES was equated by the total volume of load lifted (repetitions x sets x load). Blood samples, collected pre-exercise (Pre) and post-exercise (Post) at 1 and 24 hours (24 h), were analyzed for total and free testosterone, total cortisol, and CK. In general, testosterone and cortisol showed little change within or between the different RES, possibly because of the relatively low volume lifted and/or the small muscle mass activated by the bench press exercise. Cortisol was elevated after the 75%-1RM RES at the Post sample, with this response also significantly exceeding the other RES. The 24 h CK response was also elevated after the 75%-1RM RES, thereby suggesting greater training strain for the same volume of load. These results confirm previous recommendations regarding the prescription of resistance exercise and the importance of total volume as a stimulus for activating the endocrine system and achieving long-term adaptation [09094].

One study examined the effects of heavy resistance training on physiological acute exercise-induced fatigue (5 x 10 RM leg press) changes after two loading protocols with the same relative intensity (%) (5 x 10 RM) and the same absolute load (kg) (5 x 10 RM) as in pretraining in men (n=12). Exercise-induced neuromuscular (maximal strength and muscle power output), acute cytokine and hormonal adaptations (i.e. total and free testosterone, cortisol, growth hormone (GH), insulin-like growth factor-1 (IGF-1), IGF binding protein-3 (IGFBP-3), interleukin-1 receptor antagonist (IL-1ra), IL-1beta, IL-6, and IL-10 and metabolic responses (i.e. blood lactate) were measured before and after exercise. The resistance training induced similar acute responses in serum cortisol concentration but increased responses in anabolic hormones of free testosterone and growth hormone. This enhanced hormonal and cytokine response to strength exercise at a given relative exercise intensity after strength training occurred with greater accumulated fatigue and metabolic demand (i.e. blood lactate accumulation). The magnitude of metabolic demand or the fatigue experienced during the resistance exercise session influences the hormonal and cytokine response patterns. Similar relative intensities may elicit not only higher exercise-induced fatigue but also an increased acute hormonal and cytokine response during the initial phase of a resistance training period [09095].
similar acute responses in serum cortisol concentration but increased responses in anabolic hormones of free testosterone and GH, as well as inflammation-responsive cytokine IL-6 and the anti-inflammatory cytokine IL-10, when the same relative load was used. This response was balanced by a higher release of pro-inflammatory cytokines IL-1beta and cytokine inhibitors (IL-1ra) when both the same relative and absolute load was used after training. This enhanced hormonal and cytokine response to strength exercise at a given relative exercise intensity after strength training occurred with greater accumulated fatigue and metabolic demand (i.e. blood lactate accumulation). The magnitude of metabolic demand or the fatigue experienced during the resistance exercise session influences the hormonal and cytokine response patterns. Similar relative intensities may elicit not only higher exercise-induced fatigue but also an increased acute hormonal and cytokine response during the initial phase of a resistance training period [09096].

Short-term effects on resistance training

The aim of one review is to highlight two emerging concepts for the elite athlete using the resistance-training model with short-term effects of testosterone (T) and cortisol (C) on the neuromuscular system; and the dose-response training role of these endogenous hormones. Exogenous evidence confirms that T and C can regulate long-term changes in muscle growth and performance, especially with resistance training. This evidence also confirms that changes in T or C concentrations can moderate or support neuromuscular performance through various short-term mechanisms (e.g. second messengers, lipid/protein pathways, neuronal activity, behaviour, cognition, motor-system function, muscle properties and energy metabolism). The possibility of dual T and C effects on the neuromuscular system offers a new paradigm for understanding resistance-training performance and adaptations. Endogenous evidence supports the short-term T and C effects on human performance. Several factors (e.g. workout design, nutrition, genetics, training status and type) can acutely modify T and/or C concentrations and thereby potentially influence resistance-training performance and the adaptive outcomes. This novel short-term pathway appears to be more prominent in athletes (vs non-athletes), possibly due to the training of the neuromuscular and endocrine systems. However, the exact contribution of these endogenous hormones to the training process is still unclear. Research also confirms a dose-response training role for basal changes in endogenous T and C, again, especially for elite athletes. Although full proof within the physiological range is lacking, this athlete model reconciles a proposed permissive role for endogenous hormones in untrained individuals. It is also clear that the steroid receptors (cell bound) mediate target tissue effects by adapting to exercise and training, but the response patterns of the membrane-bound receptors remain highly speculative. This information provides a new perspective for examining, interpreting and utilizing T and C within the elite sporting environment. For example, individual hormonal data may be used to better prescribe resistance exercise and training programmes or to assess the trainability of elite athletes. Possible strategies for acutely modifying the hormonal milieu and, thereafter, the performance/training outcomes were also identified. The limitations and challenges associated with the analysis and interpretation of hormonal research in sport (e.g. procedural issues, analytical methods, research design) were another discussion point [11083].

One study examined the effects of short-cycle sprints on power, strength, and salivary hormones in elite rugby players. Thirty male rugby players performed an upper-body power and lower-body strength (UPLS) and/or a lower-body power and upper-body strength (LPUS) workout using a crossover design (sprint vs. control). A 40-second upper-body or lower-body cycle sprint was performed before the UPLS and LPUS workouts, respectively, with the control sessions performed without the sprints. Bench throw (BT) power and box squat (BS) 1 repetition maximum (1RM) strength were assessed in the UPLS workout, and squat jump (SJ) power and bench press (BP) 1RM strength were assessed in the LPUS workout. Saliva
was collected across each workout and assayed for testosterone (Sal-T) and cortisol (Sal-C). The cycle sprints improved BS (2.6 ± 1.2 %) and BP (2.8 ± 1.0 %) 1RM but did not affect BT and SJ power. The lower-body cycle sprint produced a favorable environment for the BS by elevating Sal-T concentrations. The upper-body cycle sprint had no hormonal effect, but the workout differences (%) in testosterone and cortisol concentrations correlated to the BP, along with the testosterone/cortisol. In conclusion, the cycle sprints improved the BP and BS 1RM strength of elite rugby players but not power output in the current format. The improvements noted may be explained, in part, by the changes in absolute or relative hormone concentrations. These findings have practical implications for prescribing warm-up and training exercises [11084].

Effect of different types of training

In the last years, mainly 2 high-intensity-training (HIT) protocols became common: first, a Wingate-based "all-out" protocol and second, a 4×4 min protocol. However, no direct comparison between these protocols exists, and also a comparison with high-volume-training (HVT) is missing. Therefore, the aim of one study was to compare these 3 endurance training protocols on metabolic, hormonal, and psychological responses. Twelve subjects performed: 1) HVT (130 min at 55 % peak power output, PPO); 2) 4×4 min at 95 percent PPO; 3) 4×30 s all-out. Human growth hormone (hGH), testosterone, and cortisol were determined before (pre) and 0', 30', 60', 180' after each intervention. Metabolic stimuli and perturbations were characterized by lactate, blood gas (pH, BE, HCO$_3^-$, pO$_2$, PCO$_2$), and spirometric analysis. Furthermore, changes of the person's perceived physical state were determined. The 4×30 s training caused the highest increases in cortisol and hGH, followed by 4×4 min and HVT. Testosterone levels were significantly increased by all 3 exercise protocols. Metabolic stress was highest during and after 4×30 s, followed by 4×4 min and HVT. The 4×30 s training was also the most demanding intervention from an athlete's point of view. In conclusion, the results suggest that 4×30 s and 4×4 min promote anabolic processes more than HVT, due to higher increases of hGH, testosterone, and the T/C ratio. It can be speculated that the acute hormonal increase and the metabolic perturbations might play a positive role in optimizing training adaptation and in eliciting health benefits as it has been shown by previous long term training studies using similar exercise protocols [13199].

Effect of different short-time types of exercise

Hormonal responses to exercise could be used as a marker of overreaching. A short exercise protocol that induces robust hormonal elevations in a normal trained state should be able to highlight hormonal changes during overreaching. One study compared plasma and salivary cortisol and testosterone responses to 4 exercise trials at continuous cycle to fatigue at 75 percent of peak power output ($W_{max}$) (FAT), 30-minute cycle alternating 1-minute 60 percent and 1 minute 90 percent $W_{max}$ (60/90), 30-minute cycle alternating 1-minute 55 percent and 4-minute 80 percent $W_{max}$ (55/80), and squatting 8 sets of 10 repetitions at 10 repetition maximum (RESIST). Blood and saliva samples were collected pre-exercise and at 0, 10, 20, 30, 40, 50, and 60 minute postexercise. Pre- to postexercise plasma cortisol increased in all exercise trials, except 60/90. Increases in 55/80 remained above pre-exercise levels for the entire postexercise period. Salivary cortisol increased from pre- to postexercise in FAT and 55/80 trials only. Once elevated after 55/80, it remained so for the postexercise period. Plasma testosterone increased from pre- to postexercise in all trials except 55/80. Saliva testosterone increased from pre- to postexercise in all trials with the longest elevation occurring after 55/80. Area under the curve analysis indicated that the exercise response of salivary hormones was greater in all cycle trials (cortisol) and in the 60/90 and 55/80 trials (testosterone) compared with the other trials. The study indicates that
the 55/80 cycle protocol induces a prolonged salivary and plasma cortisol and salivary testosterone response compared with the other trials and so may be a useful diagnostic tool of overreaching [11085].

Explosive performances

The primary objective of one study was to analyze the relationship between testosterone levels and vertical jumping performance in elite men and women athletes. The secondary objective was to verify whether testosterone levels and vertical jumping performance were different in men and women athletes and if those measurements were different between different athletic groups. Seventy (22 women and 48 men) elite athletes in track and field (sprinters), handball, volleyball, and soccer competing at national and international levels participated in the study. After 10 hours of fasting and 1 day of rest, blood samples were drawn from the antecubital vein for determining testosterone levels. Vertical jumping tests consisted of countermovement jumps conducted on a resistive platform connected to a digital timer. Resting testosterone levels in women were 10 percent of those of the men. Countermovement jump performance was significantly different between women and men athletes, with women's jumping ability 86 percent of that of men. A significant positive relationship was identified between testosterone levels and vertical jump performance when all data were considered [06053].

Active recovery versus passive recovery

The aim of one study was to compare the effects of active (A) versus passive (P) recovery during high-intensity interval training on the acute hormonal and metabolic response. Twelve triathletes/cyclists performed four 4 min intervals on a cycle ergometer, either with A- or P-recovery between each bout. Testosterone, hGH, cortisol, VEGF, HGF and MIF were determined pre, 0', 30', 60' and 180' after both interventions. Metabolic perturbations were characterized by lactate, blood gas and spirometric analysis. A-recovery caused significant increases in circulating levels of cortisol, testosterone, T/C ratio, hGH, VEGF and HGF. Transient higher levels were found for cortisol, testosterone, hGH, VEGF, HGF and MIF after A-recovery compared to P-recovery, despite no differences in metabolic perturbations. A-recovery was more demanding from an athlete's point of view. Based on the data of testosterone, hGH and the T/C-ratio, as well as on the data of VEGF and HGF it appears that this kind of exercise protocol with A-recovery phases between the intervals may promote anabolic processes and may lead to pro-angiogenic conditions more than with P-recovery. These data support the findings that also the long term effects of both recovery modes seem to differ, and that both can induce specific adaptations [13200].

The exercise-induced metabolic stress can be influenced by the mode of recovery and is associated with acute hormonal responses. Therefore, it is hypothesized that active recovery between high intensity intervals reduces the metabolic stimulus and therefore the hormonal response compared to passive recovery. Twelve male cyclist/triathletes performed four 30s all-out intervals, either with active (A) or passive (P) recovery between each bout. Human growth hormone (hGH), testosterone and cortisol, vascular endothelial growth factor (VEGF), hepatocyte growth factor (HGF) and macrophage migration inhibitory factor (MIF) were determined pre, 0', 30', 60' and 180' after both interventions. Metabolic stimuli and perturbations were characterized by lactate, blood gas (pH, BE, HCO₃⁻, PO₂, PCO₂), and spirometric analysis. Both interventions caused a transient increase in circulating levels of cortisol, testosterone, testosterone/cortisol-ratio, hGH, VEGF and HGF. Transient differences between A- and P-recovery were found only for testosterone and HGF directly after exercise, despite significant differences in metabolic disturbances (lactate, acid base status). Based on
the data of testosterone, hGH and the testosterone/cortisol-ratio, as well as on the data of VEGF and HGF it appears that this kind of exercise protocol may promote anabolic processes and may lead to pro-angiogenic conditions independent of the mode of recovery. However transient differences between A- and P-recovery were shown for testosterone and HGF. In contrast, cortisol and hGH, which are known to be sensitive for metabolic perturbations (e.g. pH) showed no differences. Therefore, it is proposed that if a certain threshold for metabolic perturbations is exceeded, a hormonal response is induced, which does not differ between A- and P-recovery [13201].

Influence of red color

One study examined the testosterone responses of men to an exercise bout simulating a competitive sporting effort in order to determine if the wearing of red-colored apparel influenced the hormonal response. Male subjects (n = 10) were placed into sets of matched-pairs and performed VO2max cycle ergometry exercise test to exhaustion to simulate the competitive effort. Each member of a pairing was randomly assigned to one of two treatment groups-the wearing of red-colored clothing, or the wearing of black-colored clothing. Blood samples were collected before exercise (REST), an immediate postexercise sample was collected at exhaustion (EXH), and a final sample was taken at 15 min into recovery (REC) from exercise. Blood was biochemically analyzed for total testosterone. In response to the exercise, performance characteristics (i.e. VO2max and maximal workload) of treatment groups did not differ significantly. A significant increase in the testosterone was observed in both treatment groups postexercise at EXH and at REC as compared to REST. However, no differences were observed between treatment groups in the before or postexercise hormonal concentrations. These findings suggest that the wearing of red-colored apparel had no affects on the testosterone responses to an exercise bout simulating a competition [06054].

Pre-game free testosterone concentrations and outcome

To assess the measures of salivary free-testosterone and cortisol concentrations across selected rugby union matches according to the game outcome 22 professional male rugby union players were studied across 6 games (3 wins and 3 losses). Hormone samples were taken 40 minutes prior to the game (pre) and 15 minutes after (post). The hormonal data was grouped and compared against competition outcomes. These competition outcomes included wins and losses and a game ranked performance score (1 to 6). Across the entire team, pre-game testosterone concentrations were significantly higher during winning games than losses. Analysis by playing position further revealed that, for the backs, pre-game testosterone concentrations and the T/C ratio were significantly greater before a win than a loss. Game ranked performance score (1 to 6) correlated to the team's pre-game testosterone concentrations. The backs also showed that pre-game testosterone and the T/C ratio correlated to game ranked performance. Analysis of the forwards' hormone concentrations did not distinguish between game outcomes nor did it correlate with game ranked performance. Game venue (home vs away) only affected post-game concentrations of testosterone and cortisol. It was concluded that monitoring game day concentrations of salivary free-testosterone may assist with identifying competitive readiness in rugby union matches. The link between pre-game T/C ratio and rugby players in the backs position suggest that monitoring weekly training loads and enhancing recovery modalities between games may also assist with favourable performance and outcome in rugby union matches [13196].

Pre-game testosterone level: home advantage
The home advantage is a robust phenomenon that occurs in the world of amateur and professional sport. Athletic teams have been shown to win significantly more games in their home venue as compared to their opponents' venue. Studies have suggested that the home advantage may be related to familiarity with the facility, increased crowd density and even pre-competition hormonal levels. The present study investigated pre-competition physiological and psychological states of elite hockey players in the home and away venues. Physiological measures included salivary cortisol and testosterone, which were assessed using enzyme immunoassays. In addition, pre-competition psychological states were assessed using the Competitive State Anxiety Inventory-2. Physiological measures indicated that the players had significantly higher pre-game testosterone when playing in their home venue as compared to their opponents' venue; however, this difference was not due to a pre-game rise in testosterone while competing at home. Furthermore, players showed a trend toward higher pre-game cortisol when playing in their home venue. Psychological measures indicated that players were more self-confident when playing in their home venue and also had higher somatic and cognitive anxiety when playing in their opponents' venue. The study supports the notion that there are differences in pre-competition hormonal and psychological states that may play a key role in the "home advantage" [06055].

Effect of testosterone on myoblasts

It was investigated the ability of testosterone (T) to restore differentiation in multiple population doubled (PD) murine myoblasts, previously shown to have a reduced differentiation in monolayer and bioengineered skeletal muscle cultures versus their parental controls (CON). Cells were exposed to low serum conditions in the presence or absence of T (100 nM) ± PI3K inhibitor (LY294002) for 72 h and 7 days (early and late muscle differentiation respectively). Morphological analyses were performed to determine myotube number, diameter (microm) and myonuclear accretion as indices of differentiation and myotube hypertrophy. Changes in gene expression for myogenin, mTOR and myostatin were also performed. Myotube diameter in CON and PD cells increased from 17.32 ±2.56 microm to 21.02 ± 1.89 microm and 14.58 ± 2.66 microm to 18.29 ± 3.08 microm, respectively after 72 h of T exposure. The increase was comparable in both PD (+25 %) and CON cells (+21 %) suggesting a similar intrinsic ability to respond to exogenous T administration. T treatment also significantly increased myonuclear accretion (% of myotubes expressing 5+ nuclei) in both cell types after 7 days exposure. Addition of PI3K inhibitor (LY294002) in the presence of T attenuated these effects in myotube morphology (in both cell types) suggesting a role for the PI3K pathway in T stimulated hypertrophy. Finally, PD myoblasts showed reduced responsiveness to T stimulated mRNA expression of mTOR vs. CON cells and T also reduced myostatin expression in PD myoblasts only. The present study demonstrates testosterone administration improves hypertrophy in myoblasts that basally display impaired differentiation and hypertrophic capacity versus their parental controls, the action of testosterone in this model was mediated by PI3K/Akt pathway [13202].

Testosterone levels after concussions

A 27-year-old man was admitted to an outpatient clinic with symptoms of loss at libido, erectile dysfunction and fatigue. He had been playing soccer from the age of 7, for the last 10 years as a high-level professional. During that time repeated mild head-trauma without loss of consciousness had occurred, mainly triggered by excessive header-training and occasional collisions. Serum levels of testosterone and luteinizing hormone were low. A gonadotropin releasing hormone loading test revealed significant gonadotropin responses, therefore pituitary gonadotropic insufficiency was unlikely. Further pituitary insufficiency of any other axis was also excluded by insulin hypoglycemia test. Magnetic resonance imaging
of the brain revealed no significant abnormalities of the hypothalamic-pituitary unit. Testosterone substitution, at first applied transdermally, then intramuscularly, was initiated after approval by the National Anti Doping Agency. Four months later most of the symptoms had regressed. It was concluded that pituitary deficiency in the course of craniocerebral trauma is frequent and may be transient or permanent, mostly affecting somatotropic or gonadotropic function. Hormonal imbalances may also be observed after mild but repeated trauma without loss of consciousness and should be considered in cases of isolated pituitary dysfunction, since such traumas may often occur in contacts sports such as boxing or intensive soccer play [13203].

Effect of soccer

The main aim of one study was to analyse the impact of an official match on hormonal and redox status, muscle damage and inflammation and neuromuscular function. Seven high-level male soccer players from the same team performed an official match and data were collected 72 h before, 24, 48 and 72 h post-match. Plasma testosterone/cortisol ratio (T/C), creatine kinase (CK), superoxide dismutase (SOD), glutathione peroxidase (GPX) and reductase (GR) activities, myoglobin (Mb), C-reactive protein (CRP), uric acid (UA), protein sulfhydryls (-SH), malondialdehyde (MDA) concentrations and total antioxidant status (TAS) were measured. Sprint, jump and change of direction performance, and maximal isokinetic knee extension and flexion were obtained as neuromuscular functional parameters. Cortisol increased and T/C decreased until 48 h recovery. Mb, CRP and -SH increased at 24 h recovery. CK, TAS, SOD and MDA increased up to 48 h recovery. GR increased and GPX decreased at 24 h recovery. Jump performance decreased 24 h post-match, but no significant alterations in sprint, change of direction and muscle strength were observed. In conclusion, an official match resulted in changes in plasma biomarkers until 48 h of recovery period, without major impact on performance [13198].

Effect of golf

The purpose of one investigation was to study the effects of 36 continuous holes of competitive golf on salivary testosterone, cortisol, and testosterone-to-cortisol ratio and their relation to performance in eight elite male collegiate golfers (age 20 years). Thirty-six holes of a 54-hole NCAA golf tournament were played on the first day of the competition. A saliva sample was taken 45 minutes prior to the round and immediately following each hole for a total of 37 samples per subject. Time matched baseline samples were collected on a different day to account for circadian variation. Six-hole areas under the curve (AUC) values were calculated for endocrine measures. Significant increases were noted for cortisol during competition, however, testosterone did not change during competition compared to baseline. Testosterone-to-cortisol (T/C) ratio was significantly lower throughout the competition compared to baseline measures. Thirty-six-hole AUC testosterone-to-cortisol ratio response was correlated to 36-hole score. There was a high correlation between pre-round testosterone, T/C ratio response, and 36-hole score. CSAI-2 somatic anxiety was correlated to pre-round cortisol and testosterone response. These results indicate a significant hormonal response during 10 hours of competitive golf. Good golf performance (low golf scores) in this competition was related to low T/C ratio [07088].

Overreaching

The purpose of one study was to study the effect of an 8-week Finnish military basic training period (BT) on physical fitness, body composition, mood state, and serum biochemical parameters among new conscripts; to determine the incidence of overreaching (OR); and to
evaluate whether initial levels or training responses differ between OR and noOR subjects. Fifty-seven males (20 years) were evaluated before and during BT. Overreaching subjects had to fulfill 3 of 5 criteria: decreased aerobic physical fitness (VO\(_{2\text{max}}\)), increased rating of perceived exertion (RPE) in 45-minute submaximal test at 70 percent of VO\(_{2\text{max}}\) or sick absence from these tests, increased somatic or emotional symptoms of OR, and high incidence of sick absence from daily service. VO\(_{2\text{max}}\) improved during the first 4 weeks of BT. During the second half of BT, a stagnation of increase in VO\(_{2\text{max}}\) was observed, basal serum sex hormone-binding globulin (SHBG) increased, and insulin-like growth factor-1 and cortisol decreased. Furthermore, submaximal exercise-induced increases in cortisol, maximum heart rate, and postexercise increase in blood lactate were blunted. Of 57 subjects, 33 percent were classified as OR. They had higher basal SHBG before and after 4 and 7 weeks of training and higher basal serum cortisol at the end of BT than noOR subjects. In addition, in contrast to noOR, OR subjects exhibited no increase in basal testosterone/cortisol ratio but a decrease in maximal La/RPE ratio during BT. As one-third of the conscripts were overreached, training after BT should involve recovery training to prevent overtraining syndrome from developing. The results confirm that serum SHBG, cortisol, and testosterone/cortisol and maximal La/RPE ratios could be useful tools to indicate whether training is too strenuous [11086].

**Older men**

To examine the relationship between different measures of testosterone and estradiol (E\(_2\)), muscle mass, muscle strength, and physical performance; and to test whether the association of sex hormone level with muscle strength and physical performance was independent of muscle mass. A cross-sectional survey on 1489 community-dwelling men older than 64 years of age had serum levels of testosterone and E\(_2\) measured by mass spectrometry, and sex hormone-binding globulin (SHBG) levels were measured by immunoradioassay. Muscle mass was examined by dual-energy X-ray absorptiometry and physical performance was assessed by hand-grip strength, gait speed, step length and chair-stand test. Appendicular skeletal mass (ASM) was positively associated with total testosterone, free testosterone, and total E\(_2\) but not with free E\(_2\). After adjustment for age, serum SHBG and relative ASM, both with total testosterone and free testosterone were significantly associated with grip strength, narrow-walk speed and the composite neuromuscular score. Higher total E\(_2\), but not free E\(_2\) was associated with lower grip strength after adjustment for age, FT, SHBG and relative ASM. Testosterone level was related to both muscle mass, to strength and to physical performance. Total E\(_2\) level, though related to muscle mass positively, affected muscle strength adversely in older men [11087].

**Females**

Physical exercise is known to strongly stimulate the endocrine system in both sexes. Among these hormones, androgens (e.g. testosterone, androstenedione, dehydroepiandrosterone) play key roles in the reproductive system, muscle growth and the prevention of bone loss. In female athletes, excessive physical exercise may lead to disorders, including delay in the onset of puberty, amenorrhoea and premature osteoporosis. The free and total fractions of circulating androgens vary in response to acute and chronic exercise/training (depending on the type), but the physiological role of these changes is not completely understood. Although it is commonly accepted that only the free fraction of steroids has a biological action, this hypothesis has recently been challenged. Indeed, a change in the total fraction of androgen concentration may have a significant impact on cells (inducing genomic or non-genomic signalling). The purpose of one review, therefore, was to visit the exercise-induced changes in androgen concentrations and emphasize their potential effects on female physiology.
Despite some discrepancies in the published studies (generally due to differences in the types and intensities of the exercises studied, in the hormonal status of the group of women investigated and in the methods for androgen determination), exercise is globally able to induce an increase in circulating androgens. This can be observed after both resistance and endurance acute exercises. For chronic exercise/training, the picture is definitely less clear and there are even circumstances where exercise leads to a decrease of circulating androgens. It was suggest that those changes have significant impact on female physiology and physical performance [11088].

The purpose of one study was to investigate the influence of a 14-week swimming training program on psychological, hormonal, and performance parameters of elite women swimmers. Ten Olympic and international-level elite women swimmers were evaluated 4 times along the experiment (i.e., in T1, T2, T3, and T4). On the first day at 8:00 am, before the blood collecting at rest for the determination of hormonal parameters, the athletes had their psychological parameters assessed by the profile of mood-state questionnaire. At 3:00 am, the swimmers had their anaerobic threshold assessed. On the second day at 3:00 am, the athletes had their alactic anaerobic performance measured. Vigor score and testosterone levels were significantly lower in T4 compared with T3. In addition, the rate between the peak blood lactate concentration and the median velocity obtained in the alactic anaerobic performance test increased in T4 compared with T3. For practical applications, the swimming coaches should not use a tapering with the present characteristics to avoid unexpected results [11089].

The association between androgens and competition in women has been understudied compared with men. The current study examined the link between testosterone and competition in elite female athletes, using a sample of female wrestlers that included athletes competing at both the national and international level. In a repeated-measures design, saliva samples were collected before and after wrestling bouts, with comparable samples of wins and losses, and subsequently analyzed for testosterone. Study results showed a 22 percent increase in circulating bioavailable testosterone from pre- to postbout, which was a significant difference. There was no significant difference in testosterone between win or loss outcomes. These findings showing a link between individual head-to-head competition and testosterone in women demonstrate that women's androgenic responses to environmental contexts are dynamic and may be an important factor to address in research on competitive performance [09101].

In a previous study, sprint training has been shown to increase muscle cross-sectional area in women but not in men [Eur J Appl Physiol Occup Physiol 1996; 74: 375]. It was hypothesized that sprint exercise induces a different hormonal response in women than in men. Such a difference may contribute to explaining the observed gender difference in training response. Metabolic and hormonal response to three 30-s sprints with 20-min rest between the sprints was studied in 18 physically active men and women. Significant accumulation of blood lactate and plasma ammonia after sprint exercise was greater in men. Serum insulin increased after sprint exercise more so in women than in men, while plasma glucose increased in men, but not in women. Serum growth hormone (GH) increased in both women and men reaching similar peak levels, but with different time courses. In women the peak serum GH level was observed after sprint 1, whereas in men the peak was observed after sprint 3. Serum testosterone tended to decrease in men and increase in women. Serum cortisol increased approx. 10-15 percent after sprint exercise, independent of gender. It was concluded that women elicited a greater response of serum GH and insulin to sprint exercise. This may contribute to explaining the earlier observed muscle hypertrophy in women in response to sprint training [09103].
**Effects in a young female**

A 14-year-old Caucasian girl was referred to the endocrine clinic for evaluation of voice deepening, facial hirsutism, and acne starting 2 years previously. She had been a competitive tennis player since age 7 years, practicing for 4-6 hours daily. Adrenal ultrasonography revealed a round left 4.6 × 5.3-cm adrenal mass. Laparoscopic left adrenalectomy was performed. The histologic findings were compatible with a benign adrenocortical tumor. Postoperatively, androgen levels dropped to within the normal range. Breast development proceeded normally, menarche occurred 2 months after tumor resection, and menses has been regular since then. Muscle strength of the dominant and nondominant upper and lower extremities was measured 1 month before surgery and 1 year later, using an isokinetic dynamometer (Biodex Systems II, Biodex, Shirley, NY, USA). There was no significant decrease in overall muscle strength after removal of the virilizing tumor and the marked drop in circulating androgens. In addition, the patient maintained her age category, number 1, national tennis ranking. The results suggest that even extremely high levels of tumor-related circulating androgens had no evident effect on muscle strength and competitive performance in a female adolescent tennis player. The lack of beneficial effect on performance in adolescents, combined with the potentially hazardous side effects of anabolic steroids, suggests that teenage athletes should avoid their use [11090].

**Adolecents**

One study investigated the effect of repeated bouts of short-term, high-intensity cycling exercise on the salivary cortisol, testosterone and immunoglobulin (A) concentrations of 15-16 year old boys. Seventeen apparently healthy schoolchildren (aged 15.5 ± 0.4 years) participated in this study. All participants completed 6 x 8 s sprints, interspersed with 30 s recovery intervals on a cycle ergometer. Using the passive drool method, salivary samples were taken before, and 5 min after, exercise. There were significant changes in both salivary testosterone and cortisol, 5 min after completing 6 x 8 s cycle sprints. No significant differences were recorded for immunoglobulin A. The increases in testosterone and cortisol reported confirm that repeated bouts of short-term, high-intensity exercise produces significant physiological hormonal responses in adolescent boys, but does not affect mucosal immune function [09097].

**Biking**

To determine whether cycling has an effect on serum PSA, gonadotropins, and uroflowmetric parameters a total of 34 healthy male athletes from the National Cycling Team and 24 healthy male student volunteers from University and medical staff were prospectively enrolled in a study. Blood samples for serum total prostate-specific antigen (tPSA), free PSA (fPSA), fPSA/tPSA, follicle-stimulating hormone (FSH), luteinizing hormone (LH), and testosterone determinations were obtained before and after cyclists completed 300 km bicycle ride and with each cyclist seated without changing posture and with minimal movement for 10 minutes before blood collection. The cyclists also performed uroflowmetric and postvoid residual urine volume analysis before, and 1 hour after cycling course. Blood samples from the control group were drawn for serum hormones. They also underwent uroflowmetric and postvoid residual analysis. The athletes and the control group were well matched by age. There was no significant difference between the two groups in terms of serum tPSA, fPSA, f/t PSA values, FSH, LH, and testosterone levels and uroflowmetric parameters. The differences between pre- and postcycling values for tPSA, fPSA, f/t PSA, FSH, LH, and uroflowmetric parameters were not statistically significant. The postcycling serum testosterone level was significantly lower than precycling levels (mean, 6034 ng/dL vs
425 ng/dL. There was no correlation between body mass index values, postcycling serum FSH, LH levels, age, and testosterone levels [09098].

Response to marathon running

Exercise is known to be a powerful stimulus for the endocrine system. The hormonal response to exercise is dependent on several factors including the intensity, duration, mode of exercise (endurance versus resistance), and training status of the subject. The aim of one study was to determine the steroid hormonal response (immediately after a race and 1 week later) to endurance exercise under the real conditions of the classic Athens marathon in a group of well-trained, middle-aged, non-elite athletes. Blood samples were drawn 1 week before the race, directly after completion of the race, and 1 week later. Serum cortisol and prolactin showed distinct rises 1 h after the race and returned to baseline 1 week later. Androstenedione and dehydroepiandrosterone sulphate did not show any changes. Total testosterone as well as free testosterone dropped significantly 1 h after the race but returned to baseline 1 week later. In this particular group of non-elite, middle-aged marathon runners, the race resulted in an acute increase in serum cortisol and prolactin levels and in a concomitant decline in testosterone level. The aforementioned changes returned to baseline 1 week later [09099].

Effects on immune system

Intense exercise is known to cause temporary impairments in immune function. Few studies, however, have investigated the effects of intense competitive exercise on immunoendocrine variables in elite team sport athletes. The aim of one study was to evaluate the time course of changes in selected immunoendocrine and inflammatory markers following an international rugby union game. Blood samples were taken from players (n=10) on camp entry, the morning of the game (pre), immediately after (post) and 14 and 38 h into a passive recovery period. Players lost 1.4 ± 0.2 kg of body mass during the game (ambient conditions, 11 degrees C). An acute phase inflammatory response was observed as reflected through immediate significant increases in serum cortisol and IL-6 (post) followed by delayed increases in serum creatine kinase (CK; 14 h) activity and C-reactive protein (CRP; 38 h). Following a large decrease in serum testosterone to cortisol (T/C) ratio immediately post and 14 h after exercise, T/C values then significantly increased above those observed at camp entry 38 h into recovery. This rebound anabolic stimulus may represent a physiological requirement for recovery following intense tissue damage resulting from game collisions [09100].

Testosterone and age

To examine the association between aging and physical function in men by testing a theoretically based model of aging, hormones, body composition, strength, and physical function with data obtained from men enrolled in the Boston Area Community Health/Bone (BACH/Bone) a cross-sectional, observational survey was performed population-based. Testosterone, estradiol, sex hormone-binding globulin, lean and fat mass, grip strength, and summated index of physical function (derived from walk and chair stand tests). Measures of grip strength and physical function declined strongly with age. For instance, 10 years of aging was associated with a 0.49-point difference (scale 0-7) in physical function. Age differences in total testosterone and estradiol concentrations were smaller than age differences in their free fractions. Weak or nonsignificant age-adjusted correlations were
observed between hormones and measures of physical function, although path analysis revealed a positive association between testosterone and appendicular lean mass and a strong negative association between testosterone and total fat mass. Lean and fat mass, in turn, were strongly associated with grip strength and physical function, indicating the possibility that testosterone influences physical function via indirect associations with body composition. The authors concluded that age-related decline in serum testosterone concentration in men has a weak association with physical strength and functional outcomes through its associations with lean and fat mass [08123].

Aging athletes

A high prevalence of late-onset male hypogonadism has been observed in general population. Sport-participation influences the neuroendocrine system and may decrease serum testosterone. One preliminary study was designed to estimate the prevalence and the symptoms of undiagnosed testosterone deficiency in aging athletes. This observational survey was performed in 183 caucasian male athletes >50 years, in the setting of pre-participation screening. Pituitary-gonadal hormones and symptoms of hypogonadism were investigated. Serum total testosterone (TT), sex hormone binding globulin, luteinizing hormone (LH), follicle stimulating hormone (FSH), prolactin (PRL), free-T4, and thyroid stimulation hormone (TSH) were assayed, and free T, bioactive T, and the LH/TT ratio were calculated. The International Index of Erectile Dysfunction (IIEF-15) and the Center for Epidemiological Studies Depression Scale (CES-D) were administered. Hypogonadal athletes were compared with eugonadal athletes as controls. Prevalence and clinical symptoms of severe (TT < 8 nmol/L) or mild (8 nmol/L ≤ TT < 12 nmol/L) testosterone deficiency were investigated. The mean sample age was 62 ± 8 years (range 50-75). Severe or mild testosterone deficiency was observed in 12 and 18 percent, respectively, of overall athletes, with the highest prevalence in athletes >70 years (28 % and 25 %, respectively). TT did not correlate with age, training duration, or questionnaire scores. No differences were observed for nonspecific symptoms of hypogonadism, IIEF-15 and CES-D scores between eugonadal and severe hypogonadal athletes. It was concluded that independently of its etiology, a significant percentage of aging athletes had undiagnosed testosterone deficiency. In a relevant number of these cases, testosterone deficiency was not overtly symptomatic. The results suggest that sport-participation per se can influence the symptoms of hypogonadism. The history of clinical symptoms may be inaccurate to diagnose testosterone deficiency in aging athletes [10082].

In the HORMA (Hormonal Regulators of Muscle and Metabolism in Aging) Trial, supplemental testosterone and recombinant human growth hormone (rhGH) enhanced lean body mass, appendicular skeletal muscle mass, muscle performance, and physical function, but there was substantial interindividual variability in outcomes. One hundred and twelve men aged 65-90 years received testosterone gel (5 g/d vs 10 g/d via Leydig cell clamp) and rhGH (0 vs 3 vs 5 μg/kg/d) in a double-masked 2 × 3 factorial design for 16 weeks. Outcomes included lean tissue mass by dual energy x-ray absorptiometry, one-repetition maximum strength, Margaria stair power, and activity questionnaires. We used pathway analysis to determine the relationship between changes in hormone levels, muscle mass, strength, and function. Increases in total testosterone of 1046 ng/dL (95 % confidence interval 1040 to1051) and 898 ng/dL (95 % confidence interval 892 to 904) were necessary to achieve median increases in lean body mass of 1.5 kg and appendicular skeletal muscle mass of 0.8 kg, respectively, which were required to significantly enhance one-repetition maximum strength (≥ 30 %). Co-treatment with rhGH lowered the testosterone levels (quantified using liquid chromatography-tandem mass spectrometry) necessary to reach these lean mass thresholds. Changes in one-repetition maximum strength were associated with increases in stair climbing power. Pathway analysis supported the model that changes
in testosterone and insulin-like growth factor 1 levels are related to changes in lean body mass needed to enhance muscle performance and physical function. Testosterone's effects on physical activity were mediated through a different pathway because testosterone directly affected Physical Activity Score of the Elderly. To enhance muscle strength and physical function, threshold improvements in lean body mass and appendicular skeletal muscle mass are necessary and these can be achieved by targeting changes in testosterone levels. rhGH augments the effects of testosterone. To maximize functional improvements, the doses of anabolic hormones should be titrated to achieve target blood levels [10456].

**Effects of long flights**

Mild hypobaric hypoxia caused by pressurisation may contribute to alter rhythmicity after long-haul flights, independently of the number of time zones crossed. In this controlled crossover study, we assessed the effects of two levels of hypoxia, equivalent to 8000 ft and 12,000 ft above sea level, on the rhythm of plasma concentrations of three hormones: testosterone, LH, and FSH. A hypoxia-induced decrease in LH and FSH has often been reported during mountaineering while testosterone is considered a marker of fatigue. Sixteen healthy male volunteers, aged 23-39 years, spent 8 h in a hypobaric chamber (08:00-16:30), simulating conditions at 8000 ft. This was followed by an additional 8 h four weeks later, simulating conditions at 12,000 ft. Plasma hormones were assayed every 2 h over two 24-h cycles (control and hypoxic-exposure cycles). It was found no significant effects of hypoxia on the circadian profile of the gonadal axis hormones and, therefore, conclude that these hormones do not serve as valuable markers of post-flight alterations of the circadian system in human [06056].

**Influence of space flights**

Limited data suggest that testosterone is decreased during space flight, which could contribute to bone and muscle loss. The main objective was to assess testosterone and hormone status in long- and short-duration space flight and bed rest environments and to determine relationships with other physiological systems, including bone and muscle. Blood and urine samples were collected before, during, and after long-duration space flight. Samples were also collected before and after 12- to 14-d missions and from participants in 30- to 90-d bed rest studies. Space flight studies were conducted on the International Space Station and before and after Space Shuttle missions. Bed rest studies were conducted in a clinical research center setting. Data from Skylab missions are also presented. All of the participants were male, and they included 15 long-duration and nine short-duration mission crew members and 30 bed rest subjects. Serum total, free, and bioavailable testosterone were measured along with serum and urinary cortisol, serum dehydroepiandrosterone, dehydroepiandrosterone sulfate, and SHBG. Total, free, and bioavailable testosterone was not changed during long-duration space flight but was decreased on landing day after these flights and after short-duration space flight. There were no changes in other hormones measured. Testosterone concentrations dropped before and soon after bed rest, but bed rest itself had no effect on testosterone. Thus, there was no evidence for decrements in testosterone during long-duration space flight or bed rest [11443].

**Effects of diet on testosterone metabolites**

Longitudinal profiling of urinary steroids was investigated by using a gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS) method. The carbon isotope ratio
of three urinary testosterone (T) metabolites: androsterone, etiocholanolone, 5beta-androstane-3alpha,17beta-diol (5beta-androstenediol) together with 16(5alpha)-androstene-3alpha-ol (androstenol) and 5beta-pregnanediol (5beta-pregnanediol) were measured in urine samples collected from three top-level athletes over 2 years. Throughout the study, the subjects were living in Switzerland and were residing every year for a month or two in an African country. $^{13}$C-enrichment larger than 2.5 per thousand was observed for one subject after a 2-month stay in Africa. The findings reveal that $^{13}$C-enrichment caused by a diet change might be reduced if the stay in Africa was shorter or if the urine sample was not collected within the days after return to Switzerland. The steroids of interest in each sample did not show significant isotopic fractionation that could lead to false positive results in antidoping testing. In contrast to the results obtained with the carbon isotopic ratio, profiling of urinary testosterone/epitestosterone (T/E) ratios was found to be unaffected by a diet change [06057].

**Influence of zinc**

There is fairly scarce information about the effects of zinc, an essential trace element, on performance. Studies concerned with the relation between zinc and exercise mostly concentrate on the distribution of this element in the body in response to exercise. The objective of one study was to explore how zinc supplementation affects testosterone levels and its relation with lactate in rats subjected to acute swimming exercise. Thirty adult male rats of Sprague-Dawley species were equally allocated to 3 groups. Group 1: Control. Group 2: Group subjected to 30-minute acute swimming exercise. Group 3: Group supplemented with intraperitoneal (i.p.) zinc (3 mg/kg day) for 4 weeks and subjected to 30-minute swimming exercise. Blood samples collected from all experimental animals by decapitation method were analyzed to determine free and total testosterone and lactate levels in the plasma. Group 3 had the highest free and total testosterone levels, followed by Group 1 and Group 2. The highest lactate levels were found in Group 2 and the levels in Group 3 were higher than those in Group 1. Results of the study demonstrate that zinc supplementation leads to a significant increase in testosterone levels and a significant decrease in lactate levels. In conclusion, physiological doses of zinc supplementation can be useful for performance [06058].

**In hypogonadal men**

Testosterone replacement therapy in hypogonadal men has been used for > 60 years. To describe serum and urinary hormones, androgens metabolites and testosterone/epitestosterone ratio profiles after testosterone administration in male hypogonadal volunteers, and, to evaluate their possible usefulness in detecting doping with testosterone in treated hypogonadal athletes a controlled open label design versus placebo study was performed. There were ten male volunteers affected by severe hypogonadism (serum testosterone < 2.31 ng/mL). Serum and urinary parameters were evaluated, by radioimmunoassay and gas chromatography-mass spectrometry, before and at different time points for seven/three weeks after a single administration of testosterone enanthate (250 mg) or placebo respectively. As partially known, testosterone administration increased, with great individual variability, urinary concentrations of glucuronide testosterone, androsterone, etiocholanolone, 5alphaandrostane-3alpha17betadiol, 5betaandrostane-3alpha17betadiol, testosterone/epitestosterone and testosterone/LH ratios; and decreased epitestosterone and 5alphaandrostane-3beta17betadiol/5betaandrostane-3alpha17betadiol ratio. Serum testosterone and dihydrotestosterone increased in all volunteers, and concentrations higher than the upper reference limits were observed in many volunteers until two weeks after
testosterone administration. Whereas the observed prolonged hyperandrogenism partially limited data interpretation, the reported characteristics of variation of urinary parameters might be used to suspect testosterone misuse in hypogonadal athletes treated with testosterone enanthate. In this sense, while the actual threshold for ratio of testosterone to epitestosterone ratio was confirmed of reduced usefulness, it was suggested a contemporary evaluation of whole urinary androgen metabolites profile and serum androgens, at specific time points after testosterone enanthate administration. Moreover, an adequate tailoring of treatment, to avoid transitory hyperandrogenism, is highly advisable [09104].

Testosterone has a steeply dose-dependent effect on muscle mass and strength irrespective of gonadal status. So, for reasons of fairness, people who engage in competitive sports should not administer exogenous testosterone raising their blood testosterone levels beyond the range of normal. There is a ban on exogenous anabolics for men and women in sports, but an exception has been made for men with androgen deficiency due to pituitary or testicular disease. Men who receive testosterone administration for the indication hypogonadism have an interest in the use of testosterone preparations generating blood testosterone levels within the normal range of healthy, eugonadal men. On the grounds of a positive correlation between blood testosterone concentrations muscle and volume/strength, they are best served with a parenteral testosterone preparation, rather than transdermal testosterone, but they should not run the risk of being excluded from competition because of supraphysiological testosterone levels. The latter is a realistic risk with the traditional parenteral testosterone esters. The new parenteral testosterone undecanoate preparation offers much better perspectives. Its pharmacokinetics have been investigated in detail and there is a fair degree of predictability of resulting blood testosterone levels with use of this preparation [08150].

**Testosterone level as an indicator of gender**

Based on DNA analysis of a historical case, the authors describe how a female athlete can be unknowingly confronted with the consequences of a disorder of sex development resulting in hyperandrogenism emerging early in her sports career. In such a situation, it is harmful and confusing to question sex and gender. Exposure to either a low or high level of endogenous testosterone from puberty is a decisive factor with respect to sexual dimorphism of physical performance. Yet, measurement of testosterone is not the means by which questions of an athlete's eligibility to compete with either women or men are resolved. It might be justifiable to use the circulating testosterone level as an endocrinological parameter, to try to arrive at an objective criterion in evaluating what separates women and men in sports competitions, which could prevent the initiation of complicated, lengthy and damaging sex and gender verification procedures. In 1949, the Dutch track athlete Foekje Dillema (1926–2007) came to prominence on the world athletic stage. She started to rival Fanny Blankers-Koen, the world-famous Dutch track athlete who won four gold medals during the 1948 Summer Olympics in London and was elected Female Athlete of the Century by the International Association of Athletics Federations (IAAF) in 1999. In contrast, Dillema's career was of short duration, with a dramatic ending. In 1950, she was expelled for life by the Royal Dutch Athletics Federation, due to the results of a 'sex test', for which details or results were never revealed and no records are available. Her 1950 national record of 24.1 s for the 200 m, which she took from Fanny Blankers-Koen, was erased, and only after her death 57 years later was she reinstated by the Royal Dutch Athletics Federation. The verification of the sex of athletes has been an issue for many decades. It should be noted that reports and reviews on this topic refer to gender verification, rather than sex verification. However, what counts in competitive sports is a person's sex characteristics. Trying to avoid the word sex,
given its charged nature, can only cause confusion. Herein, it was use the term sex for the biological and physiological characteristics that define men and women, as compared to gender and gender identity in reference to the socially and individually perceived sexual identity of an individual from birth to puberty and adulthood. Sex verification in 1950 was based solely on physical examination, predating hormone assays or sex chromosome analysis. Following discovery of the Barr body in female cells in 1949, it took some 12 years before it was known that this body represents an inactivated X chromosome; from the late 1960s its detection was used in sex verification tests in the context of sports competitions. Subsequent tests focused on the male-specific region of the Y chromosome, particularly the male sex determining SRY gene. However, opposition to sex verification for female athletes with laboratory-based genetic testing developed in the 1970s and 1980s, because these tests did not encompass the complexities of disorders of sex development (DSDs). Since the 2000 Summer Olympics, questioned sex and gender is evaluated on a case-by-case basis by a team of specialists in the areas of endocrinology, genetics, gynaecology and psychology. To broaden the perspective on sportswomen confronted with questioned sex characteristics, we have investigated the case of Foekje Dillema, with informed consent from her heirs, by means of DNA analysis of samples from worn clothing. Appreciating the nature of the samples tested, it was applied DNA methodology and lab quality standards used in human forensics. The DNA analysis indicates that Foekje Dillema had a 46,XX/46,XY mosaic condition with a rare origin, which was interpreted as leading to hyperandrogenism from her puberty [12111].

To have, or not to have, a Y chromosome is the primary decisive factor in human sexual differentiation, but there are exceptions. A prominent example is offered by 46,XY females who have the complete form of androgen insensitivity syndrome (cAIS), when the testes produce testosterone but the body is not able to respond to androgens (testosterone and its more powerful metabolite dihydrotestosterone) due to mutation of the X-encoded androgen receptor. Consequently, these individuals are born and raised as girls, and have a female gender identity. Action of testosterone through binding to the androgen receptor in the developing fetal brain is the predominant factor in programming human male gender identity, and the female gender identity of 46,XY cAIS women is explained by loss of this androgenic effect. In sports, 46,XY cAIS women can be expected to have a disadvantage compared to 46,XX women with a functional androgen receptor, the latter profiting from stimulation of muscle strength by a low level of circulating testosterone. A moderate pubertal and postpubertal excess of testosterone in a young woman can give extra muscle development and other signs of hyperandrogenism, but it would be a rude error to even suggest that this would affect her female gender identity. Competitive athletes exploit fortunate combinations of natural differences in physical and mental personal characteristics, including individual variation of the endogenous testosterone level. The World Anti-Doping Agency states that an athlete's sample will be found positive if the concentration of an endogenous androgenic steroid hormone is above the range normally found in humans, and is not likely consistent with normal endogenous production, unless the elevated concentration of the steroid hormone (or metabolites or markers) is attributable to a physiological or pathological condition. Strictly speaking, a female athlete is free to benefit from any endogenous source of androgen production. Some female athletes may benefit, probably to a small extent, from increased androgen production originating from a polycystic ovary. This is viewed as acceptable by the IAAF, who stated that conditions that may provide some advantages but nevertheless are acceptable include congenital adrenal hyperplasia, androgen-producing tumours and an ovulatory androgen excess associated with a polycystic ovary. According to these regulations, hyperandrogenism caused by ovotesticular DSD would be unacceptable only if sex and gender verification would provide evidence that the female athlete in fact is a man [12111].
Transdermal testosterone

The screening of testosterone (T) misuse for doping control is based on the urinary steroid profile, including T, its precursors and metabolites. Modifications of individual levels and ratio between those metabolites are indicators of T misuse. In the context of screening analysis, the most discriminant criterion known to date is based on the T glucuronide (TG) to epitestosterone glucuronide (EG) ratio (TG/EG). Following the World Anti-Doping Agency (WADA) recommendations, there is suspicion of T misuse when the ratio reaches 4 or beyond. While this marker remains very sensitive and specific, it suffers from large inter-individual variability, with important influence of enzyme polymorphisms. Moreover, use of low dose or topical administration forms makes the screening of endogenous steroids difficult while the detection window no longer suits the doping habit. As reference limits are estimated on the basis of population studies, which encompass inter-individual and inter-ethnic variability, new strategies including individual threshold monitoring and alternative biomarkers were proposed to detect T misuse. The purpose of this study was to evaluate the potential of ultra-high pressure liquid chromatography (UHPLC) coupled with a new generation high resolution quadrupole time-of-flight mass spectrometer (QTOF-MS) to investigate the steroid metabolism after transdermal and oral T administration. An approach was developed to quantify 12 targeted urinary steroids as direct glucuro- and sulfo-conjugated metabolites, allowing the conservation of the phase II metabolism information, reflecting genetic and environmental influences. The UHPLC-QTOF-MSE platform was applied to clinical study samples from 19 healthy male volunteers, having different genotypes for the UGT2B17 enzyme responsible for the glucuroconjugation of T. Based on reference population ranges, none of the traditional markers of T misuse could detect doping after topical administration of T, while the detection window was short after oral TU ingestion. The detection ability of the 12 targeted steroids was thus evaluated by using individual thresholds following both transdermal and oral administration. Other relevant biomarkers and minor metabolites were studied for complementary information to the steroid profile, including sulfoconjugated analytes and hydroxy forms of glucuroconjugated metabolites. While sulfoconjugated steroids may provide helpful screening information for individuals with homozygous UGT2B17 deletion, hydroxy-glucuroconjugated analytes could enhance the detection window of oral testosterone undecanoate (TU) doping [13190].

The legally defensible proof of the abuse of endogenous steroids in sports is currently based on carbon isotope ratio mass spectrometry (IRMS), i.e. a comparison between $^{13}$C/$^{12}$C ratios of diagnostic precursors and metabolites of testosterone. The application of this technique requires a chromatographic baseline separation of respective steroids prior to IRMS detection and hence laborious sample pre-processing of the urinary steroid extracts including clean up by solid-phase extraction and/or liquid chromatography. Consequently, an efficient pre-selection of suspicious control urine samples is essential for appropriate follow up confirmation by IRMS and effective doping control. Two single transdermal administration studies of testosterone (50 mg Testogel® and Testopatch® at 3.8 mg in 16 h, respectively) were conducted and resulting profiles of salivary testosterone and urinary steroid profiles and corresponding carbon isotope ratios were determined. Conventional doping control markers (testosterone/epitestosterone ratio, threshold concentrations of androsterone, etiocholanolone, or androstanediol) did not approach or exceed critical thresholds. In contrast to these moderate variations, the testosterone concentration in oral fluid increased from basal values (30-142 pg/mg) to peak concentrations above 1000 pg/mg. It is likely that this significant increase in oral fluid is due to a pulsatile elevation of free (protein unbound) circulating testosterone after transdermal administration and may be assumed to represent a more diagnostic marker for transdermal testosterone administration [13191].
The screening of testosterone (T) misuse for doping control is based on the urinary steroid profile, including T, its precursors and metabolites. Modifications of individual levels and ratio between those metabolites are indicators of T misuse. In the context of screening analysis, the most discriminant criterion known to date is based on the T glucuronide (TG) to epitestosterone glucuronide (EG) ratio (TG/EG). Following the World Anti-Doping Agency (WADA) recommendations, there is suspicion of T misuse when the ratio reaches 4 or beyond. While this marker remains very sensitive and specific, it suffers from large inter-individual variability, with important influence of enzyme polymorphisms. Moreover, use of low dose or topical administration forms makes the screening of endogenous steroids difficult while the detection window no longer suits the doping habit. As reference limits are estimated on the basis of population studies, which encompass inter-individual and inter-ethnic variability, new strategies including individual threshold monitoring and alternative biomarkers were proposed to detect T misuse. The purpose of this study was to evaluate the potential of ultra-high pressure liquid chromatography (UHPLC) coupled with a new generation high resolution quadrupole time-of-flight mass spectrometer (QTOF-MS) to investigate the steroid metabolism after transdermal and oral T administration. An approach was developed to quantify 12 targeted urinary steroids as direct glucuro- and sulfo-conjugated metabolites, allowing the conservation of the phase II metabolism information, reflecting genetic and environmental influences. The UHPLC-QTOF-MS(E) platform was applied to clinical study samples from 19 healthy male volunteers, having different genotypes for the UGT2B17 enzyme responsible for the glucuroconjugation of T. Based on reference population ranges, none of the traditional markers of T misuse could detect doping after topical administration of T, while the detection window was short after oral TU ingestion. The detection ability of the 12 targeted steroids was thus evaluated by using individual thresholds following both transdermal and oral administration. Other relevant biomarkers and minor metabolites were studied for complementary information to the steroid profile, including sulfoconjugated analytes and hydroxy forms of glucuroconjugated metabolites. While sulfoconjugated steroids may provide helpful screening information for individuals with homozygous UGT2B17 deletion, hydroxy-glucuroconjugated analytes could enhance the detection window of oral T undecanoate (TU) doping [13192].

Age-related hormonal decline is gradual and less recognized in men than in women. Symptoms are oftentimes ignored and non-specific. Fatigue, lack of concentration, mood swings, decreased sexual desire, erectile dysfunction, infertility, hair loss, reduced muscle and bone mass, and weight gain are a few of the symptoms of male hypogonadism. This disorder is linked to reduction in quality of life, and poorer health outcomes as it may increase the risk for cardiovascular disease, diabetes mellitus, metabolic syndrome, Alzheimer's disease and premature death. Different modalities of testosterone replacement therapy have evolved over 70 years, and sales continue to grow. Each preparation is differentiated by route of delivery, ease of use, cost and pharmacokinetics. Topical or transdermal testosterone replacement therapy, including patches and gels, are the most modern formulations on the market. These are more expensive treatments, but yield more physiological concentrations of testosterone. The International Society of Andrology, International Society for the Study of the Aging Male, European Association of Urology, European Academy of Andrology, American Society of Andrology (ISA/ISSAM/EAU/EAA/ASA), the Endocrine Society, and the American Association of Clinical Endocrinologists (AACE) have published clinical practice guidelines for hypogonadism diagnosis, treatment and monitoring that are more or less in general agreement with each other. The ISA/ISSAM/EAU/EAA/ASA proposes 230 ng/dL, the Endocrine Society recommends 300 ng/dL and the AACE suggests 200 ng/dL as the lower limit of serum total testosterone at which patients will benefit from testosterone replacement therapy (TRT). Total testosterone is the most widely used measurement for establishing biochemical hypogonadism. Free testosterone should be measured when total testosterone
is nondiagnostic, such as in chronic illness, obesity and alcoholism; however, parameters are lacking. The Endocrine Society and AACE recommend against TRT in patients with haematocrit >50 percent. ISA/ISSAM/EAU/EAA/ASA proposes dose adjustments and/or periodic phlebotomy to keep haematocrit <52–55 percent. TRT stimulates the bone marrow production of erythrocytes, resulting in increased haematocrit in some men, with the possibility of hyperviscosity side effects. Restoration of testosterone levels to the eugonadal range reverses signs and symptoms of hypogonadism, except for infertility, and may alleviate co-morbidities associated with hypogonadism. The risks of TRT are few, but in theory there have been concerns about worsening of benign prostatic hyperplasia (BPH), acceleration of pre-existing prostate cancer, exacerbation of sleep apnoea and congestive heart failure, increased risk for liver toxicity and tumour, gynecomastia, testicular atrophy and infertility, acne and oily skin and hair loss. Patient understanding of and compliance with both treatment and monitoring are of utmost importance to achieve clinical success with maximum benefit and minimum risk [12008].

Topical preparations

Commercially available testosterone replacement therapy (TRT) preparations have evolved from invasive to non-invasive treatments over the past 70 years. What initially began as subdermal testosterone pellet implants in 1940, evolved to intramuscular testosterone esters in 1954, to oral testosterone undecanoate in 1977, to transdermal delivery as scrotal patches in 1992, as non-scrotal patches in 1995, as topical gels in 2002, and as underarm roll-on solution in 2010. Other recent additions to TRT are the shortacting buccal testosterone and the long-acting intramuscular testosterone undecanoate, used extensively in Europe. Nasal sprays and oral preparations are currently under development. Choosing among these different preparations requires an understanding of their pharmacokinetics. The intramuscular testosterone esters are popular forms of TRT since they are inexpensive and require infrequent dosing. Testosterone propionate is administered every 2 to 3 days. Testosterone enanthate and cypionate are administered every 2 to 3 weeks, gain peak concentrations shortly after injection, and decline gradually after 7 to 15 days. New on the market is the longer-acting testosterone undecanoate (Nebido®) that is administered every 12-16 weeks, approximately 4 times a year. The drawbacks of intramuscular testosterone administration are the discomfort of injections, the resulting wide peak-to-trough fluctuations in serum testosterone levels, leading to instability in mood, libido and sexual function, and the inability to rapidly withdraw treatment if necessitated by adverse effects. The subdermal testosterone pellet implants are used commonly outside of the US. About 3 to 6 pellets of 200 mg unmodified testosterone are implanted subcutaneously every 4 to 6 months, providing stable physiological levels of testosterone. Downsides include discomfort and inconvenience from required minor surgery, extrusion of the pellets, and rarely, bleeding, infection and fibrosis at insertion site. The oral testosterone undecanoate, although a popular route of delivery, has disappeared from the market. It requires multiple, high daily doses due to low bioavailability (rapidly inactivated by first-pass hepatic metabolism). It carries the risks of gastrointestinal upset and hepatotoxicity, including cholestatic jaundice, hepatic tumours and vascular abnormalities of the liver. Buccal testosterone bypasses first-pass hepatic metabolism by entering the venous drainage from the mouth into the superior vena cava. The shortacting buccal testosterone (Striant®) is new to the market and contains testosterone 30 mg applied twice daily to a depression in the gums above the incisors. It restores physiological testosterone and dihydrotestosterone (DHT) levels within 4 hours after application, and steady-state concentrations are achieved within 24 hours. Side effects are gum irritation, which resolves over time, and low possibility of secondary transference via saliva [12008].
Transdermal preparations

Scrotal patches were the first transdermal TRT on the market but have now been replaced by non-scrotal patches and gels. In general, the gels cost more than the patches. According to Intercontinental Marketing Services Health 2009 data, global sales of testosterone therapies have grown to more than USD 1 billion per year, with sales of testosterone gels in the US accounting for USD 700 million. The major advantages of transdermal delivery include ease of use, avoidance of peaks and troughs found with other routes, and maintenance of relatively stable serum testosterone concentrations, leading to stability in energy, mood and libido. Topical preparations also appear to be associated with lesser risk of erythrocytosis and minimal effects on lipid profiles compared with intramuscular injections, and do not appear to be associated with hepatoxicity compared with oral forms containing methylated testosterone. The scrotal testosterone patch (Testoderm®), no longer available on the market, enables rapid absorption through the thin, highly vascularized scrotal skin. The scrotal skin has high 5alpha-reductase activity, which catalyzes the conversion of testosterone to DHT. It has been found that the scrotal testosterone patch delivers physiological levels of testosterone, but supraphysiological levels of DHT, which raised concerns regarding its long-term effects on the prostate gland. It also requires clipping of scrotal hair prior to nightly application, and use of brief-type underwear after application. The non-scrotal testosterone patch (Androderm®), still available in the market, comes in different patch sizes and doses (2, 2.5, 4 and 5 mg), and is worn nightly for 24 hours on the back, thigh, upper arm or abdomen. The 2 mg patch has a total contact surface area of 32 cm² with a 6.0 cm² central drug delivery reservoir containing testosterone 9.7 mg unique selling proportion (USP) for delivery of testosterone 2 mg per day, while the 4 mg patch has a total contact surface area of 39 cm² with a 12.0 cm² central drug delivery reservoir containing testosterone 19.5 mg USP for delivery of testosterone 4 mg per day. Testosterone USP is a white crystalline powder or crystals chemically described as 17X-hydroxyandrost-4-en-3-one. The adhesive side of the patch should be applied to a clean, dry area, and not over bony prominences or on a part of the body that may be subject to prolonged pressure. The recommended starting dose is one 4 mg/day system (not two 2 mg/day systems) applied nightly for 24 hours, delivering approximately 4 mg of testosterone per day. Skin rash (66 %) is a side effect of the patch, and necessitates discontinuation of therapy if quite severe. The rash may sometimes be prevented by topical corticosteroid pretreatment. Testosterone is continuously absorbed over a 24-hour dosing period through a non-rate-limiting microporous membrane with mean minimum testosterone concentration (Cmin) of 280 ng/dL, time-average testosterone concentration (Cave) of 517 ng/dL, maximum plasma testosterone concentration (Cmax) of 765 ng/dL, and time to Cmax (tmax) of 8 hours. An increase from 1 to 3 transdermal testosterone patches results in a linear increase in cumulative amounts of testosterone released. The use of three transdermal systems yields supraphysiological levels of testosterone, which is of possible benefit for patients who fail 1- and 2-patch regimens, particularly obese hypogonadal men. The optimal sites for this transdermal system are the back > thigh > upper arm > abdomen. The chest and the shin have lower and more variable rates of absorption. During steadystate, the average DHT:T and estradiol (E2):T ratios were approximately 1:10 and 1:200, respectively. Upon removal of the patch, serum testosterone concentrations decrease with an apparent half-life of 1.3 hours, and reach hypogonadal concentrations within 24 hours. There is no accumulation of testosterone during continuous treatment [12008].

Gels and solutions

The testosterone gels are widely available on the market. Skin rash (6 %) can also occur with gels, but is usually less severe and rarely results in discontinuation of therapy as it can the
patch. The primary concern with gels is potential for secondary exposure to another person, particularly to children, which in theory may result in inappropriate enlargement of genitalia, premature development of pubic hair, advanced bone age, increased libido, aggressive behaviour, and central or peripheral precocious puberty. Careful practices after every application, such as thoroughly washing hands and avoiding skin contact with another person, would avoid these consequences. Patients are also advised to avoid swimming or showering or washing the administration site for a minimum of 2 hours after application. Testim® is a clear-to-translucent gel that comes in 5 g and 10 g tubes, which contain 50 mg and 100 mg of testosterone, respectively. The recommended starting dose is 50 mg of testosterone (one 5 g tube) applied once daily in the morning to the shoulders and upper arms. It is generally well tolerated and is effective at raising testosterone levels, but requires a comparatively large weight of medication to be applied. It also has a musky odour that some patients do not like. Testogel/Androge® is a clear, odourless formulation that comes in a multi-dose pump. Each compression of the pump yields 1.25 g of gel, containing 12.5 mg of testosterone. The recommended starting dose is 50 mg of testosterone (four pump actuations) applied topically once daily in the morning to the shoulders, upper arms or stomach. Testim® has a more favourable pharmacokinetic profile than the testosterone patches (Andropatch® and Androderm®) and than another testosterone gel (Androgel®). This is likely attributable to the inclusion of pentadecalactone in the formulation, which provides increased emollient qualities and therefore is less drying to the skin, enabling higher testosterone absorption. Approximately 10 percent of the applied testosterone dose is absorbed across skin of average permeability, and provides continuous transdermal delivery of testosterone over a 24-hour period. Testosterone and DHT concentrations increase in parallel. In a 30-day efficacy trial response in sexual activity, desire and mood improved within the first week of Testim® use, with maximal response by the end of 2 weeks, and was maintained throughout the study. In a 90-day European trial, Testim® gel at two doses (50 and 100 mg/day, delivering 5 and 10 mg daily doses of testosterone, respectively) showed a significantly higher improvement of sexual function, motivation and desire and performance; a higher incidence of spontaneous erections; a higher reduction of percentage fat; and fewer adverse skin reactions than Andropatch® (two 2.5 mg patches, each delivering 12.2 mg of testosterone). These data are comparable to a 90-day US trial comparing Testim® gel (50 mg and 100 mg/day doses), Androderm® (two 2.5 mg patches), and a placebo gel. After 90 days, Testim® 100 mg/day showed significant improvements in sexual motivation, desire and performance, and a higher number of spontaneous erections than placebo. Both the Testim® 50mg and 100mg/day doses also showed significantly improved lean body mass, and reduced fat mass and fat percentage than the patch and the placebo. In a bioequivalence study comparing two commercially available testosterone gels, Testim® provided higher serum levels and greater bioavailability than Androgel®. TheCmax and the 24-hour systemic availability (area under the plasma concentration-time curve; AUC0–24) estimates for Testim® of total testosterone, DHT and free testosterone were 30 percent and 30, 19 and 11 percent, and 38 and 47 percent higher than for Androgel®, respectively. In a 180-day trial, serum testosterone concentrations increased to physiological range within first day of treatment with Androgel® 1 percent testosterone gel applied to arms, shoulders or abdomen. These levels were maintained in 87 percent of the study patients for the entire duration of the study. In another trial, gel application to four separate sites produced slightly higher, but not statistically significant, concentrations than repeated application to only one site. This suggested that the surface area of gel application had only a modest impact on the pharmacokinetic parameters of testosterone concentration. Androgel® has a newer, more concentrated, 1.62 percent low-volume formulation that allows the amount of applied gel required to be reduced, with each compression of the pump yielding 1.25 g of gel, containing 20.25 mg of testosterone. The recommended starting dose for this newer 1.62 percent formulation is 41 mg of testosterone (two pump actuations) applied topically once daily in the morning to the shoulders and upper arms, and titrated between 1.25 and 5.0 g a day. The
newer Androgel® 1.62 percent formulation has increased viscosity, reduced volume of application and increased skin permeation compared with the 1 percent gels, and is found to be safe, efficacious and well tolerated. More than 77 percent of hypogonadal men achieved normal serum testosterone levels as reported in a 12-month trial. In a cross-over trial, pharmacokinetics and relative bioavailability were compared following application of 5 g (81 mg of testosterone dose) daily of Androgel® 1.62 percent testosterone gel for 7 days to the abdomen, the upper arms/shoulders, or alternating abdomen and upper arms/shoulders. On both days 1 and 7, mean serum testosterone, DHT and E2 concentrations were higher for the upper arms/shoulders group than for the abdomen group. The alternating sites group yielded concentrations similar to the abdomen group on day 1 (both applied to the abdomen), and to the upper arms/shoulders group on day 7 (both applied to the upper arms/shoulders). Approximately 30-40 percent lower testosterone bioavailability was observed when applied to the abdomen than to the upper arms/shoulders, but both sites still yielded eugonadal serum testosterone levels (300 to 1000 ng/dL). Steady-state testosterone concentrations were achieved by day 2 on either site. After administration of the last dose, serum testosterone concentrations return to hypogonadal levels within 48 hours after abdominal application, and 72 hours after application to upper arms/shoulders. Skin washing as early as 2 hours after gel application had little impact on bioavailability and was effective in reducing residual testosterone on the skin to prevent secondary transference. Recently developed 2 percent testosterone gels are marketed as Tostran®, Fortigel®, Itnogen®, Tostrex®, and Fortesta®. Patients find this 2 percent concentration a favourable TRT because it is low in volume, and is easy to apply and titrate. Fortesta®, for example, is a clear, odourless gel that also comes in a metered-dose pump. Each pump compression delivers 0.5 g of gel, containing 10 mg of testosterone. It is applied to the front and inner thighs, and not the upper body, with a recommended starting dose of 40 mg of testosterone (four pump actuations) once daily in the morning, and titrated between 10 and 70 mg per day in 10 mg increments, as determined by the serum testosterone concentration. It is generally well tolerated, with the most common side effect being mild to moderate transient skin reactions, without serious adverse reactions. In a 90-day trial, once-daily topical application of 2 percent testosterone gel restored normal levels of testosterone in more than 75 percent of hypogonadal patients, with a low risk of supraphysiological testosterone levels. It provides steady levels throughout the day, with mean $C_{\text{ave}}$ of 438.6 ng/dL, and $C_{\text{max}}$ of 827.6 ng/dL at day 90, and more than 80 percent of subjects only required 60 mg testosterone or less. Axiron® is the newest option for topical TRT, and is actually the first pharmaceutical product to be applied underarm. It is a fragrance-free testosterone solution that comes in a metered-dose pump with a silicone applicator (rather than using hands), with each pump depression delivering 1.5 mL of solution containing 30 mg of testosterone. The recommended starting dose is 60 mg of testosterone (one pump actuation to each axilla, no shaving required) once every morning, and adjusted to a minimum of 30 mg and maximum of 120 mg daily, as judged by the serum testosterone concentration from a single blood draw 2 to 8 hours after applying the testosterone solution and at least 14 days after starting treatment or following dose adjustment. After application of the solution to the axillae, ethanol and isopropanol evaporate, leaving testosterone and octisalate. The octisalate is a thickening agent that increases the permeability of testosterone, which becomes absorbed through the skin to the systemic circulation over time. In a 120-day efficacy trial, 84 percent of hypogonadal men achieved eugonadal testosterone concentrations (300 to 1050 ng/dL). Steady-state serum testosterone, free testosterone and DHT were attained by day 15 of daily dosing of the standard initial dose of 60 mg of testosterone. Significant improvements in mood, sexual desire and activity, and general physical and mental health were noted. Adverse events reported include mild skin irritation, erythema and oedema. Deodorant and antiperspirants do not interfere with the efficacy of Axiron® [12008].
Male hypogonadism is a significant and growing problem that can be successfully treated with testosterone replacement therapy. A new formulation of testosterone gel (1.62%) was developed with increased viscosity, reduced volume of application, and increased skin permeation compared with other currently available testosterone gels. It was evaluated the efficacy and safety of titrated doses of 1.62 percent testosterone gel after daily application to the skin of hypogonadal men for 182 days. It was a multicenter, randomized, double-blind, placebo-controlled study in hypogonadal men (234 active; 40 placebo), 18 to 80 years of age with average serum total testosterone concentrations <300 ng/dL and prostate-specific antigen <2.5 ng/mL. Topical testosterone gel (1.62%), 1.25 g, 2.5 g, 3.75 g, and 5.0 g, or placebo gel was applied once daily to either upper arms/shoulders or abdomen. Dose adjustments were made on days 14, 28, and 42. The percentage of subjects with serum total testosterone average concentrations within the normal range of 300-1,000 ng/dL on study days 14, 56, 112, and 182. Following titration, significantly more subjects receiving active treatment had testosterone C values (range 82% to 83%) within the eugonadal range compared with placebo (range 29% to 37%) on all study days. The 1.62 percent gel was safe and well tolerated. It was concluded that, treatment with 1.62 percent testosterone gel was safe and efficacious, resulting in an acceptable percentage of hypogonadal males achieving eugonadal serum testosterone levels.

Current approaches to diagnosing testosterone deficiency do not consider the physiological consequences of various testosterone levels or whether deficiencies of testosterone, estradiol, or both account for clinical manifestations. It was provided 198 healthy men 20 to 50 years of age with goserelin acetate (to suppress endogenous testosterone and estradiol) and randomly assigned them to receive a placebo gel or 1.25 g, 2.5 g, 5 g, or 10 g of testosterone gel daily for 16 weeks. Another 202 healthy men received goserelin acetate, placebo gel or testosterone gel, and anastrozole (to suppress the conversion of testosterone to estradiol). Changes in the percentage of body fat and in lean mass were the primary outcomes. Subcutaneous- and intraabdominal-fat areas, thigh-muscle area and strength, and sexual function were also assessed. The percentage of body fat increased in groups receiving placebo or 1.25 g or 2.5 g of testosterone daily without anastrozole (mean testosterone level, 44 ± 13 ng per deciliter, 191 ± 78 ng per deciliter, and 337 ± 173 ng per deciliter, respectively). Lean mass and thigh-muscle area decreased in men receiving placebo and in those receiving 1.25 g of testosterone daily without anastrozole. Leg-press strength fell only with placebo administration. In general, sexual desire declined as the testosterone dose was reduced. The amount of testosterone required to maintain lean mass, fat mass, strength, and sexual function varied widely in men. Androgen deficiency accounted for decreases in lean mass, muscle size, and strength; estrogen deficiency primarily accounted for increases in body fat; and both contributed to the decline in sexual function. The findings support changes in the approach to evaluation and management of hypogonadism in men.

Effect of postexercise ethanol ingestion

Alcohol (ethanol) and resistance exercise can independently affect circulating bioavailable testosterone concentration. The purpose of one study was to examine the testosterone bioavailability and the anabolic endocrine milieu in response to acute ethanol ingestion after a bout of heavy resistance exercise. Eight resistance-trained men (25 years) completed two identical acute heavy resistance exercise tests (AHRET: six sets of 10 repetitions of Smith machine squats) separated by 1 week. Post-AHRET, participants consumed either 1.09 g of grain ethanol per kilogram lean mass (EtOH condition) or no ethanol (placebo condition). Blood samples were collected immediately before exercise (PRE), immediately after exercise.
(IP), and every 20 min postexercise for 300 min. Samples after IP were pooled into phases (20-40 min, 60-120 min, and 140-300 min after exercise) and analyzed for total testosterone (TT) and free testosterone (FT), sex hormone-binding globulin (SHBG), cortisol, and estradiol. Peak blood ethanol concentration (0.088 ± 0.015 g/dL) was achieved 60-90 min postexercise. TT and FT were elevated significantly at IP for both conditions. At 140-300 min postexercise, TT, FT, and free androgen index were significantly higher for EtOH (TT: 22.5 ± 12.5 nmol·L; FT: 40.5 ± 7.6 pmol·L) than for placebo (TT: 13.9 ± 6.8 nmol·L; FT: 22.7 ± 10.0 pmol·L). No differences between conditions were noted for SHBG, cortisol, or estradiol. It was concluded that postexercise ethanol ingestion affects the hormonal milieu including testosterone concentration and bioavailability during recovery from resistance exercise [13204].

Effect on cocaine's vascular effects

Neural plasticity has been observed in the bed nucleus of the stria terminalis (BNST) following exposure to both cocaine and androgenic-anabolic steroids. Here we investigated the involvement of the BNST on changes in cardiovascular function and baroreflex activity following either single or combined administration of cocaine and testosterone for 10 consecutive days in rats. Single administration of testosterone increased values of arterial pressure, evoked rest bradycardia and reduced baroreflex-mediated bradycardia. These effects of testosterone were not affected by BNST inactivation caused by local bilateral microinjections of the nonselective synaptic blocker CoCl2. The single administration of cocaine as well as the combined treatment with testosterone and cocaine increased both bradycardiac and tachycardiac responses of the baroreflex. Cocaine-evoked baroreflex changes were totally reversed after BNST inactivation. However, BNST inhibition in animals subjected to combined treatment with cocaine and testosterone reversed only the increase in reflex tachycardia, whereas facilitation of reflex bradycardia was not affected by local BNST treatment with CoCl2. In conclusion, the present study provides the first direct evidence that the BNST play a role in cardiovascular changes associated with drug abuse. Our findings suggest that alterations in cardiovascular function following subchronic exposure to cocaine are mediated by neural plasticity in the BNST. The single treatment with cocaine and the combined administration of testosterone and cocaine had similar effects on baroreflex activity, however the association with testosterone inhibited cocaine-induced changes in the BNST control of reflex bradycardia. Testosterone-induced cardiovascular changes seem to be independent of the BNST [13205].

Interaction with NSAIDs

Testosterone and epitestosterone are secreted mainly as glucuronide metabolites and the urinary ratio of testosterone glucuronide to epitestosterone glucuronide, often called T/E, serves as a marker for possible anabolic steroids abuse by athletes. UDP-glucuronosyltransferase (UGT) 2B17 is the most important catalyst of testosterone glucuronidation. The T/E might be affected by drugs that interact with UGT2B17, or other enzymes that contribute to testosterone glucuronidation. Non-steroidal anti-inflammatory drugs (NSAIDs) are commonly used by sportsmen and we have examined the effect of two NSAIDs, diclofenac and ibuprofen, on testosterone and epitestosterone glucuronidation in human liver microsomes. In parallel, we have studied the inhibitory effect of these NSAIDs on recombinant UGT2B17 and UGT2B15, as well as other human hepatic UGTs that revealed low but detectable testosterone glucuronidation activity, namely UGT1A3, UGT1A4, UGT1A9 and UGT2B7. Both diclofenac and ibuprofen inhibited testosterone glucuronidation.
in microsomes, as well as UGT2B15 and UGT2B17. Interestingly, UGT2B15 was more sensitive than UGT2B17 to the two drugs, particularly to ibuprofen. Human liver microsomes lacking functional UGT2B17 exhibited significantly higher sensitivity to ibuprofen, suggesting that UGT2B15 plays a major role in the residual testosterone glucuronidation activity in UGT2B17-deficient individuals. Nonetheless, a minor contribution of other UGTs, particularly UGT1A9, to testosterone glucuronidation in such individuals cannot be ruled out at this stage. The epitestosterone glucuronidation activity of human liver microsomes was largely insensitive to ibuprofen and diclofenac. Taken together, the results highlight potential interactions between NSAIDs and androgen glucuronidation with possible implications for the validity of doping tests [09105].

**Influence on gastric ulcer precursors**

In one study, it was demonstrated that Helicobacter pylori absorbs a steroid prehormone (pregnenolone) and two androgens (dehydroepiandrosterone and epiaンドロステロン), glucosylates these steroids, and utilizes glucosyl-steroid hormone compounds as the membrane lipid components. The only common structure among the steroid prehormone and the two androgens is a 3beta-OH in the steroid framework. The results indicate that the 3beta-OH in the steroid hormones is a crucial conformation required for steroid glucosylation by H. pylori. In addition, it was found that H. pylori absorbs and holds estrogens possessing 3-OH (estrone and estradiol) into the membrane. The effective absorption of estrogen into the membrane appeared to be controlled by the number of hydroxyl groups modifying the steroid framework. In contrast, H. pylori induced neither membrane absorption nor glucosylation of the other steroid hormones possessing 3=O (progesterone, androstenedione and testosterone) or 3alpha-OH (androsterone). These results indicate that H. pylori selectively absorbs 3beta-OH and 3-OH steroid hormones, and utilizes only 3beta-OH steroid hormones as the materials for glucosylation [09106].

**Laboratory techniques**

The metabolic effect of multiple oral testosterone undecanoate (TU) doses over 4 weeks was assessed in seven voluntary men. The protocol was designed to detect accumulation of the substance by choosing the appropriate spot urines collections time and to study the urinary clearance of the substance after weeks of treatment. Urines were analysed by a new GC/C/isotope ratio mass spectrometry (IRMS) method to establish the delta 13C-values of testosterone metabolites (androsterone and etiocholanolone) together with an endogenous reference compound (16(5alpha)-androsten-3alpha-ol). The significant differences in inter-individual metabolism following TU intake was illustrated by large variations in delta 13C-values of both T metabolites (maximum Deltadelta 13C-values = 5.5 per thousand), as well as by very stable longitudinal T/E profiles and carbon isotopic ratios in the first hours following administration. According to T/E ratios and delta(13)C-values, the washout period after 80 mg TU intake was less than 48 h for all subjects and no accumulation phenomenon was observed upon chronic oral administration [06062].

Testosterone abuse is conventionally assessed by the urinary testosterone/epitestosterone (T/E) ratio, levels above 4.0 being considered suspicious. A deletion polymorphism in the gene coding for UGT2B17 is strongly associated with reduced testosterone glucuronide (TG) levels in urine. Many of the individuals devoid of the gene would not reach a T/E ratio of 4.0 after testosterone intake. Future test programs will most likely shift from population based- to individual-based T/E cut-off ratios using Bayesian inference. A longitudinal analysis is
dependent on an individual's true negative baseline T/E ratio. The aim was to investigate whether it is possible to increase the sensitivity and specificity of the T/E test by addition of UGT2B17 genotype information in a Bayesian framework. A single intramuscular dose of 500mg testosterone enanthate was given to 55 healthy male volunteers with either two, one or no allele (ins/ins, ins/del or del/del) of the UGT2B17 gene. Urinary excretion of TG and the T/E ratio was measured during 15 days. The Bayesian analysis was conducted to calculate the individual T/E cut-off ratio. When adding the genotype information, the program returned lower individual cut-off ratios in all del/del subjects increasing the sensitivity of the test considerably. It will be difficult, if not impossible, to discriminate between a true negative baseline T/E value and a false negative one without knowledge of the UGT2B17 genotype. UGT2B17 genotype information is crucial, both to decide which initial cut-off ratio to use for an individual, and for increasing the sensitivity of the Bayesian analysis [10079].

The determination of the carbon isotope ratio in androgen metabolites has been previously shown to be a reliable, direct method to detect testosterone misuse in the context of antidoping testing. Here, it was examine the variability in the $^{13}$C/$^{12}$C ratios in urinary steroids in a widely heterogeneous cohort of professional soccer players residing in different countries (Argentina, Italy, Japan, South-Africa, Switzerland and Uganda). Carbon isotope ratios of selected androgens in urine specimens were determined using gas chromatography/combustion/isotope ratio mass spectrometry (GC-C-IRMS). Urinary steroids in Italian and Swiss populations were found to be enriched in $^{13}$C relative to other groups, reflecting higher consumption of C3 plants in these two countries. Importantly, detection criteria based on the difference in the carbon isotope ratio of androsterone and pregnanediol for each population were found to be well below the established threshold value for positive cases. The results obtained with the tested diet groups highlight the importance of adapting the criteria if one wishes to increase the sensitivity of exogenous testosterone detection. In addition, confirmatory tests might be rendered more efficient by combining isotope ratio mass spectrometry with refined interpretation criteria for positivity and subject-based profiling of steroids [09107].

Carbon isotope ratio of androgens in urine specimens is routinely determined to exclude an abuse of testosterone or testosterone prohormones by athletes. Increasing application of gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS) in the last years for target and systematic investigations on samples has resulted in the demand for rapid sample throughput as well as high selectivity in the extraction process particularly in the case of conspicuous samples. For that purpose, it was presented herein the complimentary use of an SPE-based assay and an HPLC fractionation method as a two-stage strategy for the isolation of testosterone metabolites and endogenous reference compounds prior to GC/C/IRMS analyses. Assays validation demonstrated acceptable performance in terms of intermediate precision (range: 0.1-0.4 per thousand) and Bland-Altman analyses revealed no significant bias (0.2 per thousand) [09108].

It is necessary to develop a sensitive and simple method to monitor testosterone and its epimer epitestosterone. An off-line immunoaffinity extraction followed by capillary electrophoresis for simultaneous determination of testosterone and epitestosterone has been described in this paper. Anti-epitestosterone monoclonal antibody which is specific to both testosterone and epitestosterone had been prepared and immobilized on a Sepharose 4B stationary phase. The immunoaffinity column was used for sample cleanup, extraction and preconcentration. After elution and reconstitution, testosterone and epitestosterone in the sample were separated and quantified by micellar electrokinetic chromatography. The immunoaffinity column was evaluated in different parameters such as the retention mechanism, selectivity, binding capacity, elution protocol, and reusability. It was satisfactory to apply this method to analyze testosterone and epitestosterone in spiked urine sample with
Athletes have increasingly used testosterone and other endogenous anabolic steroids that cannot be detected by conventional gas chromatography-mass spectrometry. This led to gas chromatography-combustion-isotope ratio mass spectrometry (GC/C/IRMS), which measures the relative amount of $^{13}$C in urinary steroids. Because exogenous testosterone is relatively low in $^{13}$C content, this study will determine if consuming a diet low in $^{13}$C plants, such as soy, can be confused with a GC/C/IRMS-positive test for exogenous testosterone. A cross-sectional study in which 22 vegetarians known to consume a diet depleted of $^{13}$C isotope were compared with a geographic control group of 14 subjects consuming a normal diet. Comparisons were made with respect to dietary analysis, isoflavones, and urinary steroid measurements using GC-C-IRMS. The delta$^{13}$C values for 2 major metabolites of testosterone (androsterone and etiocholanolone) were significantly lower for the vegetarians than the controls. The vegetarians excreted a median of 23 micromol/d of total isoflavones compared with 2.7 micromol/d for the control group, which was a significant difference. The carbon isotope ratios of urinary testosterone metabolites of vegetarians consuming a diet that is markedly depleted of $^{13}$C content were lower than that of control subjects, but not low enough to result in World Anti-Doping Agency criteria for a positive IRMS analysis [09110].

The metabolism of testosterone is revisited. Four previously unreported metabolites were detected in urine after hydrolysis with KOH using a liquid chromatography-tandem mass spectrometry method and precursor ion scan mode. The metabolites were characterized by a product ion scan obtained with accurate mass measurements. Androsta-4,6-dien-3,17-dione, androsta-1,4-dien-3,17-dione, 17-hydroxy-androsta-4,6-dien-3-one and 15-androsten-3,17-dione were proposed as feasible structures for these metabolites on the basis of the mass spectrometry data. The proposed structures were confirmed by analysis of synthetic reference compounds. Only 15-androsten-3,17-dione could not be confirmed, owing to the lack of a commercially available standard. That all four compounds are testosterone metabolites was confirmed by the qualitative analysis of several urine samples collected before and after administration of testosterone undecanoate. The metabolite androsta-1,4-dien-3,17-dione has a structure analogous to that of the exogenous anabolic steroid boldenone. Specific transitions for boldenone and its metabolite 17β-hydroxy-5β-androst-1-en-3-one were also monitored. Both compounds were also detected after KOH treatment, suggesting that this metabolic pathway is involved in the endogenous detection of boldenone previously reported by several authors [10457].

A sensitive and rapid liquid chromatographic (LC) method for the simultaneous determination of testosterone (T) and epitestosterone (E) in human urine samples has been developed and elaborated. The ratio of the both steroids (T/E) in human urine is a widely used as doping control indicator. A sample pretreatment by solid-phase extraction (SPE) after hydrolysis using 36% hydrochloric acid for determination of total level of T has been applied. Unconjugated (free) forms of the both androgens were determined without hydrolysis steps, what makes novelty of the method, because simplifies the proposed procedure. In turn, the measurements of urinary free T and E provided the diagnostic information for excess adrenal production of steroids. The proposed LC assay was evaluated by analyzing a series of urine samples containing T, E and methytestosterone (MT) as internal standard at the range of concentration 2-300 ng/mL of both analyzed hormones. The proposed method was fully validated for specificity, linearity, limits of detection and quantitation, precision and trueness according to the current requirements concerning analytical methods. Interestingly, the developed LC method allows to obtain a sensitive enhancement with respect to UV detection with the quantitation limit for T and E equaled 2 ng/mL. The method was selective and reliable for identity and enables to detect changes of endogenous levels of T and E in urine independently of fluctuations characteristic for both analyzed endogenous hormone level in
It was presented a powerful 3D sensing platforms using novel disc-ring microelectrode array devices and exploit them for the competitive immunosensing of testosterone. Each device contains a microelectrode array that consists of a large number of individual microdiscs and is used as the substrate for immune-functionalization and assay performance. One micrometer above it, a second microelectrode array, this time consisting of microrings, is used as the working electrode for electrochemical monitoring. The physical separation of these two functions allows the incorporation of relatively thick biocomponent layers during immunofunctionalization of the microdiscs without negatively affecting electrochemical detection at the rings. Moreover, it permits electrochemical activation of the latter immediately before substrate addition and hence enables optimal electrode performance. The optimized assay showed a linear range between 0.01 and 10 ng/mL and a limit of detection of 12.5 pg/mL testosterone with detection times of 45 min [11078].

The detection of an intact ester of testosterone in plasma is leading towards unequivocal proof of the administration of exogenous testosterone. In the current study, a sensitive screening method for the detection of nine testosterone esters in human plasma was developed. By preparing oxime derivatives of intact testosterone esters, the sensitivity of the assay was increased. Furthermore, the method included liquid-liquid extraction (LLE) as sample clean-up, as well as online separation of the target analytes from the derivatization solution. The analysis was performed by liquid chromatography (LC) coupled to tandem mass spectrometry (MS/MS). The method developed herein is simple and rapid, and was validated according to World Anti-Doping Agency (WADA) guidelines [13216].

**Testosterone versus epitestosterone**

Ordinarily, testosterone and epitestosterone are produced in equal amounts, and testosterone cannot be converted to epitestosterone. Accordingly, use of exogenous testosterone should increase the relative amount of testosterone versus epitestosterone (T/E ratio). The first tests at the 1983 Pan American Games used a 6:1 T/E ratio as the cut-off for a positive test. Fifteen athletes tested positive; additional athletes withdrew from competition and were not tested. Athletes soon recognized that taking epitestosterone along with testosterone could prevent a positive drug test. For this reason, epitestosterone is included on WADA’s list of prohibited substances. In 2005, WADA reduced the upper limit for an allowable T/E ratio to 4:1. Epitestosterone changes, or more importantly, changes in the T/E ratio as a function of winning or losing a competition are unstudied. The mechanisms of epitestosterone production, synthesis, and binding are still not well characterized. Knowing that the T/E ratio is a critical metric of doping and that competition alters testosterone concentrations, should anti-doping agencies be concerned that the T/E ratio may be subject to systematic fluctuations as a function of exertion, competition, victory and defeat? Knowing that testosterone concentrations can change up to 100 percent post-competition, false positives in doping assessment based on the T/E ratio are plausible. This is especially true for winners, who tend to experience testosterone increases from both winning and exertion and are most likely to be tested post-competition [12100].

A series of molecularly imprinted polymers have been prepared and investigated as stationary phases in high performance liquid chromatography for the separation of testosterone and epitestosterone using non-polar mobile phases. The polymers were imprinted using 5alpha-dihydrotestosterone as template, and all retain testosterone more strongly than its 17alpha-OH epimer. The best polymer was prepared using trifluoromethylacrylic acid as functional monomer (interacting with the template via hydrogen
bonds), divinylbenzene as “inert” cross-linker, and chloroform as porogen. It also included a steroid-based cross-linker, which may interact with the template via van der Waals interactions to lend additional “shape selectivity”. A 250×4.6 mm column packed with this polymer gave baseline resolution of testosterone and epitestosterone (15 microg each) in under 20 min. Preparation of the steroid based cross-linker included the selective reduction of 5α-dihydrötestosterone (17beta-hydroxy-5alpha-androstan-3-one) to the 3alpha,17beta-diol using K-selectride [11079].

A thin sheet of polydimethylsiloxane membrane was used as an extraction phase for solid-phase microextraction. Compared with fiber or rod solid-phase microextraction geometries, the thin film exhibited much higher extraction capacity without sacrificing extraction time due to its higher area-to-volume ratio. The analytical method involved direct extraction of unconjugated testosterone (T) and epitestosterone (ET) followed by separation on a C18 column and detection by selected reaction monitoring in positive ionization mode. The limit of detection was 1 ng/l for both T and ET. After method validation, free (unconjugated) T and ET were extracted and quantified in real samples. Since T and ET are extensively metabolized, the proposed method was also applied to extract the steroids after enzymatic deconjugation of urinary-excreted steroid glucuronides. The proposed method allows quantification of both conjugated and unconjugated steroids, and revealed that there was a change in the ratio of T to ET after enzymatic deconjugation, indicating different rates of metabolism [11080].

**TLC-densitometry method**

Anabolic androgenic steroids (AAS) are widely misused for the enhancement of performance in sports. Several drugs are available that contain different combinations or individual steroids in different dosage form. This paper describes a TLC densitometric method for simultaneous determination of four AAS of testosterone derivatives including testosterone propionate (TP), testosterone phenyl propionate (TPP), testosterone isocaproate (TI) and testosterone deaconate (TD) in their pharmaceutical products. Separation was carried out on Al based TLC plates, pre-coated with silica gel 60F-254 using hexane and ethyl acetate (8.5:1.5, v/v). Spots at Rf 0.31 ± 0.01, 0.34 ± 0.01, 0.40 ± 0.01 and 0.45 ± 0.02 were recognized as TPP, TP, TI and TD, respectively. Quantitative analysis was done by densitometric measurements at λmax 251 nm for all derivatives. The developed method was validated as per ICH guidelines. Method was found linear over the concentration range of 200-1200 ng/spot with the correlation coefficient of 0.995, 0.993, 0.995 and 0.996 for TP, TPP, TI, TD, respectively. Limit of detection for all derivatives were in the range of 16.7-22.3 ng/spot while limit of quantitation were found to be in the range of 55.7-70.9 ng/spot. It was concluded that the developed TLC method can be applied for the simultaneous routine analysis of testosterone derivatives in their individual and combined pharmaceutical formulations [12112].

**Mobility spectrometry separations**

UPLC-ion mobility spectrometry separations combined with mass spectrometry (UPLC-IM-MS) and tandem mass spectrometry (UPLC-IM-MS/MS) have been investigated for the simultaneous determination of testosterone and epitestosterone glucuronides in urine. The glucuronide epimers of testosterone and epitestosterone were separated by ion mobility spectrometry prior to mass analysis on the basis of differences in their collision cross sections, which have been measured in nitrogen. Combining ion mobility separation with UPLC/MS enhances the analysis of these low-abundance steroids in urine by selective interrogation of specific retention time, mass-to-charge and mobility regions. Detection limits
for the UPLC-IM-MS/MS analysis of TG and ETG were 9.9 ng/mL and 98 ng/mL respectively, equivalent to 0.7 ng/mL and 7.4 ng/mL in urine, with linear dynamic ranges corresponding to 0.7-108 ng/mL and 7.4-147 ng/mL in urine [11446].

Analysis of the transcriptome

The abuse of anabolic steroid hormones in human sports and animal husbandry is an ubiquitous problem and therefore a tight control program in both areas is very important. Within these control programs, hormone residues are detected by immunoassays or chromatographical methods in combination with mass spectrometry. With these methods, all known substances can be detected; yet new xenobiotic growth promoters and new ways of application are difficult to detect. Therefore it is important to develop new sensitive screening methods to enable an efficient control for misused anabolic substances. The detection of their physiological action is a promising approach. Anabolic steroid hormones directly influence the expression of specific genes and thus the analysis of the transcriptome of different target tissues and matrices is of great interest. One review described our recent efforts made concerning the analysis of gene expression changes in different tissues, different species and under different anabolic treatments [11447].

Experimental

Declines in skeletal muscle size and strength, often seen with chronic wasting diseases, prolonged or high-dose glucocorticoid therapy, and the natural aging process in mammals, are usually associated with reduced physical activity and testosterone levels. However, it is not clear whether the decline in testosterone and activity are causally related. Using a mouse model, it was found that removal of endogenous testosterone by orchidectomy results in an almost complete cessation in voluntary wheel running but only a small decline in muscle mass. Testosterone replacement restored running behavior and muscle mass to normal levels. Orchidectomy also suppressed the IGF-I/Akt pathway, activated the atrophy-inducing E3 ligases MuRF1 and MAFBx, and suppressed several energy metabolism pathways, and all of these effects were reversed by testosterone replacement. The study also delineated a distinct, previously unidentified set of genes that is inversely regulated by orchidectomy and testosterone treatment. These data demonstrate the necessity of testosterone for both speed and endurance of voluntary wheel running in mice and suggest a potential mechanism for declined activity in humans where androgens are deficient [11096].
One of the most frequently misused steroid precursors (prohormones) is 19-norandrostenedione (4-estrene-3,17-dione), which is, after oral administration, readily metabolised to nor testosterone, also known as nandrolone (Durabolin®). In one study it was characterised molecular mechanisms of its action determined its tissue specific androgenic and anabolic potency after subcutaneous administration and investigated potential adverse effects. Receptor binding tests demonstrate that norandrostenedione binds with high selectivity to the androgen receptor (AR). The potency of norandrostenedione to transactivate androgen receptor dependent reporter gene expression was 10 times lower as compared to dihydrotestosterone (DHT). In vivo experiments in orchiectomised rats demonstrated that subcutaneous treatment with norandrostenedione resulted only in a stimulation of the weight of the levator ani muscle; the prostate and seminal vesicle weights remained completely unaffected. Like testosterone, administration of norandrostenedione resulted in a stimulation of androgen receptor and myostatin mRNA expression in the gastrocnemius muscle. Norandrostenedione did not affect prostate proliferation, the liver weight and the expression of the tyrosine aminotransferase gene (TAT) in the liver. Summarizing these data it is obvious that norandrostenedione, if administrated subcutaneous and in contrast to its metabolite nandrolone, highly selectively stimulates the growth of the skeletal muscle but has only weak androgenic properties [08157].

19-Norandrosterone (19-NA) as its glucuronide derivative is the target metabolite in antidoping testing to reveal an abuse of nandrolone or nandrolone prohormone. To provide further evidence of a doping with these steroids, the sulfoconjugate form of 19-norandrosterone in human urine might be monitored as well. In one study, the profiling of sulfate and glucuronide derivatives of 19-norandrosterone together with 19-noretiocholanolone (19-NE) were assessed in the spot urines of 8 male subjects, collected after administration of 19-nor-4-androstenedione (100 mg). An LC/MS/MS assay was employed for the direct quantification of sulfoconjugates, whereas a standard GC/MS method was applied for the assessment of glucuroconjugates in urine specimens. Although the 19-NA glucuronide derivative was always the most prominent at the excretion peak, inter-individual variability of the excretion patterns was observed for both conjugate forms of 19-NA and 19-NE. The ratio between the glucuro- and sulfoconjugate derivatives of 19-NA and 19-NE could not discriminate the endogenous versus the exogenous origin of the parent compound. However, after ingestion of 100 mg 19-nor-4-androstenedione, it was observed in the urine specimens that the sulfate conjugates of 19-NA was detectable over a longer period of time with respect to the other metabolites [08158].

The detection of 19-norandrosterone (19-NA) in a competitor's urine sample is taken as prima facie evidence of administration of nandrolone or other 19-norsteroid but a potential problem is that administration of norethisterone, a progestogen used for menstrual disorders and for hormonal contraception, also results in the excretion of 19-NA that can exceed the laboratory reporting threshold of 2 ng/mL. The contribution of norethisterone to urinary 19-NA with and without 19 norandrostenedione, a known norethisterone tablet impurity, requires evaluation. Preparations containing, either <2 ng or 1 mug 19-norandrostenedione impurity per 5 mg of norethisterone, administered to female volunteers (n=10) in doses comparable to those used for menstrual disorders (5 mg three times daily for 10 days), resulted in maximal 19-NA concentrations of 51 and 63 ng/mL, respectively. The maximal concentration of 19-NA, 2 h post-administration of a single 1 mug dose of 19-norandrostenedione, was 2.4 ng/mL. These results prove unequivocally that norethisterone is metabolized to 19-NA and that there is only a minor contribution from the impurity 19-norandrostenedione. Administration to women (n=30) of a single contraceptive tablet containing norethisterone (1
mg) with one of the highest proportions of the impurity 19-norandrostenedione (approximately 0.5 mug, 0.05 %, w/w) resulted in a urinary 19-NA concentration of 9.1 ng/mL, with a maximum concentration ratio of 19-NA to the norethisterone metabolite 3alpha,5beta-tetrahydroxynorethisterone of 0.36. These data should remove the need for time-consuming follow-up investigations to consider whether doping with 19-norandrogens has occurred [08159].

19-Norandrosterone (19-NA) is the principal urinary metabolite of the anabolic steroid nandrolone and its prohormones. The administration of these 19-nor androgens is prohibited in sport by the WADA but, even so, adverse findings for 19-NA continue to be commonly reported. Little is known about the urinary concentrations of 19-NA that can occur in women who are not using anabolic steroids, including those using oral contraceptives containing the 19-nor progestogen norethisterone. In 2004, WADA lowered the reporting threshold for 19-NA for females from 5 to 2 ng/mL. The lack of any substantial data on 19-NA excretion in women prompted this large-scale investigation. In this investigation, single untimed urines collected from 1202 female volunteers, 38 of whom were taking norethisterone containing contraceptives, were analysed for 19-NA. None of the women was a competitive athlete and pregnancy had been excluded by a urinary test for human chorionic gonadotropin (hCG). Only one sample exceeded the 19-NA reporting threshold having a concentration of 4.1 ng/mL. This sample was from a user of a norethisterone-containing contraceptive [08160].

The finding of measurable amounts of 19-norandrostenedione in norethisterone tablets prompted us to develop an assay to quantify this steroid. 19-Norandrostenedione is an anabolic steroid whose use in sport is prohibited by WADA. The assay was developed using isotope dilution and liquid chromatography-tandem mass spectrometry (LC-MS/MS) for the quantification of 19-norandrostenedione in norethisterone formulations, with [3,4-(13)C(2)]-19-norandrostenedione as the internal standard. The results showed amounts up to 1.01 ± 0.01 mug per tablet in those containing 5 mg of norethisterone or norethisterone acetate (0.02 %, w/w) and up to 0.5 ± 0.01 mug per tablet (0.05 %, w/w) in oral contraceptive tablets containing 0.35-1.5 mg of norethisterone or norethisterone acetate. No tablet tested exceeded the British Pharmacopoeia limit of 0.1 percent for this impurity [08161].

The administration of 19-norsteroids such as 19-nortestosterone (nandrolone), 19-norandrostene-3,17-dione and 19-norandrostene-3,17-diol (delta-4 and -5 isomers) has been shown to lead mainly to the excretion of 19-norandrosterone (NA), 19-noretioclanolone (NE), and 19-norepiandrosterone (NEA). The latter is found exclusively as its sulfocojugate while the others are usually excreted as their glucuronide derivative. The sulfate derivatives, generally persistent, may be prevalent at the end of the excretion period. After intramuscular administration of the long-lasting preparations of nandrolone, the metabolites may be detected for months, but metabolites formed after oral ingestion are excreted massively the first hours and remain detectable for only a few days [09111].

The abuse of anabolic androgenic steroids (AASs) is not only a problem in the world of sports but is associated with the polydrug use of nonathletes. Investigations of the neurochemical effects of AAS have focused in part on the monoaminergic systems, involving, among other things, the development of dependence. It has previously been shown that pretreatment with nandrolone decanoate attenuates dose-dependently the increase in extracellular dopamine (DA) concentration evoked by amphetamine and 3,4-methylenedioxyxymethamphetamine in the nucleus accumbens (NAC). The aim of this study was to investigate whether the nandrolone pre-exposure modulates the acute neurochemical and behavioral effects of cocaine in rats and whether the effects are long lasting. DA, 5-hydroxytryptamine (5-HT), and their metabolites were measured from samples collected from the NAc by microdialysis. The behavior of the animals was recorded. The present study
demonstrates that five injections of nandrolone (5 and 20 mg/kg) inhibited cocaine-evoked DA and 5-HT outflow in the NAc, locomotor activity (LMA), and stereotyped behavior in experimental animals, and that these effects are seen even after elimination of nandrolone from bloodstream. Given that accumbal outflow of DA and 5-HT, as well as LMA and stereotyped behavior, is related to gratification of stimulant drugs, this study suggests that nandrolone, at the doses tested, has a significant effect on the pleasurable properties of cocaine. Furthermore, because neurochemical and behavioral responses were still attenuated after a fairly long recovery period, it seems that nandrolone may induce long-lasting changes in the brains of rat [10083].

Nandrolone or nortestosterone, an anabolic-androgenic steroid, has been prohibited by doping control regulations for more than 30 years. Although its main metabolism in the human body was already known at that time, and detection of its misuse by gas or liquid chromatographic separation with mass spectrometric detection is straightforward, many interesting aspects regarding this doping agent have appeared since. Over the years, nandrolone preparations have kept their position among the prohibited substances that are most frequently detected in WADA-accredited laboratories. Their forms of application range from injectable fatty acid esters to orally administered nandrolone prohormones. The long detection window for nandrolone ester preparations and the appearance of orally available nandrolone precursors have changed the pattern of misuse. At the same time, more refined analytical methods with lowered detection limits led to new insights into the pharmacology of nandrolone and revelation of its natural production in the body. Possible contamination of nutritional supplements with nandrolone precursors, interference of nandrolone metabolism by other drugs and rarely occurring critical changes during storage of urine samples have to be taken into consideration when interpreting an analytical finding. A set of strict identification criteria, including a threshold limit, is applied to judge correctly an analytical finding of nandrolone metabolites. The possible influence of interfering drugs, urine storage or natural production is taken into account by applying appropriate rules and regulations [10084].

It was investigated the effects of the menstrual cycle, oral contraception and physical training on exhaustive exercise-induced changes in the excretion of nandrolone metabolites. i.e.19-norandrosterone (19-NA), and 19-noretiocholanolone (19-NE), in young women. Twenty-eight women were allocated to an untrained group (n=16) or a trained group (n=12), depending on their physical training background. The untrained group was composed of nine oral contraceptive users (OC+) and seven eumenorrheic women (OC-), while the trained group was entirely composed of OC+ subjects. Three laboratory sessions were conducted in a randomized order: a prolonged exercise test, a short-term exercise test and a control session. Urine specimens were collected before and 30, 60 and 90 min after the exercise test and at the same times of the day during the control session. Urinary concentrations of nandrolone metabolites were determined by gas chromatography coupled to mass spectrometry. Urinary concentrations of 19-NA and 19-NE ranged from undetectable levels to 1.14 and 0.47 ng/mL, respectively. Nandrolone excretion was not affected by the menstrual cycle phase (early follicular vs mid-luteal), prior physical training, oral contraception or acute physical exercise. Therefore, a urinary concentration of 2 ng/mL of 19-NA appears to be fair as the upper acceptable limit in doping control tests for female athletes [10085].

One study describes development and subsequent validation of a reversed phase high performance liquid chromatographic (RP-HPLC) method for the estimation of nandrolone phenylpropionate, an anabolic steroid, in bulk drug, in conventional parenteral dosage formulation and in prepared nanoparticle dosage form. The chromatographic system consisted of a Luna Phenomenex, CN (250 mm x 4.6 mm, 5 microm) column, an isocratic mobile phase comprising 10 mM phosphate buffer and acetonitrile (50:50, v/v) and UV
detection at 240 nm. Nandrolone phenylpropionate was eluted about 6.3 min with no interfering peaks of excipients used for the preparation of dosage forms. The method was linear over the range from 0.050 to 25 microg/mL in raw drug. The intra-day and inter-day precision values were in the range of 0.22-0.61 percent and 0.44-0.88 percent, respectively. Limits of detection and quantitation were 0.010 microg/mL and 0.050 microg/mL, respectively. The results were validated according to International Conference on Harmonization guidelines in parenteral and prepared nanoparticle formulation. The validated HPLC method is simple, sensitive, precise, accurate and reproducible [11097].

Nandrolone is an androgenic-anabolic steroid (AAS) with diverse medical applications but taken indiscriminately by some to rapidly increase muscle mass. The aim of this study was to evaluate the genotoxic and clastogenic potential of nandrolone (Deca-durabolin®) in vivo in different cells of mice, using the comet assay and micronucleus test, respectively. The animals received subcutaneous injection of the three doses of the steroid (1.0, 2.5 and 5.0 mg kg(-1) body weight). Cytotoxicity was assessed by scoring 200 consecutive total polychromatic (PCE) and normochromatic (NCE) erythrocytes (PCE-NCE ratio). The results showed a significant dose-related increase in the frequency of DNA damage in leukocytes, liver, bone marrow, brain and testicle cells at the three tested doses and a significant increase of the micronucleated polychromatic erythrocytes at all tested doses. Under our experimental conditions, the nandrolone steroid hormone showed genotoxic and clastogenic effects when administered subcutaneously to mice [11098].

Nandrolone or 19-nortestosterone (19-NT) is an anabolic androgenic steroid (AAS) produced first for androgen replacement therapy as a testosterone analog. Due to its higher potency than testosterone itself it has been misused for doping purposes and forbidden in sports in 1976. Since then, and despite the appearance of other doping products, 19-NT preparations have remained one of the most abused substances in sports as well as in the society. Nandrolone is mainly metabolized in the liver into 19-norandrosterone prior to glucuronidation and excretion through urine over an extended period of time. 19-NT is mainly metabolized into 19-norandrosterone (19-NA) prior to glucuronidation and excretion via urine. Whereas 19-NT is known to be detectable in the serum for only 2-5 weeks after injection, urinary 19-NA in its glucuronidated form is detectable up to 1 year after injection of 19-NT and this excretion is prone to very large inter-individual variation. Several UGTs (i.e. UGT2B7, UGT2B15, and UGT2B17) are thought to be the major enzymes responsible for conjugation of androgens in human. An in vitro study using recombinant enzymes expressed in insect cells showed that UGT1A4 and UGT2B7 are the two main enzymes responsible of 19-norandrosterone glucuronidation. However, the identity of the enzyme involved in nandrolone metabolism in vivo together with their relative contribution and regulation remain unknown. Inhibition assays using human liver microsomes (HLM) incubated with 19-norandrosterone and selective inhibitors confirmed that UGT2B7 and UGT2B15 are involved in 19-norandrosterone glucuronidation, since the presence of the specific UGT2B7 and UGT2B15 inhibitors gemfibrozil and valproic acid inhibited the 19-norandrosterone glucuronidation by 35 and 45 percent, respectively. HLM were genotyped for UGT2B15 D85Y, UGT2B7 H268Y, and the UGT2B17 deletion polymorphism. The glucuronidation activity on 19-norandrosterone was significantly higher in UGT2B15 DD than in the other UGT2B15 genotypes. Moreover, human liver cancer HepG2 cells were exposed to androgens to determine if the transcriptional activity of the genes of interest was affected. Only UGT2B7 mRNA expression was significantly increased (1.8-folds) after incubation with nandrolone decanoate. These results show that the UGT2B7 and UGT2B15 are involved in 19-norandrosterone glucuronidation and that the UGT2B15 polymorphism (D85Y) is the only UGT genetic variation that influences the glucuronidation activity. This could partly explain the inter-individual variation in 19-norandrosterone excretion. Several genetic polymorphisms in UGTs have been reported to have an impact on their ability to metabolize androgens. A
frequent polymorphism in UGT2B7 gene leading to a histidine to tyrosine substitution in codon 268 (H268Y) has shown variable functional impact with different substrates. The results indicate that androgens induce enzymes involved in its own elimination, which may further contribute to the inter-individual variability in disposition of 19-NA after the administration of nandrolone in healthy volunteers [13220].

**Physiology**

*Effects on mitochondria*

Respiratory failure in patients with COPD may be caused by insufficient force production or insufficient endurance capacity of the respiratory muscles. Anabolic steroids may improve respiratory muscle function in COPD. The effect of anabolic steroids on mitochondrial function in the diaphragm in emphysema is unknown. In an emphysematous male hamster model, we investigated whether administration of the anabolic steroid nandrolone decanoate (ND) altered the activity of mitochondrial respiratory chain complexes in the diaphragm. The bodyweight of hamsters treated with ND was decreased after treatment compared with initial values, and serum testosterone levels were significantly lower in hamsters treated with ND than in control hamsters. No difference in the activity of mitochondrial respiratory chain complexes in the diaphragm between normal and emphysematous hamsters was observed. Treatment with ND did not change the activity of mitochondrial respiratory chain complexes in the diaphragm of both normal and emphysematous hamsters. In emphysematous hamsters, administration of ND decreased the activity of succinate:cytochrome C oxidoreductase compared with ND treatment in normal hamsters. It was concluded that anabolic steroids have negative effects on the activity of succinate:cytochrome C oxidoreductase and anabolic status in this emphysematous hamster model [06103].

*Effect on dynorphin A in the brain*

The misuse of anabolic androgenic steroids (AAS) seems to produce profound effects on the central nervous system, leading to aggressive behavior and increased sensitivity to other drugs of abuse. The present study addresses the effect on the enzymatic transformation, here called dynorphin converting enzyme-like activity. The formation of the mu/delta opioid peptide receptor-prefering Leu-enkephalin-Arg(6) from the kappa opioid peptide receptor-prefering dynorphin A was measured in rats treated with nandrolone decanoate. Significant variations in enzymatic transformation were observed in several brain regions. An altered receptor activation profile in these regions may be one contributory factor behind AAS-induced personality changes [06104].

**Metabolism**

19-Nortestosterone-derived anabolic steroids show promising anabolic:androgenic dissociation. Almost simultaneously with the development of prohormones of testosterone, 19-nor analogues were developed as precursors of 19-nortestosterone and these substances are also prohibited in sports. In doping control, 19-norandrosterone, the major urinary metabolite of 19-nortestosterone is used as the primary indicator for the misuse of these substances, although it can also naturally occur in urine in small concentrations or as an artefact by demethylation of androsterone. Moreover, several oral contraceptives including norethisterone and lynestrenol are metabolised to norandrosterone and could give rise to inadvertent positive doping cases. To avoid false positive doping tests, due to a possibly endogenous origin of norandrosterone or the use of oral contraceptives, several
precautions have been taken by WADA, including the inclusion of a threshold value (2 ng/mL) and the obligation for laboratories to test for pregnancy and for the presence of tetrahydronoretisterone when norandrosterone is found in urine of women [06004].

**Norandrostenedione and norandrostenediol**

In the 1990s, 19-norandrost-4-ene-3,17-dione, 19-norandrost-5-ene-3,17-dione, 19 norandrost-4-ene-3beta,17beta-diol and 19-norandrost-5-ene-3beta,17beta-diol became available as over-the-counter anabolic steroids in the US under the DSHEA. Several studies on the in vivo and in vitro metabolism of these steroids have been performed. So far, all excretion studies with norandrostenedione and norandrostenediol have also identified 19-norandrosterone as the major urinary metabolite [06004].

Prohormones such as 19-norandrostenediol (estr-4-ene-3beta,17beta-diol) have been added to the list of prohibited substances of the World Anti-Doping Agency because they are metabolized to the common nandrolone metabolites norandrosterone and noretiocholanolone. So far, no studies on the metabolism and in vivo conversion of 19-norandrostenediol after oral or sublingual administration have been reported nor have had quantified data on resulting plasma nandrolone levels. In the present study, an open-label crossover trial with eight healthy male volunteers was conducted. After application of capsules or sublingual tablets of 19-norandrostenediol plasma concentrations of 19-norandrostenediol, nandrolone as well as major metabolites (19-norandrosterone and 19-noretiocholanolone) were determined using a validated assay based on gas chromatography/mass spectrometry. The administration of 100-mg capsules of 19-norandrostenediol yielded maximum plasma total concentrations (i.e., conjugated plus unconjugated compounds) of 1.1 ± 0.7 ng/mL for 19-norandrostenediol, 4.0 ± 2.6 ng/mL for nandrolone, 154.8 ± 130.8 ng/mL for 19-norandrosterone, and 37.7 ± 6.9 ng/mL for 19-noretiocholanolone. The use of 25-mg sublingual tablets resulted in 3.3 ± 1.0 ng/mL for 19-norandrostenediol, 11.0 ± 6.4 ng/mL for nandrolone, 106.3 ± 40.1 ng/mL for 19-norandrosterone, and 28.5 ± 20.8 ng/mL for 19-noretiocholanolone. Most interestingly, the pharmacologically active unconjugated nandrolone was determined after administration of sublingual tablets (up to 5.7 ng/mL) in contrast to capsule applications. These results demonstrate the importance of prohibiting prohormones such as 19-norandrostenediol, in particular, since plasma concentrations of nandrolone between 0.3 to 1.2 ng/mL have been reported to influence endocrinological parameters [06105].

**Norethandrolone and ethylestrenol**

The metabolism of norethandrolone (17alpha-ethyl-17alpha-hydroxy-estr-4-en-3-one) has been investigated in man. 17alpha-ethyl-5alpha-estran-3alpha,17beta-diol, 17alpha-ethyl-5beta-estran-3alpha,17beta-diol and 17alpha-ethyl-5beta-estran-3alpha,17beta,21-triol were identified as the major urinary metabolites. In man, ethylestrenol is metabolized to norethandrolone. However, contrarily to earlier findings, de-ethynylation of both norethandrolone and ethylestrenol can occur and small amounts of 19-norandrosterone (higher than the threshold concentration of 2.0 ng/ml) can be detected in urine after administration of these steroids [06004].

**Norethisterone and lynestrenol**

Norethisterone acetate and lynestrenol are progestins used as oral contraceptives in women and are prodrugs of norethisterone. Norethisterone is metabolized in vivo to 5alpha- and 5beta-dihydronorethisterone and tetrahydronorethisterone. In urine, tetrahydronorethisterone is used as a marker for the use of norethisterone acetate. In addition, norandrosterone and other metabolites can also be detected in concentrations exceeding the doping threshold concentration. Administration of lynestrenol in therapeutic doses can also result in the detection of norandrosterone in concentrations higher than 2 ng/ml. However the precautions
taken by WADA [59] for norethisterone allow for avoiding false positive doping tests due to the use of this type of oral contraceptives [06004].

**Methyl-19-nortestosterone**

Several substances including 18-methyl-19-nortestosterone, 7alpha-methyl-19-nortestosterone and 17alpha-methyl-19-nortestosterone have been described in the literature and/or are available via the internet. Also 7alpha,11beta-dimethyl-19-nortestosterone has also been reported as a highly potent anabolic androgenic steroid. 7alpha-Methyl-19-nortestosterone, also referred to as MENT, is a potent androgen with a low oral activity, and promoted as a long-acting contraceptive in men in clinical trials. Three metabolites of 7alpha-methyl-19-nortestosterone have been reported, including 7alpha-methyl-5(10)-estrene-3alpha-ol-17-one and — analogous to the 19-nortestosterone metabolism — 7alpha-methyl-5beta-estran-3alpha-ol-17-one and 7alpha-methyl-5beta-estran-3alpha-ol-17-one. 18-Methyl-19-nortestosterone was listed on the 2005 WADA list of prohibited substances (13-ethyl-17alpha-hydroxy-4-ene-3-one), but not on the 2006 list. In humans 18-methyl-19-nortestosterone is metabolized to 18-methyl-norandrostosterone (18-methyl-5beta-estran-3alpha-ol-17-one) and 18-methylnoretiocholanolone (18-methyl-5beta-estran-3alpha-ol-17-one). No data on the metabolism of 17alpha-methyl-19-nortestosterone and 7alpha,11alpha-dimethyl-19-nortestosterone is available [06004].

**Tibolone**

Tibolone ((7alpha,17alpha)-17-hydroxy-7-methyl-19-norpregn-5(10)-en-20-yn-3-one) is a steroid structurally related to norsteroids, commonly used in hormone replacement therapy during menopause and prohibited in sports. In vitro and in vivo studies have shown that the major metabolite of tibolone is 3alpha-hydroxy-tibolone. Other metabolites include 3beta-hydroxy-tibolone and delta4-tibolone. All metabolites, as well as the parent compound, are excreted as sulphates [06004].

**Protein disulphide isomerase (PDI)**

Protein disulphide isomerase (PDI) in the endoplasmic reticulum catalyzes the rearrangement of disulphide bridges during folding of secreted proteins. It binds various molecules that inhibit its activity. But here, it was looked for molecules that would potentiate its activity. PDI reductase activity was measured in vitro using di-eosin-oxidized glutathione as substrate. Its classical inhibitor bacitracin was found to exert a biphasic effect: stimulatory at low concentrations (10^{-6} M) and inhibitory only at higher concentrations (10^{-3}-10^{-3} M). The weak estrogenic molecule bisphenol A was found to exert a weak inhibitory effect on PDI reductase activity relative to the strong oestrogens, ethynylestradiol, and diethylstilbestrol. Like 19-nortestosterone, fluoxetine was found to exert a potentiating effect on PDI reductase activity and their potentiating effects could be reversed by increasing concentrations of oestrogens. In conclusion, this paper provides the first identification of potentiators of PDI activity that are potential pharmaceuticals against pathologies affecting protein folding such as Alzheimer's disease [11449].

**Diagnostic metabolites**

Quantities of various anabolic steroids have been found in dietary supplements without their presence being disclosed on the label. The aim of this study was to quantify the excretion patterns of the diagnostic metabolites, 19-norandrostosterone (19-NA), and 19-noretioccholanolone (19-NE) after ingestion of small doses of 19-nor-4-androstene-3,17-dione
(19-norandrostenedione). Eleven males and nine females entered the laboratory in the morning after an overnight fast. An initial urine sample was collected, and volunteers then ingested 500 mL of water containing 5 g of creatine monohydrate and 1.0, 2.5, or 5.0 microg of 19-norandrostenedione. The volume of each urine void was measured, and an aliquot was taken. Baseline urinary 19-NA concentrations were 0.19 ± 0.14 ng/mL. Ingestion of the supplement resulted in peak mean urinary 19-NA concentrations of 0.68 ± 0.36, 1.56 ± 0.86, and 3.89 ± 3.11 ng/mL in the 1.0-, 2.5-, or 5.0-microg trials, respectively. Under current WADA regulations, ingestion of the 1.0-microg dose produced 0 positive doping tests, 5 subjects (20 %) tested positive in the 2.5-microg trial, and 15 subjects (75 %) had urinary 19-NA concentrations exceeding 2 ng/mL after ingesting creatine containing 5.0 microg of the steroid. The recovery of the ingested dose was highly variable between individuals, with values ranging from 11 to 84 percent. Ingestion of trace amounts of 19-norandrostenedione can result in transient elevations of urinary 19-NA and 19-NE concentrations. The addition of as little as 2.5 microg of 19-norandrostenedione to a supplement (0.00005 % contamination) appears sufficient to result in a doping violation in some individuals [09112].

One study examined the influence of a supplement matrix on the excretion pattern of nandrolone metabolites in response to ingestion of a trace amount of 19-norandrostenedione. Ten male and nine female volunteers were recruited. On two occasions subjects entered the laboratory in the morning following an overnight fast. After an initial urine collection, subjects ingested either 500 mL of plain water or a commercially-available energy bar: 10 mug of 19-orandrostenedione was added to each. The volume of each urine sample passed over the next 24 h was measured and an aliquot retained for analysis. All samples were analysed for the metabolites 19-norandrosterone (19-NA) and 19-noretiocohanolone (19-NE) by GCMS. The total volume of urine passed was significantly higher in the water trial (than in the bar trial. Baseline urinary 19-NA concentrations were all below the limit of quantification for the assay. Peak urinary 19-NA was lower in the water trial than in the bar trial. The time elapsed between ingestion of the supplement and the peak urinary 19-NA concentration was longer following ingestion of the bar than on the water trial. There was no difference in the total recovery of 19-NA+19-NE between the liquid and solid supplements. It was concluded that peak 19-NA concentrations were higher, and occurred later, when the 19-norandrostenedione was added to a solid supplement. This may be due to a slower rate of absorption, and/or a reduced diuresis, resulting in a longer period for the metabolites to accumulate in the urine [09113].

Effects of the menstrual cycle

It was investigated the effects of the menstrual cycle, oral contraception and physical training on exhaustive exercise-induced changes in the excretion of nandroloane metabolites (19-norandrosterone, and 19-noretiocholanolone) in young women. Twenty-eight women were allocated to an untrained group (n=16) or a trained group (n=12), depending on their physical training background. The untrained group was composed of nine oral contraceptive users (OC+) and seven eumenorrheic women (OC-), while the trained group was entirely composed of OC+ subjects. Three laboratory sessions were conducted in a randomized order: a prolonged exercise test, a short-term exercise test and a control session. Urine specimens were collected before and 30, 60 and 90 min after the exercise test and at the same times of the day during the control session. Urinary concentrations of nandrolone metabolites were determined by gas chromatography coupled to mass spectrometry. Urinary concentrations of 19-NA and 19-NE ranged from undetectable levels to 1.14 and 0.47 ng/mL, respectively. Nandrolone excretion was not affected by the menstrual cycle phase (early follicular vs mid-luteal), prior physical training, oral contraception or acute physical exercise.
Therefore, a urinary concentration of 2 ng/mL of 19-norandrosterone appears to be fair as the upper acceptable limit in doping control tests for female athletes [09114].

**Influence on hypothalamic-pituitary-adrenal axis**

Elite athletes, body builders and adolescents misuse anabolic-androgenic steroids (AAS) in order to increase muscle mass or to enhance physical endurance and braveness. The high doses misused are associated with numerous adverse effects. The purpose of one study was to evaluate the impact of chronic supratherapeutic AAS treatment on circulating hormones and gene expression in peripheral tissues related to such adverse effects. Quantitative real-time PCR was used to measure expression levels of in total 37 genes (including peptide hormones, cell membrane receptors, nuclear receptors, steroid synthesising enzymes and other enzymes) in the pituitary, testes, adrenals, adipose tissue, kidneys and liver of male Sprague-Dawley rats after 14-day administration of the AAS nandrolone decanoate, 3 or 15 mg/kg. Plasma glucose and levels of adrenocorticotropic hormone (ACTH), adiponectin, corticosterone, ghrelin, insulin and leptin were also measured. It was found several expected effects on the hypothalamic-pituitary-gonadal axis, while the treatment also caused a number of other not previously identified changes in circulating factors and gene transcription levels such as the dose-dependent reduction of the beta3-adrenergic receptor in adipose tissue, reduction of both circulating and mRNA levels of adiponectin, up-regulation of both hydroxyethylglutaryl-CoA-reductase, the rate-limiting enzyme in de novo synthesis of cholesterol, and the receptor for ACTH in the adrenals. The results provide evidence for wide ranging effects of AAS on the, adipose tissue and substrates of the renal control of blood pressure [09115].

**Effect on muscles**

Vascular endothelial growth factor (VEGF) is a key compound for induction of angiogenesis in both physiological and pathological conditions. The aim of one study was to investigate the effect of androgenic-anabolic steroids (AAS) administration on VEGF mRNA expression in the rat soleus muscle after jumping training. Wistar rats were grouped into: sedentary; nandrolone decanoate-treated sedentary; trained without AAS, and trained and treated with AAS. Exercised groups performed a 7-weeks water-jumping program. Animals killed immediately after the last exercise bout showed significantly increased VEGF mRNA expression; however, the AAS treatment completely inhibited this effect. These results suggest that the AAS may be strongly prejudicial to muscle remodeling and performance at least partially due to an impaired angiogenesis [09116].

**Effect of training**

Exercise is a potent stimulus for release of growth hormone (GH), cortisol, testosterone and prolactin, and prolonged exercise inhibits insulin secretion. These responses seem to be specific to the type of exercise but this has been poorly characterised primarily because they have not been compared during exercise performed by the same individuals. It was investigated hormone responses to resistance, sprint and endurance exercise in young men using a repeated measures design in which each subject served as their own control. Eight healthy non-obese young adults (18-25 years) were studied on four occasions in random order: 30-s cycle ergometer sprint (Sprint), 30-min resistance exercise bout (Resistance), 30-min cycle at 70 % VO_{2max} (Endurance), and seated rest in the laboratory (Rest). Cortisol, GH, testosterone, prolactin, insulin and glucose concentrations were measured for 60 min after
the four different interventions. Endurance and sprint exercise significantly increased GH, cortisol, prolactin and testosterone. Sprint exercise also increased insulin concentrations, whereas this decreased in response to endurance exercise. Resistance exercise significantly increased only testosterone and glucose. Sprint exercise elicited the largest response per unit of work, but the smallest response relative to mean work rate in all hormones. In conclusion, the nature and magnitude of the hormone response were influenced by exercise type, perhaps reflecting the roles of these hormones in regulating metabolism during and after resistance, sprint and endurance exercise [13221].

**Effect of winning or losing**

One study assessed the responses of salivary-free testosterone (T) and cortisol (C) concentrations across selected training workouts and their association with the subsequent competition outcomes in professional rugby league. Thirteen rugby league players were assessed for salivary-free T and C concentrations across 5 training workouts performed 3-4 days before a competitive game. The game outcomes included wins and losses and game-ranked performance (1-5) based on the number of points scored, the points differential, and a coach rating. Data were pooled across the winning (n=3) and losing (n=2) outcomes. Pooled free T concentrations (absolute and relative changes) were significantly elevated across those workouts that preceded winning games, but not the losses, and the relative (percent) T changes were significantly higher before winning (31 %) than before losing (3 %). Both outcomes were associated with workout decreases in pooled free C concentrations and the relative C changes were not significantly different between wins (-23 %) and losses (-26 %). In conclusion, the free T responses to selected training workouts showed some association with subsequent winning (being elevated) and losing (no change) during a limited number of competitive games in professional rugby league. Speculatively, the free T responses to a midweek workout might provide an early sign of team readiness to compete or to recovery state, thereby providing a novel format for implementing training or management strategies to improve the competition outcomes [13222].

**Effect on healing of muscle injuries**

Although testosterone administration elicits well-documented anabolic effects on skeletal muscle mass, the enhancement of muscle regeneration after injury has not been widely examined. The purpose of one study was to determine whether anabolic steroid administration improves skeletal muscle regeneration from bupivacaine-induced injury. Male C57BL/6 mice were castrated 2 weeks before muscle injury induced by an intramuscular bupivacaine injection into the tibialis anterior (TA) muscle. Control mice received an intramuscular PBS injection. Anabolic steroid (nandrolone decanoate, ND), 6 mg/kg, or sesame seed oil was administered at the time of initial injury and continued every 7 days for the study's duration. Mice were randomly assigned to one of four treatment groups for 5, 14, or 42 days of recovery, as follows: 1) control (uninjured); 2) ND only (uninjured + ND); 3) bupivacaine only (injured); or 4) bupivacaine + ND (injured + ND). TA morphology, protein, and gene expression were analyzed at 14 and 42 days after injury; protein expression was analyzed at 5 days after injury. After 14 days of recovery, the injury and injury + ND treatments induced small-diameter myofiber incidence and also decreased mean myofiber area. The increase in small-myofiber incidence was 65% greater in injury + ND muscle compared with injury alone. At 14 days, injury + ND induced a fivefold increase in muscle IGF-I mRNA expression, which was greater than injury alone. Muscle Akt activity and glycogen synthetase kinase-3beta activity were also induced by injury + ND at 14 days of recovery, but not by injury alone. ND had a main effect for increasing muscle MyoD and cyclin D1 mRNA expression at 14 days. After 42 days of recovery, injury + ND increased large-diameter myofiber incidence compared with injury only. Nandrolone decanoate (ND) administration can enhance castrated mouse muscle regeneration during the recovery from
bupivacaine-induced injury [09117].

One study analyzed the effect of nandrolone decanoate (ND) on muscle repair and the expression of myogenic regulatory factors following cryoinjury in rat skeletal muscle. Adult male Wistar rats were randomly divided into 4 groups: control group, sham group, cryoinjured group treated with ND and non-injured group treated with ND. Treatment consisted of subcutaneous injections of ND (5 mg/kg) twice a week. After sacrifice, the tibialis anterior muscle was removed for the isolation of total RNA and analysis of myogenic regulatory factors using real-time PCR as well as morphological analysis using the hematoxylin-eosin assay. There was a significant increase in MyoD mRNA after 7 days and in myogenin mRNA after 21 days in the cryoinjured ND group in comparison to other groups in the same period. The morphological analysis revealed no edema or myonecrosis after 7 days as well as no edema or inflammatory infiltrate after 14 days in the cryoinjured ND group. In conclusion the anabolic steroid nandrolone decanoate can modulate the muscle repair process in rats following cryoinjury by influencing the expression of regulatory myogenic factors and phases of muscle repair [13230].

Positive effect on nerve regeneration

Recovery from peripheral nerve repair is frequently incomplete. Hence drugs that enhance nerve regeneration are needed clinically. In 40 rats, a 40-mm segment of the left median nerve was removed and interposed between the stumps of a sectioned right median nerve. Starting 7 days after nerve grafting and continuing over a 6-month period, we administered nandrolone at a dose of 5 mg/kg/week to half the rats (n = 20). All rats were assessed behaviorally for grasp function and nociceptive recovery for up to 6 months. At final assessment, reinnervated muscles were tested electrophysiologically and weighed. Results were compared between rats that had received versus not received nandrolone and versus 20 nongrafted controls. Rats in the nandrolone group recovered finger flexion faster. At 90 days postsurgery, they had recovered 42 percent of normal grasp strength versus just 11 percent in rats grafted but not treated with nandrolone. At 180 days, the average values for grasp strength recovery in the nandrolone and no-nandrolone groups were 40 and 33 percent of normal values for controls, respectively. At 180 days, finger flexor muscle twitch strength was 16 percent higher in treated versus nontreated rats. Thresholds for nociception were not detected in either group 90 days after nerve grafting. At 180 days, nociceptive thresholds were significantly lower in the nandrolone group. It was concluded that nandrolone decanoate improved functional recovery in a model of deficient reinnervation [13231].

Side effects

It was reported the case of a 50-year-old body-builder Caucasian man with a long-standing abuse of nandrolone and erythropoietin that developed a ventricular septal defect following acute myocardial infarction. This mechanical complication led to cardiogenic shock ultimately treated with the implantation of a circulatory support by means of extracorporeal membrane oxygenation. The patient subsequently underwent orthotopic heart transplantation. The association of intense isometric exercise, abuse of erythropoietin and nandrolone is likely to have predisposed to coronary thrombus formation and acute myocardial infarction, as the patient presented no traditional cardiovascular risk factors [09118].

Effect on male fertility
High doses of anabolic-androgenic steroids (AAS) are used by some athletes to increase muscle mass, that is often associated with male infertility. The aim of one study was to investigate the possible cause/s of male infertility using a rat model by analysing sperm quality, including its protamine content and DNA integrity, as well as pregnancy rate. Five groups of male Wistar rats were treated for 10 weeks as follows: nandrolone decanoate (10 mg/kg per week) (ND); running exercise (50 min per day, 5 days a week) (EX); Combination of ND and exercise (ND-EX); nandrolone decanoate solvent (Sham); and control without any injection or exercise (CO). Deterioration in sperm quantity was observed in all test groups. The frequency of fertile rats was decreased in the ND-EX and ND groups. Chromomycin-A3 staining showed a protamine deficiency in the epididymal spermatozoa in the ND-EX rats. Chromatin analysis indicated an abnormal maturation of the sperm nuclei in all test groups compared with the controls. TUNEL analyses showed a highly significant increase in apoptosis in the EX, ND, and ND-EX groups. The data show that a combination of exercise and high doses of nandrolone decanoate negatively influences the DNA integrity and protamine content resulting in lower sperm quality and reduced pregnancy rate [13223].

Cardiotoxic effects

The association between synthetic androgen (SA) abuse and sudden cardiac death is often cited in literature; in this respect, to date there are little data on the effects of chronic administration of supraphysiological doses of SA on tonic cardiac autonomic control. In one study it was shown that chronic treatment with a high dose of nandrolone decanoate (ND) induces cardiac parasympathetic dysfunction and disturbances in ventricular depolarization in both sedentary and exercised rats. One study shows, unequivocally, that the blockade of the renin-angiotensin system (RAS), and particularly of angiotensin II type 1 receptor (AT1R) by losartan, prevents QT prolongation and that the administration of chronic, supraphysiological doses of ND induces parasympathetic autonomic dysfunction. This positive feedback of the pharmacological blockade of the receptor has been tested on an experimental basis, both on groups of sedentary rats and on groups of rats forced to exercise; in both cases, QT prolongation and parasympathetic autonomic dysfunction have been prevented, thus demonstrating that exercise does not alter the effects of the receptor blockade. This article is inscribed in the interesting line of research that moves from the assertion that the mechanisms by which supraphysiological doses of SA cause cardiac depolarization disturbances and autonomic dysfunction have not yet been clearly established. More generally, it is extremely important and very opportune to see how and why the use of chronic supraphysiological doses of SA induces cardiovascular disorders up to determine sudden cardiac death in healthy young athletes. Animal model studies have been conducted to evaluate the impact of SA supraphysiological doses on the cardiovascular system and on myocardial injury and to understand the pathogenesis of ventricular remodelling and dysfunction, of ventricular arrhythmias and of sudden cardiac death associated with SA-abuse. Taken together, these studies support the hypothesis that supraphysiological doses of SA induce adrenergic overstimulation and myocardial injury in addition to cardiac dysautonomia. In fact, the electrical and histological remodelling induced by SA may create a substrate causing electrical disturbances and sudden cardiac death. Some authors suggested that nandrolone could cause the release of intracellular calcium and thereby explain the pro-arrhythmic effects observed in rats. In a recent experimental study, researchers treated rats with supraphysiological doses of ND in association with exercise, and they observed an increase in heart collagen concentration associated with the activation of the cardiac RAS. These pathophysiological changes undoubtedly provide an anatomo-pathological substrate that may explain the increased propensity to the generation and continuation of malignant cardiac arrhythmias. An explanation, placed at the base of these pathogenic mechanisms, resides in the alteration of the sympathetic autonomic activity modulated by the RAS. It is well known that many deleterious actions on the cardiovascular
system are connected to the function of the AT1R. The stimulation of AT1R is involved in modulating cell growth and proliferation of vascular smooth muscle cells, cardiomyocytes and endothelial cells, thus being at the basis of endothelial dysfunction, atherosclerotic vascular phenomena, congestive heart failure and, finally, myocardial infarction. All the pathological phenomena listed above are combined and are determined by the AT1R mediation which underlies the pathogenesis of left ventricular remodelling, of myocardium hypertrophy and fibrosis and of cardiac apoptosis. Regarding fibrosis, many experimental data appear to show that the RAS plays an important role in the development of myocardial fibrosis and of left ventricle hypertrophy. Conversely, the blocking of AT1R determines the regression of the phenomena of ventricular hypertrophy. Recently, the same research group presented the results about heart rate variability analysis in human and animal model, showing a SA-induced cardiac autonomic imbalance, with reduction in parasympathetic cardiac modulation and increase in sympathetic cardiac modulation. These data are in accord with post-mortem histopathological data from SA users, because the presence of contraction band necrosis in the myocardium is associated with adrenergic overstimulation. One study group has over the years shown that major cardiac abnormalities, found experimentally in the hearts of rats treated with high doses of SA, are due to overstimulation of adrenergic mechanisms. Moreover, the study group has investigated the role of cytokines and the interactions of TNF-alpha in the induction of cardiac apoptotic mechanism, which represents a line of research worthy of attention. Again, the findings based on data from experimental studies in animals, support the hypothesis that the combined effects of strenuous exercise and of the abuse of SA, stimulating the sympathetic nervous system, may predispose to myocardial injury and consequent heart failure mediated by oxidative stress. These cardiovascular effects of SA are mediated by genomics (intracellular androgen receptor – nuclear transcription – gene expression) and non-genomic mechanisms. The sympathetic modulatory role of the RAS is quite recently reiterated in literature: during physical inactivity vasomotor sympathetic tone is inhibited, while sympathetic activation is enhanced as a result of physical stress. Certainly, experimental studies have the duty to determine the influence of physical activity in causing cardiac dysfunction. In this study, this has been carried out by the authors with great care, and the conclusions are that cardiac autonomic dysfunction and repolarisation disturbances also occur in exercised rats, which were administered supraphysiological doses of SA. From the data presented, it can be realized that to date considerable research has led to the identification of a growing number of SA-adverse effects due to abuse in healthy athletes. However, it should be kept in mind that, although substantial progress has been made in identifying novel mechanism of damage of SA-abuse, great efforts are still needed to elucidate their pathophysiological mechanisms [13225].

Harmful effects on brain axons

Anabolic-androgenic steroids (AAS) are used in the medical treatment of many disorders. Erythropoietin (EPO) is a hematopoietic cytokine that has anti-apoptotic, anti-oxidative, and anti-inflammatory effects. The aim of one study was to investigate the neuroprotective effects of EPO in the hippocampus, parietal cortex and prefrontal cortex, in brain damage due to nandrolone decanoate. 35 Wistar male rats were randomly divided into: (1) control group, (2) sham group, (3) nandrolone decanoate group (ND, intramuscular, 10 mg/(kg week), 8 weeks), (4) ND+low dose EPO treated group (ND+L-EPO) and (5) ND+high dose EPO treated group (ND+H-EPO). EPO was administrated by intraperitoneal injection at a dose of 100 U/(kg day) for L-EPO treatment and at a dose of 500 U/(kg day) for H-EPO treatment during 8 weeks. The number of neurons of CA1, CA2, CA3 and dentate gyrus of hippocampus, parietal cortex and prefrontal cortex were significantly less in the ND group compared with the control group. Treatment with H-EPO significantly preserved the number of neurons in hippocampus when compared with ND administrated. Besides, H-EPO
treatment decreased the number of TUNEL-positive and active caspase-3 positive cells and MDA levels and increased GPx levels when compared to ND group. In conclusion, abuse of AAS causes reduction in the number of neurons in hippocampus, parietal cortex and prefrontal cortex regions and increases oxidative damage and therefore H-EPO may be useful as a neuroprotective agent in brain injury [13226].

**Harmful effects on learning capacity**

Chronic exposure to the anabolic androgenic steroids (AAS) nandrolone decanoate (ND) in supra-physiological doses is associated with learning and memory impairments. Given the well-known beneficial effects of voluntary exercise on cognitive functions, we examined whether voluntary exercise would improve the cognitive deficits induced by chronic administration of ND. We also investigated the effects of ND and voluntary exercise on hippocampal BDNF levels. The rats were randomly distributed into 4 experimental groups: the vehicle-sedentary group, the ND-sedentary group, the vehicle-exercise group, and the ND-exercise group. The vehicle-exercise and the ND-exercise groups were allowed to freely exercise in a running wheel for 15 days. The vehicle-sedentary and the ND-sedentary groups were kept sedentary for the same period. Vehicle or ND injections were started 14 days prior to the voluntary exercise and continued throughout the 15 days of voluntary exercise. After the 15-day period, the rats were trained and tested on a water maze spatial task using four trials per day for 5 consecutive days followed by a probe trial two days later. Exercise significantly improved performance during both the training and retention of the water maze task, and enhanced hippocampal BDNF. ND impaired spatial learning and memory, and this effect was not rescued by exercise. ND also potentiated the exercise-induced increase in hippocampal BDNF levels. These results seem to indicate that voluntary exercise is unable to improve the disruption of cognitive functions by chronic ND. Moreover, increased levels of BDNF may play a role in ND-induced impairments in learning and memory. The harmful effects of ND and other AAS on learning and memory should be taken into account when athletes decide to use AAS for performance or body image improvement [13229].

**Effect on hypertension**

The aims of one study were to evaluate the effects of nandrolone (ND) on cardiac inflammatory cytokines, ACE activity, troponin I, and the sensitivity of the Bezold-Jarisch reflex (BJR). Male Wistar rats were administered either ND (20 mg/kg; DECA) or vehicle (control animals; CONT) for 4 weeks. BJR was analyzed by measuring the bradycardia and hypotension responses elicited by serotonin administration (2-32 μg/kg). Mean arterial pressure (MAP) was assessed and myocyte hypertrophy was determined by the heart weight/body weight ratio and by morphometric analysis. Matrix collagen deposition was assessed by histological analysis of the picrosirius red-stained samples. Mesenteric vascular reactivity was performed and central venous pressure (CVP) evaluated. Cardiac inflammatory cytokine levels and angiotensin-converting enzyme (ACE) activity were studied as well the biomarker of cardiac lesion, troponin I. DECA group showed enhancement of matrix type I collagen deposition and cardiac ACE activity compared with the CONT. Interleukin (IL)-10 was reduced and pro-inflammatory cytokines (TNF-alpha and IL-6) were increased in the DECA group compared with CONT. Cardiac injury was observed in the DECA group shown by the reduction in cardiac troponin I compared with the CONT group. Animals in the DECA group also developed myocyte hypertrophy and reduction of BJR sensitivity. The MAP of animals treated with ND reached hypertensive levels. No changes in CVP and vascular reactivity were observed in both experimental groups. It was concluded that high doses of ND elicit cardiotoxic effects with cardiac remodelling and injury. Cardiac
changes reduce the BJR sensitivity. Together, these abnormalities contributed to the development of hypertension in animals in the DECA group [13224].

**Effect on peripheral nerve injury**

Suboptimal recovery following repair of major peripheral nerves has been partially attributed to denervation atrophy. Administration of anabolic steroids in conjunction with neurotization may improve functional recovery of chronically denervated muscle. The purpose of one study was to evaluate the effect of the administration of nandrolone on muscle recovery following prolonged denervation in a rat model. Eight groups of female Sprague-Dawley rats (15 rats per group, 120 in all) were divided into 3- or 6-month denervated hind limb and sham surgery groups and, then, nandrolone treatment groups and sham treatment groups. Evaluation of treatment effects included nerve conduction, force of contraction, comparative morphology, histology (of muscle fibers), protein electrophoresis (for muscle fiber grouping), and immunohistochemical evaluation. Although a positive trend was noted, neither reinnervated nor normal muscle showed a statistically significant increase in peak muscle force following nandrolone treatment. Indirect measures, including muscle mass (weight and diameter), muscle cell size, muscle fiber type, and satellite cell counts, all failed to support significant anabolic effect. Thus, there does not seem to be a functional benefit from nandrolone treatment following reinnervation of either mild or moderately atrophic muscle (related to prolonged denervation) in a rodent model [13227].

**Effect on growth hormone**

Growth hormone (GH) and anabolic androgenic steroids (AAS) are commonly used in sports communities. Several studies have suggested an association between GH and AAS. It was investigated the impact of GH in rats treated with nandrolone decanoate (ND). Male Wistar rats received ND (15 mg/kg) every third day during three weeks and were subsequently treated with recombinant human GH (1.0 IU/kg) for ten consecutive days. Plasma samples were collected and peripheral organs (i.e. heart, liver, testis and thymus) were dissected and weighed. Concentration of thirteen endogenous steroids was measured in the rat plasma samples using high specificity LC-MS/MS methods. Seven steroids were detected and quantified, and concentrations of estrone, testosterone, and androstenedione were significantly different among the groups, while concentrations of pregnenolone, DHEA, 17-hydroxyprogesterone and corticosterone were not altered. Administration of rhGH alone altered the plasma steroid distribution, and the results demonstrated significantly increased concentrations of plasma estrone as well as decreased concentrations of testosterone and androstenedione in the ND-treated rats. Administration of rhGH to ND-pretreated rats did not reverse the alteration of the steroid distribution induced by ND. Administration of ND decreased the weight of the thymus, and addition of rhGH did not reverse this reduction. However, rhGH administration induced an enlargement of thymus. Taken together, the plasma steroid profile differed in the four groups, i.e. control, AAS, rhGH and the combination of AAS and rhGH treatment [13228].

**Interaction with receptors**

Interest in anabolic steroids has been renewed in the last decade with the discovery of tissue-selective androgen receptor modulators exhibiting high myotropic and small androgenic activity. An explanation put forward by us in 1982 for the mechanism of the
preferential myotropic effect of nandrolone (19-nortestosterone) exploits the fundamental difference between the 5alpha-reductase concentrations in skeletal muscle and androgenic target tissue. In androgenic tissue, testosterone is converted to the more potent 5alpha-dihydrotestosterone whereas nandrolone is converted to a less potent derivative. As 5alpha-reduction is negligible in skeletal muscle, this explains why nandrolone shows a greater myotropic to androgenic ratio when compared with testosterone. Anabolic steroids that do not undergo 5alpha-reduction exert myotropic-androgenic dissociation because their effect in androgenic tissues is not amplified by 5alpha-reduction. Tissue selectivity by receptor modulators may be achieved by inducing specific conformational changes of the androgen receptor that affect its interaction with transcriptional coregulators. Anabolic activity is mediated by the stimulation of ribosomal RNA synthesis therefore regulation of this synthesis by anabolic steroids would deserve detailed studies [09119].

Effect of small doses on stress response

Androgenic-anabolic steroid (AAS) misuse has been associated with depression. It has been proposed that stress has a role in depression and that serotonin is involved in both endocrine responses to stress and depressive physiopathology. Although reports demonstrate that AAS chronic administration modifies components of stress-responsive hypothalamic-pituitary-adrenal axis (HPAA), no study has evaluated AAS effect on the response to stressful stimuli. We studied the effects of the subchronic administration (once a day for 14 days in rats) of a supratherapeutical dose of nandrolone decanoate (ND) on HPAA and cortical serotoninergic system response to acute restraint stress (RS). Acute RS produced the following effects: increase in CORT (in blood) and ACTH (both in blood and in pituitary corticotropes), GR depletion in hippocampus and hypothalamus cytosol and GR translocation in hippocampus nuclear fraction, cortical serotonin re-uptake stimulation and hippocampus cytosolic ERK2 activation. ND by itself, i.e. in non-stressed rats, did not modify these parameters, except for a decrease of plasma CORT and ACTH levels and an increase in hippocampus cytosolic phospho-ERK1/2. On the contrary, in stressed rats ND affected stress-induced plasma ACTH increase and prevented all other above reported stress effects, except the increase in pituitary ACTH positive cell density. The results show that the prolonged administration of a supratherapeutical dose of ND in rats, albeit did not affect in a notable way HPAA and serotonin transporter activity in the absence of stress, may deregulate the stress-induced hormonal cascade which plays a crucial role in depressive psychopathology [12162].

Aortic adaptations to exercise

In one study it was investigated the interaction between exercise-induced mitochondrial adaptation of large vessels and the effects of chronic anabolic androgenic steroids (AASs). Four groups of Sprague-Dawley rats were studied: (i) sedentary, (ii) sedentary + nandrolone-treated, (iii) aerobic exercise trained, and (iv) trained + nandrolone-treated. Aerobic training increased the levels of aortic endothelial nitric oxide synthase (eNOS) and heme oxygenase-1 (HO-1) in accordance with improved acetylcholine-induced vascular relaxation. These beneficial effects were associated with induction of mitochondrial complexes I and V, increased mitochondrial DNA copy number, and greater expression of transcription factors involved in mitochondrial biogenesis/fusion. It was also observed enhanced mitochondrial autophagy pathway activity, including increased conversion of LC3-I to LC3-II and greater expression of beclin1 and autophagy-related protein-7 (ATG7). The levels of thiobarbituric acid-reactive substances and protein carbonyls remained unchanged, whereas significant increases in catalase and mitochondrial manganese superoxide dismutase (MnSOD) levels
were observed in the aortas of trained animals, when compared with sedentary controls. Nandrolone increased oxidative stress biomarkers and inhibited exercise-induced increases of eNOS, HO-1, catalase, and MnSOD expression. In addition, it also attenuated elevated peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1alpha) and mitofusin-2 expression, and further up-regulated LC3II conversion, beclin1, ATG7, and dynamin-related protein-1 expression. These results demonstrate that nandrolone attenuates aortic adaptations to exercise by regulating mitochondrial dynamic remodelling, including down-regulation of mitochondrial biogenesis and intensive autophagy [13232].

**Nandrolone-mediated testosterone reduction during alcohol intoxication**

Human studies have indicated that the use of anabolic androgenic steroids may be associated with the abuse of alcohol and other drugs. Also, experimental animal research has indicated that chronic nandrolone administration subsequently increases voluntary alcohol drinking. The aim of one study was to test a hypothesis that alcohol-induced testosterone elevation, especially associated with stress conditions derived by nandrolone treatment, could be the underlying factor in causing increased alcohol drinking. Male alcohol-prefering AA and low drinking Wistar rats were randomly divided into control and nandrolone decanoate treated (15 mg/kg for 14 days) groups. Basal serum testosterone and corticosterone were determined before the first nandrolone treatment, after 7days of treatment, and after an additional (7/day) washout period, during which also the acute effect of alcohol (1.5 g/kg) on steroid hormones was determined. Hereafter followed a (5/week) voluntary alcohol consumption period, during the last 2 weeks of which the rats were treated again with nandrolone. Both normal and reversed dark- versus light-cycle experimental designs were used. Contrary to the hypothesis, nandrolone treatment decreased voluntary alcohol consumption in both AA and Wistar rats. Also, instead of stress causation, elevated basal testosterone and lowered basal corticosterone levels were observed after nandrolone treatment in both AA rats and Wistars. During acute alcohol intoxication the frequency of testosterone decreases was higher in the nandrolone-treated groups compared with control AA and Wistar rats. Present data support the hypothesis that nandrolone-treatment mediated attenuation of alcohol intake in both AA and Wistar rats may be the result of negative reinforcement caused by alcohol-mediated testosterone reduction [13233].

**Impact of nandrolone on biosynthesis of steroids**

Growth hormone (GH) and anabolic androgenic steroids (AAS) are commonly used in sports communities. Several studies have suggested an association between GH and AAS. It was investigated the impact of GH in rats treated with nandrolone decanoate (ND). Male Wistar rats received ND (15 mg/kg) every third day during three weeks and were subsequently treated with recombinant human GH (1.0 IU/kg) for ten consecutive days. Plasma samples were collected and peripheral organs (i.e. heart, liver, testis and thymus) were dissected and weighed. Concentration of thirteen endogenous steroids was measured in the rat plasma samples using high specificity LC-MS/MS methods. Seven steroids were detected and quantified, and concentrations of estrone, testosterone, and androstenedione were significantly different among the groups, while concentrations of pregnenolone, DHEA, 17-hydroxyprogesterone and corticosterone were not altered. Administration of rhGH alone altered the plasma steroid distribution, and the results demonstrated significantly increased concentrations of plasma estrone as well as decreased concentrations of testosterone and androstenedione in the ND-treated rats. Administration of rhGH to ND-pretreated rats did not reverse the alteration of the steroid distribution induced by ND. Administration of ND decreased the weight of the thymus, and addition of rhGH did not reverse this reduction.

721
However, rhGH administration induced an enlargement of thymus. Taken together, the plasma steroid profile differed in the four groups, i.e. control, AAS, rhGH and the combination of AAS and rhGH treatment [13234].

Effects of nandrolone on recovery of denervated muscle

Suboptimal recovery following repair of major peripheral nerves has been partially attributed to denervation atrophy. Administration of anabolic steroids in conjunction with neurotization may improve functional recovery of chronically denervated muscle. The purpose of one study was to evaluate the effect of the administration of nandrolone on muscle recovery following prolonged denervation in a rat model. Eight groups of female Sprague-Dawley rats (15 rats per group, 120 in all) were divided into 3- or 6-month denervated hind limb and sham surgery groups and, then, nandrolone treatment groups and sham treatment groups. Evaluation of treatment effects included nerve conduction, force of contraction, comparative morphology, histology (of muscle fibers), protein electrophoresis (for muscle fiber grouping), and immunohistochemical evaluation. Although a positive trend was noted, neither reinnervated nor normal muscle showed a statistically significant increase in peak muscle force following nandrolone treatment. Indirect measures, including muscle mass (weight and diameter), muscle cell size, muscle fiber type, and satellite cell counts, all failed to support significant anabolic effect. It was concluded that there does not seem to be a functional benefit from nandrolone treatment following reinnervation of either mild or moderately atrophic muscle (related to prolonged denervation) in a rodent model [13235].

Genotoxic effects

To evaluate the impact potential of nandrolone decanoate on DNA damage in multiple organs of Wistar rats by means of single-cell gel (comet) assay and micronucleus test. A total of 15 animals were distributed into three groups of five animals each as follows: control group was animal not exposed to nandrolone decanoate; experimental group was animals exposed to nandrolone decanoate for 24 h at 5 mg/kg subcutaneously; and experimental group was animals exposed to nandrolone decanoate for 24 h at 15 mg/kg subcutaneously. Significant statistical differences were noted in peripheral blood, liver, and heart cells exposed to nandrolone decanoate at the two doses evaluated. A clear dose-response relationship was observed between groups. Kidney cells showed genetic damage at only the highest dose (15 mg/kg) used. However, micronucleus data did not show remarkable differences among groups. In conclusion, the present study indicates that nandrolone decanoate induces genetic damage in rat blood, liver, heart, and kidney cells as shown by single-cell gel (comet) assay results [13236].

Nandrolone is an androgenic-anabolic steroid (AAS) with diverse medical applications but taken indiscriminately by some to rapidly increase muscle mass. The aim of one study was to evaluate the genotoxic and clastogenic potential of nandrolone (Deca-Durabolin®) in vivo in different cells of mice, using the comet assay and micronucleus test, respectively. The animals received subcutaneous injection of the three doses of the steroid (1.0, 2.5 and 5.0 mg/kg body weight). Cytotoxicity was assessed by scoring 200 consecutive total polychromatic (PCE) and normochromatic (NCE) erythrocytes (PCE-NCE ratio). The results showed a significant dose-related increase in the frequency of DNA damage in leukocytes, liver, bone marrow, brain and testicle cells at the three tested doses and a significant increase of the micronucleated polychromatic erythrocytes at all tested doses. Under our
experimental conditions, the nandrolone steroid hormone showed genotoxic and clastogenic effects when administered subcutaneously to mice [12163].

**Upregulation of aromatase expression**

Several doping agents, such as anabolic androgenic steroids (AAS) and peptide hormones like insulin-like growth factor-I (IGF-I), are employed without considering the potential deleterious effects that they can cause. In addition, androgens are used in postmenopausal women as replacement therapy. However, there are no clear guidelines regarding the optimal therapeutic doses of androgens or long-term safety data. In this study we aimed to determine if two commonly used AAS, nandrolone and stanozolol, alone or in combination with IGF-I, could activate signaling involved in breast cancer cell proliferation. Using a human breast cancer cell line, MCF-7, as an experimental model we found that both nandrolone and stanozolol caused a dose-dependent induction of aromatase expression and, consequently, estradiol production. Moreover, when nandrolone and stanozolol were combined with IGF-I, higher induction in aromatase expression was observed. This increase involved phosphatidylinositol 3-kinase (PI3K)/AKT and phospholipase C (PLC)/protein kinase C (PKC), which are part of IGF-I transductional pathways. Specifically, both AAS were able to activate membrane rapid signaling involving IGF-I receptor, extracellular regulated protein kinases 1/2 (ERK1/2) and AKT, after binding to estrogen receptor (ER), as confirmed by the ability of the ER antagonist ICI182, 780 to block such activation. The estrogenic activity of nandrolone and stanozolol was further confirmed by their capacity to induce the expression of the ER-regulated gene, CCND1 encoding for the cell cycle regulator cyclin D1, which represents a key protein for the control of breast cancer cell proliferation. In fact, when nandrolone and stanozolol were combined with IGF-I, they increased cell proliferation to levels higher than those elicited by the single factors. Taken together these data clearly indicate that the use of high doses of AAS, as occurs in doping practice, may increase the risk of breast cancer. This potential risk is higher when AAS are used in association with IGF-I. This might be the first report directly associating AAS with this type of cancer [12164].

**Effect of small doses on stress response**

Androgenic-anabolic steroid (AAS) misuse has been associated with depression. It has been proposed that stress has a role in depression and that serotonin is involved in both endocrine responses to stress and depressive physiopathology. Although reports demonstrate that AAS chronic administration modifies components of stress-responsive hypothalamic-pituitary-adrenal axis (HPAA), no study has evaluated AAS effect on the response to stressful stimuli. We studied the effects of the subchronic administration (once a day for 14 days in rats) of a supratherapeutical dose of nandrolone decanoate (ND) on HPAA and cortical serotoninergic system response to acute restraint stress (RS). Acute RS produced the following effects: increase in CORT (in blood) and ACTH (both in blood and in pituitary corticotropes), GR depletion in hippocampus and hypothalamus cytosol and GR translocation in hippocampus nuclear fraction, cortical serotonin re-uptake stimulation and hippocampus cytosolic ERK2 activation. ND by itself, i.e. in non-stressed rats, did not modify these parameters, except for a decrease of plasma CORT and ACTH levels and an increase in hippocampus cytosolic phospho-ERK1/2. On the contrary, in stressed rats ND affected stress-induced plasma ACTH increase and prevented all other above reported stress effects, except the increase in pituitary ACTH positive cell density. The results show that the prolonged administration of a supratherapeutical dose of ND in rats, albeit did not affect in a notable way HPAA and
serotonin transporter activity in the absence of stress, may deregulate the stress-induced hormonal cascade which plays a crucial role in depressive psychopathology [12162].

Genotoxic effects

Nandrolone is an androgenic-anabolic steroid (AAS) with diverse medical applications but taken indiscriminately by some to rapidly increase muscle mass. The aim of one study was to evaluate the genotoxic and clastogenic potential of nandrolone (Deca-Durabolin®) in vivo in different cells of mice, using the comet assay and micronucleus test, respectively. The animals received subcutaneous injection of the three doses of the steroid (1.0, 2.5 and 5.0 mg/kg body weight). The results showed a significant dose-related increase in the frequency of DNA damage in leukocytes, liver, bone marrow, brain and testicle cells at the three tested doses and a significant increase of the micronucleated polychromatic erythrocytes at all tested doses. Under our experimental conditions, the nandrolone steroid hormone showed genotoxic and clastogenic effects when administered subcutaneously to mice [12163].

Upregulation of aromatase expression

Several doping agents, such as anabolic androgenic steroids (AAS) and peptide hormones like insulin-like growth factor-I (IGF-I), are employed without considering the potential deleterious effects that they can cause. In addition, androgens are used in postmenopausal women as replacement therapy. However, there are no clear guidelines regarding the optimal therapeutic doses of androgens or long-term safety data. In this study we aimed to determine if two commonly used AAS, nandrolone and stanozolol, alone or in combination with IGF-I, could activate signaling involved in breast cancer cell proliferation. Using a human breast cancer cell line, MCF-7, as an experimental model we found that both nandrolone and stanozolol caused a dose-dependent induction of aromatase expression and, consequently, estradiol production. Moreover, when nandrolone and stanozolol were combined with IGF-I, higher induction in aromatase expression was observed. This increase involved phosphatidylinositol 3-kinase (PI3K)/AKT and phospholipase C (PLC)/protein kinase C (PKC), which are part of IGF-I transductional pathways. Specifically, both AAS were able to activate membrane rapid signaling involving IGF-I receptor, extracellular regulated protein kinases 1/2 (ERK1/2) and AKT, after binding to estrogen receptor (ER), as confirmed by the ability of the ER antagonist ICI182, 780 to block such activation. The estrogenic activity of nandrolone and stanozolol was further confirmed by their capacity to induce the expression of the ER-regulated gene, CCND1 encoding for the cell cycle regulator cyclin D1, which represents a key protein for the control of breast cancer cell proliferation. In fact, when nandrolone and stanozolol were combined with IGF-I, they increased cell proliferation to levels higher than those elicited by the single factors. Taken together these data clearly indicate that the use of high doses of AAS, as occurs in doping practice, may increase the risk of breast cancer. This potential risk is higher when AAS are used in association with IGF-I. This might be the first report directly associating AAS with this type of cancer [12164].

Endogenous or exogenous origin of nandrolone

On the one hand, 19-norandrosterone (NA) is the most abundant metabolite of the synthetic anabolic steroid 19-nortestosterone and related prohormones. On the other hand, small
amounts are biosynthesized by pregnant women and further evidence exists for physiological origin of this compound. The World Anti-Doping Agency (WADA) formerly introduced threshold concentrations of 2 or 5 ng of NA per ml of urine to discriminate 19-nortestosterone abuse from biosynthetic origin. Recent findings showed however, that formation of NA resulting in concentrations in the range of the threshold levels might be due to demethylation of androsterone in urine, and the WADA 2006 Prohibited List has defined NA as endogenous steroid. To elucidate the endogenous or exogenous origin of NA, $^{13}$C/$^{12}$C-analysis is the method of choice since synthetic 19-nortestosterone is derived from C(3)-plants by partial synthesis and shows delta$^{13}$C(VPDB)-values of around -28 per thousand. Endogenous steroids are less depleted in $^{13}$C due to a dietary mixture of C(3)- and C(4)-plants. An extensive cleanup based on two high performance liquid chromatography cleanup steps was applied to quality control and doping control samples, which contained NA in concentrations down to 2 ng per ml of urine. $^{13}$C/$^{12}$C-ratios of NA, androsterone and etiocholanolone were measured by gas chromatography/combustion/isotope ratio mass spectrometry. By comparing delta$^{12}$C(VPDB)-values of androsterone as endogenous reference compound with NA, the origin of NA in doping control samples was determined as either endogenous or exogenous [06107].

**Significance of 19-norandrosterone in athletes' urine**

Nandrolone and other 19-norsteroid potent anabolic steroids have been prohibited in sports for 30 years. The detection of the main urinary metabolite – 19-norandrosterone – in amounts greater than 2 ng/ml constitutes an adverse analytical finding. The presence in nutritional sport supplements of steroids not listed on the label has undoubtedly resulted in positive tests, but inadvertent consumption of meat containing residues of hormonal treatment should not realistically cause apprehension. Although highly improbable, athletes should prudenty avoid meals composed of pig offal in the hours preceding the test since the consumption of edible parts of a non-castrated pig, containing 19-nortestosterone, has been shown to results in the excretion of 19-norandrosterone in the following hours. Norsteroid metabolites are formed during pregnancy and excreted as minor metabolites of norethisterone, and minute amounts have been identified in some male and female samples when using more sensitive techniques of detection. Whereas exercise does not seem to be a significant factor in 19-norandrosterone excretion, some rare urine samples were found to be a suitable medium for in situ 19-demethylation of urinary metabolites [06106].

**Laboratory techniques**

Nandrolone, an anabolic steroid, is used for the treatment of several diseases and is available in various pharmaceutical formulations. The most widely used pharmaceutical formulation is Deca-Durabolin®, but other products, such as Keratyl eye drops solution, are also currently administered. Nandrolone is one of the most abused anabolic steroid in sports. Analyses for this anabolic steroid according to the World Anti-Doping Agency (WADA) protocol are based on the identification of the nandrolone two main urinary metabolites which, in humans, are glucuronides of 19-norandrosterone and 19-noretiocholanolone. A positive cut off limit of 2 ng/mL has been set by the anti-doping code for the first metabolite, 19-norandrosterone. In this preliminary study, an eye drops solution (Keratyl®) containing a therapeutic dose of a nandrolone sodium sulphate was administered to several male volunteers during 3 days and urines were collected during 3 weeks. Surprisingly, contrary to all expectations, the urinary concentrations measured in urines reached 450 ng/mL and 70 ng/mL for norandrosterone and noretiocholanolone, respectively. Moreover, concentration...
levels near to 2 ng/mL were found, more than 2 weeks after the last administration, depending on individual metabolism. Inter-variability as well as intra-variability of nandrolone excretion kinetic, regarding this particular administration mode, were also evaluated. Quantification of nandrolone metabolites was performed by GC–MS. The method was previously validated in terms of specificity, precision, linearity, LOD, LOQ, robustness, accuracy and the expanded uncertainty was also evaluated [07089].

**Liquid chromatography/tandem mass spectrometry**

A confirmatory method for the simultaneous determination of nandrolone (alpha and beta) and trenbolone (alpha and beta) in urine samples by liquid chromatography electrospray mass spectrometry (LC-MS-MS) was developed. After an enzymatic deconjugation, the urine was subjected to a one-step cleanup on a commercially available immunoaffinity chromatography cartridge. The analytes were detected by liquid chromatography-positive ion electrospray tandem mass spectrometry using deuterium labelled internal standards. The analytical procedure was applicable to bovine and swine urine samples. The procedure was validated as a quantitative confirmatory method according to the Commission Decision 2002/657/EC criteria. The results obtained showed that the method was suitable for statutory residues testing regarding the following performance characteristics: instrumental linearity, specificity, precision (repeatability and intra-laboratory reproducibility), recovery, decision limit (CCalpha), detection capability (CCbeta) and ruggedness. The decision limits (CCalpha) obtained, were between 0.54 and 0.60 μg/L; the recovery was above 64 percent for all the analytes. Repeatability was between 1.6 percent and 5.7 percent and within-laboratory reproducibility between 1.6 percent and 6.0 percent for all the steroids [09121].

19-Norandrosterone sulfate (19-NAS) is the sulfoconjugated form of 19-norandrosterone (19-NA), the major metabolite of the steroid nandrolone. A sensitive and accurate liquid chromatography/tandem mass spectrometry (LC-MS/MS) assay was developed for the direct measurement of 19-NAS in human urine samples. The method involved a quaternary amine SPE protocol and subsequently injection of the extract onto an analytical column (Uptisphere ODB, 150 mm x 3.0 mm, 5 microm) for chromatographic separation and mass spectrometry detection in negative electrospray ionisation mode. The sulfoconjugate of 19-NA was identified in urine by comparison of mass spectra and retention time with a reference substance. The limit of detection (LOD) and lowest limit of quantification (LLOQ) of 19-NAS were of 40 pg/mL and 200 pg/mL, respectively. For a nominal concentration of 2 ng/mL, recovery (94 %), intra-day precision (2.7 %), intra-assay precision (6.6 %) and inter-assay precision (14.3 %) were determined. Finally, this analytical method was applied for quantifying the concentration of 19-NAS in doping samples, using calibration curves (0.2-20 ng/mL) and the standard-addition method. The results show the feasibility of applying this LC-MS/MS assay as a complementary tool to detect misuse of nandrolone or nandrolone precursors [07090].

Determination of nandrolone metabolites in human urine: comparison between liquid chromatography/tandem mass spectrometry and gas chromatography/mass spectrometry. Nandrolone (19-nortestosterone) is an androgenic anabolic steroid illegally used as a growth-promoting agent in animal breeding and as a performance enhancer in athletics. Therefore, its use was officially banned in 1974 by the Medical Commission of the International Olympic Committee (IOC). Following nandrolone administration, the main metabolites in humans are 19-norandrosterone, 19-norethiocolanolone and 19-norepiandrosterone, and their presence in urine is the basis of detecting its abuse. One work was undertaken to determine, in human urine, nandrolone metabolites (phase I and phase II) by developing and comparing multiresidue liquid chromatography/tandem mass spectrometry (LC/MS/MS) and gas chromatography/mass spectrometry (GC/MS) methods. A double extraction by solid-phase
extraction (SPE) was necessary for the complete elimination of the interfering compounds. The proposed methods were also tested on a real positive sample, and they allow us to determine the conjugated/free fractions ratio reducing the risk of false positive or misleading results and they should allow laboratories involved in doping control analysis to monitor the illegal use of steroids. The advantages of LC/MS/MS over GC/MS (which is the technique mainly used) include the elimination of the hydrolysis and derivatization steps: it is known that during enzymatic hydrolysis several steroids can be converted into related compounds and deconjugation is not always 100 percent effective. The validation parameters for the two methods were similar (limit of quantification (LOQ) <1 ng/mL and percentage coefficient of variance (CV %) <16.4), and both were able to confirm unambiguously all the analytes, thus confirming the validity of both techniques [10344].

19-Norandrosterone (19-NA) is the major metabolite of the steroid nandrolone, one of the most commonly abused anabolic androgenic agents. 19-NA exists mainly as the glucuronide form in human urine. A candidate reference measurement procedure for 19-NA in urine involving isotope dilution coupled with liquid chromatography/tandem mass spectrometry (LC/MS/MS) has been developed and critically evaluated. The 19-NA glucuronide was enzymatically hydrolyzed, and the 19-NA along with its internal standard (deuterated 19-NA) was extracted from urine using liquid-liquid extraction prior to reversed-phase LC/MS/MS. The accuracy of the measurement of 19-NA was evaluated by a recovery study of added 19-NA. The recovery of the added 19-NA ranged from 99.1 to 101.4 percent. This method was applied to the determination of 19-NA in urine samples fortified with 19-NA glucuronide at three different concentrations (equivalent to 1, 2, and 10 ng/mL 19-NA). Excellent reproducibility was obtained with within-set coefficients of variation (CVs) ranging from 0.2 to 1.2 percent, and between-set CVs ranging from 0.1 to 0.5 percent. Excellent linearity was also obtained with correlation coefficients of all linear regression lines (measured intensity ratios vs mass ratios) ranging from 0.9997 to 0.9999. The detection limit for 19-NA at a signal-to-noise ratio of approximately 3 was 16 pg. The mean results of 19-NA yielded from hydrolysis of 19-NA glucuronide compared well with the theoretical values (calculated from the conversion of 19-NA glucuronide to 19-NA) with absolute relative differences ranging from 0.2 to 1.4 percent. This candidate reference measurement procedure for 19-NA in urine, which demonstrates good accuracy and precision and low susceptibility to interferences, can be used to provide an accuracy base to which routine methods for 19-NA can be compared and that will serve as a standard of higher order for measurement traceability [06108].

**Cyclic, differential pulse and square-wave voltammetry**

The electrochemical behaviour of nandrolone was investigated by cyclic, differential pulse and square-wave voltammetry in phosphate buffer system at fullerene-C60-modified electrode. The modified electrode shows an excellent electrocatalytic activity towards the oxidation of nandrolone resulting in a marked lowering in the peak potential and considerable improvement of the peak current as compared to the electrochemical activity at the bare glassy carbon electrode. The oxidation process is shown to be irreversible and diffusion-controlled. A linear range of 50 microM to 0.1 nM is obtained along with a detection limit and sensitivity of 0.42 nM and 0.358 nA/nM, respectively, in square-wave voltammetric technique. The effect of interferents, stability and reproducibility of the proposed method were also studied. The described method was successfully employed for the determination of nandrolone in human serum and urine samples. A cross-validation of observed results by GC-MS indicates that the results are in good agreement with each other [07091].

**Gas chromatography-tandem mass spectrometry**

727
A rapid sample treatment procedure for the gas chromatography-tandem mass spectrometry (GC-MS) determination of 19-nortestosterone (19-NT) in animal tissues has been developed. In our optimized procedures, enzymatic hydrolysis with beta-glucuronidase from Escherichia coli was performed in an acetate buffer (pH 5.2, 0.2 mol/L). Next, the homogenate was mixed with methanol and heated at 60 °C for 15 min, then placed in an ice-bath at -18 °C for 2 h. After liquid-liquid extraction with n-hexane, the analytes were subjected to a normal-phase solid phase extraction (SPE) C₁₈ cartridge for clean-up. The dried organic extracts were derivatized with heptafluorobutyric anhydride (HFBA), and then the products were injected into GC-MS. Using electron impact mass spectrometry (EI-MS) with positive chemical ionization (PCI), four diagnostic ions (m/z 666, 453, 318, and 306) were determined. A standard calibration curve over the concentration range of 1-20 ng/g was reached, and the detection limit was 0.3 ng. When applied to spiked samples collected from bovine and ovine, the recoveries ranged from 63 to 101 percent with relative standard deviation (RSD) between 2.7 and 8.9 percent. The procedure is a highly efficient, sensitive, and more economical method which offers considerable potential to resolve cases of suspected nandrolone doping in husbandry animals [11099].

**Experimental**

The abuse of anabolic androgenic steroids (AASs) is not only a problem in the world of sports but is associated with the polydrug use of nonathletes. Investigations of the neurochemical effects of AAS have focused in part on the monoaminergic systems, involving, among other things, the development of dependence. It has previously been shown that pretreatment with nandrolone decanoate attenuates dose-dependently the increase in extracellular dopamine (DA) concentration evoked by amphetamine and 3,4-methylenedioxyamphetamine in the nucleus accumbens (NAc). The aim of the study was to investigate whether the nandrolone pre-exposure modulates the acute neurochemical and behavioral effects of cocaine in rats and whether the effects are long lasting. DA, 5-hydroxytryptamine (5-HT), and their metabolites were measured from samples collected from the NAc by microdialysis. The behavior of the animals was recorded. The study demonstrated that five injections of nandrolone (5 and 20 mg/kg) inhibited cocaine-evoked DA and 5-HT outflow in the NAc, locomotor activity (LMA), and stereotyped behavior in experimental animals, and that these effects are seen even after elimination of nandrolone from bloodstream. Given that accumualt outflow of DA and 5-HT, as well as LMA and stereotyped behavior, is related to gratification of stimulant drugs, the study thus suggests that nandrolone, at the doses tested, has a significant effect on the pleasurable properties of cocaine. Furthermore, because neurochemical and behavioral responses were still attenuated after a fairly long recovery period, it seems that nandrolone may induce long-lasting changes in the brains of rat [10086].

One of the most frequently misused steroid precursors (prohormones) is 19-norandrostenedione (estr-4-ene-3,17-dione). Recently it has been shown that norandrostenedione stimulates skeletal muscle growth after s.c. administration in a highly selective manner but exhibits only weak androgenic activity in rats. Because most abusers take norandrostenedione orally, the aim of this study was to compare the anabolic and androgenic potency of norandrostenedione between s.c. and oral application. Orchiectomised rats were treated with norandrostenedione either s.c. (1 mg/kg body weight/day) or orally (0.1, 1 and 10 mg/kg body weight/day). The tissue weights of the levator ani, the seminal vesicle and the prostate were analysed to determine the anabolic and androgenic activity. Heart and liver wet weights were examined to identify side effects. Serum concentrations of norandrostenedione and its metabolite nandrolone were
determined. GCMC analysis revealed that free and glucuronidated norandrostenedione and nandrolone were detectable in the serum after oral and s.c. administration and that norandrostenedione was converted to nandrolone in comparable amounts independent of the route of administration. In agreement to a previous study s.c. application of norandrostenedione stimulates skeletal muscle growth but has only weak androgenic effects. In contrast, after oral administration of norandrostenedione neither stimulation of the prostate nor the levator ani could be observed in the doses administered in this study. Interestingly, and in contrast to s.c. treatment, oral administration of norandrostenedione resulted in a dose-dependent decrease of body weight. In summary, oral administration of norandrostenedione, at least in the rat, seems to be a very ineffective strategy for stimulating skeletal muscle mass increases but may be associated with side effects [09122].

Anabolic-androgenic steroids are used at high doses by athletes for improving athletic ability, physical appearance and muscle mass. Unfortunately, the abuse of these agents has significantly increased. It has been established that exercise and high doses of anabolic-androgenic steroids may influence the hypothalamic-pituitary-gonadal axis, which can in turn affect testicular apoptosis. However, the effect of the combination of exercise and high dose of anabolic-androgenic steroids on testicular apoptosis is not known. It was investigated the combined effects of exercise and high doses of nandrolone decanoate on apoptosis in the spermatogenic cell lineage. Five groups of male Wistar strain albino rats were treated as follows for 8 weeks: solvent of nandrolone decanoate (peanut oil) as a vehicle (Sham); nandrolone decanoate (10 mg/kg/weekly) (nandrolone decanoate); exercise (1 hr/day, 5 days a week) (exercise); nandrolone decanoate (10 mg/kg/weekly) and exercise (1 hr/day, 5 days a week) (nandrolone decanoate exercise); and sedentary control without any injection or exercise (control). Apoptosis in the male germ line was characterized by TUNEL, caspase-3 assay and transmission electron microscopy. The weights of the testis and accessory sex organs, as well as sperm parameters significantly decreased in the experimental groups relative to the sham and control groups. Germ cell apoptosis and a significant decrease in the number of germ cell layers in nandrolone decanoate exercise-treated testes were observed. Exercise training seems to increase the extent of apoptotic changes caused by supraphysiological dose of nandrolone decanoate in rats, which in turn affects fertility [09123].

There is still controversy about the effect of anabolic steroid on connective tissue. One study examined the hypothesis that the local use of nandrolone decanoate, an anabolic steroid on rotator cuff, facilitates the healing process when used in combination with surgical repair. Forty-eight male rabbits were divided in four groups with anabolic steroids (Nandrolone Decanoate 10 mg/kg) and immobilization as variables. The groups were the following: first group, nonsteroid use-immobilization; second group, nonsteroid use-nonimmobilization; third group, steroid use-immobilization; fourth group steroid use-nonimmobilization. Every rabbit underwent a rotator cuff incision and reconstruction. Fifteen days later the tendons were sent for biomechanical and histological evaluation. It was shown that groups that did not receive anabolic steroids showed better healing and more tendon strength in comparison to groups that received anabolic steroids. Microscopic examination of specimens from the groups without the use of anabolic steroid showed extensive fibroblastic activity whereas the specimens from those groups with anabolic steroid use showed focal fibroblastic reaction and inflammation. Immobilization provided better results in the groups with anabolic steroid use but it did not influence healing in groups without steroids. It was concluded that the effect of local nandrolone decanoate use on a rotator cuff tear is detrimental, acting as a healing inhibitor [10346].
DEHYDROEPIANDROSTERONE (DHEA)

Testosterone precursors, also called prohormones, are precursors in the endogenous production of testosterone. Androstenedione (Andro), dehydroepiandrosterone (DHEA), and androstenediol are the three testosterone precursors that are marketed heavily. The efficacy and safety of these prohormones were not well established, but they were believed to have the same androgenic effects on building muscle mass and strength as anabolic-androgenic steroids (AASs). The theory is to increase the body’s endogenous production of testosterone by increasing the concentration of testosterone precursors exogenously. The short- and long-term side effects also were not well known, but theoretically they may cause the same adverse side effects as AASs [07009].

In 1994, the Dietary Supplement Health and Education Act allowed for the US marketing and sale of “natural” dietary supplements without the US Food and Drug Administration (FDA) regulation for guaranteeing the purity and safety of these substances. The passage of the Dietary Health and Education Act of 1994 allowed for these precursors to be sold over the counter as “natural” dietary supplements without regulation. In 1996, androstenedione and DHEA became available in the United States market as over-the-counter nutritional supplements. Dosages as high as androstenedione,100 to 300 mg per day, and DHEA,150 mg per day, were recommended. These prohormones became an attractive performance-enhancing alternative to using illegal AASs, which were banned by most major sports organizations. They were classified as natural substances and were not regulated by the FDA. They became popular supplements among athletes, and, thus, became readily available to the adolescent population [07009].

Dehydroepiandrosterone (DHEA) and its sulfated derivative (DHEA-S) are the most abundant circulating steroid hormones in humans. The circulation of large amounts of dehydroepiandrosterone and its sulfated derivative) suggests a physiological role in human physiology. In the central nervous system, DHEA is considered a neurosteroid with a wide range of functions. Large amounts of DHEA and DHEA-S are produced during fetal development, but after birth, this production falls sharply and remains low for several years, after which the synthesis resumes and the levels peak during the second decade of life. By the third decade, an age-dependent decline in DHEA and DHEA-S levels ensues and progresses with advancing age. Clinical studies have shown that DHEA improved endothelial function in hypercholesterolemic men and on cutaneous vascular and brachial artery reactivity in postmenopausal women, inhibited vascular inflammation, and reduced risk factors for ischemic heart disease (IHD) in men. Reduced levels of DHEA-S in men correlated with congestive heart failure (CHF). DHEA reduced vascular risk markers and therefore may be protective against vascular and cardiovascular diseases (CVDs). Some studies have suggested that DHEA is associated with reduced mortality in men and women, improves physical function in frail women, and ameliorates sexual dysfunction in both genders. Thus the data available in the literature point to a multitude of physiological effects of DHEA including

- improved endothelial function
- improved cellular immunity
- attenuation of the inflammatory process
- amelioration of atherosclerosis
- neuroprotection against ischemia
- increased bone density
- improved physical strength
- improved sexual function
The pleiotropic effects of DHEA on the metabolism and function of many tissues and organs cannot be explained only on the basis that DHEA is a precursor of other sex steroids such as testosterone and estradiol but must take into consideration the direct effect of DHEA itself and other unique 7alpha and 7beta-hydroxylated derivatives of DHEA. Specific receptors for DHEA and its derivatives have been characterized. The recent findings that DHEA activates specific biochemical pathways and alters cellular function via binding to a membrane receptor have provided novel molecular mechanisms of action for this hormone. In addition, the discovery that other DHEA metabolites with unique cellular function via interaction with receptor molecules has increased renewed interest in DHEA action. The modulatory effects of DHEA on the immune system may contribute to an attenuation of immunosenescence as well as positive results in the treatment of autoimmune diseases. In the latter, some of its effects may be a consequence of the antagonization of corticosteroid-induced side effects and direct modulation of inflammatory substances (e.g. Th1–Th2 cells; IL-2; IL-6; TNFalpha). A number of preclinical and clinical studies demonstrated that DHEA prevents or reduces the progression of atherosclerosis DHEA mediates its action via multiple signaling pathways involving specific membrane receptors and via transformation into androgen and estrogen derivatives (e.g. androgens, estrogens, 7alpha and 7beta DHEA, and 7alpha and 7beta epiandrosterone derivatives) acting through their specific receptors. These pathways include: nitric oxide synthase activation, modulation of gamma-amino butyric acid receptors, N-methyl D-aspartate receptors sigma receptors (Sigma-1), differential expression of inflammatory factors, adhesion molecules and reactive oxygen species, among others. Clinical and epidemiological studies suggested that low DHEA levels might be associated with ischemic heart disease, endothelial dysfunction, atherosclerosis, bone loss, inflammatory diseases, and sexual dysfunction. Most importantly, no significant adverse or negative side effects of DHEA were reported in clinical studies of men and women. It was concluded that DHEA modulates endothelial function, reduces inflammation, improves insulin sensitivity, blood flow, cellular immunity, body composition, bone metabolism, sexual function, and physical strength in frailty and provides neuroprotection, improves cognitive function, and memory enhancement. DHEA possesses pleiotropic effects and reduced levels of DHEA and DHEA-S may be associated with a host of pathologies; however, the clinical efficacy of DHEA supplementation in ameliorating patho-physiological symptoms remains to be evaluated [11451].

Dehydroepiandrosterone (DHEA) mediates its action via multiple signalling pathways involving specific membrane receptors and via transformation into androgen and oestrogen derivatives (e.g. androgens, oestrogens, 7alpha and 7beta DHEA, and 7alpha and 7beta epiandrosterone derivatives) acting through their specific receptors and is associated with ischaemic heart disease, endothelial dysfunction, atherosclerosis [12125].

It was studied blood serum levels of neurosteroids, dehydroepiandrosterone and its sulfate, in individuals with personality disorders convicted of serious violent crimes. The data were compared with that of a group of mentally and physically healthy persons convicted of acquisitive crimes, and with that of the control group. Significant increase in DHEA in both groups of convicts in comparison with the control was shown. The level of dehydroepiandrosterone sulfate remained unchanged. Increased dehydroepiandrosterone level in the convicted individuals with personality disorders is probably more associated with detention stress than directly with psychopathology or criminal aggression [12174].

**Physiology**
Dehydroepiandrosterone (DHEA) is secreted by the zona reticularis of the adrenal cortex and is converted into potent sex steroids in peripheral target cells. As oral DHEA administration can lead to dose-dependent increases in circulating androgens, which may reach high supraphysiologic levels in women, it has been included in the list of prohibited substances by the World Anti-Doping Agency. However, evidence for an ergogenic activity of DHEA is still largely nonexistent. Randomized trials in elderly subjects with an age-dependent decrease in DHEA have provided little or no evidence for enhanced physical performance after long-term administration of DHEA, 50 mg/d, and smaller short-term studies in healthy male athletes using higher doses were completely negative. Thus the widely perceived performance-enhancing activity of DHEA is still more myth than reality. However, because studies in female athletes are still lacking, an ergogenic activity of high-dose DHEA in this population cannot be excluded but is expected to be associated with adverse events like hirsutism, acne, and alopecia [10094].

Testosterone precursors are involved in the endogenous production of testosterone. DHEA is produced naturally in the adrenal glands and gonads. DHEA is converted to androstenedione or androstenediol in the steroid synthesis pathway. Androstenedione and androstenediol are converted to testosterone in the testes and any tissue cells that contain androgen or estrogen receptors. Adipose, bone, muscle, breast, prostate, liver, brain, and skin can be affected. The conversion of androstenedione and androstenediol to testosterone is regulated by the enzymes 17beta-hydroxysteroid dehydrogenase and 3beta-hydroxysteroid dehydrogenase, respectively. The increased circulating levels of androstenedione and testosterone can be aromatized to estrone and estradiol. Gonadal production of testosterone and estrogen is regulated by a negative-feedback system. The peripheral conversion of androgens and estrogens depends upon the quantity of circulating steroid precursors and not on any physiologic regulation system. These precursors bind poorly to androgen receptors and have few inherent androgenic-anabolic properties. The theory is that by increasing the circulating concentration of steroid precursors, the body’s endogenous production of testosterone increases and promotes anabolic effects in peripheral tissues. It has been found that low to moderate doses of these precursors do not increase testosterone levels significantly; however, at high doses, testosterone levels can be increased significantly. Therefore, the increased testosterone levels may build muscle mass, increase strength, and improve athletic performance [07009].

Metabolism

The synthesis and metabolism of DHEA involves a host of enzymes with different tissue distributions. The synthesis of DHEA requires the activity of the enzyme 20alpha, 22 desmolase (CYP11A1), a cholesterol side-chain cleaving enzyme, which converts cholesterol into pregnenolone. Loss of activity of this enzyme is incompatible with life. The other enzyme is 17alpha-hydroxylase/17, 20 lyase (CYP17), which converts pregnenolone to DHEA by first hydroxylating pregnenolone at the 17alpha position followed by cleavage of the C17, C20 side chain. Deficiency in this enzyme has serious health implications. DHEA is produced mainly by the adrenal cortex and to a limited extent by the testes as well as the ovaries, and is rapidly sulfated by sulfotransferases into DHEA-S. The latter is more stable with longer half-life and its levels remain stable throughout the day. Furthermore, DHEA-S levels are not altered significantly by the menstrual cycle. However, DHEA-S can be rapidly hydrolyzed back to DHEA by sulfatases, in response to metabolic demand. DHEA is also transformed via 3beta-hydroxysteroid dehydrogenases (3β-HSD) into androstenedione. The latter can be transformed by the 17beta-hydroxysteroid dehydrogenases (17β-HSD) into testosterone or via the aromatase into estrone. Alternatively, andione can be transformed into 5alpha-androstenedione (5α-adione) via the 5α-reductase enzyme system, and this
derivative may be transformed into 5alpha-dihydrotestosterone (5alpha-DHT). Testosterone may be converted into 5alpha-DHT via the 5alpha-reductase or into estradiol via the aromatase enzyme. Animals have lower systemic levels of DHEA, but the CNS concentration is approximately 600 times higher [11451].

**Molecular and cellular mechanism of DHEA**

The most controversial aspect of DHEA action in human physiology is that no specific nuclear receptor protein had been identified or characterized for DHEA. It is well recognized that glucocorticoids (e.g. cortisol), mineralocorticoids (e.g. aldosterone), androgens (e.g., testosterone and 5alpha-DHT), progestins (e.g. progesterone), and estrogens (e.g. estradiol) elicit their physiological functions via binding to specific nuclear receptors (genomic mechanism). Recent studies have documented that most steroid hormones, including androgens, estrogens, glucocorticoids, and progestins, also elicit physiological responses by nongenomic activation of distinct subpopulations of non-nuclear receptors. Inhibition of phosphatidylinositol 3-kinase (PI3K)/protein kinase B (known as Akt) abolished the effect of DHEA on nuclear factor kB (NF-kB) activation, suggesting that DHEA mediated its function via activation of NF-kB via the PI3K/AKT pathway. It was postulated that DHEA-S directly activates recombinant PKC-beta in a cell-free assay. The authors suggested that PKC-beta acts as an intracellular receptor for DHEA-S in human neutrophils. In addition to its function via direct DHEA receptors, androgen and estrogen metabolites of DHEA also exert biological functions. It has been shown that growth of prostatic epithelial cells and prostate-specific antigen expression were induced by DHEA via stimulation of NF-kB DNA-binding activity, and these functions were blocked by an androgen receptor antagonist bicalutamide as well as androgen receptor small inhibitory RNAs. DHEA binding specifically and with high affinity to membrane receptors and eliciting a host of biological responses strongly supports the existence of a molecular and cellular mechanism of action for this steroid hormone. [11451].

**Effects of DHEA on body composition, bone metabolism, and skin**

The effect of DHEA on body composition and bone metabolism has been investigated in a number of clinical studies. DHEA treatment for 1 year in aging men resulted in significant reduction in body fat mass and increased muscle strength when compared with baseline and placebo. Furthermore, DHEA treatment resulted in weight loss in obese patients. Short-term studies in men and women using DHEA daily for 3-4 months, however, did not reveal any significant changes in body composition. However, 6 months of treatment with DHEA, in healthy, nonobese men aged 50-65, led to reduced fat mass by 6 percent. In the area of muscle function, knee extension/flexion strength, and lumbar back strength increased significantly by 15 percent and 14 percent, respectively. DHEA also resulted in significant decreases in abdominal visceral fat by 7 percent and abdominal subcutaneous fat by 6 percent as measured by magnetic resonance imagery (MRI) and significantly reduced the insulin area under the curve during an oral glucose tolerance test and significantly increased the insulin sensitivity index. DHEA reduced triglyceride and low density lipoprotein (LDL) levels and improved HDL levels but not total cholesterol levels in subjects aged 65-82 years. In elderly men with low baseline DHEA-S, treatment with DHEA significantly improved bone mineral density (BMD) for total body and lumbar spine after 6 months, and DHEA improved BMD in patients with osteoporosis. The protective effect of DHEA on the bone is partly mediated by conversion of DHEA to androgens and estrogens in human osteoblasts. DHEA appears to also have positive effects on skin structure and function. DHEA improves skin hydration and brightness, increases sebum production, and possibly prevents wrinkles. Several studies have attempted to provide insight into the molecular bases for such observations and have demonstrated that topical DHEA increases pro-collagen production in
postmenopausal women as well as both young and elderly men. DHEA has also been reported to attenuate, via conversion to estrogen and estrogen receptors, age-related impairment to wound healing [11451].

**Role of DHEA in sexual function**

The Massachusetts Male Aging Study presented an inverse correlation of the serum levels of DHEA-S and the incidence of erectile dysfunction (ED). Serum levels of DHEA-S in patients with ED were lower than in healthy volunteers under 60 years of age. Furthermore, DHEA treatment in men was associated with higher mean scores for all five domains of the International Index of Erectile Function. It has been demonstrated an association between DHEA-S and sexual dysfunction in 348 men. DHEA treatment improved sexual interest with improvement in desire, arousal, activity, interest, fantasy and drive, and relationship. In patients with type 1 diabetes with ED, DHEA showed the most pronounced improvement of all hormonal parameters analyzed. All these effects were observed after 16 weeks of treatment but not after 8 weeks. The role of DHEA in sexual function in women has been explored in several studies. It has been shown replacement therapy with DHEA in women with androgen insufficiency, and sexual dysfunction showed a significant decrease in sexual distress and a significant increase in desire, arousal, lubrication, satisfaction, and orgasm. It has also been shown that DHEA significantly improved desire, arousal, activity, interest, fantasy and drive, and relationship. Low DHEA-S levels but not testosterone levels correlated with sexual dysfunction symptoms. Although DHEA has improved sexual function in men and women to varying degrees, perhaps in certain subpopulations, this improvement may be related to the levels of baseline DHEA-S in the individuals recruited for the studies. In addition, most domains of sexual function are impacted by the levels of circulating testosterone. Thus, testosterone deficiency, albeit derived from reduced testosterone biosynthesis or via reduced DHEA conversion to testosterone, may contribute to sexual dysfunction. Thus, baseline testosterone should be considered together with baseline DHEA when investigating decline of DHEA and sexual function. The discrepancies between the aforementioned studies deserve further investigation. The effects of DHEA in the CNS are at least mediated by its direct modulation of central receptors like N-methyl D-aspartate receptors, sigma1, and GABA_A as well as by stimulation of substances like allopregnanolone and beta-endorphin, which are crucial for behavior and mood. The action of DHEA may be responsible for the beneficial clinical results seen in patients with different forms of depression, stress, and psychiatric disorders. In addition, the observed DHEA effects on neurogenesis and neuronal survival have important implications for future therapy. DHEA levels in men and women between 18 and 40 years of age ranges from 1.330 to 7.780 ng/mL with median concentrations of 2-3 ng/mL, respectively. Thus, the levels of free DHEA are approximately 100-fold higher than free testosterone. Because DHEA is rapidly converted to DHEA-S, the levels of the latter are thought to be more physiologically relevant. DHEA-S levels are approximately three orders of magnitude higher than total testosterone (3-5 µg/mL vs 3-5 ng/mL) and approximately five orders of magnitude higher than free T (3-5 µg/mL vs 20 pg/mL), which strongly argue against the notion that DHEA is a biologically irrelevant steroid hormone. More specifically, age-related decline of DHEA-S by 80-90 percent is more pronounced than the decline in testosterone. There is a lack of large, prospective, long-term trials with DHEA to establish evidence-based medicine. In the current environment where DHEA is regarded as a nutritional supplement, there is no financial incentive to invest in long-term large clinical studies. The latter explains why the majority of the clinical studies on DHEA were carried out by academic institutions with smaller numbers of patients and short-time durations. Such studies may be viewed as pilot studies. Conflicting results or discrepancies in data obtained in the various reported studies may be attributed to poor study designs and confounding factors. These include
- dose of DHEA and duration of the study
- clinical trials versus pharmacological intervention
- healthy adults versus patients with chronic illnesses
- young versus older patients
- normal versus patients with adrenal insufficiency
- use of other medications

Epidemiological, observational, or intervention studies differ significantly in design and end points. In addition, differences in dosages, duration of treatment, formulations, route of administration, study population, sample size, statistical power, and clinical end points as well as adjustments (e.g. for smoking, alcohol consumption, and body weight) have an important influence on the outcome. DHEA administration in men is not yet an established medical treatment. In addition, in most countries, there are no preparations available that have been approved by the regulatory agencies. In the United States, DHEA is categorized as nutritional supplement with little quality control, with varying preparations having different DHEA concentrations and are available over the counter. For these reasons, caution should be exercised in treating with DHEA and physicians should educate their patients before recommending DHEA as a supplement. Progress in this area is likely to be minimal until a pharmaceutical-grade oral preparation is established. Pharmacokinetics of absorption and its variability among people has to be determined. Large, long-term prospective studies will have to be commenced, which will have to identify beneficial clinical effects due to DHEA itself and those due to its conversion products, estradiol, testosterone, and 7 hydroxy derivatives. There are enough preliminary clinical and preclinical data to warrant pursuing further clinical studies [11451].

Normal values related to age

Dehydroepiandrosterone (DHEA) is a “pro-hormone” or precursor of testosterone that is available as an over-the-counter supplement in many countries. It is promoted as a wonder supplement capable of promoting youthfulness, virility and enhanced strength or body composition. In men aged 20-70 years, ingesting a single dose of 50-100 mg DHEA increases serum DHEA concentrations up to sevenfold and increases serum androstenedione concentrations approximately fourfold, but serum testosterone and dihydrotestosterone (DHT) concentrations are not changed. In older men (50-70 years), ingesting a single dose of 50-100 mg DHEA raises serum estradiol concentrations by 24-39 percent to the upper normal range. Prolonged ingestion of DHEA in doses ranging from 50 to 1600 mg/day in 20-65-year-old men produces dose-dependent increases in serum DHEA, DHEA sulphate and androstenedione, but has no effect on serum testosterone or DHT. Thus, ingestion of DHEA in men increases only weak precursor hormones, with little or no increase in more potent androgens or estrogens. More chronic intake of DHEA in doses of 50-1600 mg/day in men does not alter energy or protein metabolism, body mass or lean body mass. Intake of DHEA during resistance training does not augment the gains in lean mass or muscle strength in male college students or middle-aged men. It appears that DHEA does not promote fat loss or muscle gain or augment adaptations to resistance training in healthy men. Surprisingly, DHEA is classified as an androgenic/anabolic steroid and banned by the World Anti-Doping Agency and other anti-doping codes [10347].

Influence of menstrual cycle

Mood changes occur often in the luteal phase of menstrual cycle. Steroids modulating GABAA and NAMD receptors in the brain, namely allopregnanolone, were suggested as a
factor of premenstrual syndrome. Another neurosteroid influencing the well-being is dehydroepiandrosterone. In the past decade it was shown by several authors that some dehydroepiandrosterone derivatives, especially those with 7-hydroxy- or 7-oxo group, exert a higher activity than dehydroepiandrosterone itself. It was also reasonable to see whether the levels of circulating 7-hydroxy-derivatives of dehydroepiandrosterone differ in the follicular and luteal phase of the menstrual cycle. Steroids known to exert neuroprotective effects, namely 7alpha- and 7beta-hydroxy-dehydroepiandrosterone, 5-androstene-3beta,7alpha, 17beta-triol and 5-androstene-3beta,7beta,17beta-triol, were determined in midfollicular and midluteal phase of the menstrual cycle of 22 healthy women with a regular menstruation cycle. Whereas the maternal steroids, dehydroepiandrosterone and androstene-3beta,17beta-diol showed no significant difference between the phases of menstrual cycle, the levels of their 7-hydroxylated metabolites were significantly lower in the luteal phase. It is suggested that the observed decrease of 7-hydroxylated metabolites during the luteal phase may be a factor related to the etiopathogenesis of mood change and neurocognitive disturbances, which are known to be more accented in that particular phase of the menstrual cycle [11332].

In women

One study was intended to investigate various hormones during competition among female athletes. Subjects were elite female soccer players (n=9). Blood samples and profiles of mood states (POMS) were obtained before (Pre), during 3 days of competition (Competition), and after competition (Post-3 days). Serum concentrations were determined for dehydroepiandrosterone sulfate (DHEAS), cortisol (C), prolactin (PRL), testosterone (T), adrenocorticotropic hormone (ACTH), luteinising hormone (LH), and follicle stimulating hormone (FSH). Levels of C and PRL increased significantly during competition compared with Pre. Levels of LH increased significantly during competition (3rd day) compared with Pre. Levels of DHEAS changed significantly during competition, whereas levels of T, ACTH, and FSH were unchanged during competition. The fatigue score of POMS increased significantly during competition (2nd day) compared with Pre. It was thus demonstrated that competitive stress affected hormonal status in female athletes. These findings suggest that hormonal changes reflect physical and mental stress during competition [06118].

Elderly women

Studies disputed the widely promoted anti-aging effect of dehydroepiandrosterone (DHEA) supplementation; however, conflicting data exist on whether physiological DHEA supplementation enhances exercise training effects on body composition, physical performance, and cardiometabolic risk in healthy postmenopausal women. The aim of one study was to determine whether 12 weeks of DHEA supplementation (50 mg/d) in postmenopausal women enhances exercise-related changes in body composition, physical performance, and cardiometabolic risk. Thirty-one sedentary, postmenopausal, Caucasian women (mean 64 years) completed the study. Participants were randomized to one of two 12-week interventions: exercise training plus 50 mg/d of DHEA (n=17), or exercise training plus placebo (n=14). The exercise intervention consisted of both endurance (4 d/wk) and resistance (3 d/wk) exercise components. The main outcomes were measures of body composition, physical performance, and measures of cardiometabolic risk. DHEA treatment with exercise resulted in increases in circulating sulfated DHEA (650 %), total testosterone (100 %), estradiol (165 %), estrone (85 %), and IGF-I (30 %). Although exercise training alone significantly improved physical performance, body composition, and insulin sensitivity, administration of DHEA provided no additional benefits. It was concluded that 12 weeks of combined endurance and resistance training significantly improved body composition,
physical performance, insulin sensitivity, and low-density lipoprotein cholesterol particle number and size, whereas DHEA had no additional benefits [07093].

**Efficacy in performance enhancement**

Athletes use testosterone precursors with the belief that they will boost testosterone levels and, thereby, achieve the same anabolic effects of AASs. They are promoted to enhance performance by reducing fat, building muscle mass, increasing strength, and improving sexual performance. Studies of the efficacy of these testosterone precursors have not demonstrated any significant improvements in enhancing performance. The “Andro Project” in 2000 studied the effects of healthy men, 35 to 65 years of age, taking androstenedione or androstenediol, 200 mg daily, in the setting of a 12-week high-intensity resistance-training program. Total testosterone levels increased by 16 percent after 1 month, but had returned to pretreatment levels by the end of the 12 weeks. The study also found that estrone and estradiol levels remained elevated significantly (up to 97%). Neither androstenedione nor androstenediol significantly improved lean body mass or increased muscle strength compared with placebo. They also found that there was an adverse effect on high-density lipoprotein (HDL) cholesterol and an increase in the coronary heart disease risk. It has also been studied the effects of daily oral supplementation with androstenedione, 300 mg, or DHEA, 150 mg, in healthy men 19 to 29 years of age with 8 weeks of resistance training. They found that serum androstenedione levels were elevated, but no significant increases in testosterone levels occurred, and it did not significantly enhance the adaptations to resistance training with changes in body composition or strength. They also examined the effects of a single dose of DHEA, 50 mg, and found a 150 percent increase in androstenedione levels within 60 minutes but no increases in testosterone levels. A 2002 review of studies found that most studies showed

- acute oral ingestion of androstenedione or androstenediol, at least 200 mg, modestly and transiently increased serum testosterone levels in men
- elevation of circulating estrogen levels
- dosages of androstenedione or androstenediol, less than 300 mg/day for as long as 12 weeks, had no effects on body composition, muscle mass, or performance
- significantly decreased serum HDL cholesterol levels and increases in the cardiovascular disease risk

A summary of research from 1999 in 2002, showed a consensus in that no significant increases in muscle mass or strength was found with a single dose or daily ingestion. High dosages of androstenedione, 200 to 300 mg/day, significantly increased serum testosterone levels in young healthy men by 34 percent and increased estradiol levels by 128 percent. The increases in testosterone levels were temporary, and daily doses up to 12 weeks showed significant increases in estradiol and estrone levels but did not show any significant increases in baseline testosterone levels. Other studies also showed no increase in muscle protein synthesis with supplementation with DHEA or androstenedione and no increase in muscle fiber cross-sectional area with a combination of androstenedione ingestion and resistance training compared with placebo. Studies also showed that androstenedione supplementation in men increased serum androstenedione levels; a low daily dose (100 mg) did not increase serum testosterone levels significantly, but a high daily dose (300 mg) increased serum testosterone levels and serum estrogen levels. Investigations on the efficacy of DHEA, with dosages up to 150 mg/d, revealed neither change in testosterone levels, nor significant changes in lean muscle mass or strength compared with placebo. Several reasons have been suggested for the lack of efficacy of androstenedione on improving muscle mass and strength. First, oral supplementation must undergo first-pass
hepatic metabolism before it reaches the circulation. Second, only 2 percent of an oral dose is converted to testosterone; a large percentage is converted to testosterone glucuronide, which is biologically inactive. Third, the peripheral aromatization of testosterone to estradiol may limit the available level of testosterone to bind and activate androgen receptors. In summary, the testosterone precursors DHEA, androstenedione, and androstenediol have little inherent androgen action. The ergogenic claims regarding prohormone supplementation have not been supported by controlled studies. Studies have demonstrated repeatedly that acute and long-term administration of oral androstenedione, androstenediol, or DHEA does not effectively increase serum testosterone levels and fails to produce any significant changes in lean body mass, muscle strength, or performance improvement compared with placebo. High doses of androstenedione seem to increase serum levels of estrogens, primarily through peripheral aromatization [07009].

The purpose of one study was to examine salivary cortisol, dehydroepiandrosterone (DHEA), and testosterone responses to the bench press in an international powerlifting competition and to determine whether these salivary hormone concentrations could be used to predict performance. Twenty-six elite athletes (13 females and 13 males) provided saliva samples during the official weighing-in and after the last attempt at the bench press, as well as at baseline on a non-competition day. Performance index was determined with the Wilks formula, which adjusts powerlifting scores according to body mass. Salivary cortisol concentrations were significantly increased in all subjects after the bench press, whereas DHEA concentrations were significantly increased in women but not in men after the bench press. No significant change in testosterone concentrations was observed during the experiment in either men or women, which resulted in a marked decrease in the testosterone/cortisol ratio. The performance index showed no significant correlation with any of the hormone responses to competition. In conclusion, despite the increase in stress adrenocortical hormone responses to an international powerlifting competition, these hormone concentrations alone are not predictors of bench press performance in elite powerlifting athletes [10462].

Effects of walking training

It was hypothesized that physical exercise in postmenopausal women could interfere with the molecular interrelationship of the immune-endocrine system and be effective even in women in whom training determined a reduction of spontaneous physical activity (SPA). For this reason, we investigated the effects of an aerobic program on plasma dehydroepiandrosterone sulfate (DHEA-S) and cytokine levels in relationship to SPA modification. Thirty-two postmenopausal women (mean age, 56 years) were enrolled in the study. Inclusion criteria were as follows: age younger than 65 years, body mass index higher than 18.5 and lower than 35 kg/m, no pharmacological treatments, and no history of chronic, cardiovascular, or orthopedic diseases. Before and after 3 months of walking training at moderate intensity (40-50 min, 4 d/wk), they were evaluated for SPA, body composition, energy intake, and levels of plasma cytokines (tumor necrosis factor alpha [TNF-alpha], interleukin [IL]-1alpha, IL-1beta, IL-2, IL-8, and IL-10), C-reactive protein, DHEA-S, cortisol, and estrogen. At baseline, SPA did not correlate with either DHEA-S level or cytokine levels. There was negative correlation between DHEA-S and both TNF-alpha and IL-2. After the intervention program, 16 women showed increased SPA, and 16 women showed decreased SPA. Independent of these changes in SPA, both TNF-alpha levels and cortisol-to-DHEA-S ratio decreased, whereas DHEA-S levels increased. In postmenopausal women, walking training, rather than SPA, influences DHEA-S and cytokine concentrations and their correlations, thus interfering with adrenal steroids and the inflammatory markers network. Physical exercise acts in parallel on menopausal neuroendocrine alterations and on the systemic inflammatory profile independent of SPA changes [12175].
Effects on asthma

Dehydroepiandrosterone (DHEA) is considered as an important immunomodulating and anti-inflammatory hormone. Despite the continuing interest in DHEA replacement therapy, our knowledge of its effects upon asthma is very limited. DHEA is able to reverse cytokine imbalances associated with asthma, may prevent and attenuate allergic inflammation in airways, and does not possess the undesirable side effects of glucocorticoids; therefore, it may be potentially applied in the treatment of asthma. The steroid-sparing effect observed with DHEA clinically could appear especially favorable in asthmatic patients receiving oral treatment and those inhaling high doses of glucocorticoids. In addition, DHEA and its analogs might prove useful in reversing relative glucocorticoids insensitivity in patients with corticosteroid-resistant asthma [10460].

Adverse effects

The adverse effects of oral supplementation with testosterone precursors are not well known. The lack of long-term studies makes it difficult to identify the dangers and risks of using these nutritional supplements. Adverse effects are most likely underreported because it is difficult to determine the prevalence of prohormone use and the disparity in product labeling of nutritional supplements. DHEA was reported to cause irreversible virilization in women (hair loss, hirsutism, deepened voice) and gynecomastia in men. Androstenedione use was found to have an adverse effect on coronary heart disease risk and to cause a significant reduction in serum HDL cholesterol. Long-term increased levels of unopposed circulating estrogens potentially could induce hormone-sensitive malignancies, such as uterine, breast, and prostate cancer. Theoretically, high doses of prohormones could increase androgen levels and have the same adverse as AAS use, such as liver dysfunction, glucose intolerance and diabetes, malignancies, menstrual irregularities, infertility, testicular atrophy, impotence, male pattern baldness, acne, or aggressive behavior [07009].

DHEA metabolites activate estrogen receptors

Dehydroepiandrosterone (DHEA) levels were reported to associate with increased breast cancer risk in postmenopausal women, but some carcinogen-induced rat mammary tumor studies question this claim. The purpose of this study was to determine how DHEA and its metabolites affect estrogen receptors alpha or beta (ERalpha or ERbeta)-regulated gene transcription and cell proliferation. In transiently transfected HEK-293 cells, androstenediol, DHEA, and DHEA-S activated ERalpha. In ERbeta transfected HepG2 cells, androstenedione, DHEA, androstenediol, and 7-oxo DHEA stimulated reporter activity. ER antagonists ICI 182,780 (fulvestrant) and 4-hydroxytamoxifen, general P450 inhibitor miconazole, and aromatase inhibitor exemestane inhibited activation by DHEA or metabolites in transfected cells. ERbeta-selective antagonist R,R-THC (R,R-cis-diethyl tetrahydrochrysene) inhibited DHEA and DHEA metabolite transcriptional activity in ERβ-transfected cells. Expression of endogenous estrogen-regulated genes: pS2, progesterone receptor, cathepsin D1, and nuclear respiratory factor-1 was increased by DHEA and its metabolites in an ER-subtype, gene, and cell-specific manner. DHEA metabolites, but not DHEA, competed with 17beta-estradiol for ERα and ERβ binding and stimulated MCF-7 cell proliferation, demonstrating that DHEA metabolites interact directly with ERalpha and ERbeta in vitro, modulating estrogen target genes in vivo [12176].
DHEA in vascular disease

Dehydroepiandrosterone (DHEA) is a steroid hormone derived from cholesterol synthesized by the adrenal glands. DHEA and its 3beta-sulphate ester (DHEA-S) are the most abundant circulating steroid hormones. In human, there is a clear age-related decline in serum DHEA and DHEA-S and this has suggested that a relative deficiency in these steroids may be causally related to the development of a series of diseases associated with aging including cardiovascular diseases (CVD). This commentary aims to highlight the action of DHEA in CVD and its beneficial effect in therapy. We thus discuss the possible impact of serum DHEA decline and DHEA supplementation in diseases such as hypertension, coronary artery disease and atherosclerosis. More specifically, we provide evidence for a beneficial action of DHEA in the main disease of the pulmonary circulation: pulmonary hypertension. We also examine the potential cellular mechanism of action of DHEA in terms of receptors (membrane/nuclear) and associated signaling pathways (ion channels, calcium signaling, PI3K/AKT/eNos pathway, cGMP, RhoA/RhoK pathway). It was shown that DHEA acts as an anti-remodeling and vasorelaxant drug. Since it is a well-tolerated and inexpensive drug, DHEA may prove to be a valuable molecule in CVD but it deserves further studies both at the molecular level and in large clinical trials [12177].

Androst-5-ene-3beta,7 beta,17beta-triol (betaAET) is an anti-inflammatory metabolite of DHEA that is found naturally in humans, but in rodents only after exogenous DHEA administration. Unlike DHEA, C-7-oxidized DHEA metabolites cannot be metabolized into potent androgens or estrogens, and are not peroxisome proliferators in rodents. The objective of our current studies was to characterize the pharmacology of betaAET to enable clinical trials in humans. The pharmacology of betaAET was characterized by pharmacokinetics, drug metabolism, nuclear hormone receptor interactions, androgenicity, estrogenicity, and systemic toxicity studies. betaAET’s acute anti-inflammatory activity and immune modulating characteristics were measured in vitro in RAW264.7 cells and in vivo in murine models with parenteral administration. betaAET was rapidly metabolized and cleared from circulation in mice and monkeys. betaAET was weakly androgenic and estrogenic in immature rodents, but not bound by androgen, estrogen, progesterone, or glucocorticoid nuclear hormone receptors. betaAET did not induce peroxisome proliferation, nor was it systemically toxic or trophic for sex hormone responsive tissues in mature rats and monkeys. betaAET significantly attenuated acute inflammation both in vitro and in vivo, augmented immune responses in adult mice, and reversed immune senescence in aged mice. betaAET may contribute to the anti-inflammatory activity in rodents attributed to DHEA. Unlike DHEA, betaAET’s anti-inflammatory activity cannot be ascribed to activation of PPARs, androgen, or estrogen nuclear hormone receptors. Exogenous betaAET is unlikely to produce untoward toxicity or hormonal perturbations in humans [11333].

Laboratory techniques

It was recently taken advantage of the unique power of DNA microarrays to compare the genomic expression profile of tetrahydrogestrinone (THG) with that of dihydrotestosterone (DHT), the most potent natural androgen, thus clearly demonstrating that THG is an anabolic steroid. In 2004, the U.S. Controlled Substances Act has been modified to include androstenedione (4-dione) as an anabolic steroid. However, despite the common knowledge that dehydroepiandrosterone (DHEA) is the precursor of testosterone, DHEA has been
excluded from the list of anabolic steroids. It was thus used the same DNA microarray technology to analyze the expression profile of practically all the 30,000 genes of the mouse genome modulated by DHEA and DHT in classical androgen-sensitive tissues. Daily subcutaneous injections of DHT (0.1 mg) or DHEA (3 mg) for 1 month in gonadectomized C57BL6/129 SV mice increased ventral prostate, dorsal prostate, seminal vesicle and preputial gland weight (p<0.01 for all tissues). As early as 24h after single injection of the two steroids, 878, 2681 and 14 probe sets were commonly stimulated or inhibited in the prostate (ventral+dorsal), seminal vesicles and preputial glands, respectively, compared to tissues from gonadectomized control animals. After 7 days of daily treatment with DHEA and DHT, 629, 919 and 562 probe sets were commonly modulated in the same tissues while after 27 days of treatment, 1195, 5127 and 2883 probe sets were modulated, respectively. In analogy with the data obtained with THG, the present microarray data provide an extremely precise and unquestionable genomic signature and proof of the androgenic/anabolic activity of DHEA. Such data add to the literature showing that DHEA is transformed into androgens in the human peripheral tissues as well as in laboratory animal species, including the monkey, thus exerting potent androgenic/anabolic activity. The present microarray approach to identify anabolic compounds is applicable to all potential androgenic/anabolic compounds [06119].

According to the WADA rules urine samples containing dehydroepiandrosterone (DHEA) concentrations greater than 100 ng/mL shall be submitted to isotope ratio mass spectrometry (IRMS) analysis. The threshold concentration is based on the equivalent to the glucuronide, and the DHEA concentrations have to be adjusted for a specific gravity value of 1.020. In 2006, 11,012 doping control urine samples from national and international federations were analyzed in the Cologne doping control laboratory, 100 (0.9 %) of them yielding concentrations of DHEA greater than 100 ng/mL. Sixty-eight percent of the specimens showed specific gravity values higher than 1.020, 52 percent originated from soccer players, 95 percent were taken in competition, 85 percent were male urines, 99 percent of the IRMS results did not indicate an application of testosterone or related prohormones. Statistical evaluation showed significantly different DHEA concentrations between specimens taken in- and out-of-competition, whereas females showed smaller DHEA values than males for both types of control. Also a strong influence of the DHEA excretion on different sport disciplines was detectable. The highest DHEA values were detected for game sports (soccer, basketball, handball, ice hockey), followed by boxing and wrestling. In 2007, 6622 doping control urine samples were analyzed for 3alpha,5-cyclo-5alpha-androstan-6beta-ol-17-one (3alpha,5-cyclo), a DHEA metabolite which was described as a useful gas chromatography-mass spectrometry (GC-MS) screening marker for DHEA abuse. Nineteen urine specimens showed concentrations higher than the suggested threshold of 140 ng/mL, six urine samples yielded additionally DHEA concentrations higher than 100 ng/mL, none of them showing positive IRMS findings. These results should be taken into consideration in future discussions about threshold values for endogenous steroids in doping control [08156].

According to World Anti-Doping Agency (WADA) rules (WADA Technical Document-TD2004EAAS) urine samples containing dehydroepiandrosterone (DHEA) concentrations greater than 100 ng/mL shall be submitted to isotope ratio mass spectrometry (IRMS) analysis. The threshold concentration is based on the equivalent to the glucuronide, and the DHEA concentrations have to be adjusted for a specific gravity value of 1.020. In 2006, 11,012 doping control urine samples from national and international federations were analyzed in the Cologne doping control laboratory, 100 (0.9 %) of them yielding concentrations of DHEA greater than 100 ng/mL. Sixty-eight percent of the specimens showed specific gravity values higher than 1.020, 52 percent originated from soccer players, 95 percent were taken in competition, 85 percent were male urines, 99 percent of the IRMS results did not indicate an application of testosterone or related prohormones. Only one urine
sample was reported as an adverse analytical finding having 319 ng/mL DHEA (screening result), more than 10,000 ng/mL androsterone and depleted carbon isotope ratio values for the testosterone metabolites androsterone and etiocholanolone. Statistical evaluation showed significantly different DHEA concentrations between specimens taken in- and out-of-competition, whereas females showed smaller DHEA values than males for both types of control. Also a strong influence of the DHEA excretion on different sport disciplines was detectable. The highest DHEA values were detected for game sports (soccer, basketball, handball, ice hockey), followed by boxing and wrestling. In 2007, 6622 doping control urine samples were analyzed for 3alpha,5-cyclo-5alpha-androstan-6beta-ol-17-one (3alpha,5-cyclo), a DHEA metabolite which was described as a useful gas chromatography-mass spectrometry (GC-MS) screening marker for DHEA abuse. Nineteen urine specimens showed concentrations higher than the suggested threshold of 140 ng/mL, six urine samples yielded additionally DHEA concentrations higher than 100 ng/mL, none of them showing positive IRMS findings. These results should be taken into consideration in future discussions about threshold values for endogenous steroids in doping control [07094].

**Current medical recommendations**

Current evidence shows that the testosterone precursors DHEA, androstenedione, and androstenediol do not offer any substantial performance-enhancing benefits. The potential adverse effects of these substances produce a significant health risk, especially to the pediatric and adolescent population. At higher doses, they were shown to minimally and temporarily elevate testosterone levels and to increase estrogen levels. No significant health or medical benefits exist, except for the possible antiaging properties of DHEA. As a result of the increasing evidence of the potential harmful health effects of these prohormones, the FDA has placed androstenedione on the schedule III controlled substance list and has not approved androstenedione or DHEA for any indication [07009].
BOLDENONE, BOLDIONE AND BOLANDIOL

Overviews

Boldenone, which was synthesized with the aim of producing a long-acting injectable methandrostenolone, is meanwhile one of the most frequently detected AAS, generally exposed via GC/MS, that allows identification of the active drug and its main metabolite, 5beta-androst-1-en-17beta-ol-3-one. Boldenone and epiboldenone sulphates, which are markers for the exogenous origin of boldenone, may be employed to decrease the number of samples to be analyzed by isotope ratio mass spectrometry. Boldenone and epiboldenone sulphates, which are markers for the exogenous origin of boldenone, may be employed to decrease the number of samples to be analyzed by isotope ratio mass spectrometry [12011].

Boldenone is an androgenic anabolic steroid intensively used for growth promoting purposes in animals destined for meat production and as a performance enhancer in athletics. Therefore its use is officially banned either in animals intended for consumption or in humans. Because most anabolic steroids are completely metabolized and usually no parent steroid is excreted, metabolite identification is crucial to detect the illegal use of anabolic steroids either in humans or in livestock. 17alpha- and 17beta-boldenone 17-glucuronides were synthesized, purified and characterized in order to provide suitable standards for the identification and quantification of these metabolites [08163].

Boldenone (BOL) is an androgenic steroid that improves the growth and food conversion in food-producing animals. In most countries worldwide, this anabolic steroid is forbidden for human uses and meat production as it was developed for veterinary use. Recently, BOL is used by bodybuilders in both off season and pre-contest, where it is well known for increasing vascularity while preparing for a bodybuilding contest. One study was designed to investigate the physiological and biochemical changes in rabbits after injection with the growth promoter BOL. A total of 32 adult New Zealand rabbits were divided into four groups, where the control group includes animals that were injected intramuscularly with olive oil and dissected after 3 weeks. The remaining three experimental groups included animals that received one, two and three intramuscular injections of 5 mg/kg body weight BOL, respectively, and were dissected after 3, 6 and 9 weeks, respectively. The animals from practice appeared healthy and did not show clinical signs of disease and none of the rabbits died during the experimental period. Serum total protein, globulin, alanine aminotransferase, asparate aminotransferase, urea, creatinine, testosterone, luteinizing hormone and follicle-stimulating hormone levels were significantly increased while serum direct bilirubin, albumin and albumin/globulin ratio were significantly decreased after one, two and three intramuscular injections of BOL as compared to their relative values in the control group. These findings explain the common phenomena in athletes and bodybuilders who suffer from infertility, renal and hepatic alterations following injection with some drugs as steroids (BOL) to build muscles [13245].

Aiming at the facilitated differentiation of endogenous boldenone production from exogenous (and thus illicit) administration, potential markers were desirable and subject of a recent application and metabolism study. In urine specimens of a volunteer who ingested 20 mg of boldenone, the sulfates of boldenone and epiboldenone were detected and their structures confirmed by isolation, solvolysis, and subsequent comparison to reference material of the unconjugated compounds. In contrast to the presence of these analytes in post-administration urine samples, three out of four routine doping control specimens containing boldenone and its phase-I-metabolite 5beta-androst-1-en-17beta-ol-3-one of natural
(endogenous) origin (as demonstrated by isotope-ratio mass spectrometry) did not contain the sulfoconjugates of boldenone and its epimer. These two analytes might therefore support the distinction of boldenone application and its endogenous production [13012].

Since administration studies, such-like those with boldenone are not possible with non-approved/designer steroids, metabolism studies with promagnon, methylclostebol, and methasterone were conducted with a chimeric mouse model transplanted with human hepatocytes. As demonstrated earlier, the humanized liver enables a proxy human metabolism to a certain extent, permitting the investigation of the metabolic fate and renal elimination of these compounds by means of GC-MS. While the elimination study with promagnon yielded mainly one equivocal metabolic product (methylclostebol), methylclostebol as the administered compound was found to generate a variety of singly and doubly hydroxylated and/or reduced products with promagnon (4-chloro-17alpha-methyl-androst-4-ene-3beta,17beta-diol) as metabolite of methylclostebol being an adequate target for doping controls. In addition, the degradation and elimination of methasterone in the chimeric mouse model was studied. The comparison of human and mouse post-administration urine samples however revealed rather limited similarities and it was suggested that the chimeric mice utilized different metabolic pathways. Nevertheless, two compounds assigned to 2alpha,17alpha-dimethyl-5alpha-androstane-2beta,3alpha,16,17beta-tetrol and x,16-dihydroxy-methasterone (with x being a non-identified position) were observed and proposed as additional putative human urinary metabolites. As in most of the aforementioned studies, the authors stressed that all structural assignments were not supported yet by chemical synthesis and that further work was necessary to confirm the tentatively postulated compositions [13012].

**Boldenone potency compared with other anabolic steroids**

Bolandiol is a synthetic anabolic steroid that increases lean body mass and bone mineral density without significant stimulation of sex accessory glands in castrate adult male rats. Since bolandiol suppresses gonadotropins and endogenous testosterone production, it was investigated its mechanism of action. It was compared the potency of bolandiol in vitro and in vivo with T, 5alpha-dihydrotestosterone (DHT), 19-nortestosterone (19-NT) and estradiol (E$_2$). Bolandiol bound with lower affinity to the recombinant rat androgen receptor (AR) than the other androgens and had low, but measurable, affinity for recombinant human progesterin receptors (PR-A, PR-B), and estrogen receptors (ERAlpha and beta-1). Functional agonist activity was assessed in transcription assays mediated by AR, PR, or ER. Bolandiol was stimulatory in all these assays, but only 4-9 percent as potent as T, DHT, and 19-NT via AR, 1 percent as potent as progesterone via PR, and 3 percent and 1 percent as potent as E$_2$ acting through ERAlpha or ERbeta, respectively. In immature castrate rats, bolandiol was equipotent to testosterone in stimulating growth of the levator ani muscle but less potent than T in stimulating growth of the sex accessory glands. Bolandiol also stimulated uterine weight increases in immature female rats, which were partly blocked by ICI 182,780, but it was not aromatized in vitro by recombinant human aromatase. In contrast to testosterone, stimulation of sex accessory gland weights by bolandiol was not inhibited by concomitant treatment with the dual 5alpha-reductase inhibitor dutasteride. As bolandiol exhibits tissue selectivity in vivo, it may act via AR, PR, and/or ER, utilize alternative signaling pathway(s) or transcriptional coregulators, and/or be metabolized to a more potent selective steroid [09130].

**Effect on reproductive functions**
One study was conducted to evaluate the adverse effects of the anabolic steroid, boldenone undecylenate (BOL) on reproductive functions of male rabbits. Thirty white New Zealand mature male rabbits were divided into three groups (10 rabbits each). Group A rabbits served as a control group. Group B rabbits received 4.4 mg/kg body weight (bwt) BOL 5 percent oily solution. Group C rabbits received 8.8 mg/kg bwt BOL. Rabbits were injected intramuscularly twice weekly for two months. BOL had no significant effect on the bwt and bwt gain. Testes and epididymis weights were decreased significantly in the BOL-treated groups. BOL caused significant reduction in serum testosterone level, seminal volume, sperm motility, and sperm count. No abnormalities were detected in the sperm morphology of the BOL-treated groups. Histopathological alterations in the testes and epididymis were marked in the group C rabbits. These results indicate that administration of BOL exerts a significant harmful effect on the reproductive functions of male rabbits [12165].

Boldenone (androgenic steroid) is used in improvement of the growth and food conversion in food-producing animals. In addition, it is used by bodybuilders during both off-season and precontest, where it is well known for increasing vascularity while preparing for a bodybuilding contest. One study was designed to investigate the possible effect of growth promoter boldenone undecylenate on the structure and functions of rabbit testes. A total of 32 adult New Zealand rabbits were divided into 4 groups. The first group in the control group includes animals that were intramuscularly injected with olive oil and dissected after 3 weeks. Three experimental groups include animals that receive 1, 2, and 3 intramuscular injections of 5 mg/kg body weight boldenone, and dissected after 3, 6, and 9 weeks, respectively. Treating rabbits with boldenone increased the testosterone levels compared to the control group. Seminiferous tubules of the rabbit testis treated with boldenone showed reduced development and degeneration of the germinal epithelium, leading to debris and syncytial cell formation in the lumina of seminiferous tubules. The immunohistochemical results indicated severe reduction in proliferating cell nuclear antigen-positive spermatogonia in boldenone-treated animals as compared to the control group. These findings explain the common phenomena among athletics and bodybuilders who suffer from infertility as they were injected with some drugs such as steroids (boldenone) to build muscles [12166].

Possible endogenous origin

Boldenone (17-hydroxy-androsta-1,4-diene-3-one) and boldione (androst-1,4-diene-3,17-dione), are currently listed as exogenous anabolic steroids by the World Anti-Doping Agency. However, it has been reported that these analytes can be produced endogenously. Interestingly, only for boldenone a comment is included in the list on its potential endogenous origin. In this study, the endogenous origin of boldione in human urine was investigated, and the potential influence of phytosterol consumption was evaluated. It was carried out a 5-week in vivo trial with both men (n=6) and women (n=6) and measured alpha-boldenone, beta-boldenone, boldione, androstenedione, beta-testosterone and alpha-testosterone in their urine using gas chromatography coupled to multiple mass spectrometry (GC-MS-MS). The results demonstrate that endogenous boldione is sporadically produced at concentrations ranging from 0.75 ngm/L to 1.73 ngm/L, whereas endogenous boldenone could not be proven. It was also tested the effect of the daily consumption of a commercially available phytosterol-enriched yogurt drink on the presence of these analytes in human urine. Results from this study could not indicate a relation of boldione-excretion with the consumption of phytosterols at the recommended dose. The correlations between boldione and other steroids were consistently stronger for volunteers consuming phytosterols than for those refraining from phytosterol consumption. This preliminary in vivo trial indicates the endogenous origin of boldione or boldione in human urine, independent on the presence of
any structural related analytes such as phytosterols [09129].

Boldenone (androsta-1,4-dien-17beta-ol-3-one, Bo) is an anabolic steroid known to have been used in cattle breeding or equine sport as a doping agent for many years. Although not clinically approved for human application, boldenone or its main metabolite 5beta-androst-1-en-17beta-ol-3-one (BM1) were detected in several doping control samples. For more than 15 years the possibility of endogenous boldenone production in human beings has been discussed. This is a challenging issue for doping control laboratories as boldenone belongs to the list of prohibited substances of the World Anti-Doping Agency and therefore the chance for false positive testing is significant. By GC/C/IRMS (gas chromatography/combustion/isotope ratio mass spectrometry) it should be possible to analyze the $^{13}$C/$^{12}$C ratio of either boldenone or BM1 and to distinguish whether their source is endogenous or exogenous. Therefore a method was developed to determine the $^{13}$C/$^{12}$C ratios of boldenone, BM1, pregnanediol, androsterone, etiocholanolone, and testosterone from a single urine specimen. The validity of the method was ensured by repeated processing of urine fortified with 2-50 ng/mL boldenone and BM1. The specificity of the method was ensured by gas chromatography/mass spectrometry determinations. Out of 23 samples investigated throughout the last four years, 11 showed $^{13}$C/$^{12}$C ratios of boldenone or BM1 inconsistent with an exogenous origin. Two of these samples were collected from the same athlete within a one-month interval, strongly indicating the chance of endogenous Bo production by this athlete [10087].

For over a decade there has been an intensive debate on the possible natural origin of boldenone (androst-1,4-diene-17beta-ol-3-one, 17beta-boldenone) in calf urine and several alternative markers to discriminate between endogenously formed boldenone and exogenously administered boldenone have been suggested. The currently approved method for proving illegal administration of beta-boldenone(ester) is the detection of beta-boldenone conjugates. Because of the fractionation approach used in this method there is no need for conjugated reference standards which often are not available. The disadvantage of needing three analytical runs to determine the conjugated status of each of the metabolites was overcome by using fast chromatography [08188].

Boldenone (17-hydroxy-androsta-1,4-diene-3-one, Bol) and boldione (androsta-1,4-diene-3,17-dione, ADD), are currently listed as exogenous anabolic steroids by the World Anti-Doping Agency. However, it has been reported that these analytes can be produced endogenously. Interestingly, only for Bol a comment is included in the list on its potential endogenous origin. In one study, the endogenous origin of ADD in human urine was investigated, and the potential influence of phytosterol consumption was evaluated. It was carried out a 5-week in vivo trial with both men (n=6) and women (n=6) and measured alpha-boldenone, beta-boldenone, boldione, androstenedione, beta-testosterone and alpha-testosterone in their urine using gas chromatography coupled to multiple mass spectrometry (GC-MS-MS). The results demonstrate that endogenous ADD is sporadically produced at concentrations ranging from 0.751 ng/mL to 1.73 ng/mL, whereas endogenous Bol could not be proven. We also tested the effect of the daily consumption of a commercially available phytosterol-enriched yogurt drink on the presence of these analytes in human urine. Results from this study could not indicate a relation of ADD-excretion with the consumption of phytosterols at the recommended dose. The correlations between ADD and other steroids were consistently stronger for volunteers consuming phytosterols (test) than for those refraining from phytosterol consumption (control). Excretion of AED, bT and aT did not appear to be dependent on the consumption of phytosterols. This preliminary in vivo trial indicates the endogenous origin of boldione or ADD in human urine, independent on the presence of any structural related analytes such as phytosterols [09128].
Urinary samples contaminated with faecal boldenone

One potential explanation for the presence of beta-boldenone in calf urine is contamination of the sample with feces containing beta-boldenone. It has been demonstrated that after oral and intramuscular administration of beta-boldenone esters, several metabolites are formed and excreted in urine. One of the (minor) metabolites is 6beta-hydroxy-17alpha-boldenone. This paper describes an analytical method that can discriminate between unconjugated boldenone, its glucuronide- and sulphate-conjugates, 6beta-hydroxy-17alpha/beta-boldenone and coprostanol, a marker for fecal contamination. The method was applied to all samples suspected to contain boldenone within the Dutch National Residue Control Plan. Approximately 10,000 samples of urine were screened (LC-MS) in 2004-2005 by VWA-East, one of the official Dutch control laboratories, from which 261 samples were suspected to contain boldenone. These samples were all analyzed for their conjugation state, 6beta-hydroxy-17alpha/beta-boldenone and for the presence of coprostanol. Alfa-boldenone, the major metabolite in bovine urine after boldenone-ester administration, was found in a large number of these samples. The presence of alpha-boldenone was proven also to be a result of fecal contamination. None of the samples tested contained residues of the metabolite 6beta-hydroxy-17alpha/beta-boldenone. Not finding this metabolite indicates that the origin of alpha-boldenone conjugates is endogenous. The results confirm that the presence of unconjugated beta-boldenone and alpha-boldenone conjugates next to alpha-boldenone are no indicators for illegal administration of boldenone-esters. No indications were obtained that conjugated beta-boldenone can be of endogenous origin [06111].

Influence of renal function

The widespread use of reporting estimated glomerular filtration rate (eGFR) alongside serum creatinine has led to a heightened appreciation of renal disease. However, creatinine is recognized as an insensitive marker of true GFR and therefore can lead to misdiagnosis of renal dysfunction in the absence of true pathology. It was reported a case of a 37-year-old male referred due to abnormal eGFR and creatinine in the absence of clinical signs, symptoms or other biochemical abnormalities of renal disease. Subsequent investigations based on a high index of suspicion for exogenous substance abuse led to a novel observation of significantly raised creatinine due to the presence of boldenone, an equine anabolic steroid commonly abused in body building [11101].

Metabolism of 1-ene-steroids

5alpha-Androst-1-ene derivatives are widely known as potent anabolic steroids. Although the metabolism of boldenone was elucidated and an adequate detection method was developed boldenone remained a popular steroid for misuse. Hence, the boldenone analogues were next on the list to be introduced on the prohormone market after testosterone precursors and their 19-nor-analogues [06004].

Stenbolone

Stenbolone acetate (17beta-acetoxy-2-methyl-5alpha-androst-1- en-3-one) is a registered anabolic steroid. After oral administration of stenbolone acetate glucuronidated stenbolone and several metabolites were detected. Besides the 16-hydroxy and 17-keto metabolites a minor metabolite hydroxylated at C-18, 2-methyl-5alpha-androst-1-ene-18-ol-3,17-dione, was
also found [06004].

**Quinbolone**

Quinbolone (17beta-(1-cyclopenten-1-yloxy)-androsta-1,4-dien-3-one) is the 17beta cyclopentene ether of boldenone and is reportedly metabolised to boldenone [06004].

**Boldione**

Boldione (1,4-androstadiene-3,17-dione) is marketed as an orally active precursor of boldenone and is available as a nutritional supplement in the United States. In cattle it was shown to be a metabolite of boldenone and endogenous. In man, 1,4-androstadiene-3,17-dione was identified as a metabolite and precursor of boldenone. Two excretion studies with orally administered 1,4-androstadiene-3,17-dione have been performed so far and have shown that this steroid is partially excreted unchanged. Besides the major metabolite boldenone, two other unidentified metabolites has been detected, maybe 5beta-androst-1-ene-3alpha-ol,17-one as the major metabolite and 5beta-androst-1-ene-17beta-ol-3-one, 5beta-androst-1-ene-3alpha,17-one as the major metabolite and 5beta-androst-1-ene-6beta-ol-3,17-dione as other metabolites. These metabolites were previously identified as metabolites of boldenone [06004].

The occurrence of boldione metabolites conjugated with cysteine and N-acetylcysteine in human urine was evaluated. Methods based on precursor ion scan of the protonated aminoacid (m/z 122 and m/z 164 for cysteine and N-acetylcysteine respectively) and neutral losses of the aminoacids (121 Da and 163 Da for cysteine and N-acetylcysteine respectively) were applied for the open detection of conjugates. Results for urine samples collected before and after boldione administration were compared. Using this approach, 24 metabolites (eleven conjugates with cysteine and thirteen conjugated with N-acetylcysteine) were detected. The metabolites were characterized by mass spectrometry and their potential structures were proposed based on this information. The structures of nine of these metabolites were confirmed by the synthesis of the conjugates. According to these results, a metabolic pathway for boldione involving this type of conjugation was presented. This is the first time that cysteine conjugates are presented for exogenous anabolic androgenic steroids and the first report of N-acetylcysteine conjugates for steroids [12168].

Boldione (1,4-androstadien-3,17-dione) is included in the list of prohibited substances, issued by the World Anti-Doping Agency (WADA). Endogenous production of low concentrations of boldione has also been reported. The objective of this study was to assess boldione metabolism in humans. Detection of boldione metabolites was accomplished by analysis by liquid chromatography coupled to tandem mass spectrometry of urine samples obtained after administration of the drug and subjected to different sample preparation procedures to analyze the different metabolic fractions (free, glucuronides, sulphates and released in basic media). In addition to boldione, eight metabolites were detected in the free fraction. Four of them were identified by comparison with standards: 6β-hydroxy-boldenone (M3), androsta-1,4,6-triene-3,17-dione (M5), (5alpha)-1-androstenedione (M6) and (5alpha)-1-testosterone (M8). Metabolite M7 was identified as the 5β-isomer of 1-androstenedione, and metabolites M1, M2 and M4 were hydroxylated metabolites and tentative structures were proposed based on mass spectrometric data. After beta-glucuronidase hydrolysis, five additional metabolites excreted only as conjugates with glucuronic acid were detected: boldenone, (5beta)-1-testosterone (M9), and three metabolites resulting from reduction of the 3-keto group. Boldenone, epiboldenone, and hydroxylated metabolites of boldione, boldenone and 1-testosterone were detected as conjugates with sulfate. In addition, boldione and seven
metabolites (boldenone, M2, M3, M4, M5, M7 and M9) increased their concentration in urine after treatment of the urine in alkaline conditions. In summary, 15 boldione metabolites were detected in all fractions. The longer detection time was observed for metabolite M4 after alkaline treatment of the urine, which was detected up to 5 days after boldione administration [12169].

Experimentally

Boldenone (BOL) is a derivative of the testosterone that has dual effects on humans, both directly and indirectly; directly as injection to build muscles and indirectly as through consuming meat of animals that were treated with BOL. However, the action of these steroids on different body organs structures is still unclear; therefore, the aim of the present study was to investigate the effect of the intramuscular injection of BOL undecylenate on the different organ structures. A total of 10 adult New Zealand rabbits were divided into two main groups, the first group was the control group, which includes animals that were injected intramuscularly with olive oil and the second group included animals that received two intramuscular injections of 5 mg/kg body weight BOL dissected after 6 weeks. Our results showed that intramuscular injection of rabbits with BOL showed hypertrophy in both skeletal and cardiac muscles, disturbances of the hepatocytes radially arranged cords with multifocal hepatocellular vacuolations in the liver, glomerulus mass reduction with multifocal glomerular injury in the kidney, disturbances of the cycle of spermatogenesis in the testes. In conclusion, using BOL, while preparing for a young bodybuilding contest, may cause an alteration in the histological structure of most of the body organs; these findings suggested that especially young people who misuse anabolic androgenic steroids should be careful if they want to use such steroids to enhance their strength and endurance [013246].

Laboratory techniques

Boldenone is one of the most frequently detected anabolic androgenic steroids in doping control analysis. Boldenone misuse is commonly detected by the identification of the active drug and its main metabolite, 5beta-androst-1-en-17beta-ol-3-one (BM1), by gas chromatography-mass spectrometry (GC-MS), after previous hydrolysis with β-glucuronidase enzymes, extraction and derivatization steps. However, some cases of endogenous boldenone and BM1 have been reported. Nowadays, when these compounds are detected in urine at low concentrations, isotope ratio mass spectrometry (IRMS) analysis is needed to confirm their exogenous origin. The aim of the present study was to identify boldenone metabolites conjugated with sulphate and to evaluate their potential to improve the detection of boldenone misuse in sports. Boldenone was administered to a healthy volunteer and urine samples were collected up to 56 h after administration. After a liquid-liquid extraction with ethyl acetate, urine extracts were analysed by liquid chromatography tandem mass spectrometry (LC-MS/MS) using electrospray ionisation in negative mode by monitoring the transition of m/z 365-350, specific for boldenone sulphate. Boldenone sulphate was identified in the excretion study urine samples and, moreover, another peak with the same transition was observed. Based on the MS/MS behaviour the metabolite was identified as epiboldenone sulphate. The identity was confirmed by isolation of the LC peak, solvolysis and comparison of the retention time and MS/MS spectra with an epiboldenone standard. These sulphated metabolites have not been previously reported in humans and although they account for less than 1% of the administered dose, they were still present in urine when the concentrations of the major metabolites, boldenone and BM1, were at the level of endogenous origin. The sulphated metabolites were also detected in 10 urine samples tested
positive to boldenone and BM1 by GC-MS. In order to verify the usefulness of these new metabolites to discriminate between endogenous and exogenous origin of boldenone, four samples containing endogenous boldenone and BM1, confirmed by IRMS, were analysed. In 3 of the 4 samples, neither boldenone sulphate nor epiboldenone sulphate were detected, confirming that these metabolites were mainly detected after exogenous administration of boldenone. In contrast, boldenone sulphate and, in some cases, epiboldenone sulphate were present in samples with low concentrations of exogenous boldenone and BM1. Thus, boldenone and epiboldenone sulphates are additional markers for the exogenous origin of boldenone and they can be used to reduce the number of samples to be analysed by IRMS. In samples with boldenone and BM1 at the concentrations suspicion for endogenous origin, only if boldenone and epiboldenone sulphates are present, further analysis by IRMS will be needed to confirm exogenous origin [12167].

Boldione (1,4-androstanediene-3,17-dione) is a direct precursor (prohormone) to the anabolic steroid boldenone (1,4-androstanediene-17beta-ol-3-one). It is advertised as a highly anabolic/androgenic compound promoting muscularity, enhancing strength and overall physical performance, and is available on the Internet and in health stores. One work was undertaken to determine and characterize boldione and its metabolites in human urine, using both liquid chromatography with electrospray ionization mass spectrometry and gas chromatography with mass spectrometry and derivatization. Boldione and its three metabolites were detected in dosed human urine after dosing a healthy volunteer with 100 mg boldione. The excretion studies showed that boldione and its metabolites were detectable in urine for 48 h after oral administration, with maximum excretion rates after 1.8 and 3.6 h (boldenone case). The amounts of boldione and boldenone excreted in urine from this 100 mg dose were 34.45 and 15.95 mg, respectively [06109].

Sulfo-conjugates of boldenone and its phase-I metabolites were studied concerning their utility as markers for boldenone administration and as a means to differentiate endogenous boldenone (metabolite) production from the illicit use of the AAS. In an elimination study with 20 mg of boldenone, urine samples were collected up to 56 h post-administration and subjected to LLE and LC-MS/MS analysis comprising specific ion transitions for boldenone (and epiboldenone) sulfate. The sulfo-conjugates were indeed found up to 56 h, and the applicability of these marker compounds to routine doping control samples was tested by analyzing specimens of earlier AAFs with boldenone and samples containing evidently endogenously produced boldenone metabolites as verified by IRMS. In 3 out of 4 cases of naturally/endogenously occurring boldenone, sulfates of boldenone and epiboldenone were not detected, suggesting that these analytes can serve as indicators (though not as proof) for exogenous sources of boldenone in athletes’ doping control samples. Analogously, metandienone was subjected to elimination studies with particular emphasis on sulfo-conjugated metabolites. In agreement with an earlier report, the utility of sulfated 18-nor-17beta-hydroxymethyl,17alpha-methyl-androst-1,4,13-trien-3-one as long-term metabolite was outlined, which was detected in post-administration studies up to 26 days by means of LC-MS/MS [13009].

Boldione is an anabolic androgenic steroid (AAS) related to boldenone, androstenedione, and testosterone bearing two double bonds in C1 and C4 positions. Boldione is rapidly transformed to the well-known AAS boldenone, being both compounds included in the list of prohibited substances and methods published yearly by the World Anti-Doping Agency (WADA). After the administration of boldione to a male volunteer, the already described urinary metabolites of boldenone produced after reduction in C4, oxydoreduction in C3 and C17, and hydroxylation have been detected. In addition, minor new metabolites have been detected and their structure postulated after mass spectrometric analyses. Finally, the reduction of the double bound in C1 produces metabolites identical to the endogenously
produced ones. A method based on gas chromatography coupled to isotope ratio mass spectrometry (GC/IRMS) after a urine sample purification by high performance liquid chromatography (HPLC) permitted to confirm the main synthetic like boldione/boldenone metabolite (17beta-hydroxy-5beta-androst-1-en-3-one) and boldenone at trace levels (<5 ng/mL) and then to establish its synthetic or endogenous origin, and to determine the exogenous origin of metabolites with the same chemical structure of the endogenous ones. The detection of pseudoendogenous androgens of synthetic origin partially overlapped boldenone and its main metabolite detection, being an additional proof of synthetic steroids misuse. By the use of IRMS, the correct evaluation of the modifications of the steroid profile after the administration of synthetic AAS that could be converted into endogenous like ones is possible [13247].

**Conjugated and unconjugated**

Natural occurrence or illegal treatment of boldenone (BOLD) presence in cattle urine is under debate within the European Union. Separation of conjugated and unconjugated forms of 17alpha-boldenone (alpha-BOLD) and 17beta-boldenone (beta-BOLD) and presence of related molecules as androsta-1,4-diene-3,17-dione (ADD) appear critical points for the decision of an illegal use. The aim of one study was a new analytical approach of BOLD and ADD confirmation in cattle urine. The separation between conjugated and unconjugated forms of BOLD was obtained by a preliminary urine liquid-liquid extraction step with ethyl acetate. In this step the organic phase extracts only unconjugated BOLD and ADD, while BOLD in conjugated form remain in urine phase. Afterwards the urine phase, contains conjugated BOLD, was subjected to an enzymatic deconjugation. Solid-phase extraction (OASIS-HLB Waters) was used for the purification and concentration of analytes in organic and urine phases and liquid chromatography ion electrospray tandem mass spectrometry (LC-MS-MS) was applied for the confirmation of BOLD and ADD, using deuterium-labelled 17beta-boldenone (BOLD-d3) as internal standard. The method was validated as a quantitative confirmatory method according to the Commission Decision 2002/657/CE. The results obtained demonstrate that the developed method show very high specificity, precision, trueness and ruggedness. Decision limits (CCalpha) smaller than 0.5 ng/mL were obtained for each analyte [06110].

**In cattle**

17Beta-boldenone (17beta-BOLD) and Boldione (ADD) are steroid compounds with androgenic activity, likely to be used as growth promoters in cattle. Different studies still ongoing aiming to distinguish between "natural" occurrence or illegal BOLD source had already indicated that their metabolism in cattle is of relevant significance. To identify metabolites as in vivo markers to support the thesis of exogenous administration, a further approach to the in vitro biotransformation of 17beta-BOLD and ADD was performed using different subcellular fractions obtained from both liver and kidney of untreated cattle. Polar and non-polar metabolites obtained from incubated parent compounds were formerly separated by high performance liquid chromatography (HPLC) elution and successively identified by liquid chromatography tandem mass spectrometry (LC-MS/MS) detection. The bovine liver was the target tissue of the main metabolic reaction transforming 17beta-BOLD to ADD and vice versa. The presence of 6beta-hydroxy-17beta-BOLD, produced from both compounds when NADPH was added as cofactors to liver post mitochondrial and microsomal fractions suggests that cytochrome P450-dependent enzymes could be involved in the biotransformation, as it occurs for 6beta-hydroxylation of 17beta-testosterone. The results indicated that the urinary excretion profile in vivo of 6beta-hydroxy-17beta-BOLD and 16alpha-hydroxy-17beta-BOLD could be studied together with 17alpha- and 17beta-BOLD
Boldenone is an androgenic steroid that improves the growth and food conversion in food producing animals. In most countries worldwide, this anabolic steroid is forbidden for meat production. Until recently, the control of its illegal use was based either on 17beta-boldenone or 17alpha-boldenone (its main metabolite in cattle) identification in edible tissues, hair, faeces or urine. Recent observations and data tend to demonstrate the natural occurrence (but not ubiquitous) in cattle of these steroids, making the analytical strategy of the control more complicated. It was investigated the metabolism of boldenone in cattle after intramuscular and oral treatment of boldenone, boldenone esters and boldione. The central objective was to elucidate the structures of the main metabolites (phase I and phase II) in urine, with main objective to be further in position to compare boldenone urinary profiles of treated and non-treated animals. Nine metabolites have been identified, only four were present whatever the treatment and the administered boldenone source. Nevertheless, all of them have been detected at least once in non-treated animals which did not permit us to use them as biomarkers of an illegal treatment. At last, but not at least, all metabolites were found mainly glucuro-conjugated, and rarely sulfo-conjugated, with the only exception of 17beta-boldenone. Current investigations are showing the absence of 17beta-boldenone sulfoconjugate in non-treated animals; that would permit to distinguish non-treated from treated animals with boldione, boldenone and boldenone esters [06113].
OTHER SPECIFIED ANABOLIC ANDROGENIC STEROIDS

Oxandrolone

The discovery and implementation of the long-term metabolite of metandienone, namely 17beta-hydroxymethyl-17alpha-methyl-18-norandrost-1,4,13-trien-3-one, to doping control resulted in hundreds of positive metandienone findings worldwide and impressively demonstrated that prolonged detection periods significantly increase the effectiveness of sports drug testing. For oxandrolone and other 17-methyl steroids, analogs of this metabolite have already been described, but comprehensive characterization and pharmacokinetic data are still missing. In this report, the synthesis of the two epimeric oxandrolone metabolites-17beta-hydroxymethyl-17alpha-methyl-18-nor-2-oxa-5alpha-androsta-13-en-3-one and 17alpha-hydroxymethyl-17beta-methyl-18-nor-2-oxa-5alpha-androsta-13-en-3-one-using a fungus (Cunninghamella elegans) based protocol is presented. The reference material was fully characterized by liquid chromatography nuclear magnetic resonance spectroscopy and high resolution/high accuracy mass spectrometry. To ensure a specific and sensitive detection in athlete's urine, different analytical approaches were followed, such as liquid chromatography-tandem mass spectrometry (QqQ and Q-Orbitrap) and gas chromatography-tandem mass spectrometry, in order to detect and identify the new target analytes. The applied methods have demonstrated good specificity and no significant matrix interferences. Linearity (R(2) > 0.99) was tested, and precise results were obtained for the detection of the analytes (coefficient of variation <20%). Limits of detection (S/N) for confirmatory and screening analysis were estimated at 1 and 2 ng/mL of urine, respectively. The assay was applied to oxandrolone post-administration samples to obtain data on the excretion of the different oxandrolone metabolites. The studied specimens demonstrated significantly longer detection periods (up to 18 days) for the new oxandrolone metabolites compared to commonly targeted metabolites such as epioxandrolone or 18-nor-oxandrolone, presenting a promising approach to improve the fight against doping [13237].
metabolites such as epioxandrolone or 18-nor-oxandrolone, presenting a promising approach to improve the fight against doping [13238].

**Stanozolol**

Anabolic-androgenic steroids (AAS) represent one of the most frequently detected classes of prohibited substances in doping controls. Due to their long-lasting beneficial effects on athletic performance, utmost retrospection via urine analysis is desirable and accomplished by targeting long-term metabolites of the respective drugs. In case of stanozolol, a substantial variety of metabolites has enabled the identification of numerous adverse analytical findings in the past, and recent studies concerning complementary phase-I and phase-II metabolites has further expanded the windows of opportunity for detecting the abuse of stanozolol. In this study, the utility of liquid chromatography-high resolution/high accuracy (tandem) mass spectrometry (LC-MS/MS) for the detection of 3'-OH-stanozolol glucuronide in sports drug testing is presented and the identification of two additional and so far unreported metabolites is shown. The structures of the complementary glucuronic acid conjugates were attributed to stanozolol-N-glucuronide and 17-epistanozolol-N-glucuronide. By means of chemical synthesis, stanozolol-N-glucuronide was prepared and used to corroborate the suggested structures. The 3'-OH-stanozolol glucuronide and the newly identified target compounds were implemented into routine sports drug test assays consisting of direct injection LC-MS/MS or solid-phase extraction (SPE) followed by LC-MS/MS. A considerably expanded detection window for stanozolol abuse was demonstrated compared to the use of conventional phase-I metabolites and methodologies based on, for example, low resolution LC-MS/MS or gas chromatography-tandem mass spectrometry (GC-MS/MS). The commercial availability of 3'-OH-stanozolol glucuronide has been of great value for confirmatory purposes, and 17-epistanozolol-N-glucuronide was found to be a favourable long-term metabolite for doping controls as it was observed up to 28 days post-administration of the drug. Applying the established methodology over a period of six months to 659 routine sports drug testing samples, a total of 85 adverse analytical findings was uncovered, 72 of which would have remained undetected using earlier employed GC-MS/MS approaches [13239].

Stanozolol is one of the most frequently detected anabolic steroids in doping control samples. This compound is metabolized to a large extent and its metabolites can be detected in urine much longer than the parent compound. The main stanozolol metabolites are excreted in urine as glucuronide conjugates and 3'-hydroxy-stanozolol glucuronide is one of the most important in human urine. Therefore enzymatic hydrolysis is usually applied prior to extraction. In one article a method for the sensitive detection of intact 3'-hydroxy-stanozolol glucuronide, by liquid chromatography tandem mass spectrometry, is described. The method takes advantage of an easy and fast sample preparation based on a single solid-phase extraction avoiding enzymatic hydrolysis or derivatization. It allows to detect stanozolol abuse in human urine at 25 pg/mL. The method was validated according to Eurachem guidelines. The matrix effect, expressed as ion enhancement, was +14 percent. The extraction recovery of the method was 93%. The limit of detection (LOD), whereby all WADA-criteria in chromatography and mass spectrometry are fulfilled, was determined at 50 pg/mL. Application of the method to an excretion study revealed that the 3'-hydroxy-stanozolol glucuronide could be confirmed for 10 days after oral administration of 2 mg of stanozolol, prolonging detection times compared to other metabolites and methodologies by almost 50 percent [13799].

Aiming at the improved detection of stanozolol misuse in sport, an LC-MS/MS-based
methodology targeting the long-term metabolite 3'-hydroxystanozolol glucuronide was presented. Following SPE with cation-exchange mixed-mode adsorber resin, urine extracts were analyzed by conventional triple quadrupole detection in SRM mode; the selectivity and intensity of ion transitions allowed for LODs as low as 25 pg/mL, thus providing a viable tool for extended retrospection in sports drug test samples [13009].

for confirmatory purposes, and 17-epistanozolol-N-glucuronide was found to be a favourable long-term metabolite for doping controls as it was observed up to 28 days post-administration of the drug. Applying the established methodology over a period of six months to 659 routine sports drug testing samples, a total of 85 adverse analytical findings was uncovered, 72 of which would have remained undetected using earlier employed GC-MS/MS approaches [13241].

Anabolic androgenic steroids are used in the sport context to enhance muscle mass and strength and to increase muscle fatigue resistance. Since muscle fatigue has been related to oxidative stress caused by an exercise-linked reactive oxygen species (ROS) production, we investigated the potential effects of a treatment with the anabolic androgenic steroid stanozolol against oxidative damage induced on rat skeletal muscle mitochondria by an acute bout of exhaustive exercise. Mitochondrial ROS generation with complex I- and complex II-linked substrates was increased in exercised control rats, whereas it remained unchanged in the steroid-treated animals. Stanozolol treatment markedly reduced the extent of exercise-induced oxidative damage to mitochondrial proteins, as indicated by the lower levels of the specific markers of protein oxidation, glycoxidation, and lipoxidation, and the preservation of the activity of the superoxide-sensitive enzyme aconitase. This effect was not due to an enhancement of antioxidant enzyme activities. Acute exercise provoked changes in mitochondrial membrane fatty acid composition characterized by an increased content in docosahexaenoic acid. In contrast, the postexercise mitochondrial fatty acid composition was not altered in stanozolol-treated rats. The results suggest that stanozolol protects against acute exercise-induced oxidative stress by reducing mitochondrial ROS production, in association with a preservation of mitochondrial membrane properties [11104].

The canine phase I and phase II metabolism of the synthetic anabolic-androgenic steroid stanozolol was investigated following intramuscular injection into a male greyhound. The major phase I biotransformation was hydroxylation to give 6alpha-hydroxystanozolol which was excreted as a glucuronide conjugate and was identified by comparison with synthetically derived reference materials. An analytical procedure was developed for the detection of this stanozolol metabolite in canine urine using solid phase extraction, enzyme hydrolysis of glucuronide conjugates and analysis by positive ion electrospray ionisation ion trap LC-MS [09124].

The abuse of stanozolol is quite widespread in sports. Its analysis is challenging and this has led to the development of new methods to improve its detection. A method was developed and validated for the detection of the three main monohydroxylated metabolites of stanozolol. The excretion profile of these metabolites was studied in four healthy male volunteers. The excretion study samples, after a single oral dose of drug, showed that 3'-OH-stanozolol was excreted at the highest concentration, followed by 16beta-OH stanozolol, with 4beta-OH stanozolol as the least excreted. Ninety-eight old doping samples with adverse analytical findings for 3'-OH-stanozolol were reanalysed using this method. This showed 3'-OH-stanozolol and 16beta-OH stanozolol in all the 98 samples whereas 4beta-OH-stanozolol was identified in 90 samples. The percentage of positive identifications of stanozolol in Indian sportspeople has increased markedly in the last five years, from 32 percent in 2004 to 82 percent in 2009; however, this may be due to the more effective detection of stanozolol metabolites. It can thus be concluded that the marked increase in percent positive of stanozolol in Indian sportspersons in 2009 may be due to the improved detection by a more effective LCMS/MS method [09125].

The applicability of LC-MS/MS in precursor ion scan mode for the detection of urinary stanozolol metabolites has been studied. The product ion at m/z 81 has been selected as specific for stanozolol metabolites without a modification in A- or N-rings and the product ions
at m/z 97 and 145 for the metabolites hydroxylated in the N-ring and 4-hydroxy-stanozolol metabolites, respectively. Under these conditions, the parent drug and up to 15 metabolites were found in a positive doping test sample. The study of a sample from a chimeric uPA-SCID mouse collected after the administration of stanozolol revealed the presence of 4 additional metabolites. The information obtained from the product ion spectra was used to develop a SRM method for the detection of 19 compounds. This SRM method was applied to several doping positive samples. All the metabolites were detected in both the uPA-SCID mouse sample and positive human samples and were not detected in none of the blank samples tested; confirming the metabolic nature of all the detected compounds. In addition, the application of the SRM method to a single human excretion study revealed that one of the metabolites (4xi,16xi-dihydroxy-stanozolol) could be detected in negative ionization mode for a longer period than those commonly used in the screening for stanozolol misuse (3'-hydroxy-stanozolol, 16beta-hydroxy-stanozolol and 4beta-hydroxy-stanozolol) in doping analysis. The application of the developed approach to several positive doping samples confirmed the usefulness of this metabolite for the screening of stanozolol misuse. Finally, a tentative structure for each detected metabolite has been proposed based on the product ion spectra measured with accurate masses using UPLC-QTOF MS [09126].

The applicability of LC-MS/MS in precursor ion scan mode for the detection of urinary stanozolol metabolites has been studied. The product ion at m/z 81 has been selected as specific for stanozolol metabolites without a modification in A- or N-rings and the product ions at m/z 97 and 145 for the metabolites hydroxylated in the N-ring and 4-hydroxy-stanozolol metabolites, respectively. Under these conditions, the parent drug and up to 15 metabolites were found in a positive doping test sample. In addition, the application of the SRM method to a single human excretion study revealed that one of the metabolites (4xi,16xi-dihydroxy-stanozolol) could be detected in negative ionization mode for a longer period than those commonly used in the screening for stanozolol misuse (3'-hydroxy-stanozolol, 16beta-hydroxy-stanozolol and 4beta-hydroxy-stanozolol) in doping analysis. The application of the developed approach to several positive doping samples confirmed the usefulness of this metabolite for the screening of stanozolol misuse [09127].

Anabolic androgenic steroids, such as stanozolol, are typically misused by athletes during preparation for competition. Out-of-competition testing presents a unique challenge in the current anti-doping detection system owing to logistic reasons. Analysing hair for the presence of a prohibited drug offers a feasible solution for covering the wider window in out-of-competition testing. To assist in vivo studies aiming to establish a relationship between drug levels detected in hair, urine and blood, sensitive methods for the determination of stanozolol and its major metabolite 3'-hydroxystanozolol were developed in pigmented hair, urine and serum, using brown Norway rats as a model system and liquid chromatography tandem mass spectrometry (LC-MS/MS). For method development, spiked drug free rat hair, blood and urine samples were used. The newly developed method was then applied to hair, urine and serum samples from five brown Norway rats after treatment (intraperitoneal) with stanozolol for six consecutive days at 5.0 mg/kg/day. The assay for each matrix was linear within the quantification range with determination coefficient (r²) values above 0.995. The respective assay was capable of detecting 0.125 pg/mg stanozolol and 0.25 pg/mg 3'-hydroxystanozolol with 50 mg hair; 0.063 ng/mL stanozolol and 0.125 ng/mL 3'-hydroxystanozolol with 100 microL of urine or serum. The accuracy, precision and extraction
recoveries of the assays were satisfactory for the detection of both compounds in all three matrices. The average concentrations of stanozolol and 3'-hydroxystanozolol, were as follows: hair = 70 ± 22 pg/mg and 13 ± 3 pg/mg; urine = 4 ± 6 ng/mL and 9 ± 7 ng/mL; serum = 8 ± 4 ng/mL and 7 ± 2 ng/mL, respectively. The developed methods are sensitive, specific and reproducible for the determination of stanozolol and 3'-hydroxystanozolol in rat hair, urine and serum. These methods can be used for in vivo studies further investigating stanozolol metabolism, but also could be extended for doping testing. Owing to the complementary nature of these tests, with urine and serum giving information on recent drug use and hair providing retrospective information on habitual use, it is suggested that blood or urine tests could accompany hair analysis and thus avoid false doping results [12116].

Since stanozolol and 3'-hydroxystanozolol are structurally different from most AAS, they can be more difficult to detect in urine than other AAS, and thus require bespoke methods. Depending on the dose administered, once in the body, stanozolol gets rapidly metabolised and the metabolites are generally detected in urine until ca. 6 days. Thus, urinalysis generally fails to determine the long term history of an individual’s drug use, which is a major hindrance in cases of performance-enhancing drugs used in preparation for competition. Stanozolol, along with other AAS, is a so called “training drug” which is taken for a prolonged period, typically in cycles, during preparation, in order to obtain the desired performance-enhancing effects. Furthermore, urinalysis also fails to distinguish between chronic use and single, accidental exposure of drugs [12116].

An extensive literature has documented adverse effects on mental health in anabolic androgenic steroids (AAS) abusers. Depression seems a common adverse reaction in AAS abusers. Recently it has been reported that in a rat model of AAS abuse stanozolol induces behavioural and biochemical changes related to the pathophysiology of major depressive disorder. In the present study, we used the model of AAS abuse to examine possible changes in the monoaminergic system, a neurobiological substrate of depression, in different brain areas of stanozolol-treated animals. Wistar rats received repeated injections of stanozolol (5mg/kg, s.c.), or vehicle (propylene glycol, 1 ml/kg) once daily for 4 weeks. Twenty-four hours after last injection, changes of dopamine (DA) and relative metabolite levels, homovanillic acid (HVA) and 3,4-dihydroxy phenylacetic acid (DOPAC), serotonin (5-HT) and its metabolite levels, 5-hydroxy indolacetic acid (5-HIAA), and noradrenaline (NA) amount were investigated in prefrontal cortex (PFC), nucleus accumbens (NAC), striatum (STR) and hippocampus (HIPP). The analysis of data showed that after chronic stanozolol, DA levels were increased in the HIPP and decreased in the PFC. No significant changes were observed in the STR or in the NAC. 5-HT and 5-HIAA levels were decreased in all brain areas investigated after stanozolol exposure; however, the 5-HIAA/5-HT ratio was not altered. Taken together, the data indicate that chronic use of stanozolol significantly affects brain monoamines leading to neurochemical modifications possibly involved in depression and stress-related states [12170].

Methyltestosterone

Since a few years more and more products have appeared on the market for dietary supplements containing steroids that had never been marketed as approved drugs, mostly without proper labeling of the contents. Syntheses and few data on pharmacological effects are available dated back mainly to the 1950s or 1960s. Only little knowledge exists about effects and side effects of these steroids in humans. The present study reports the identification of Δ6-methyltestosterone in a product named “Jungle Warfare”, which was obtained from a web-based supplement store. The main urinary metabolites, 17alpha-hydroxy-17beta-
The androgen 17alpha-methyltestosterone (17alpha-meT) is one of the most commonly abused anabolic androgenic steroids (AAS). We assessed the impact of 17alpha-meT after bilateral infusion into the dorsomedial hypothalamus (DMH) in female anxiety. A paradoxical effect in Vogel conflict test (VCT) behavior was noted: while AAS infusion induced an increase in the latency to display the appetitive reaction of the task, it also increased the number of punished responses. No changes in elevated plus maze (EPM) behavior were noted. However, AAS infusion induced an increase in social interactions. Changes in social interactions were mimicked by muscimol infusion and counteracted by co-infusion of AAS plus the GABAA receptor (GABA-A-R) antagonist GABAzine. A reduction of systolic blood pressure was registered after AAS infusion in the DMH. No changes in fluid intake or locomotor behaviors were noted. It was concluded that the AAS 17alpha-meT modulates distinct anxiety domains in females through a fast-acting mechanism [06120].

Methyltestosterone (MT) is one of the most frequently detected anabolic androgenic steroids in doping control analysis. MT misuse is commonly detected by the identification of its two main metabolites excreted as glucuronide conjugates, 17alpha-methyl-5alpha-androstane-3alpha,17beta-diol and 17alpha-methyl-5beta-androstane-3alpha,17alpha-diol. The detection of these metabolites is normally performed by gas chromatography-mass spectrometry, after previous hydrolysis with beta-glucuronidase enzymes, extraction and derivatization steps. The aim of the present work was to study the sulphate fraction of MT and to evaluate their potential to improve the detection of the misuse of the drug in sports. MT was administered to healthy volunteers and urine samples were collected up to 30 days after administration. After an extraction with ethyl acetate, urine extracts were analysed by liquid chromatography tandem mass spectrometry using electrospray ionisation in negative mode by monitoring the transition m/z 385 to m/z 97. Three diol sulphate metabolites (S1, S2 and S3) were detected. Potential structures for these metabolites were proposed after solvolysis and mass spectrometric experiments: S1, 17alpha-methyl-5beta-androstane-3alpha,17beta-diol 3alpha-sulphate; S2, 17beta-methyl-5alpha-androstan-3alpha,17alpha-diol 3alpha-sulphate; and S3, 17beta-methyl-5beta-androstane-3alpha,17alpha-diol 3alpha-sulphate. Synthesis of reference compounds will be required in order to confirm the structures. The retrospectivity of these sulphate metabolites in the detection of MT misuse was compared with the obtained with previously described metabolites. Metabolite S2 was detected up to 21 days after MT administration, improving between 2 and 3 times the retrospectivity of the detection compared to the last long-term metabolite of MT previously described, 17alpha-hydroxy-17beta-methylandrostane-4,6-dien-3-one [12178].

Methyltestosterone (MT) is one of the most frequently detected anabolic androgenic steroids in doping control analysis. MT misuse is commonly detected by the identification of its two main metabolites excreted as glucuronide conjugates, 17alpha-methyl-5alpha-androstane-3alpha,17beta-diol and 17alpha-methyl-5beta-androstane-3alpha,17beta-diol. The detection of these metabolites is normally performed by gas chromatography-mass spectrometry, after
previous hydrolysis with beta-glucuronidase enzymes, extraction and derivatization steps. The aim of the present work was to study the sulphate fraction of MT and to evaluate their potential to improve the detection of the misuse of the drug in sports. MT was administered to healthy volunteers and urine samples were collected up to 30 days after administration. After an extraction with ethyl acetate, urine extracts were analysed by liquid chromatography tandem mass spectrometry using electrospray ionisation in negative mode by monitoring the transition m/z 385 to m/z 97. Three diol sulphate metabolites (S1, S2 and S3) were detected. Synthesis of reference compounds will be required in order to confirm the structures. The retrospectivity of these sulphate metabolites in the detection of MT misuse was compared with the obtained with previously described metabolites. Metabolite S2 was detected up to 21 days after MT administration, improving between 2 and 3 times the retrospectivity of the detection compared to the last long-term metabolite of MT previously described, 17alpha-hydroxy-17beta-methylandrostan-4,6-dien-3-one [13242].

**Biomarkers**

Methyltestosterone (MT) is one of the most frequently detected anabolic androgenic steroids in doping control analysis. MT misuse is commonly detected by the identification of its two main metabolites excreted as glucuronide conjugates, 17alpha-methyl-5alpha-androstan-3alpha,17beta-diol and 17alpha-methyl-5beta-androstan-3alpha,17beta-diol. The detection of these metabolites is normally performed by gas chromatography-mass spectrometry, after previous hydrolysis with beta-glucuronidase enzymes, extraction and derivatization steps. The aim of the present work was to study the sulphate fraction of MT and to evaluate their potential to improve the detection of the misuse of the drug in sports. MT was administered to healthy volunteers and urine samples were collected up to 30 days after administration. After an extraction with ethyl acetate, urine extracts were analysed by liquid chromatography tandem mass spectrometry using electrospray ionisation in negative mode by monitoring the transition m/z 385 to m/z 97. Three diol sulphate metabolites (S1, S2 and S3) were detected. Potential structures for these metabolites were proposed after solvolysis and mass spectrometric experiments: S1, 17alpha-methyl-5beta-androstan-3alpha,17beta-diol 3alpha-sulphate; S2, 17beta-methyl-5alpha-androstan-3alpha,17alpha-diol 3alpha-sulphate; and S3, 17beta-methyl-5beta-androstan-3alpha,17alpha-diol 3alpha-sulphate. Synthesis of reference compounds will be required in order to confirm the structures. The retrospectivity of these sulphate metabolites in the detection of MT misuse was compared with the obtained with previously described metabolites. Metabolite S2 was detected up to 21 days after MT administration, improving between 2 and 3 times the retrospectivity of the detection compared to the last long-term metabolite of MT previously described, 17alpha-hydroxy-17beta-methylandrostan-4,6-dien-3-one [12179].

**Side effects**

*Hyperthyreoidimus*

In one paper it was reported different effects of methyltestosterone administration on thyroid function in two twin brothers, one of whom suffered from hypothyroidism, while the other was apparently healthy. Methyltestosterone, which is a non-aromatisable androgen, resulted in a marked reduction of thyroxine-binding globulin (TBG), irrespectively of the patient’s hormonal status, while the impact on free thyroid hormones depended on baseline thyroid function. The research shows that a possibility of the use of non-aromatisable androgens or other
drugs affecting TBG levels should be taken into consideration in all hypothyroid patients receiving levothyroxine, in whom thyroid hormone status suddenly changes without any apparent reason [13243].

**Neurological damage**

Anabolic-androgenic steroids (AAS) are lipophilic hormones often taken in excessive quantities by athletes and bodybuilders to enhance performance and increase muscle mass. AAS exert well known toxic effects on specific cell and tissue types and organ systems. The attention that androgen abuse has received lately should be used as an opportunity to educate both athletes and the general population regarding their adverse effects. Among numerous commercially available steroid hormones, very few have been specifically tested for direct neurotoxicity. It was evaluated the effects of supraphysiological doses of methandienone and 17alpha-methyltestosterone on sympathetic-like neuron cells. Vitality and apoptotic effects were analyzed, and immunofluorescence staining and western blot performed. In this study, we demonstrate that exposure of supraphysiological doses of methandienone and 17alpha-methyltestosterone are toxic to the neuron-like differentiated pheochromocytoma cell line PC12, as confirmed by toxicity on neurite networks responding to nerve growth factor and the modulation of the survival and apoptosis-related proteins ERK, caspase-3, poly (ADP-ribose) polymerase and heat-shock protein 90. It was observed, in contrast to some previous reports but in accordance with others, expression of the androgen receptor (AR) in neuron-like cells, which when inhibited mitigated the toxic effects of AAS tested, suggesting that the AR could be binding these steroid hormones to induce genomic effects. It was also noted elevated transcription of neuritin in treated cells, a neurotropic factor likely expressed in an attempt to resist neurotoxicity. Taken together, these results demonstrate that supraphysiological exposure to the AAS methandienone and 17alpha-methyltestosterone exert neurotoxic effects by an increase in the activity of the intrinsic apoptotic pathway and alterations in neurite networks [13244].

The combined analytical capabilities of GC-MS and LC-MS/MS were employed in a study concerning alternative long-term metabolites of methyltestosterone. In an elimination study with orally administered methyltestosterone, urine samples were collected over a period of 30 days, and sulfate-conjugated phase-II metabolites in particular were screened using a dedicated selected reaction monitoring (SRM) approach. Three analytes were observed and suggested to consist of 17alpha-methyl-5beta-androstane-3alpha,17beta-diol 3-sulfate, 17beta-methyl-5alpha-androstane-3alpha,17alpha-diol 3-sulfate, and 17beta-methyl-5beta-androstane-3alpha,17alpha-diol 3-sulfate as supported by GC-MS analyses (providing Kovats indices and EI mass spectra) of the deconjugated substances. Targeting of 17beta-methyl-5alpha-androstane-3alpha,17alpha-diol 3-sulfate by LC-MS/MS enabled the expanded retrospectivity (up to 21 days) and considering that, the synthesis of reference substance to verify the postulated structure of the metabolite(s) was suggested [13009].

**Laboratory techniques**

Electrospray ionization tandem mass spectrometry (ESI-MS/MS) was used to investigate the effect of different substitutions introduced during metabolism on fragmentation patterns of four anabolic steroids including methyltestosterone, methandrostenolone, cis-androstosterone and adrenosterone, along with their metabolites. Collision-induced dissociation (CID) analysis was performed to correlate the major product ions of 19 steroids with structural features. The analysis is done to portray metabolic alteration, such as incorporation or reduction of double bonds, hydroxylations, and/or oxidation of hydroxyl moieties to keto functional group on steroidal skeleton which leads to drastically changed product ion spectra from the respective classes of steroids, therefore, making them difficult to identify. The comparative ESI-MS/MS study also revealed some characteristic peaks to differentiate
different steroidal metabolites and can be useful for the unambiguous identification of anabolic steroids in biological fluid. Moreover, LC-ESI-MS/MS analysis of fermented extract of methyltestosterone, obtained by Macrophomina phaseolina was also investigated [12180].

**Desoxymethyltestosterone (DMT)**

Desoxymethyltestosterone (DMT) is a steroid recently identified to be misused as a doping agent. Since, the knowledge of functions of this substance is rather limited, it was our aim to characterise the pharmacological profile of DMT and to identify potential adverse side effects. DMT was synthesised, its purity was confirmed and its biological activity was tested. The potency of Madol (DMT) to transactivate androgen receptor (AR) dependent reporter gene expression was two times lower as compared to dihydrotestosterone (DHT). Receptor binding tests demonstrate that DMT binds with high selectivity to the AR, binding to the progesterone receptor (PR) was low. In vivo experiments in orchietomised rats demonstrated that treatment with DMT resulted only in a stimulation of the weight of the levator ani muscle; the prostate and seminal vesicle weights remained unaffected. Like testosterone, administration of DMT resulted in a stimulation of IGF-1 and myostatin mRNA expression in the gastrocnemius muscle. In the prostate proliferation was stimulated by TP (testosteronepropionate), but remained unaffected by DMT. Remarkably, treatment with DMT, in contrast to TP, resulted in a significant increase of the heart weight. In the liver, DMT slightly stimulates the expression of the tyrosine aminotransferase gene (TAT). Our results demonstrate that DMT is a potent AR agonist with an anabolic activity. Besides the levator ani weight, DMT also modulates the gene expression in the musculus gastrocnemius. The observed stimulation of TAT expression in the liver and the significant increase of the heart weight after DMT treatment can be taken as an indication for side effects. Summarizing these data it is obvious that DMT is a powerful anabolic steroid with selective androgen receptor modulators (SARM) like properties and some indications for toxic side effects. Therefore, there is a need for a strict control of a possible misuse [06121].

**Metabolism**

Madol (17alpha-methyl-5alpha-androst-2-en-17beta-ol), also called desoxymethyltestosterone (DMT) was independently detected by two research groups in 2004. Madol was patented in 1961 but has never been approved by the FDA. In vitro and excretion studies with a baboon indicated that madol was only partially metabolised and that it is largely excreted unchanged in urine. Indications of the presence of a metabolite containing two more oxygen atoms and another less unsaturated metabolite were tentatively given, without further structural characterization. Madol was included as a target substance in the methods used to detect anabolic steroids at the 2004 Olympic Games in Athens. These analyses did not result in an adverse analytical finding. In 2005, madol evolved from the clandestine underground to the commercial supplement market and became directly available via the internet [06004].

**Methylnortestosterone**

The contribution of lymphatic transport to the oral bioavailability of methylnortestosterone (M) after oral administration of the lipophilic prodrug methylnortestosterone undecanoate (MU) has been evaluated, and the sensitivity of lymphatic MU transport to lymphatic lipid transport has been investigated. M and MU were administered intravenously and orally to greyhound dogs to determine absolute bioavailability after oral dosing of MU. MU was also administered orally with differing quantities of food (lipid) to lymph duct-cannulated greyhound dogs to
investigate the relative roles of lymph versus blood transport on M bioavailability and the effect of lipid load on systemic exposure. The relationship between lymphatic lipid and MU transport was further investigated in anesthetized rats. The oral bioavailability of M after administration of MU was found to be highly dependent on coadministration of food, and the bioavailability of M increased approximately 700 percent in fed versus fasted animals. In both cases, lymph diversion resulted in negligible systemic exposure of M, indicating almost complete dependence on lymphatic transport of MU for systemic exposure of M. Lymphatic transport of MU was even more highly dependent on the quantity of coadministered lipid and increased more than 50-fold with increasing lipid load. Therefore, increasing the quantity of food or lipid coadministered with MU stimulated a significant increase in the lymphatic transport of MU and systemic exposure of M. The lipid sensitivity of lymphatic transport of MU is significantly higher than previously observed for more metabolically stable compounds, suggesting a role for coadministered lipid in promoting avoidance of enterocyte-based cleavage of MU [09131].

Testing

The misuse of the anabolic steroid methyltestosterone is currently routinely monitored in doping control laboratories by gas chromatography-mass spectrometry (GC-MS) of two of its metabolites: 17alpha-methyl-5beta-androstane-3beta,17beta-diol and 17alpha-methyl-5beta-androstane-3beta,17beta-diol. Due to the absence of any easy ionizable moiety these metabolites are poorly detectable using liquid chromatography tandem mass spectrometry (LC-MS/MS) with electrospray ionization (ESI). In one study, the metabolism of methyltestosterone has been reinvestigated by the use of a precursor ion scan method in LC-ESI-MS/MS. Two metabolites have been detected using this method. Both compounds have been confirmed in post-administration urine samples of an uPA-SCID mouse with humanized liver and were characterized by LC-MS/MS and GC-MS using both quadrupole and time of flight (TOF) analysers. From the detailed study of the fragmentation, these metabolites were proposed to be epimethyltestosterone and a dehydrogenated compound. Epimethyltestosterone has previously been described as a minor metabolite while the occurrence of the oxidized metabolite has not been reported. Comparison with the synthesis reference revealed that the structure of the dehydrogenated metabolite is 6-ene-epimethyltestosterone. A selected reaction monitoring method including 3 transitions for each metabolite has been developed and applied to samples from an excretion study and to samples declared positive after GC-MS analysis. 6-Ene-epimethyltestosterone was found in all samples showing its applicability in the detection of methyltestosterone misuse [09132].

Fluoxymesterone

Anabolic androgenic steroids (AAS) are testosterone derivatives used either clinically, in elite sports, or for body shaping with the goal to increase muscle size and strength. Clinically developed compounds and nonclinically tested designer steroids often marketed as food supplements are widely used. Despite the considerable evidence for various adverse effects of AAS use, the underlying molecular mechanisms are insufficiently understood. Here, we investigated whether some AAS, as a result of a lack of target selectivity, might inhibit 11beta-hydroxysteroid dehydrogenase 2 (11beta-HSD2)-dependent inactivation of glucocorticoids. Using recombinant human 11beta-HSD2, we observed inhibitory effects for several AAS. Whereas oxymetholone, oxymesterone, danazol, and testosterone showed medium inhibitory potential, fluoxymesterone was a potent inhibitor of human 11beta-HSD2 (half-maximal inhibitory concentration [IC50] of 60-100 nM in cell lysates; IC50 of 160 nM in intact SW-620, and 530nM in MCF-7 cells). Measurements with rat kidney microsomes and
lysates of cells expressing recombinant mouse 11beta-HSD2 revealed much weaker inhibition by the AAS tested, indicating that the adverse effects of AAS-dependent 11beta-HSD2 inhibition cannot be investigated in rats and mice. Furthermore, we provide evidence that fluoxymesterone is metabolized to 11-oxofluoxymesterone by human 11beta-HSD2. Structural modeling revealed similar binding modes for fluoxymesterone and cortisol, supporting a competitive mode of inhibition of 11beta-HSD2-dependent cortisol oxidation by this AAS. No direct modulation of mineralocorticoid receptor (MR) function was observed. Thus, 11beta-HSD2 inhibition by fluoxymesterone may cause cortisol-induced MR activation, thereby leading to electrolyte disturbances and contributing to the development of hypertension and cardiovascular disease [12172].

**Dihydrotestosterone (DHT, androstanolone)**

Following a transdermal application of 250 mg of dihydrotestosterone (DHT) or an oral administration of 50 mg of dehydroepiandrosterone (DHEA), the ratios of DHT/EpiT, DHT/5beta-androstan-3alpha,17beta-diol, and 5alpha-androstan-3alpha,17beta-diol/5beta-androstan-3alpha,17beta-diol or DHEA/EpiT, 16alpha-OH-dehydroepiandrosterone/EpiT, 7beta-OH-dehydroepiandrosterone/EpiT, and 5beta-androstan-3alpha,17beta-diol/5alpha-androstan-3alpha,17beta-diol were found suitable to support the detection of a DHT or DHEA abuse respectively [12016].

Steroid 5alpha-reductase inhibitors are used to treat benign prostatic hyperplasia and androgenic alopecia, but the role of 5alpha-dihydrotestosterone (DHT) in mediating testosterone's effects on muscle, sexual function, erythropoiesis, and other androgen-dependent processes remains poorly understood. To determine whether testosterone's effects on muscle mass, strength, sexual function, hematocrit level, prostate volume, sebum production, and lipid levels are attenuated when its conversion to DHT is blocked by dutasteride (an inhibitor of 5alpha-reductase type 1 and 2) the 5alpha-Reductase Trial was a randomized controlled trial of healthy men aged 18 to 50 years comparing placebo plus testosterone enanthate with dutasteride plus testosterone enanthate from 2005 through 2010. Eight treatment groups received 50, 125, 300, or 600 mg/week of testosterone enanthate for 20 weeks plus placebo (4 groups) or 2.5 mg/d of dutasteride (4 groups). The primary outcome was change in fat-free mass; secondary outcomes: changes in fat mass, muscle strength, sexual function, prostate volume, sebum production, and hematocrit and lipid levels. A total of 139 men were randomized; 102 completed the 20-week intervention. Men assigned to dutasteride were similar at baseline to those assigned to placebo. The mean fat-free mass gained by the dutasteride groups was 0.6 kg when receiving 50 mg/week of testosterone enanthate, 2.6 kg for 125 mg/week, 5.8 kg for 300 mg/week, and 7.1 kg for 600 mg/week. The mean fat-free mass gained by the placebo groups was 0.8 kg when receiving 50 mg/wk of testosterone enanthate, 3.5 kg for 125 mg/week, 5.7 kg for 300 mg/week, and 8.1 kg for 600 mg/week. The dose-adjusted differences between the dutasteride and placebo groups for fat-free mass were not significant. Changes in fat mass, muscle strength, sexual function, prostate volume, sebum production, and hematocrit and lipid levels did not differ between groups. It was concluded that changes in fat-free mass in response to graded testosterone doses did not differ in men in whom DHT was suppressed by dutasteride from those treated with placebo, indicating that conversion of testosterone to DHT is not essential for mediating its anabolic effects on muscle [12173].

It was performed a pilot study using human peripheral blood lymphocytes (PBL) as a novel system to identify new biomarkers of dihydrotestosterone (DHT) and insulin-like growth factor-1 (IGF-1) abuse in sport. First, to obtain a gene signature, we treated cultures of lymphocytes from sedentary males with three doses of 0.237 microg/ml DHT, each of which is 80-fold the physiological concentration in young adult male serum, at days 0, 2 and 4, or
with a single dose of 1.25 microg/ml IGF-1, which is 5-fold the physiological concentration in young adult male serum. It was then used the Human Genome U133 Plus 2.0 microarray to identify a gene signature related to DHT or IGF-1 administration. Gene expression was evaluated after 7 and 21 days of DHT treatment, and after 24 h, 72 h and 7 days of IGF-1 treatment. Microarray analysis yielded a list of genes whose expression was altered after DHT or IGF-1 treatment. Among these it was selected the genes that are most representative of the pathways associated with skeletal and muscular disorders using the IPA bioinformatics tool. It was identified six (IDO1, CXCL13, CCL1, GZMB, VDR and IL2RA) and two (FN1 and RAB31) genes that were up-regulated in lymphocytes from sedentary subjects after 7 days of DHT and IGF-1 treatment, respectively. The expression of these genes in lymphocytes from differently trained athletes was either down-regulated or similar to that in lymphocytes from sedentary subjects. This finding suggests that up-regulation was due to the drug and not to physical exercise. In conclusion, it was demonstrate that PBL can be useful in anti-doping checks, and we describe new biomarkers of DHT and IGF-1 abuse which can be included in the Athlete’s Biological Passport [13258].

Dihydrotestosterone (DHT) exerts both functional and signaling effects extending beyond the effects of testosterone in rodent skeletal muscle. As a primer for investigating the role of DHT in human skeletal muscle function, this study aimed to determine whether circulating DHT is acutely elevated in men following a bout of repeat sprint exercise and to establish the importance of training status and sprint performance to this response. Fourteen healthy active young men performed a bout of repeat sprint cycle exercise at a target workload based on an incremental work-rate maximum (10 × 30 s at 150 % $W_{\text{max}}$ with 90-s recovery). Venous blood samples were collected preexercise and 5 and 60 min after exercise. Five minutes after exercise, there were significant elevations in total testosterone, free testosterone, and DHT, which returned to baseline after 1 h. Changes in DHT with exercise (5 min postexercise - preexercise) correlated significantly with changes in TT and FT. Sprinting cadence correlated with changes in FT, DHT and TT, and habitual training volume correlated with the change in TT. In conclusion, the data demonstrate that DHT is acutely elevated following sprint cycle exercise and that this response is influenced by cycling cadence. The importance of DHT in the context of exercise training and sports performance remains to be determined [13259].

Enzyme immunoassays (EIA) are commonly utilized for the evaluation of androgens in biological fluids; however, careful consideration must be given to cross-reactivity with other endogenous sex-steroid hormones. Our purpose was to determine the validity of a commonly-utilized commercially-available dihydrotestosterone (DHT) EIA. Serum samples obtained from older hypogonadal men who participated in a 12-month randomized controlled trial evaluating the effects of testosterone-enanthate (125 mg/week) or vehicle in combination with finasteride (5 mg/day) or placebo were assayed for DHT via EIA and using a validated gold-standard LC-MS/MS approach. Additionally, commercially-available (DHT-free) buffer containing graded testosterone doses was evaluated by DHT immunoassay. DHT concentrations measured via EIA were 79 percent to >1000 percent higher than values obtained by LC-MS/MS, with the largest differences (415-1128 %) occurring in groups receiving finasteride. Both LC-MS/MS and EIA indicated that testosterone-enanthate increased serum DHT to a similar magnitude. In contrast, finasteride-induced reductions in DHT were detected by LC-MS/MS, but not EIA. No significant associations were present for DHT concentrations between measurement techniques. Cross-reactivity of testosterone with the immunoassay ranged from 18 to 99 percent and DHT concentrations measured by EIA were highly associated with the spiked testosterone concentrations in DHT-free buffer. In conclusion, we provide evidence invalidating a commonly-utilized commercially-available DHT immunoassay because significant cross-reactivity exists between testosterone and the EIA and because the changes in DHT observed via EIA were not associated with a validated
gold-standard measurement technique. The cross-reactivity of testosterone is particularly concerning because testosterone is present in 100-fold greater concentrations than is DHT within the circulation [13260].

**Dehydroepiandrosterone**

One study aimed to determine the role of DHEA-S (dehydroepiandrosterone-sulphate) in coping against the exercise training mixing aerobic and resistance components. During 5-day successive exercise training, 16 young male participants (19 ± 2 years) received either a placebo (flour capsule) or DHEA (100 mg/day) in a double-blinded and placebo-controlled design. Oral DHEA supplementation significantly increased circulating DHEA-S by 2.5-fold, but a protracted drop (35 %) was observed from Day 3 during training. In the placebo group, only a minimal DHEA-S reduction (17 %) was observed. Changes in testosterone followed a similar pattern as DHEA-S. Muscle soreness was elevated significantly on Day 2 for both groups to a similar extent. Lower muscle soreness was observed in the DHEA-supplemented group on Day 3 and Day 6. In the placebo group, training increased circulating creatine kinase (CK) levels by approximately ninefold, while only a threefold increase was observed in the DHEA-supplemented group. This mix-type exercise training improved glucose tolerance in both groups, while lowering the insulin response to the glucose challenge, but no difference between treatments was observed. The results suggest that DHEA-S may play a role in protecting skeletal muscle from exercise training-induced muscle damage [13261].

Evidence links dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) to crucial military health issues, including operational stress, resilience, and traumatic brain injury. This study evaluated the anabolic, neuroprotective, and neuroexcitatory properties of DHEA(S) in healthy military men. A salivary sample was obtained from 42 men and assayed for DHEA(S), testosterone, nerve growth factor (NGF; which supports nerve cell proliferation), and salivary alpha amylase (sAA; a proxy of sympathetic nervous system function). Separate regression analyses were conducted with DHEA and DHEAS as independent variables, and testosterone, NGF, and sAA as dependent variables, respectively. The models explained 23 percent of variance in testosterone, 17 percent of variance in NGF, and 7.4 percent of variance in sAA. Standardized beta coefficients revealed that DHEA independently influenced testosterone, whereas DHEAS independently influenced NGF and sAA. DHEA demonstrated anabolic properties, whereas DHEAS demonstrated neuroprotective and neuroexcitatory properties in military men. This area of study has broad implications for stress inoculation, traumatic brain injury rehabilitation, and regenerative medicine in military personnel [13262].

**Diurnal secretion**

Diurnal patterns of cortisol and dehydroepiandrosterone (DHEA) secretion, the two main peripheral secretory products of the hypothalamic-pituitary-adrenal neuroendocrine stress axis, have been well characterized in rest conditions but not in relation to physical exercise. The purpose of one investigation was therefore to determine the effects of an intense 90-min aerobic exercise on the waking diurnal cortisol and DHEA cycles on three separate days [without exercise, with morning exercise (10:00-11:30 h), and with afternoon exercise (14:00-15:30 h)] in nine recreationally trained soccer players. Saliva samples were collected at awakening, 30 min after awakening, and then every 2 h from 08:00 to 22:00 h. A burst of secretory activity was found for cortisol but not for DHEA after awakening. Overall, diurnal decline for both adrenal steroids was observed on resting and exercise days under all conditions. However, there was a significant increase in salivary cortisol concentrations on
the morning-exercise and afternoon-exercise days at, respectively, 12:00 h and 16:00 h, versus the other trials. This acute response to exercise was not evident for DHEA. The results of this investigation indicate that 90 min of intense aerobic exercise does not affect the circadian pattern of salivary adrenal steroids in recreationally trained athletes over a 16-h waking period, despite a transitory increase in post-exercise cortisol concentration. Further studies are necessary to determine whether these results are applicable to elite athletes or patients with cortisol or DHEA deficiency [13263].

**Deposterone**

The indiscriminate use of anabolic androgenic steroids (AAS) has motivated researchers to investigate the mutagenic action of these substances. One study, using the mouse bone marrow micronucleus test, evaluates the genotoxic potential of testosterone cypionate (deposteron). Male Swiss mice received intramuscular injections of deposteron at three doses. The animals were sacrificed 24, 48, or 72h after treatment and bone marrow was removed immediately, followed by scoring to count the micronuclei in 2000 polychromatic erythrocytes (PCE). Two-hundred erythrocytes/animal were analyzed to determine the PCE-NCE (normochromatic erythrocyte) relationship and to determine the cytotoxic effects. The animals treated with deposteron at the highest dose presented greater numbers of micronuclei. The highest dose caused a decrease in the PCE/NCE relationship, indicating a cytotoxic effect. It was conclude that Deposteron is genotoxic and cytotoxic in mice [13264].

**Dromastanolone**

A 26-year-old male presented with three weeks of jaundice after the self-initiation of the injectable anabolic steroid, Mastabol (Dromastanolone Di-Propionate; 17 beta-Hydroxy-2alpha-methyl-5alpha-androstan-3-one propionate). He reported dark urine, light stools, and pruritus. He denied abdominal pain, intravenous drug use, intranasal cocaine, blood transfusions, newly placed tattoos, or sexually transmitted diseases. He used alcohol sparingly. Physical exam revealed jaundice with deep scleral icterus. The liver was palpable 2 cm below the right costal margin with no ascites. The peak bilirubin was 23.6 mg/dL, alkaline phosphatase was 441 units/L, aspartate aminotransferase/alanine aminotransferase were 70 units/L and 117 units/L respectively. A working diagnosis of acute intrahepatic cholestasis was made. Liver biopsy revealed a centrilobular insult with neutrophilic infiltrates and Ito cell hyperplasia consistent with acute drug induced cholestasis. The patient's clinical symptoms resolved and his liver enzymes, bilirubin, and alkaline phosphatase normalized. Anabolic steroids with 17 alpha carbon substitutions have been associated with a bland variety of cholestatic injury with little hepatocellular injury. Cholestasis, under these circumstances, may be secondary to the binding of drugs to canalicular membrane transporters, accumulation of toxic bile acids from canalicular pump failure, or genetic defects in canalicular transport proteins. Mastabol is an injectable, 17 beta hydroxyl compound with no alpha alkyl groups at the 17 carbon position. As such, it has been reported to have little potential toxic effects on the liver. This is the first known reported case of Mastabol-induced cholestatic liver injury. It highlights the need for physicians to consider such widely available substances when faced with hepatic injury of unclear etiology [13265].

**Adrenosterone**

767
Adrenosterone (androst-4-ene-3,11,17-trione, 11-oxoandrostenedione) is an endogenous steroid hormone that has been promoted as a dietary supplement capable of reducing body fat and increasing muscle mass. It is proposed that adrenosterone may function as an inhibitor of the 11beta-hydroxysteroid dehydrogenase type 1 enzyme (11beta-HSD1), which is primarily responsible for reactivation of cortisol from cortisone. The urinary metabolism of adrenosterone was investigated, after a single oral administration in two male subjects, by gas chromatography-mass spectrometry (GC-MS) and gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS). Substantially increased excretion of 11beta-hydroxyandrosterone, 11beta-hydroxyetiocholanolone, 11-oxoandrosterone and 11-oxoetiocholanolone was observed. Minor metabolites such as 3alpha,17beta-dihydroxy-5beta-androstan-11-one, 3alpha-hydroxyandrost-4-ene-11,17-dione and 3alpha,11beta-dihydroxyandrost-4-en-17-one were also identified. The exogenous origin of the most abundant adrenosterone metabolites was confirmed by GC-C-IRMS according to World Anti-Doping Agency criteria. Through analysis of a reference population data set obtained from urine samples provided by elite athlete volunteers (n=85), GC-MS doping control screening criteria are proposed: 11beta-hydroxyandrosterone concentration greater than 10 000 ng/mL (specific gravity adjusted to 1.020) or 11beta-hydroxyandrosterone/11beta-hydroxyetiocholanolone ratio greater than 20. Urine samples fulfilling these screening criteria may be subjected to GC-C-IRMS analysis for confirmation of adrenosterone administration [09133].

It was examined the glucuronidation of androsterone (5alpha-androstane-3alpha-ol-17-one), etiocholanolone (5beta-androstane-3alpha-ol-17-one), 5alpha-androstan-3alpha-ol-17-one, 5beta-androstan-3alpha-ol-17-one, androsterone and 5beta-diol (5alpha-diol) and 5beta-androstane-3alpha,17beta-diol (5beta-diol), by 19 recombinant human UDP-glucuronosyltransferases (UGTs). The results reveal large differences in stereo- and regio-selectivity between UGT2B7, UGT2B15 and UGT2B17. UGT2B7 conjugated all 4 androgens at the 3-OH, but not at the 17-OH that is available in both diols. UGT2B7 exhibited a higher glucuronidation rate towards the steroids with a flat backbone, androsterone and 5alpha-diol, in comparison to etiocholanolone and 5beta-diol that have a bent backbone. UGT2B17 readily glucuronidated androsterone and, particularly, etiocholanolone at the 3-OH, but in the two diols it exhibited high preference for the 17-OH and low glucuronidation rate at the 3-OH. UGT2B15 did not glucuronidate any of the studied 4 androgens at the 3-OH, but it did conjugate both diols at the 17-OH, with a clear preference for 5alpha-diol. Of subfamily 1A UGTs, only UGT1A4 catalyzed the glucuronidation of androsterone and 5alpha-diol at measurable rates, even if low. UGT2A1 and UGT2A2 glucuronidated most compounds in this study, but mostly at rather low rates. An exception was the glucuronidation of etiocholanolone by UGT2A1 that revealed a very low substrate affinity in combination with very high Vmax value. The results shed new light on the substrate selectivity of individual UGTs in steroids glucuronidation. In addition they bear implications for doping analyses and its dependence of genetic polymorphism since testosterone is a precursor in the biosynthesis of all these 4 androgens, while the contribution of UGT2B17 to their glucuronidation vary greatly [09134].

Evidence suggests that in manipulating prostaglandin E2 (PGE2), it is unknowingly implicated 3alpha-hydroxysteroid dehydrogenase [E.C. 1.1.1.50], 3(or 17)alpha-hydroxysteroid dehydrogenase [E.C. 1.1.1.209] and their respective products, androsterone (ADT) and epitestosterone (EpiT), in the developmental masculinization of sex behavior. EpiT is generally regarded as a hormonally inactive 17alpha-epimer of testosterone (T). In rats, the kidney is the primary site of EpiT formation, whereas in humans it originates from the gonads, with only a small contribution secreted by the adrenals. Because the ratio of T to EpiT is nearly constant, it is presently used for assessing steroid abuse in competitive sports, where the World Anti-Doping Agency (WADA) considers a T/EpiT ratio >4 evidence of T doping. Despite its central role in the detection of illicit anabolic steroid use, our knowledge of
factors effecting EpiT production is poor. Clues in the literature, however, reveal that prostaglandin-mediated processes, such as LHRH release, may influence its production. Antimycotics, NSAIDs, and opioid analgesics used in sports medicine are all known to effect prostaglandin E2 synthesis. Primary PGs are potent inhibitors of ADT oxidation, while indomethacin, a prostaglandin blocker, powerfully inhibits 3alpha-HSD reduction and ADT oxidation. This is significant because ADT inhibits the oxidation of EpiT, and may modulate its antiandrogenic and neuroprotective effects. It is hypothesized that the T/EpiT ratio is increased by COX-2 inhibitors and opioid analgesics, and decreased by antimycotics that do not impair testosterone biosynthesis. Given the devastating personal and career consequences that may result from false positive drug tests, substantive research on the effects of PGE2 manipulations on EpiT is warranted [07095].

Androstenediol

Doping control laboratories accredited by the World Anti-Doping Agency (WADA) require criteria that allow endogenous steroids to be distinguished from their synthetic analogues in urine. Methodology based on "looking outside the metabolic box" was used in this study to identify diagnostic urinary markers of 4-androstenediol (4-ADIOL) administration. Androst-2,4-diene-17-one and androstan-3,5-diene-17-one are proposed to be formed in urine from acid-catalyzed hydrolysis of 4-ADIOL sulfoconjugate, a major phase II metabolic product of 4-ADIOL. The presence of these markers in the routine gas chromatography-mass spectrometry (GC-MS) steroid screen was suitable to identify samples requiring confirmation by gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS), to measure the carbon isotope ratio (delta^{13}C) of the androstadiene markers and confirm their likely synthetic origin based on depleted^{13}C content [11100].

Sublingual intake of 21.4 mg androstenediol increases serum testosterone concentrations whereas swallowing 200 mg androstenediol does not. The duration of increase in serum testosterone following sublingual androstenediol (SL-DIOL) is unknown. Resistance exercise (EX) following SL-DIOL may cause larger increases in serum estradiol concentrations than while at rest. This project evaluated the duration of change in, and the effects of acute EX on, the hormonal response to SL-DIOL. Six young resistance trained males consumed either placebo (PL) or SL-DIOL before a single session of EX or no exercise (Rest) in a random, double blind, crossover manner (for a total of four trials). Blood samples were collected before supplementation, and at 60, 120, 180, 240, 480, and 720 min post-supplementation, with the exercise occurring between 60 and 120 min. The serum concentration of total testosterone increased significantly at 60 min similarly in SL-DIOL-EX and SL-DIOL-Rest by approximately 115 percent, and at 120 min by approximately 107 percent with no differences due to exercise. The serum concentration of estradiol increased also significantly similarly in SL-DIOL-EX and SL-DIOL-Rest by approximately 33 percent at 60 min and approximately 45 percent at 120 min, with no differences due to exercise. Serum testosterone returned to baseline by 240 min and serum estradiol returned to baseline by 720 min post-intake. These findings indicate that SL-DIOL acutely elevates serum testosterone and estradiol concentrations, that EX does not alter the endocrine response to SL-DIOL, and that the increases in serum estradiol last between 480 and 720 min while the increases in serum testosterone last <240 min following acute SL-DIOL intake [06114].

Metabolism of 1-androstenediol and 1-androstenedione

1-Androstenediol (5alpha-androst-1-ene-3beta,17beta-diol) and 1-androstenedione (5beta-androst-1-ene-3,17-dione) were introduced on the prohormone market early this millenium.
Androstenedione was previously reported as the only metabolite of boldenone with a 5alpha-configuration. So far, only the in vivo metabolism of 1-androstenediol has been investigated and 1-androstenedione was detected as its major metabolite. An in vitro study using rat liver homogenates showed an extensive mutual metabolism of 1-androstenediol, 1-androstenedione and 1-testosterone, as well as various other hydroxylated metabolites [06004].

3alpha-Androstanediol

The abuse of anabolic-androgenic steroids (AS) is a growing problem; however, the effects and mechanisms underlying their addictive effects are not well understood. Research findings regarding androgen abuse in people and hedonic effects of androgens in laboratory rats are reviewed. Androgens, like other steroids, can have traditional actions via cognate intracellular steroid receptors, as well as other substrates. There are results that indicate that testosterone (T) metabolites may have actions in part via gamma-aminobutyric acid (GABA)(A)/benzodiazepine receptor complexes (GBRs) and/or dopaminergic neurons in the nucleus accumbens, to mediate T's positive hedonic states. This may provide the basis for positive reinforcing effects of androgen seeking and use behavior. Following a comprehensive review of the background literature, findings are presented that have explored the extent to which metabolites of T mediate euphorogenic effects of androgens by acting in the nucleus accumbens. Then results regarding whether GBRs are necessary substrates for androgens' positive hedonic effects are discussed. Lastly, research that addresses if dopaminergic neurons in the nucleus accumbens are necessary for these effects of androgens are discussed. The review provides a comprehensive examination of the hedonic properties and abuse/addiction potential of androgens and the putative mechanisms underlying these effects [07096].

Androstenedione

Androstenedione, the natural precursor of testosterone, is marketed to produce increases in free testosterone. It was widely used by the East German athletes in the 1970s and 1980s and received extensive media attention in 1998 when it was photographed in the locker of Mark McGwire during his bid to break Roger Maris’ single season home run record. Neither androstenedione nor DHEA has ever been definitively shown to increase protein synthesis, body composition, or exercise performance [07002].

Androstenedione (C_{19}H_{26}O_{2}), a precursor to testosterone, was marketed as a natural alternative to anabolic steroids, and was purported to raise blood testosterone levels and promote muscle size and strength. Current research does not support the efficacy of this supplement. In young men, 100-200 mg androstenedione taken once does not increase blood testosterone levels or stimulate muscle protein synthesis, and 100 mg androstenedione three times a day for 8 weeks or twice a day for 12 weeks does not augment gains in muscle size and strength during resistance training. Although a single dose of 300 mg androstenedione may raise blood testosterone levels slightly in young men, it is unlikely that this increase in testosterone would increase muscle size or strength. In women and middle-aged men, acute androstenedione intake raises blood testosterone levels to those typically seen in young men. The effect of a chronic intake of androstenedione on muscle strength and size has not been studied in women. In middle-aged men, 200 mg androstenedione per day does not produce gains in strength more than resistance training alone, and appears to suppress the endogenous production of testosterone. Chronic androstenedione intake may pose significant health risks. High-density lipoprotein cholesterol
is reduced with chronic androstenedione intake, corresponding to a 10-15 percent increase in cardiovascular disease risk. Androstenedione intake raises blood dihydrotestosterone and oestrogen levels, which have been linked to benign prostate hypertrophy, baldness, an increased risk of cardiovascular disease, various forms of cancer and gynecomastia in men. High blood levels of androstenedione may increase the risk of prostate cancer and pancreatic cancer as well as causing neural/behavioural changes such as increased hostility. Elevated blood levels of testosterone in both men and women may pose health risks. In summary, androstenedione does not produce either anabolic or ergogenic effects and may raise the risk of negative health consequences [09135].

Studies have shown that the administration of androstenedione significantly increases the urinary ratio of testosterone glucuronide to epitestosterone glucuronide (T/E) - measured by gas chromatography/mass spectrometry (GC/MS) - in subjects with a normal (approximately 1) or naturally high (>1) initial values. However, the urinary T/E ratio has been shown not to increase in subjects with naturally low (<1) initial values. Such cases then rely on the detection of C(6)-hydroxylated metabolites shown to be indicative of androstenedione administration. While these markers may be measured in the routine GC/MS steroid profile, their relatively low urinary excretion limits the use of gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS) to specifically confirm androstenedione administration based on depleted (13)C content. A mass spectrometry strategy was used in this study to identify metabolites of androstenedione with the potential to provide compound-specific detection. C(4)-hydroxylation was subsequently shown to be a major metabolic pathway following androstenedione administration, thereby resulting in urinary excretion of 4-hydroxyandrostenedione [09136].

**Hydroxyandrostenedione**

4-Hydroxyandrost-4-ene-3,17-dione is a second generation, irreversible aromatase inhibitor and commonly used as anti breast cancer medication for postmenopausal women. 4-Hydroxytestosterone is advertised as anabolic steroid and does not have any therapeutic indication. Both substances are prohibited in sports by the World Anti-Doping Agency, and, due to a considerable increase of structurally related steroids with anabolic effects offered via the internet, the metabolism of two representative candidates was investigated. Excretion studies were conducted with oral applications of 100mg of 4-hydroxyandrostenedione or 200mg of 4-hydroxytestosterone to healthy male volunteers. Urine samples were analyzed for metabolic products using conventional gas chromatography-mass spectrometry approaches, and the identification of urinary metabolites was based on reference substances, which were synthesized and structurally characterized by nuclear magnetic resonance spectroscopy and high resolution/high accuracy mass spectrometry. Identified phase-I as well as phase-II metabolites were identical for both substances. Regarding phase-I metabolism 4-hydroxyandrostenedione (1) and its reduction products 3beta-hydroxy-5alpha-androstane-4,17-dione (2) and 3alpha-hydroxy-5beta-androstane-4,17-dione (3) were detected. Further reductive conversion led to all possible isomers of 3xi,4xi-dihydroxy-5xi-androstan-17-one (4, 6-11) except 3alpha,4alpha-dihydroxy-5beta-androstane-4,17-dione (5). Out of the 17beta-hydroxylated analogs 4-hydroxytestosterone (18), 3beta,17beta-dihydroxy-5alpha-androstane-4-one (19), 3alpha,17beta-dihydroxy-5beta-androstane-4-one (20), 5alpha-androstane-3beta,4beta,17beta-triol (21), 5alpha-androstane-3alpha,4beta,17beta-triol (26) and 5alpha-androstane-3alpha,4alpha,17beta-triol (28) were identified in the post administration urine specimens. Furthermore 4-hydroxyandrost-4,6-diene-3,17-dione (29) and 4-hydroxyandrost-3,17-dien-3,17-dione (30) were determined as oxidation products. Conjugation was diverse and included glucuronidation and sulfatation [07098].
Androst-4-en-3-one-based steroids

Structure elucidation of steroids by mass spectrometry has been of great importance to various analytical arenas and numerous studies were conducted to provide evidence for the composition and origin of (tandem) mass spectrometry-derived product ions used to characterize and identify steroidal substances. The common product ion at m/z 97 generated from androst-4-en-3-one analogs has been subject of various studies, including stable isotope-labeling and (high resolution/high accuracy) tandem mass spectrometry, but its gas-phase structure has never been confirmed. Using high resolution/high accuracy mass spectrometry and low resolution tandem mass spectrometry, density functional theory (DFT) calculation, and infrared multiple photon dissociation (IRMPD) spectroscopy employing a free electron laser, the structure of m/z 97 derived from testosterone was assigned to protonated 3-methyl-2-cyclopenten-1-one. Product ions of m/z 97 obtained from MS(2) and MS(3) experiments of protonated 3-methyl-2-cyclopenten-1-one, 2-methyl-2-cyclopenten-1-one, 2-cyclohexen-1-one, and testosterone corroborated the suggested gas-phase ion structure, which was eventually substantiated by IRMPD spectroscopy yielding a spectrum that convincingly matched the predicted counterpart. Finally, the dissociation pathway of the protonated molecule of testosterone to m/z 97 was revisited and an alternative pathway was suggested that considers the exclusion of C-10 along with the inclusion of C-5, which was experimentally demonstrated with stable isotope labeling [12181].

Dehydrochloromethyltestosterone

The biotransformation of dehydrochloromethyltestosterone (DHCMT, 4-chloro-17β-hydroxy,17α-methylandrosta-1,4-dien-3-one) in man was studied with the aim to discover long-term metabolites valuable for the antidoping analysis. Having applied a high performance liquid chromatography for the fractionation of urinary extract obtained from the pool of several DHCMT positive urines, about 50 metabolites were found. Most of these metabolites were included in the GC-MS/MS screening method, which was subsequently applied to analyze the post-administration and routine doping control samples. As a result of this study, 6 new long-term metabolites were identified tentatively characterized using GC-MS and GC-MS/MS. The most long-term metabolite M3 was shown to be superior in the majority of cases to the other known DHCMT metabolites, such as 4-chloro-18-nor-17β-hydroxymethyl,17alpha-methylandrosta-1,4,13-trien-3-one and 4-chloro-3alpha,6beta,17beta-trihydroxy-17alpha-methyl-5beta-androst-1-en-16-one [12182].

Six formerly unrecognized urinary metabolites of dehydrochloromethyltestosterone (DHCMT, Oral-Turinabol) were characterized in post-administration study urine samples by means of GC-MS and GC-MS/MS. These additional target analytes were tentatively identified and the candidate referred to as 4-chloro-18-nor-17beta-hydroxymethyl-17alpha-methyl-5beta-androst-13-en-3alpha-ol was found to be traceable for a longer period of time than those commonly used to uncover doping with DHCMT. Proof of the attributed composition of the metabolite by means of chemical synthesis (or nuclear magnetic resonance spectroscopy, NMR) however remains to be presented [13012].

Fluoxymesterone

Employing LC-HRMS, the metabolism of fluoxymesterone was revisited and three metabolic products were described, potentially complementing routine doping controls. The structures
of these analytes were reported as 9-fluoro-17beta-ol-17alpha-methyl-11-en-5alpha-<br>androstan-3-one, its isomer 9-fluoro-17beta-ol-17alpha-methyl-11-en-5beta-androstan-3-one,<br>and 9-fluoro-17beta-ol-17alpha-methyl-5-androstan-3,6,11-trione as attributed on the basis of<br>HRMS and MS/MS data. Unfortunately, neither isotope-labeling nor comprehensive MS° or<br>H/D exchange experiments were conducted to corroborate the comparably speculative<br>dissociation pathways presented in the article, which represented the sole basis of structure<br>assignments. Also here, substantiated evidence (e.g. by chemical synthesis or NMR from<br>metabolites isolated from urine) remains to be provided [13012].

**Desoxymethyltestosterone**

In a commendable manner, the in vitro and chemical synthesis of urinary metabolites of<br>desoxymethyltestosterone (DMT, madol) followed by NMR characterization and comparison<br>to authentic administration study urine samples with GC-MS was presented. Although<br>employed as a target analyte in routine doping controls for several years, proof for the<br>assumed structure of the main metabolite was not available; hence, the proposed<br>composition of the metabolite was to be substantiated, which was accomplished by means of<br>human hepatocytes as well as chemical synthesis that eventually enabled the confirmation of<br>the analyte as 17alpha-methyl-2beta,3alpha,17beta-trihydroxy-5alpha-androstane [13012].

**Keto-androgens**

Prostate cancer is the most frequently diagnosed form of cancer in males in the United<br>States. The disease is androgen driven and the use of orchiectomy or chemical castration,<br>known as androgen deprivation therapy (ADT) has been employed for the treatment of<br>advanced prostate cancer for over 70 years. Agents such as GnRH agonists and non-<br>steroidal androgen receptor antagonists are routinely used in the clinic, but eventually<br>relapse occurs due to the emergence of castration-resistant prostate cancer. With the<br>appreciation that androgen signaling still persists in these patients and the development of<br>new therapies such as abiraterone and enzalutamide that further suppress<br>es androgen synthesis or signaling, there is a renewed need for sensitive and specific methods to quantify<br>androgen precursor and metabolite levels to assess drug efficacy. It was described the<br>development, validation and application of a stable isotope dilution liquid chromatography<br>electrospray ionization selected reaction monitoring mass spectrometry (SID-LC/ESI/SRM/MS) method for quantification of serum keto-androgens and their sulfate and<br>glucuronide conjugates using Girard-T oxime derivatives. The method is robust down to 0.2-<br>4pg on column, depending on the androgen metabolite quantified, and can also quantify<br>dehydroepiandrosterone sulfate (DHEA-S) in only 1 microL of serum. The clinical utility of<br>this method was demonstrated by analyzing serum androgens from patients enrolled in a<br>clinical trial assessing pharmacological agents to maximally suppress gonadal and adrenal androgens (Targeted Androgen Pathway Suppression, TAPS clinical<br>trial). The method was validated by correlating the results obtained with a hydroxylamine<br>derivatization procedure coupled with tandem mass spectrometry using selected reaction<br>monitoring that was conducted in an independent laboratory [13266].

**Trenbolone**

Trenbolone (17beta-hydroxy-estra-4,9,11-trien-3-one) and its derivatives such as 17alpha-<br>methyltrenbolone represent a class of highly potent anabolic-androgenic steroids, which are
prohibited in sports according to the regulation of WADA. Due to marginal gas chromatographic properties of these compounds but excellent proton affinities resulting from a large and conjugated pi-electron system, liquid chromatography-tandem mass spectrometry (LC-MS/MS) has been the method of choice for the detection of these analytes in sports drug testing. Recent findings of trenbolone and methyltrenbolone in doping control urine samples of elite athletes demonstrated the importance of a sensitive and robust analytical method, which was based on an enzymatic hydrolysis of target compounds, liquid-liquid extraction and subsequent LC-MS/MS measurement. Diagnostic product ions obtained after collision-induced dissociation of protonated molecules were found at m/z 227, 211, 199 and 198, which enabled targeted screening using multiple reaction monitoring. Using 7 model compounds (trenbolone, epitrenbolone, methyltrenbolone, ethyltrenbolone, propyltrenbolone, 17-ketotrenbolone and altrenogest), the established method was validated for specificity, lower limits of detection (0.3-3 ng/mL), recovery (72-105 %), intraday and interday precision < 20 percent [08162].

Selective androgen receptor modulators (SARMs) now under development can protect against muscle and bone loss without causing prostate growth or polycythemia. 17β-Hydroxyestra-4,9,11-trien-3-one (trenbolone), a potent testosterone analog, may have SARM-like actions because, unlike testosterone, trenbolone does not undergo tissue-specific 5α-reduction to form more potent androgens. It was tested the hypothesis that trenbolone-enanthate (TREN) might prevent orchietomy-induced losses in muscle and bone and visceral fat accumulation without increasing prostate mass or resulting in adverse hemoglobin elevations. Male F344 rats aged 3 mo underwent orchietomy or remained intact and were administered graded doses of TREN, supraphysiological testosterone-enanthate, or vehicle for 29 days. In both intact and orchietomized animals, all TREN doses and supraphysiological testosterone-enanthate augmented androgen-sensitive levator ani/bulbocavernosus muscle mass by 35-40 percent above shams and produced a dose-dependent partial protection against orchietomy-induced total and trabecular bone mineral density losses and visceral fat accumulation. The lowest doses of TREN successfully maintained prostate mass and hemoglobin concentrations at sham levels in both intact and orchietomized animals, whereas supraphysiological testosterone-enanthate and high-dose TREN elevated prostate mass by 84 and 68 percent, respectively. In summary, low-dose administration of the non-5α-reducible androgen TREN maintains prostate mass and hemoglobin concentrations near the level of shams while producing potent myotrophic actions in skeletal muscle and partial protection against orchietomy-induced bone loss and visceral fat accumulation. The findings indicate that TREN has advantages over supraphysiological testosterone and supports the need for future preclinical studies examining the viability of TREN as an option for androgen replacement therapy [11102].

Trenbolone (TRE) is a steroid used by veterinarians on livestock to increase appetite and body weight. The use of TRE has been restricted because of its harmful side effect for consumers. To effectively control TRE residue in food and food product, a rapid and convenient immunoassay was developed by preparing an anti-TRE monoclonal antibody. The immunogen and coating antigen were prepared by coupling TRE hapten with carrier proteins via 1-ethyl-3-(dimethylaminopropyl)carbodiimide hydrochloride (EDC) method. The optimized method gave an average IC₅₀ value of 0.323 ng/mL towards TRE and an average detection limit (LOD) of 0.06 ng/mL, which is much lower than the maximum residue levels (2.0 ng/g) accepted by the Joint FAO/WHO Expert Committee on Food Additives (JECFA). The specificity of the antibody was evaluated by measuring cross-reactivity of six structurally related compounds, including 19-nortestosterone (9.7 %), testosterone (0.13 %), methyltestosterone (<0.01 %), methandrosteneolone (<0.01 %), (+)-dehydroisoandrosterone (<0.001 %) and beta-estradiol (<0.001 %). The recovery rates of the test in detection of TRE-fortified animal tissue, urine and animal feed samples were in the range of 81-89 percent,
while the intra- and inter-assay coefficients of variation were less than 12 percent [11103].

Despite the widespread use of the anabolic androgen trenbolone acetate (TBA) in animal agriculture, evidence demonstrating the occurrence of TBA metabolites such as 17beta-trenbolone (17beta-TBOH), 17alpha-trenbolone (17alpha-TBOH), and trenbolone (TBO) is relatively scarce, potentially due to rapid transformation processes such as direct photolysis. Therefore, we investigated the phototransformation of TBA metabolites and associated ecological implications by characterizing the photoproducts arising from the direct photolysis of 17beta-TBOH, 17alpha-TBOH, and TBO and their associated ecotoxicity. LC-HRMS/MS analysis identified a range of hydroxylated products that were no longer photoactive, with primary photoproducts consisting of monohydroxy species and presumptive diastereomers. Also observed were higher-order hydroxylated products probably formed via subsequent reaction of primary photoproducts. NMR analysis confirmed the formation of 12,17-dihydroxy-estra-5(10),9(11),dien-3-one (12-hydroxy-TBOH; 2.2 mg), 10,12,17-trihydroxy-estra-4,9(11),dien-3-one (10,12-dihydroxy-TBOH; 0.7 mg), and a ring-opened 11,12-dialdehyde oxidation product (TBOH-11,12-dialdehyde; 1.0 mg) after irradiation of about 14 mg of 17beta-trenbolone. Though unconfirmed by NMR, our data suggest that the formation of additional isomeric products may occur, likely due to the reactivity of the unique 4,9,11 conjugated triene structure of trenbolone. In vivo exposure studies employing Japanese medaka (Oryzias latipes) indicate that low concentrations of 17alpha-TBOH photoproduct mixtures can alter ovarian follicular development, and photoproducts alter whole-body 17beta-estradiol levels. Therefore, direct photolysis yields photoproducts with strong structural similarity to parent steroids, and these photoproducts still retain enough biological activity to elicit observable changes to endocrine function at trace concentrations. These data indicate that environmental transformation processes do not necessarily reduce steroid hormone ecotoxicity [13248].

17beta-Hydroxyestra-4,9,11-trien-3-one or trenbolone is an anabolic steroid used in some meat producing countries where its use is licenced. In cattle it is metabolised into 17alpha-trenbolone. It was required to make 17alpha-[4-14C]trenbolone for use in environmental fate studies. At the same time we also had a request to make 17alpha-[4-14C]estradiol so it was combined the two syntheses and made use of the synergy to allow us to make a batch of 17alpha-[4-14C]estradiol by known methodology and then elaborate a portion of this into 17alpha-[4-14C]trenbolone. The synthesis of 17alpha-[4-14C]trenbolone from 17alpha-[4-14C]estradiol was achieved in 8 steps and 3.1 percent overall yield to give material with a radiochemical purity of 99.5 percent and specific activity of 59 mCi/mmol [13249].

Both androgenic and estrogenic steroids are widely used as growth promoters in feedlot steers because they significantly enhance feed efficiency, rate of gain, and muscle growth. However, despite their widespread use relatively little is known about the biological mechanism by which androgenic and estrogenic steroids enhance rate and efficiency of muscle growth in cattle. Treatment of feedlot steers with a combined estradiol (E2) and trenbolone acetate (TBA) implant results in an increased number of muscle satellite cells, increased expression of IGF-1 mRNA in muscle tissue, and increased levels of circulating IGF-1. Similarly, treatment of bovine satellite cell (BSC) cultures with either TBA or E2 results in increased expression of IGF-1 mRNA, increased rates of proliferation and protein synthesis, and decreased rates of protein degradation. Effects of E2 on BSC are mediated at least in part through the classical E2 receptor, estrogen receptor-alpha (ESR1), the IGF-1 receptor (IGFR1), and the G protein-coupled estrogen receptor-1 (GPER-1), formerly known as G protein-coupled receptor-30 (GPR30). The effects of TBA appear to be primarily mediated through the androgen receptor. Based on current research results, it is becoming clear that anabolic steroid-enhanced bovine muscle growth involves a complex interaction of numerous pathways and receptors. Consequently, additional in vivo and in vitro studies are
necessary to understand the mechanisms involved in this complex process. The fundamental information generated by this research will help in developing future, safe, and effective strategies to increase rate and efficiency of muscle growth in beef cattle [13250].

Trenbolone acetate (TBA) is a high-value steroidal growth promoter often administered to beef cattle, whose metabolites are potent endocrine-disrupting compounds. We performed laboratory and field phototransformation experiments to assess the fate of TBA metabolites and their photoproducts. Unexpectedly, we observed that the rapid photohydration of TBA metabolites is reversible under conditions representative of those in surface waters (pH 7, 25°C). This product-to-parent reversion mechanism results in diurnal cycling and substantial regeneration of TBA metabolites at rates that are strongly temperature- and pH-dependent. Photoproducts can also react to produce structural analogs of TBA metabolites. These reactions also occur in structurally similar steroids, including human pharmaceuticals, which suggests that predictive fate models and regulatory risk assessment paradigms must account for transformation products of high-risk environmental contaminants such as endocrine-disrupting steroids [13251].

Experimentally

The toxicokinetics of trenbolone was characterized during 500 ng/l water exposures in female rainbow trout (Oncorhynchus mykiss) and fathead minnows (Pimephales promelas). Related experiments measured various toxicodynamic effects of exposure. In both species, trenbolone was rapidly absorbed from the water and reached peak plasma levels within 8 h of exposure. Afterwards, trenbolone concentrations in trout (66-95 ng/ml) were 2-6 times higher compared with minnows (15-29 ng/ml), which was attributable to greater plasma binding in trout. During water exposures, circulating levels of estradiol (E2) rapidly decreased in both species to a concentration that was 25-40 percent of control values by 8-24 h of exposure and then remained relatively unchanged for the subsequent 6 days of exposure. In trout, changes in circulating levels of follicle-stimulating hormone were also significantly greater after trenbolone exposure, relative to controls. In both species, the pharmacokinetics of injected E2-d3 was altered by trenbolone exposure with an increase in total body clearance and a corresponding decrease in elimination half-life. The unbound percentage of E2 in trout plasma was 0.25 percent, which was similar in pre- or postvitellogenic female trout. Subsequent incubation with trenbolone caused the unbound percentage to significantly increase to 2.4 percent in the previtellogenic trout plasma. iTRAQ-based toxicoproteomic studies in minnows exposed to 5, 50, and 500 ng/l trenbolone identified a total of 148 proteins with 19 downregulated including vitellogenin and 18 upregulated. Other downregulated proteins were fibrinogens, α-2-macroglobulin, and transferrin. Upregulated proteins included amine oxidase, apolipoproteins, parvalbumin, complement system proteins, and several uncharacterized proteins. The results indicate trenbolone exposure is a highly dynamic process in female fish with uptake and tissue equilibrium quickly established, leading to both rapid and delayed toxicodynamic effects [13252].

1-Testosterone

It is assumed that 1-testosterone (5alpha-androst-1-ene-17beta-ol-3-one) cannot be produced through metabolism of 1,4-androstadiene-type steroids due to inhibition of 5alpha-reductase by the 1,2 double bond. In addition to the parent drug, 5alpha-androst-1-ene-3alpha-ol-17-one and 5alpha-androst-1-ene-3,17-dione were identified as metabolites in the glucuronide fraction. 5alpha-androst-1-ene-3alpha-ol-17-one was identified as the major metabolite of 1-testosterone. Moreover, reduction of the delta1 double bond resulted in
increased dihydrotestosterone concentrations (DHT) and consequently the rise of androsterone and other 5alpha-steroids (5alpha-androstane-3alpha,17beta-diol). A notable increase of the testosterone to epitestosterone ratio was also noticed [06004].

**Metabolism**

Since the beginning of the year 2005, the use of steroid precursors (prohormones) is illegal in the United States; nevertheless, there is still an enormous abuse of such substances. One of the most frequently misused steroids, often declared to be a prohormone, is 1-testosterone (17beta-hydroxy-5alpha-androst-1-en-3-one, 1-Testo). In one study, it was characterised molecular mechanisms of its action, determined its tissue specific androgenic and anabolic potency and investigated potential adverse effects. 1-Testo binds highly selective to the androgen receptor (AR) and has a high potency to stimulate AR dependent transactivation. In vivo an equimolar dose of 1-Testo has the same potency to stimulate the growth of the prostate, the seminal vesicles and the androgen sensitive levator ani muscle as the reference compound testosterone propionate (TP). Administration of 1-Testo, in contrast to TP, results in a significant increase of liver weight. The results demonstrate that 1-Testo, even without being metabolised, is a very potent androgen. It binds selectively to the AR and transactivates AR dependent reporter genes. In vivo it has a high androgenic and anabolic potency and increases liver weight. In summary 1-Testo can be characterised as a typical anabolic steroid. It has to be assumed that consumption of this substance is associated with adverse side effects typical for this class of compounds [06115].

**Metenolone**

The aim of one study was the investigation of effects of the metenolone enanthate (ME) that is used among athletes as doping and muscle amplifier, on hearts of male and female rats that are in puberty using morphometrical methods. A total of 36 rats which were divided into three separate groups (experiment, ME; vehicle, PO; control, C) each consisting of 6 male and 6 female rats were used. 0.5 mg/kg metenolone enanthate was applied intraperitoneally into experiment subjects 5 times a week over a period of 4 weeks. At the end of experiment, rats were euthanized and their hearts were cut at the level of musculus papillaris after the fixation in formalin. Hearts were taken out and embedded in paraffin wax. Photos were taken at cut surfaces, and thickness, diameters and surface area levels were measured. Left ventriculus mass (LVM) and left ventriculus mass index (LVMI) were calculated. In the study LVM and LVMI were found to be significantly higher in the ME group in females whereas left ventricular lumen diameter (LVLD) were found to be significantly lower. Thus left ventricular hypertrophy development was observed. LVM and LVMI were found to be similar in ME and C groups among male rats and the highest level of these data were found in the group. LVM and LVMI were higher among females. In conclusion, it has been shown that the adverse effects of ME on heart were developing starting from puberty and resulting with the enlargement of the heart and left ventricular hypertrophy and especially among females this condition was more evident. It has also been discussed that the continuous use of drugs may further enhance this condition [13253].

**Metandienone**

The metabolism of a variety of anabolic steroids frequently misused for doping purposes has been investigated in the last years. This research mainly focused on main and long-term metabolites suitable for detection, but detailed clearance mechanisms have rarely been
elucidated. Recent studies on metandienone focused on the identification of 17beta-hydroxymethyl-18alpha-methyl-18-norandrosta-1,4,13-trien-3-one (20betaOH-NorMD) as long-term metabolite, however, the metabolic pathway of its generation remained unclear. Metandienone and its Wagner-Meerwein rearrangement product 17,17-dimethyl-18-norandrosta-1,4,13-trien-3-one (NorMD) were hydroxylated by different human cytochrome P450 enzymes (CYPs). Some of their hydroxylation products were chemically synthesized and characterized by mass spectrometry to allow for their trace detection in urine samples. Following oral administration of metandienone or NorMD in one human volunteer each the post administration urines were checked for the presence of those hydroxylated metabolites using GC-MS/MS analysis. The human mitochondrial steroid hydroxylating enzymes CYP11B1 and CYP11B2 were capable to metabolize metandienone leading to the formation of 11beta-hydroxymetandienone and 18-hydroxymetandienone. Following Wagner-Meerwein rearrangement, the resulting products could be assigned to 20betaOH-NorMD and 11betaOH-NorMD. The contribution of CYP11B1 and CYP11B2 in human metabolism of metandienone was confirmed by analysis of post-administration samples of metandienone and NorMD. Combined with the results from a previous study, enzymatic pathways were identified that involve CYP21 and CYP3A4 in the hydroxylation of NorMD, while CYP21, CYP3A4 and CYP11B2 take part in 20betaOH-NorMD generation from MD. The current study represents a valuable contribution to the elucidation of clearance mechanisms of anabolic steroids and also indicates that mainly non-liver CYPs seem to be involved in these processes [12512].

There is increasing evidence that the biological activity of myostatin (MSTN), a negative regulator of muscle growth, is affected by training but also anabolic steroids. In this study, we analyzed the effects of the frequently abused anabolic steroid methandienone (Md) on the hypothalamic-pituitary-testicular axis and androgen-sensitive tissues in intact rats performing a treadmill training to simulate the situation of abusing athletes. The anabolic effects were correlated with the expression of members of the MSTN signaling cascade. Md treatment resulted in a significant stimulation of anabolic activity of the levator ani muscle, which was further increased by training, while prostate and seminal vesicle weights decreased in conformance with hormone concentrations of LH and testosterone. In gastrocnemius muscle, mRNA expression of genes of the MSTN signaling cascade (MSTN, Smad7 and MyoD) was reduced by training but not after Md treatment, in soleus muscle MSTN and its inhibitors, follistatin (FLST) and Smad-7 were only affected after training in combination with Md treatment. In summary, our data demonstrate that Md treatment of intact rats results in anabolic effects which are enhanced in combination with physical activity. Interestingly, the anabolic activity on the levator ani was increased in combination with training, although the levator ani muscle was not specifically stimulated by our training protocol. In the m. gastrocnemius and soleus, the anabolic effects correlate with changes in the expression patterns of genes involved in MSTN signaling. The data provide evidence that the decrease in the weight of androgen-sensitive sexual glands, observed after Md treatment, is caused by a suppression of endogenous testosterone synthesis. These observations provide new insights into the molecular mechanisms of the interaction between anabolic steroids, training and MSTN signaling during skeletal muscle adaptation [12096].

**Laboratory technique**

Metandienone is one of the most frequently detected anabolic androgenic steroids in sports drug testing. Metandienone misuse is commonly detected by monitoring different metabolites excreted free or conjugated with glucuronic acid using gas chromatography mass spectrometry (GC-MS) and liquid chromatography tandem mass spectrometry (LC-MS/MS) after hydrolysis with beta-glucuronidase and liquid-liquid extraction. It is known that several
metabolites are the result of the formation of sulphate conjugates in C17, which are converted to their 17-epimers in urine. Therefore, sulphation is an important phase II metabolic pathway of metandienone that has not been comprehensively studied. The aim of this work was to evaluate the sulphate fraction of metandienone metabolism by LC-MS/MS. Seven sulphate metabolites were detected after the analysis of excretion study samples by applying different neutral loss scan, precursor ion scan and SRM methods. One of the metabolites (M1) was identified and characterised by GC-MS/MS and LC-MS/MS as 18-nor-17beta-hydroxymethyl-17alpha-methylandrost-1,4,13-triene-3-one sulphate. M1 could be detected up to 26 days after the administration of a single dose of metandienone (5 mg), thus improving the period in which the misuse can be reported with respect to the last long-term metandienone metabolite described (18-nor-17beta-hydroxymethyl-17alpha-methylandrost-1,4,13-triene-3-one excreted in the glucuronide fraction) [13254].

In sports drug testing, comprehensive studies on the metabolism of therapeutic agents with misuse potential are necessary to identify metabolites that provide utmost retrospectivity and specificity. By commonly employed approaches minor and/or long-term metabolites in urine might remain undetected. Hence, an alternative strategy to unambiguously identify the majority of urinary metabolites including low-abundance representatives is desirable. Urine samples were collected for 20 days during an elimination study with an oral dose of 5 mg of 17alpha-C2H3-metandienone. The specimens were processed according to established sample preparation procedures (including fractionation and deconjugation) and subjected to gas chromatography/hydrogen isotope ratio mass spectrometry (GC/IRMS) analysis. Due to the deuteration of the administered drug, urinary metabolites bearing the deuterium label yield abundant and specific signals on the GC/IRMS instrument resulting from the substantially altered D/H ratio. The sample aliquots were measured by gas chromatography/time-of-flight (GC/Q-TOF) mass spectrometry using identical GC conditions, allowing high-resolution/high-accuracy mass data to be obtained on all urinary metabolites previously identified by IRMS. Within the IRMS chromatograms, labeled metabolites were identified up to 20 days after administration at urinary concentration down to 0.25 ng/mL. More than 50 metabolites were observed with the earlier described long-term metabolite of metandienone, 18-nor-17beta-hydroxymethyl,17alpha-methyl-androst-1,4,13-trien-3-one, being the most prominent glucuronidated metabolite in the studied time window. In the sulfocojugated steroids fraction, a yet unknown metabolite was observed at m/z 283.1997 comprising the experimentally determined elemental composition of C20H21O. In conclusion, combining IRMS with high-resolution mass spectrometry considerably facilitates and accelerates metabolite identification of deuterium-labeled compounds in urine. Of particular relevance in doping control, the principle is applicable also to other arenas of drug research, allowing the preparation and administration of e.g. radioactively labeled substances to be omitted [0255].

Metandienone is one of the most frequently detected anabolic androgenic steroids in sports drug testing. Metandienone misuse is commonly detected by monitoring different metabolites excreted free or conjugated with glucuronic acid using gas chromatography mass spectrometry (GC-MS) and liquid chromatography tandem mass spectrometry (LC-MS/MS) after hydrolysis with beta-glucuronidase and liquid-liquid extraction. It is known that several metabolites are the result of the formation of sulphate conjugates in C17, which are converted to their 17-epimers in urine. Therefore, sulphation is an important phase II metabolic pathway of metandienone that has not been comprehensively studied. The aim of this work was to evaluate the sulphate fraction of metandienone metabolism by LC-MS/MS. Seven sulphate metabolites were detected after the analysis of excretion study samples by applying different neutral loss scan, precursor ion scan and SRM methods. One of the metabolites (M1) was identified and characterised by GC-MS/MS and LC-MS/MS as 18-nor-17beta-hydroxymethyl-17alpha-methylandrost-1,4,13-triene-3-one sulphate. M1 could be detected up to 26 days after the administration of a single dose of metandienone (5 mg), thus
improving the period in which the misuse can be reported with respect to the last long-term metandienone metabolite described (18-nor-17beta-hydroxymethyl-17alpha-methylandrost-1,4,13-triene-3-one excreted in the glucuronide fraction) [13256].

In urine
Anabolic-androgenic steroids are some of the most frequently detected drugs in amateur and professional sports. Doping control laboratories have developed numerous assays enabling the determination of administered drugs and/or their metabolic products that allow retrospectives with respect to pharmacokinetics and excretion profiles of steroids and their metabolites. A new metabolite generated from metandienone has been identified as 18-nor-17beta-hydroxymethyl,17alpha-methyl-androst-1,4,13-trien-3-one in excretion study urine samples providing a valuable tool for the long-term detection of metandienone abuse by athletes in sports drug testing. The metabolite was characterized using gas chromatography/(tandem) mass spectrometry, liquid chromatography/(tandem mass spectrometry and liquid chromatography/high-resolution/high-accuracy (tandem) mass spectrometry by characteristic fragmentation patterns representing the intact 3-keto-1,4-diene structure in combination with typical product ions substantiating the proposed C/D-ring structure of the steroid metabolite. In addition, structure confirmation was obtained by the analysis of excretion study urine specimens obtained after administration of 17-CD(3)-labeled metandienone providing the deuterated analogue to the newly identified metabolite. 18-Nor-17beta-hydroxymethyl,17alpha-methyl-androst-1,4,13-trien-3-one was determined in metandienone administration study urine specimens up to 19 days after application of a single dose of 5 mg, hence providing an extended detection period compared with commonly employed strategies [06116].

In hair
A sensitive, specific and reproducible method for the quantitative determination of the anabolic metandienone in human hair has been developed. The preparation involved a decontamination step with methylene chloride. The hair sample (about 50 mg) was solubilised in 1 ml 1 M NaOH, 10 min at 95 degrees C, in presence of 2 ng of nandrolone-d(3) used as internal standard. The homogenate was neutralized and extracted using consecutively a solid-phase extraction (Isolute C(18) eluted with methanol) and a liquid-liquid extraction with pentane. The residue was derivatized by adding 5 microl MSTFA/NH(4)I/2-mercaptoethanol (250 microl; 5 mg; 15 microl) and 45 microl MSTFA, then incubated for 20 min at 60 degrees C. A 1 microl aliquot of derivatized extract was injected into the column (HP5-MS capillary column, 5 % phenyl-95 % methylsiloxane, 30 m x 0.32 mm i.d., 0.25 microm film thickness) of a Hewlett Packard (Palo Alto, CA, USA) gas chromatograph (6890 Series). Metandienone was identified using three transitions (its daughter ions at m/z 339 and 206 for the parent 444 and 191 for 206) using a Waters Quattro Micro MS-MS system. The transition m/z 444 to 206 has been used as quantification transition and the others as identification transitions. The assay was capable of detecting 2 pg/mg of metandienone when approximately 50 mg of hair material was processed. Linearity was observed for metandienone concentrations ranging from 2 to 500 pg/mg with a correlation coefficient of 0.9997. Intra-day and between-day precisions at 50 pg/mg were 13.4-16.5 percent and 22 percent, respectively, with an extraction recovery of 48 percent. The analysis of hair, cut into four segments, obtained from an athlete, revealed the presence of metandienone at the concentrations of 78, 7, 10 and 108 pg/mg in each segment of hair (0-1, 1-2, 2-3 and 3 cm to the tip) [06117].

Recently, a previously unknown urinary metabolite of metandienone, 17beta-hydroxymethyl-17 alpha-methyl-18-norandrosa-1,4,13-trien-3-one (20OH-NorMD), was discovered via LC-MS/MS and GC-MS. This metabolite was reported to be detected in urine samples up to 19 days after administration of metandienone. However, so far it was not possible to obtain
purified reference material of this metabolite and to confirm its structure via NMR. Eleven recombinant strains of the fission yeast Schizosaccharomyces pombe that express different human hepatic or steroidogenic cytochrome P450 enzymes were screened for production of this metabolite in a whole-cell biotransformation reaction. 17,17-Dimethyl-18-norandrosta-1,4,13-trien-3-one, chemically derived from metandienone, was used as substrate for the bioconversion, because it could be converted to the final product in a single hydroxylation step. The obtained results demonstrate that CYP21 and to a lesser extent also CYP3A4 expressing strains can catalyze this steroid hydroxylation. Subsequent 5 l-scale fermentation resulted in the production and purification of 10 mg of metabolite and its unequivocal structure determination via NMR. The synthesis of this urinary metandienone metabolite via S. pombe-based whole-cell biotransformation now allows its use as a reference substance in doping control assays [10088].

Mestranolon

Skeletal muscle has the ability to respond to new endogenous and exogenous physiological demands by changing its phenotypic characteristics. The large diversity of myosin heavy chain (MHC) isoforms expressed in muscle helps to form the basis for this remarkable plasticity. It is the expression and co-expression of these various MHC isoforms within a given fiber that ultimately delineates the entire range of fiber types. The prevalence of certain types of these fibers accounts for the functional and structural characteristics of a given muscle, and hence its phenotype. In an attempt to shorten recovery time and improve performance, strength and endurance athletes occasionally turn to the illicit use of anabolic-androgenic steroids (AAS). The high-intensity, aerobic exercise caused a significant increase in muscle wet weights with an additional increase following mesterolone treatment. In all three muscles, the effect of mesterolone in sedentary mice was stronger than in exercised mice suggesting that the effect of exercise partially blunted the anabolic effect of mesterolone. Skeletal muscles express a variety of different types of proteins associated with metabolism, inflammation, and contractile activity in response to exercise. A large number of different systemic and muscular proteins could also result from anabolic-androgenic steroid treatment. Although the elucidation of the complex molecular mechanisms underlying the ergogenic effects of AAS treatment was not the aim of the present study, muscle function may be improved by increasing protein synthesis or membrane stabilization. This may be accomplished via a competitive occupancy of glucocorticoid receptors by AAS which would act antagonistically to the catabolic action of glucocorticoid hormones. In the present study, adaptive differences observed among the three muscles examined implies alternative binding of the steroid to a number of androgen receptors resulting in agonistic promotion of skeletal muscle protein synthesis. Androgens receptors (AR) are expressed in satellite cells, differentiated myofibers, intramuscular fibroblasts, and different types of motoneurons. In addition, the regulation of plasmatic levels of insulin-like growth factor-1 (IGF-1), growth hormone, and thyroid hormone (as well as, the antagonism of glucocorticoids) are roles linked to anabolic-androgenic signaling. One study was undertaken to examine the effects of mesterolone (an anabolic-androgenic steroid) on the fiber type composition and cross-sectional area of skeletal muscle fibers of sedentary and high-intensity, aerobically-exercised transgenic mice. Thus, the aim was to investigate the role of mesterolone in a supposed catabolic environment. Does the interaction of anabolic hormone treatment and high-intensity aerobic exercise produce an increase in muscle mass and redistribution of skeletal muscle fiber types? Are muscles with distinct metabolic and contractile properties (i.e., fast/glycolytic vs slow/oxidative) differently modulated by the anabolic-androgenic steroid treatment combined with a high-intensity, endurance-type training program? As such, three skeletal muscles were studied under these experimental conditions: soleus (SOL), tibialis anterior.
(TA) and gastrocnemius (GAS). The entire range of pure and hybrid fiber types were delineated using myofibrillar adenosine triphosphatase (mATPase) histochemical methods allowing the detection of subtle changes in type composition. The mice used in the current study were genetically engineered to exhibit a lipid profile closer to humans allowing for a more relevant comparison. The transgenic mice (CETP(+/-)LDLr(-/-)) were engineered to exhibit a lipid profile closer to humans. Animals were divided into groups of sedentary (Sed) and/or training (Ex) mice (each treated orally with AAS or gum arabic/vehicle: Sed-C, Sed-M, ex-C, ex-M). The effects of AAS (mesterolone: M) on specific phenotypic adaptations (muscle wet weight, cross-sectional area, and fiber type composition) in three hindlimb muscles (soleus:SOL, tibialis anterior:TA and gastrocnemius:GAS) were assessed. In order to detect subtle changes in fiber type profile, the entire range of fiber types (I, IC, IIAC, IIA, IIAD, IID, IIB) was delineated using mATPase histochemistry. Body weight gain occurred throughout the study for all groups. However, the body weight gain was significantly minimized with exercise. This effect was blunted with mesterolone treatment. Both AAS treatment (Sed-M) and high-intensity, aerobic training (ex-C) increased the wet weights of all three muscles and induced differential hypertrophy of pure and hybrid fibers. Combination of AAS and training (ex-M) resulted in enhanced hypertrophy. In the SOL, mesterolone treatment (Sed-M and ex-M) caused dramatic increases in the percentages of fiber types IC, IIAC, IIAD, IID, with concomitant decrease in IIA, but had minimal impact on fiber type percentages in the predominantly fast muscles. Overall, the AAS-induced differential adaptive changes amounted to significant fiber type transformations in the fast-to-slow direction in SOL. AAS treatment had a significant effect on muscle weights and fiber type composition in SOL, TA and GAS which was even maximized in animals subjected to metabolically high-intensity aerobic exercise [13257].

**Norbolethone**

More than 100 synthetic derivatives of testosterone have been developed. As an example, norbolethone is a steroid that was developed in the 1960s by Wyeth Pharmaceuticals in Philadelphia to treat children with growth problems; it was never marketed. However, It was popular as a performance-enhancing drug because of its high anabolic activity and low androgenic activity [07002].

Norbolethone (17beta-hydroxy-13beta,17alpha-diethylgon-4-en-3-one) is an anabolic steroid found to be 16.3 times more effective in retaining nitrogen in rats than methyltestosterone. Although its promising anabolic:androgenic dissociation, this steroid was never commercialized due to its toxicity and was not explicitly listed as a prohibited substance in sports until its detection. Norbolethone is excreted as the parent compound and is metabolised to 13beta,17alpha-diethyl-5beta-gonane-3alpha,17beta-diol diol (minor metabolite) [06004].

**Phytosterols**

Cholesterol is a well-known component in fats of animal origin and it also is the precursor of natural hormones. Phytosterols appear in plants and only differ slightly in structure from cholesterol. An important difference however is the low absorption in the gut of phytosterols and their saturated derivatives, the phytostanols. As a result, there is time for all kind of reactions in faecal material inside and outside of the gut. Determination of the abuse of natural hormones may be based on gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS). Abuse of natural hormones changes the $^{13}$C/$^{12}$C ratio of some
metabolites during a relatively long time. The formation of (natural) hormones in the gut may interfere with this method. Designer drugs are mainly known from sports doping. In animal fattening, designer drugs may be used as well. Small changes in the structure of (natural) hormones may lead to a new group of substances asking for new strategies for their detection and the constatation of their abuse [06126].

Plant sterols are also known as phytosterols (or phytostanols when saturated). Most commonly, phytosterols are produced from a cycloartenol precursor which makes their synthesis different from animal sterols (zoosterols) which are derived from a lanosterol precursor. Various phytosterols have been discussed previously including gamma-oryzanol, octosanol and policosanol, and supplements containing Cissus quadrangularis. The most abundant phytosterol is sitosterol. There are differing outcome data from studies using sitosterol supplementation in terms of immune function and plasma lipid regulation. No precise effect on the athletic performance of phytosterols in general, including sitosterol, has been observed. Several studies have demonstrated that sitosterol is the most abundant phytosterol in plants and consequently in Western diets. Ultramarathon runners supplemented with β-sitosterol capsules displayed fewer cellular markers of inflammation (particularly those related to neutrophils) after a race compared with placebo-treated controls, suggesting that phytosterols may mitigate the effects of acute, strenuous exercise on immunity. However, in a study of trained runners subjected to an exercise bout of increasing intensity until exhaustion, the heart rate and blood lactate were uninfluenced by phytosterols. In a study of older sedentary adults, 6 months of endurance training reduced plasma cholesterol levels while increasing the absorption of phytosterols contained in a normal diet, suggesting that phytosterols may have beneficially regulated plasma lipids. The current limited research suggests that beta-sitosterol may mitigate the exercise-associated dysregulation of immune function and improve blood lipid profiles, though it has no direct ergogenic effects [12467].

Phytoecdysteroids
Phytoecdysteroids are analogues of arthropod steroid hormones found in plants, where they deter predation by non-adapted predators. There is potential to exploit this to develop new strategies for pest control, either by using ecdysteroids as lead molecules for the design of novel pest control agents or by alteration of ecdysteroid levels/profiles in crop plants through plant breeding or genetic modification. However, it is other properties of phytoecdysteroids that have led to a rapid recent increase in scientific and commercial interest in these molecules. They are apparently non-toxic to mammals and a wide range of beneficial pharmacological (adaptogenic, anabolic, anti-diabetic, hepatoprotective, immunoprotective, wound-healing, and perhaps even anti-tumour) activities is claimed for them. In particular, this has led to a large (and unregulated) market for ecdysteroid-containing preparations for body-builders, sportsmen, and pets, among others. Ecdysteroids are also being considered as nutraceutical additives to food products. Further, ecdysteroids are good candidates as elicitors for gene-switch systems to be used in medical gene therapy and research applications [09137].

Evolution of steroids such as sex hormones and ecdysteroids occurred independently in animal and plant kingdoms. Plants use phytoecdysteroids (PEs) to control defence interactions with some predators; furthermore, PEs can exert beneficial influence on many aspects of mammalian metabolism. Endocrine disrupting compounds such as the estrogen agonist bisphenol A (BPA) are widespread in the environment, posing a potential hormonal risk to animals and plants. Adverse BPA effects on reproductive development and function are coupled with other toxic effects. BPA bioremediation techniques could be developed by exploiting some tolerant plant species [10352].

Phytoecdysteroids are structural analogs of the insect molting hormone ec dysone. Plants comprise rich sources of ecdysteroids in high concentration and with broad structural diversity. Ecdysteroids have a number of proven beneficial effects on mammals but the hormonal effects of ecdysteroids have been proven only in arthropods. Their structures are somewhat similar to those of the vertebrate steroid hormones but there are several structural differences between the two steroid groups. Despite of these essential structural differences, ecdysteroids exert numerous effects in vertebrates that are similar to those of vertebrate hormonal steroids, and they may serve as effective anabolic, hepatoprotective, immunoprotective, antioxidant and hypoglycemic agents. Ecdysteroids do not bind to the cytosolic steroid receptors, instead, they are likely to influence signal transduction pathways, like the anabolic steroids, possibly via membrane bound receptors. The application of phytoecdysteroids is a promising alternative to the use of anabolic-androgenic steroids because of the apparent lack of adverse effects. The prospective use of phytoecdysteroids may extend to treatments of pathological conditions where anabolic steroids are routinely applied. One of the most cited aspects of phytoecdysteroid application (on the Internet) is the increase of muscle size. However in this field too stringent research is needed as an adequate cytological explanation is not yet available for the anabolic [08164].

20-Hydroxyecdysone (20E) is an ecdysteroid hormone that regulates moulting in insects. Interestingly, 20E is also found most abundantly in plant species and has anabolic effects in vertebrates, i.e. increasing muscle size without androgen influence. The effect of 20E on slow and fast fiber types of skeletal muscle has not been reported yet. Here we present that 20E affects the size (cross-sectional area) of the different fiber types in a muscle-specific manner. The effect on fiber size was modified by the distance from the site of the treatment and the presence of a regenerating soleus muscle in the animal. Besides the fiber size, 20E also increased the myonuclear number in the fibers of normal and regenerating muscles, suggesting the activation of satellite cells. According to our results 20E may provide an alternative for substitution of anabolic-androgenic steroids in therapeutic treatments against muscle atrophy [08165].
17-hydroxyandrost-3,5-diene ("Syntrax Tetrabol")

Yeast transactivation system

Anabolic-androgenic steroids are frequently misused compounds in sports, and they belong to the controlled substances according to the requirements of the World Anti-Doping Agency. The classical techniques of steroid detection are mass spectrometry coupled to gas or liquid chromatography. Biological methods that base on the ability of substances to bind the steroid receptor are not applied in routine doping control procedures so far, but they appear to be useful for characterization of steroid androgenic potential. In this study we used the yeast androgen receptor reporter system (YAS), which in the past has already successfully been applied to both various androgenic substances and also urine samples. Giving attention to the androgenic potential of steroidal dietary supplements, we exemplified the analysis using both mass spectrometry techniques and the YAS-based assay on the product "Syntrax Tetrabol" which was a confiscated dietary supplement and marketed as a steroid precursor. Identification, structure and the kinetic behavior of its excreted metabolites were analyzed by NMR, GC-MS and LC-MS/MS. The androgenic potential of the parent compound as well as its metabolites in urine was evaluated with the help of the YAS. The application of urine samples with a previous deconjugation and the inclusion of urine density values were carried out and led to increased responses on the YAS. Further, the possibility of a complementary application of structure-based instrumental analysis and biological detection of androgenicity with the help of the YAS seems to be desirable and is discussed [12183].

Designer steroids

Despite progress in the development of GC/MS and ionmobility based methodology and though it plays a key role in ASS abuse detection, it has failed to detect the so-called designer drugs, the prototype being tetrahydrogestrinone. Because these emerging drugs are devised specifically to evade detection, they impose a considerable burden on antidoping methods. A recently launched paradigm is "1-androsterone", administration of which modifies the urinary steroid profile, and in particular the ratios of androsterone/etiocholanolone and 5alpha-/5beta-androstane-3alpha,17beta-diol and the concentration of 5alpha-dihydrotestosterone. Meanwhile, 3alpha-hydroxy-5alpha-androst-1-en-17-one, a characteristic metabolite, is likely to play an important role by permitting a wider time frame of detection of steroid abuse, since screening performed as much as 9 days after a single administration of one capsule enabled its detection [12011].

The issue of a growing number of so-called designer steroids requires proper monitoring of illicitly distributed compounds. Upon detection and characterization, the knowledge regarding metabolism and excretion are particularly important to provide adequate target analytes for routine doping controls [12016].

Historically, dope-testing methods have been developed to target specific and known threats to the integrity of sport. Traditionally, the source of new analytical targets for which testing was required were derived almost exclusively from the pharmaceutical industry. More recently, the emergence of designer drugs, such as tetrahydrogestrinone that are specifically intended to evade detection, or novel chemicals intended to circumvent laws controlling the sale and distribution of recreational drugs, such as anabolic steroids, stimulants and cannabinoids, have become a significant issue. In one review, it was considered the
emergence of designer drugs and the response of dope-testing laboratories to these new threats, in particular developments in analytical methods, instrumentation and research intended to detect their abuse, and the likely future impact of these approaches [12185].

Desoxymethyltestosterone (DMT; 17beta-hydroxy-17alpha-methyl-5alpha-androst-2-ene) is a designer steroid present in hormonal supplements distributed illegally as such or in combination with other steroids, for self-administration. It figures on the list of substances prohibited in sports and its detection in athlete's urine samples is based upon the presence of the parent compound or the main urinary metabolite, which has not been characterized yet. Following its isolation from cultures of human fresh hepatocytes and S9 fractions of liver homogenates, it was possible to identify this metabolite as being 17alpha-methyl-2beta, 3alpha,17beta-trihydroxy-5alpha-androstane. Other minor metabolites were also characterized. The production, isolation, NMR, mass spectral analyses and chemical synthesis were presented [12186].

Cholesterol is a well-known component in fats of animal origin and it also is the precursor of natural hormones. Phytosterols appear in plants and only differ slightly in structure from cholesterol. An important difference however is the low absorption in the gut of phytosterols and their saturated derivatives, the phytostanols. As a result, there is time for all kind of reactions in faecal material inside and outside of the gut. Determination of the abuse of natural hormones may be based on gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS). Abuse of natural hormones changes the $^{13}$C/$^{12}$C ratio of some metabolites during a relatively long time. The formation of (natural) hormones in the gut may interfere with this method. Designer drugs are mainly known from sports doping. In animal fattening, designer drugs may be used as well. Small changes in the structure of (natural) hormones may lead to a new group of substances asking for new strategies for their detection and the constatation of their abuse [07092].

Anabolic steroids have been studied for over 50 years and during that time numerous compounds with a variety of functional groups have been produced and many have been published. Of these only a small number have been introduced to the pharmaceutical market. WADA has continued the work begun by the IOC banning the use of these agents within sport as performance enhancing substances. Athletes, however, continue to use these anabolic steroids but tighter testing and the introduction of unannounced sample collection has made this form of cheating harder. In order to try to evade detection, athletes who continue to dope are having to resort to the use of a far more dangerous form of drug – the designer steroid. These steroids are manufactured to closely resemble existing known compounds, but with sufficient chemical diversity to ensure that their detection by the WADA accredited laboratories this is more difficult. A worrying feature of the use of these compounds is that no data is available to evaluate either the efficacy or the safety of these substances. Many such drugs are now being made in clandestine ways (as demonstrated by the recent BALCO case) and then passed on to athletes who become the guinea pigs determining the potential of the substances as doping agents. Methods for the detection of these new compounds are being developed using emerging techniques such as gas chromatography or liquid chromatography attached to a variety of mass spectrometry instruments. This technology as well as vigilance by laboratories and enforcement agencies can all help in early detection of designer steroids being used for doping [10089].

Effective detection of the abuse of androgenic-anabolic steroids in human and animal sports often requires knowledge of the drug's metabolism in order to target appropriate urinary metabolites. "Designer" steroids are problematic since it is difficult to obtain ethical approval for in vivo metabolism studies due to a lack of a toxicological profile. In one study, the in vitro metabolism of estra-4,9-diene-3,17-dione was reported for the first time. This is also the first
study comparing the metabolism of a designer steroid in the three major species subject to sport's doping control; namely the equine, canine and human. In order to allow the retrospective analysis of sample testing data, the use of a high-resolution accurate-mass Thermo LTQ-Orbitrap LC-MS instrument was employed for metabolite identification of underivatised sample extracts. The full scan HR-LC-MS Orbitrap data was complimented by several further experiments targeted at elucidating more detailed structural information for the most abundant metabolites. These included; HR-LC-MS/MS of the underivatised metabolites, functional group selective chemical derivatisation followed by full scan HR-LC-MS, enzyme inhibition experiments and full scan electron ionization GC-MS analysis of methoxyamine-trimethylsilyl derivatives. The major metabolite detected in all species, and therefore the most suitable candidate for screening of estra-4,9-diene-3,17-dione abuse, was proposed to be an isomer of 17-hydroxy-estra-4,9-dien-3-one. Less significant metabolic pathways in all species included hydroxylation and reduction followed by hydroxylation. Reductive metabolism in the canine was less significant than in the other two species, while the equine was unique in producing a di-reduced metabolite (proposed to be an isomer of estra-4,9-diene-3,17-diol) and also relatively large quantities of d-ring hydroxy and hydroxy-reduced metabolites [10459].

New analogues of androgens that had never been available as approved drugs are marketed as "dietary supplement" recently. They are mainly advertised to promote muscle mass and are considered by the governmental authorities in various countries, as well as by the World Anti-doping Agency for sport, as being pharmacologically and/or chemically related to anabolic steroids. In the present study, it was reported the detection of a steroid in a product seized by the State Bureau of Criminal Investigation Schleswig-Holstein, Germany. The product "1-Androsterone" of the brand name "Advanced Muscle Science" was labeled to contain 100 mg of "1-Androstene-3b-ol,17-one" per capsule. The product was analyzed underivatized and as bis-TMS derivative by GC-MS. The steroid was identified by comparison with chemically synthesized 3beta-hydroxy-5alpha-androst-1-en-17-one, prepared by reduction of 5alpha-androst-1-ene-3,17-dione with LS-Selectride (Lithium tris-isooamyloborohydride), and by nuclear magnetic resonance. Semi-quantification revealed an amount of 3beta-hydroxy-5alpha-androst-1-en-17-one in the capsules as labeled. Following oral administration to a male volunteer, the main urinary metabolites were monitored. 1-Testosterone (17beta-hydroxy-5alpha-androst-1-en-3-one), 1-androstenedione (5alpha-androst-1-ene-3,17-dione), 3alpha-hydroxy-5alpha-androst-1-en-17-one, 5alpha-androst-1-ene-3alpha,1betaβ-diol, and 5alpha-androst-1-ene-3beta,17beta-diol were detected besides the parent compound and two more metabolites (up to now not finally identified but most likely C-18 and C-19 hydroxylated 5alpha-androst-1-ene-3,17-diones). Additionally, common steroids of the urinary steroid profile were altered after the administration of "1-Androsterone". Especially the ratios of androsterone/etiocolanolone and 5alpha-/5beta-androstane-3alpha,17beta-diol and the concentration of 5alpha-dihydrotestosterone were influenced. 3alpha-Hydroxy-5alpha-androst-1-en-17-one appears to be suitable for the long-term detection of the steroid (ab-)use, as this characteristic metabolite was detectable in screening up to nine days after a single administration of one capsule [11106].

Detection of androgenic-anabolic steroid abuse in equine sports requires knowledge of the drug's metabolism in order to target appropriate metabolites, especially where urine is the matrix of choice. Studying "designer" steroid metabolism is problematic since it is difficult to obtain ethical approval for in vivo metabolism studies due to a lack of toxicological data. In one study, the equine in vitro metabolism of eight steroids available for purchase on the Internet is reported; including androsta-1,4,6-tirome-3,17-dione, 4-chloro,17alpha-methylandrosta-1,4-diene-3,17beta-diol, estra-4,9-diene-3,17-dione, 4-hydroxyandrostenedione, 20-hydroxyecdyson, 11-keto-androstenedione, 17alpha-methyltestosterone, and tetrahydrogestrinone. In order to allow for retrospective analysis of sample testing data, the use of
a high-resolution accurate-mass Thermo LTQ-Orbitrap liquid chromatography-mass spectrometry (LC-MS) instrument was employed for metabolite identification of underivatized sample extracts. The full scan LC-HRMS Orbitrap data were complimented by LC-HRMS/MS and gas-chromatography-mass spectrometry (GC-MS) experiments in order to provide fragmentation information and to ascertain whether GC-MS was capable of detecting any metabolite not detected by LC-HRMS. With the exception of 20-hydroxyecdysone, all compounds would be metabolized by equine liver S9 and/or microsomes. With the exception of 17alpha-methyltestosterone, which produced metabolites that could only be detected by GC-MS, the metabolites of all other compounds could be identified using LC-HRMS, thus allowing retrospective analysis of previously acquired full-scan data resulting from routine equine drug testing screens. In summary, while in vitro techniques do not serve as a replacement for more definitive in vivo studies in all situations, their use does offer an alternative in situations where it would not be ethical to administer untested drugs to animals [11107].

The metabolic fate of the emerging drug candidate S107, possessing the potential for misuse as performance-enhancing agent in sports, was investigated by in vitro phase I and II experiments with human microsomal and S9 liver enzymes. The metabolites were identified by liquid chromatography-mass spectrometry with electrospray ionisation in positive mode (LC-ESI-MS/MS). Their collision-induced dissociation behaviour was studied by high-resolution/high accuracy Orbitrap MS(n) analysis, supported by stable isotope labelling, H/D-exchange experiments and density functional theory calculations. Monoxygenation accounted for the main phase I metabolic transformation due to N- and S-oxidation of the 1,4-benzothiazepine core, as substantiated by chemical synthesis, selective reduction methods and characteristic APCI in source fragmentation behaviour of the metabolites. Another dominant metabolic pathway was demethylation, yielding the N- and O-demethylated metabolite, respectively. The latter was further conjugated by glucuronidation as well as sulfonation in subsequent phase II metabolic reactions, whereas the N-demethylated metabolite was not amenable to conjugation. The active drug molecule itself was converted to two glucuronic acid conjugates, which are proposed to consist of two quaternary S107-N(+)-glucuronide isomers. All glucuronides were susceptible to enzymatic hydrolysis with β-glucuronidase (Escherichia coli). A comprehensive LC-ESI-MS(/MS)-based detection method for urine was developed and its fitness for purpose was assessed. The assay can serve as a potential screening and/or confirmation method for S107 in clinical drug testing and doping control analysis in the future [11108].

What is an androgen (anabolic-androgenic steroid)? Most would state that it is a derivative of the major sex steroid in men and most mammals, testosterone (T). Others might answer in the more generic sense: any compound that is an agonist (or partial agonist) at the androgen receptor (AR). There are seemingly enough forms of testosterone activity available to satisfy the needs of the medical population with oral, buccal, cutaneous patches (really, drug delivery devices) and gels, injectables of various durations (days to months), and implantable forms with a duration of action of 6 months or more. In the 1940s and 1950s, many pharmaceutical companies evaluated a myriad of compounds with purported anabolic activity searching for those that had anabolic (at muscle) activity without the more androgenic adverse events. It was to little avail given that there is but one AR, albeit with a greater affinity for dihydrotestosterone than for testosterone itself. Arcane testosterone chemistry produced many compounds that had sat on shelves for years without any clinical trials for evaluation for human or veterinary use or commercial promotion. In the future, the concept of selective AR agonists may come to play a much more prominent role. Such compounds may selectively produce the beneficial effects of androgens on musculoskeletal mass and strength without the androgenic adverse events. It appeared quite straightforward to begin with the steroid structure of testosterone, add multiple decorations to the various carbon
atoms, test in vitro with various cell lines that contain the AR linked to an objective outcome, for example, AR nuclear translocation or myogenic activity. Then comes the nefarious part: all certified antidoping laboratories have libraries of chromatography/mass spectroscopy (MS)/MS fragments, and each anabolic/androgenic steroid has its own unique signature. The skill is to find a compound active at the AR, but that is not yet in the library. Is this just an academic exercise in steroid biochemistry? I think not, given the example of tetrahydrogestrinone (THG). THG had been invisible to the antidoping laboratories until a sample of pure THG was presented to an antidoping lab. It had been synthesized by an underground laboratory and likely underwent enough testing (in vitro and in vivo) to determine its anabolic/androgenic activity and that it could not be detected by the then extant WADA testing procedure. There are also multiple proofs that the designer steroid methyl-1-testosterone (M1T) is an active anabolic/androgenic steroid. They set out to prove this point from the perspective of a multifaceted strategy from the source, the supplement M1T. The compound was strongly anabolic (in a dose-dependent manner) to increase the weight of the prostate, seminal vesicles, and levator ani muscle in orchidectomized rats, according to standard androgen assays in use for more than 60 year. Multiple metabolites were found in the urine of rats and men administered M1T yielding a signature for doping detection in athletes as well as a notion of the kinetics of metabolism and excretion [11554].

Various products containing rarely characterized anabolic steroids are nowadays marketed as dietary supplements. Herein, the designer steroid methyl-1-testosterone (M1T) (17beta-hydroxy-17alpha-methyl-5alpha-androst-1-en-3-one) was identified, and its biological activity, potential adverse effects, and metabolism were investigated. The affinity of M1T toward the androgen receptor (AR) was tested in vitro using a yeast AR transactivation assay. Its tissue-specific and anabolic potency and potential adverse effects were studied in a Hershberger assay (sc or oral), and tissue weights and selected molecular markers were investigated. Determination of M1T and its metabolites was performed by gas chromatography mass spectrometry. In the yeast AR transactivation assay, M1T was characterized as potent androgen. In rats, M1T dose-dependently stimulated prostate and levator ani muscle weight after sc administration. Oral administration had no effect but stimulated proliferation in the prostate and modulated IGF-I and AR expression in the gastrocnemius muscle in a dose-dependent manner. Analysis of tyrosine aminotransferase expression provided evidence for a strong activity of M1T in the liver (much higher after oral administration). In rat urine, 17alpha-methyl-5alpha-androstane-3alpha,17beta-diol, M1T, and a hydroxylated metabolite were identified. In humans, M1T was confirmed in urine in addition to its main metabolites 17alpha-methyl-5alpha-androst-1-ene-3alpha,17beta-diol and 17alpha-methyl-5alpha-androstane-3alpha,17beta-diol. Additionally, the corresponding 17-epimers as well as 17beta-hydroxymethyl-17alpha-methyl-18-nor-5alpha-androsta-1,13-dien-3-one and its 17-epimer were detected, and their elimination kinetics was monitored. It was demonstrated that M1T is a potent anabolic and anabolic steroid after oral and sc administration. Obviously, this substance shows no selective AR modulator characteristics and might exhibit liver toxicity, especially after oral administration [11450].

The pharmaceutical industry has made substantial innovations in the area of targeted drug delivery and optimization of pharmacokinetics for existing drugs to try to maximize therapeutic effect while simultaneously minimizing adverse consequences of medication abuse. These innovations, however, have not come without a price. Designer drugs and high content modified release formulations have been exploited both in casual recreational drug abuse as well as, on a much larger scale, by the criminal diversion of these products for profit. In one paper it was considered the challenges before manufacturers and regulators as they approach the problem of abuse potential of these new drug products and some of the solutions specifically designed to counteract abuse [06123].
Recently several new steroids, specifically synthetised and distributed for misuse in sports, have been detected in urine samples from athletes. The difference between these other steroids is that they have never been marketed neither as a pharmaceutical preparation nor as a “nutritional” supplement. Examples are norbolethone in 2002, tetrahydrogestrinone (THG) in 2003, and desoxymethyltestosterone, madol (17alpha-methyl-5alpha-androst-2-ene-17beta-ol) in 2004 [06004].

By using in silico models of the complexes formed by analogues of a cancer drug and its receptor, it may be possible to strategically redesign existing drugs and win the race against mutations that lead to drug resistance in prostate cancer. In Lewis Carroll's Through the Looking-Glass, the Red Queen reveals to Alice that in her world 'it takes all the running you can do, to keep in the same place. If you want to get somewhere else, you must run at least twice as fast as that!'. The predicament in prostate cancer is much the same: researchers and clinicians alike are forced to keep running merely to stay still, because the receptors targeted by prostate cancer drugs are continually undergoing mutations that prevent the drugs from working. Now, in eLife, Minna Balbas, Charles Sawyers and their colleagues at the Memorial Sloan-Kettering Cancer Center and the University of Chicago may have found a way to run twice as fast, by using a novel approach to redesign drugs to restore their clinical efficacy. Prostate cancer is driven largely by male hormones, otherwise known as androgens, acting through the androgen receptor. Consequently, the majority of cases can be treated by depriving the tumors of androgens: this is achieved by suppressing the production of androgens and by administering antiandrogen drugs, such as flutamide and bicalutamide. By binding to the same site on the receptor as endogenous androgens, these drugs – which are known as receptor antagonists – prevent the hormones from activating the receptor. With time, however – sometimes only a matter of months – the cancer returns in a form resistant to these therapies, termed “castration-resistant prostate cancer”. Resistance can arise through various means, but many cases result from mutation of the androgen receptor. This is because the gene encoding the androgen receptor is on the X chromosome, which means that men have only a single copy and therefore any change in the gene must be expressed in the protein. Over the past few years, Sawyers and collaborators have brought a number of more effective antiandrogens to the clinic, most notably enzalutamide (Enz). This drug binds to the androgen receptor with high affinity and effects a more complete blockade of receptor signaling than earlier drugs, providing significant survival benefit in advanced castration-resistant prostate cancer. Nevertheless, cases of resistance to Enz are being encountered in the clinic. Prostate cancer is poised to enter a new era of personalized health care. The next breakthroughs in therapeutics will occur with an in-depth mechanistic understanding of the events underlying disease progression and the development of resistance. The approach taken by Balbas et al. provides a compelling paradigm for improving the durability of therapies, by strategically redesigning drugs to compensate for resistance arising from mutations in their targets. The same approach could also used to extend the effectiveness of other targeted therapies before resistance arises [13267].

**Tetrahydrogestrinone (THG)**

Tetrahydrogestrinone (THG) is a steroid recently identified to be misused as doping agent. However, the knowledge on functions of this substance in humans or animal models is rather limited. Therefore, it was the aim to further characterize the pharmacological profile of THG and identify potential adverse side effects. THG was synthesized, the purity was confirmed and its biological activity was tested. The potency of THG to transactivate AR dependent reporter gene expression was two orders of magnitude lower compared to dihydrotestosterone. THG binds with high affinity but unselective to the androgen (AR),
progesterone (PR), glucocorticoid (GR) and mineralocorticoid (MR) receptor. Treatment of orchiectomised rats with THG resulted in a stimulation of prostate, seminal vesicle and levator ani muscle, indicating androgenic and anabolic properties. In the liver THG, in contrast to testosteronepropionate (TP), down regulates the expression of the GR dependent tyrosine aminotransferase gene (TAT). In summary, our results demonstrate that THG is not a specific AR agonist. THG exhibits a high binding affinity to all tested steroid hormone receptors and binds with highest affinity to the GR. The in vivo data are indicative of an anabolic and androgenic potency of THG, but the repression of TAT demonstrates that THG also interferes with the glucocorticoid hormone system. Therefore, it is conceivable that an intake will result in adverse side effects [06124].

Tetrahydrogestrinone (18a-homo-pregna-4,9,11-trien-17beta-ol-3-one) was first identified in a syringe that allegedly contained an anabolic steroid undetectable by routine doping control in sports and that was anonymously sent to USADA and the WADA-accredited doping control laboratory in Los Angeles. Although THG was never approved or marketed for any clinical indication it has been demonstrated that it was a potent androgen and progestin. Moreover, THG also binds to glucocorticoid and mineralocorticoid receptors. Interestingly, one of the side-products of the synthesis of THG starting from gestrinone is norbolethone. The detection of THG as a designer steroid caused international commotion and mass media attention, especially because it seemed to have been synthetised to remain undetectable by routine screening methods in WADA accredited doping control laboratories. THG is however detectable using liquid chromatography-tandem mass spectrometry. No in-vivo studies on the metabolism of THG have been performed. In vitro studies, however, indicate that THG is metabolised to 18a-homo-pregna-4,9,11-trien-17beta-ol-3-one and 18a-homo-pregna-4,9,11-trien-17beta,16epsilon-diol-3-one [06004].

The “designer” steroid tetrahydrogestrinone (THG) had been developed by Wyeth in the 1960s and taken to clinical trials as a potential anabolic agent, but never brought to market. It was impossible to locate any records from the clinical trials 40 years after the fact. THG had been shown to have anabolic activity. There were no publications about toxicological studies, but as a 17alpha-methyl steroid, comparison to similar structures strongly suggested the potential for some degree of hepatotoxicity. Based on this information, THG was added to the Prohibited List in 2006 [12006].

In the 1940s and 1950s, many pharmaceutical companies evaluated a myriad of compounds with purported anabolic activity searching for those that had anabolic (at muscle) activity without the more androgenic activities. It was to little avail given that there is but one androgen receptor (AR), albeit with a greater affinity for dihydrotestosterone than for testosterone itself. Arcane testosterone chemistry produced many compounds that had sat on shelves for years without any clinical trials for evaluation for human or veterinary use or commercial promotion. In the future, the concept of selective AR agonists may come to play a much more prominent role. Such compounds may selectively produce the beneficial effects of androgens on musculoskeletal mass and strength without the androgenic adverse events. Clandestine laboratories seeking to make a product to give an edge to athletes began to screen compounds for their anabolic/androgenic activities with the proviso that the compound and its metabolites be invisible to the WADA screening protocol. It appeared quite straightforward to begin with the steroid structure of testosterone, add multiple decorations to the various carbon atoms, test in vitro with various cell lines that contain the AR linked to an objective outcome, for example, AR nuclear translocation or myogenic activity. Then comes the nefarious part: all certified antidoping laboratories have libraries of chromatography/mass spectroscopy (MS)/MS fragments, and each anabolic/androgenic steroid has its own unique signature. The skill is to find a compound active at the AR, but that is not yet in the library. For example tetrahydrogestrinone (THG) had been invisible to the antidoping laboratories
until a sample of pure THG was presented to an antidoping lab. It had been synthesized by an underground laboratory and likely underwent enough testing (in vitro and in vivo) to determine its anabolic/androgenic activity and that it could not be detected by the then extant WADA testing procedure. However, within a week of obtaining that pure sample of THG, the University of California at Los Angeles (UCLA) Olympic Analytic Laboratory was able to devise a test for this compound and its metabolic products. This task was later verified by the synthesis of THG and characterized by MS and nuclear magnetic resonance spectroscopy. The UCLA laboratory developed and verified sensitive and specific methods for the rapid screening of urine samples by liquid chromatography/tandem MS, both in the natural state and with trimethylsilyl ether-oxime derivatives (as is done in the standard antidoping testing procedure). Further proof of the administration of THG was obtained from the urine of baboons injected with authentic THG. To close the loop concerning athletes, further proof of activity was determined in vitro in an AR-mediated myogenic cell line and in vivo by muscle accretion in orchidectomized male rats [12113].

**Digoxin-like effects**

For a long time, athletes have used androgenic anabolic steroids (AASs) in an inappropriate and veiled manner with the aim of improving exercise performance or for cosmetic purposes. Abuse of AASs triggers adverse effects such as hepatocarcinogenesis, heart attacks, and aggressive behavior. However, AAS-induced toxicity is not completely understood at the molecular level. In one study, it was shown, by performing a dioxin response element (DRE)-luciferase reporter gene assay, that tetrahydrogestrinone (THG), a popular and potent androgen receptor agonist, has dioxin-like effects. In addition, we showed that THG increased cytochrome P-450 1A1 (CYP1A1) mRNA and protein levels, and enzyme activity. The gene encoding CYP1A1 is involved in phase 1 xenobiotic metabolism and a target gene of the aryl hydrocarbon receptor (AhR). Using the AhR antagonist CH-223191, we also examined whether the effects of THG on DRE activation depended on AhR. The results suggest that synthetic anabolic steroids may have dioxin-like side effects that can disturb endocrine systems and may cause other side effects including cancer through AhR [12187].

**YK11**

A novel steroid compound, (17alpha,20E)-17,20-[(1-methoxyethylidene)bis(oxy)]-3-oxo-19-norpregna-4,20-diene-21-carboxylic acid methyl ester (YK11), was found to be a partial agonist of the androgen receptor (AR) in an androgen responsive element (ARE)-luciferase reporter assay. YK11 accelerates nuclear translocation of AR. Furthermore, YK11 does not induce amino/carboxyl-terminal (N/C) interaction and prevents 5α-dihydrotestosterone (DHT)-mediated N/C interaction. Thus, YK11 activates AR without causing N/C interaction, which may in turn be responsible for the partially agonistic nature of YK11 observed in the ARE-luciferase reporter system. YK11 acts as a gene-selective agonist of AR in MDA-MB 453 cells. The effect of YK11 on gene expression relative to that of androgen agonist varies depending on the gene context. YK11 activated the reporter gene by inducing the translocation of the AR into the nuclear compartment, where its amino-terminal domain (NTD) functions as a constitutive activator of AR target genes. The results suggest that YK11 might act as selective androgen receptor modulator (SARM) [11062].

**Delta6-methyltestosterone**

Since a few years more and more products have appeared on the market for dietary supplements containing steroids that had never been marketed as approved drugs, mostly without proper labeling of the contents. Syntheses and few data on pharmacological effects are available dated back mainly to the 1950s or 1960s. Only little knowledge exists about
effects and side effects of these steroids in humans. One study reports the identification of delta6-methyltestosterone in a product named "Jungle Warfare", which was obtained from a web-based supplement store. The main urinary metabolites, 17alpha-hydroxy-17beta-methylandrosta-4,6-dien-3-one (delta6-epimethyl-testosterone), 17alpha-methyl-5beta-androstane-3alpha,17beta-diol (3alpha,5beta-THMT), and 17beta-methyl-5beta-androstane-3alpha,17alpha-diol, as well as the parent compound excreted after a single oral administration were monitored by GC-MS/MS. delta6-Epimethyltestosterone and 3alpha,5beta-THMT served for long-term detection (still present in the 181-189 h urine). 17alpha-Methyltestosterone and its 17-epimer were not detected in the urines (LOD 0.3ng/mL). The highest concentrations were found in the 14-20.5h urine for delta6-epimethyltestosterone (600 ng/mL), and 3alpha,5beta-THMT (240 ng/mL) and in the 36-44.5h urine for 17beta-methyl-5beta-androstane-3alpha,17alpha-diol (7 ng/mL). For reference methyltestosterone and epimethyltestosterone were dehydrogenated with chloranil. The characterization of the products was performed by GC-MS/MS and NMR [12188].

Methylstenbolone

The use of "nutritional supplements" containing unapproved substances has become a regular practice in amateur and professional athletes. This represents a dangerous habit for their health once no data about toxicological or pharmacological effects of these supplements are available. Most of them are freely commercialized online and any person can buy them without medical surveillance. Usually, the steroids intentionally added to the "nutritional supplements" are testosterone analogues with some structural modifications. In this study, the analyzed product was bought online and a new anabolic steroid known as methylstenbolone (2,17alpha-dimethyl-17beta-hydroxy-5alpha-androst-1-en-3-one) was detected, as described on label. Generally, anabolic steroids are extensively metabolized, thus in-depth knowledge of their metabolism is mandatory for doping control purposes. For this reason, a human excretion study was carried out with four volunteers after a single oral dose to determine the urinary metabolites of the steroid. Urine samples were submitted to enzymatic hydrolysis of glucuron conjugated metabolites followed by liquid-liquid extraction and analysis of the trimethylsilyl derivates by gas chromatography coupled to tandem mass spectrometry. Mass spectrometric data allowed the proposal of two plausible metabolites: 2,17alpha-dimethyl-16epsilon,17beta-dihydroxy-5alpha-androst-1-en-3-one (S1), 2,17alpha-dimethyl-3alpha,16epsilon,17beta-trihydroxy-5alpha-androst-1-ene (S2). Their electron impact mass spectra are compatible with 16-hydroxylated steroids O-TMS derivatives presenting diagnostic ions such as m/z 231 and m/z 218. These metabolites were detectable after one week post administration while unchanged methylstenbolone was only detectable in a brief period of 45 h [12189].

Methyl-1-testosterone (M1T)

Various products containing rarely characterized anabolic steroids are nowadays marketed as dietary supplements. Herein, the designer steroid methyl-1-testosterone (M1T) (17beta-hydroxy-17alpha-methyl-5alpha-androst-1-en-3-one) was identified, and its biological activity, potential adverse effects, and metabolism were investigated. The affinity of M1T toward the androgen receptor (AR) was tested in vitro using a yeast AR transactivation assay. Its tissue-specific androgenic and anabolic potency and potential adverse effects were studied in a Hershberger assay (sc or oral), and tissue weights and selected molecular markers were investigated. Determination of M1T and its metabolites was performed by gas chromatography mass spectrometry. In the yeast AR transactivation assay, M1T was characterized as potent androgen. In rats, M1T dose-dependently stimulated prostate and
levator ani muscle weight after sc administration. Oral administration had no effect but stimulated proliferation in the prostate and modulated IGF-I and AR expression in the gastrocnemius muscle in a dose-dependent manner. Analysis of tyrosine aminotransferase expression provided evidence for a strong activity of M1T in the liver (much higher after oral administration). In rat urine, 17alpha-methyl-5alpha-androstane-3alpha,17beta-diol, M1T, and a hydroxylated metabolite were identified. In humans, M1T was confirmed in urine in addition to its main metabolites 17alpha-methyl-5alpha-androst-1-ene-3alpha,17beta-diol and 17alpha-methyl-5alpha-androstane-3alpha,17beta-diol. Additionally, the corresponding 17-epimers as well as 17beta-hydroxymethyl-17alpha-methyl-18-nor-5alpha-androsta-1,13-dien-3-one and its 17-epimer were detected, and their elimination kinetics was monitored. It was demonstrated that M1T is a potent androgenic and anabolic steroid after oral and sc administration. Obviously, this substance shows no selective AR modulator characteristics and might exhibit liver toxicity, especially after oral administration [12190].

It has been produced multiple proofs that the designer steroid methyl-1-testosterone (M1T) is an active anabolic/androgenic steroid. They set out to prove this point from the perspective of a multifaceted strategy from the source, the supplement M1T. The mass spectrum of the bis-TMS derivative was determined, followed by a metabolic study in rats in which the same compound and a large number of its metabolites were detected. In vitro activity was determined in a yeast androgen screen with an EC50 consistent with that of the more potent androgen, dihydrotestosterone (3 x 10^-9 M). The compound was strongly anabolic (in a dose-dependent manner) to increase the weight of the prostate, seminal vesicles, and levator ani muscle in orchidectomized rats, according to standard androgen assays in use for more than 60 years. Multiple metabolites were found in the urine of rats and men administered M1T yielding a signature for doping detection in athletes as well as a notion of the kinetics of metabolism and excretion. Assiduously following detailed protocols permitted the attainment of unassailable data to prove that M1T is an anabolic steroid both in vitro and in vivo and to determine a testing procedure that meets WADA standards [12113].

Laboratory techniques

New anabolic steroids show up occasionally in sports doping and in veterinary control. The discovery of these designer steroids is facilitated by findings of illicit preparations, thus allowing bioactivity testing, structure elucidation using NMR and mass spectrometry, and final incorporation in urine testing. However, as long as these preparations remain undiscovered, new designer steroids are not screened for in routine sports doping or veterinary control urine tests since the established GC/MS and LC/MS/MS methods are set up for the monitoring of a few selected ions or MS/MS transitions of known substances only. In one study, the feasibility of androgen bioactivity testing and mass spectrometric identification is being investigated for trace analysis of designer steroids in urine. Following enzymatic deconjugation and a generic solid-phase extraction, the samples are analyzed by gradient LC with effluent splitting toward two identical 96-well fraction collectors. One well plate is used for androgen bioactivity detection using a novel robust yeast reporter gene bioassay yielding a biogram featuring a 20-s time resolution. The bioactive wells direct the identification efforts to the corresponding well numbers in the duplicate plate. These are subjected to high-resolution LC using a short column packed with 1.7-microm C18 material and coupled with electrospray quadrupole time-of-flight mass spectrometry (LC/QTOFMS) with accurate mass measurement. Element compositions are calculated and used to interrogate electronic substance databases. The feasibility of this approach for doping control is demonstrated via the screening of human urine samples spiked with the designer anabolic steroid tetrahydrogestrinone. Application of the proposed methodology, complementary to the established targeted urine screening for known anabolics, will increase the chance of finding unknown emerging designer steroids, rather then being solely dependent on findings
Reductase inhibitors

5alpha-Reductase inhibitors (or 5-alpha-reductase inhibitors) are a group of drugs with antiandrogenic activity, used in the treatment of benign prostatic hyperplasia and androgenic (or androgenetic) alopecia. These drugs decrease the levels of available 5alpha-reductase prior to testosterone’s binding with the enzyme, thus reducing levels of dihydrotestosterone that derives from such a bond. 5alpha-Reductase inhibitors are clinically used in the treatment of conditions that are exacerbated by dihydrotestosterone. These indications may include mild-to-moderate benign prostatic hyperplasia and lower urinary tract symptoms and androgenic (or androgenetic) alopecia. In general, adverse drug reactions are dose-dependent and include impotence, decreased libido, decreased ejaculate volume, depression, and anxiety. In benign prostatic hyperplasia, dihydrotestosterone acts as a potent cellular androgen and promotes prostate growth; therefore, inhibiting the enzyme reduces the excessive prostate growth. In alopecia, male-pattern baldness is one of the effects of androgenic receptor activation. Thus, reducing the levels of dihydrotestosterone reduces alopecia. The aim of one study was to determine the capacity of some progesterone derivatives, to inhibit the conversion of labeled androstenedione to dihydrotestosterone (DHT) in prostate nuclear membrane fractions, where the 5alpha-reductase activity is present. The enzyme 5alpha-reductase catalyzes the 5alpha-reduction of 4-dione whereas the 17beta-hydroxysteroid dehydrogenase catalyzes the transformation of 4-dione to testosterone or 5alpha-dione to dihydrotestosterone (DHT). Moreover, we also investigated the role of unlabeled 5alpha-dione in these pathways. In order to determine the inhibitory effect of different concentrations of the progesterone derivatives in the conversion of 4-dione to DHT, homogenates of human prostate were incubated with 4-dione, NADPH and increasing concentrations of non-labeled 5α-dione. The incubating mixture was extracted and purified using thin layer chromatography. The fraction of the chromatogram corresponding to the standard of DHT was separated and the radioactivity determined. The results showed that the presence of 4-dione plus unlabelled 5alpha-dione produced similar levels of DHT as compared to 4-dione. On the other hand, the results indicated that 17alpha-hydroxyprog-4-ene-3,20-dione 5 and 4-bromo-17alpha-hydroxyprog-4-ene-3,20-dione 7b, were the most potent steroids to inhibit the conversion of 4-dione to DHT, showing IC50 values of 2 and 1.6 nM, respectively [11453].

Finasterid

The increasing use of alpha-reductase inhibitors for treatment of male pattern baldness has led to positive urine samples of athletes for finasteride, the main metabolite. Finasteride is a banned substance listed under S5. Diuretics and masking agents in the doping control regulations. A German football player was suspended by the supreme court of the German Soccer Federation for six months with additional fine after a positive result for finasteride. In this case, the laboratory explicitly used more sensitive analytical methods which could not identify any traces of anabolic steroids in the sample – a finding that is not covered by the World Anti-Doping Code. This case illustrates several critical medicolegal aspects which have to be addressed, including the questions of a psychological disease and the eligibility for a therapeutic use exemption in case of male pattern baldness [06002].

It was presented an unusual case of secondary infertility after prolonged use of low-dose finasteride for androgenetic alopecia in a 40-year-old man. It was detected sperm DNA damage in the patient. Despite such a long-term use, it was observed that impairment in
sperm DNA fragmentation index regressed after the drug was discontinued. Consequently, pregnancy occurred and resulted in live birth [12184].

Finasteride and dutasteride are 5alpha-reductase inhibitors included in the World Anti-Doping Agency's list of banned substances. Two highly sensitive and selective ELISA assays were developed for these compounds. Polyclonal rabbit antibodies were raised using synthesized haptons and other commercial products. The best immunoassay obtained, based on an antibody-coated format, showed a limit of detection of 0.01 microg/L and an IC_{50} of 0.75 microg/L for finasteride (cross-reactivity with dutasteride <4%). The second assay allowed finasteride and dutasteride determination, with limits of detection of 0.013 and 0.021 microg/L, and IC_{50} values 0.18 and 1.18 microg/L, respectively. Both assays were highly selective to a set of anabolic steroids, but they showed 37 percent and 30 percent cross-reactivity with the major urinary metabolite of finasteride, allowing its determination. The developed ELISA had better sensitivity than HPLC/MS/MS method and was applied as a screening technique to quantify dutasteride, finasteride, and its main metabolite in human urine without sample pre-treatment. Moreover, the analysis of dutasteride's excretion urines by ELISA was used to obtain its human excretion rate, essential to improve the analytical strategies about this type of drugs (permitted as medicines and prohibited in sport) and to establish an effective anti-doping policy [10093].

Androgenetic alopecia is the most common form of alopecia in men. MEDLINE, EMBASE, CINAHL, Cochrane Registers, and LILACS were searched for randomized controlled trials reported in any language that evaluated the efficacy and safety of finasteride therapy in comparison to treatment with placebo in adults with androgenetic alopecia. Outcome measures included patient self-assessment, hair count, investigator clinical assessment, global photographic assessment, and adverse effects at short term (≤12 months) and long term (≥24 months). Heterogeneity was explored by testing a priori hypotheses. Twelve studies fulfilled the eligibility criteria (3927 male patients), 10 of which demonstrated a Jadad score of 3 or more. The proportion of patients reporting an improvement in scalp hair was greater with finasteride therapy than with placebo treatment in the short term and in the long term both results were considered to have moderate-quality evidence. The number needed to treat for 1 patient to perceive himself as improved was 5.6 in the short term and 3.4 in the long term. Moderate-quality evidence suggested that finasteride therapy increased the mean hair count from baseline in comparison to placebo treatment, expressed as a percentage of the initial count in each individual, at short term and at long term. Also, the proportion of patients reported as improved by investigator assessment was greater in the short term; number needed to treat, 3.7 (moderate-quality evidence). Moderate-quality evidence suggested an increase in erectile dysfunction and a possible increase in the risk of any sexual disturbances. The risk of discontinuing treatment because of sexual adverse effects was similar to that of placebo. It was concluded that moderate-quality evidence suggests that daily use of oral finasteride increases hair count and improves patient and investigator assessment of hair appearance, while increasing the risk of sexual dysfunction [10458].

Finasteride (FIN), a widely used medication for the treatment of androgen-dependent diseases, blocks the conversion of testosterone to a more potent androgen, dihydrotestosterone (DHT). In this study, we investigated a dosing time-dependent effect and safety of FIN in rats. Androgen receptor (AR) mRNA and nuclear protein levels exhibited clear daily rhythms with the peak during the dark period in the prostate and during the light period in the liver. Repeated oral administration of FIN (5 or 100 mg/kg) at 3 h after lights on (HALO) for 2 weeks decreased serum DHT concentration throughout a 24-h period, whereas the dosing of the agent at 15 HALO decreased its level only transiently even in the higher dose group. FIN caused laboratory abnormalities in the 3 HALO group but not in the 15 HALO group. However, the effect of FIN on the prostate weight was not influenced by the
dosing time. These results suggest that the safety, but not effect, of FIN depends on its
dosing time in rats. The dosing of FIN in the active period might be a rational dosage
regimen, which is needed to be confirmed in human subjects [11105].

5alpha-Reductase inhibitors such as finasteride are prohibited in sports according to the
World Anti-Doping Agency. This class of drugs is used therapeutically to treat benign
prostatic hyperplasia, as well as male baldness, by decreasing 5alpha-reductase activity.
Accordingly, metabolic pathways of endogenous as well as synthetic steroids are influenced,
which complicates the evaluation of steroid profiles in sports drug testing. The possibility of
manipulating steroid excretion profiles and, presumably, to mask steroid abuse was
investigated in 5 administration studies with use of finasteride at different doses, with and
without coadministration of 19-norandrostenedione. The evaluation of urinary steroid profiles
demonstrated the intense effect of finasteride on numerous crucial analytical parameters, in
particular the production of 5alpha-steroids such as androsterone and 5alpha-androstane-3alpha,17beta-diol, which was significantly reduced. In addition, the excretion of the main
metabolite of norandrostenedione, norandrosterone, was significantly suppressed, by up to
84 percent, in elimination studies. For doping-control analysis the use of 5alpha-reductase
inhibitors causes considerable problems because steroid profile parameters, which are
commonly considered stable, are highly affected and complicate the detection of steroid
abuse. In addition, the suppression of production and renal excretion of 5alpha-steroids such
as 19-norandrosterone generated from anabolic agents such as 19-norandrostenedione may
lead to false-negative doping-control results, because urine specimens are reported positive
only when a threshold level of 2 ng/mL is exceeded. Finally, a method for the determination
of the major urinary metabolite of finasteride (carboxy-finasteride) in routine doping-control
screening with use of liquid chromatography-tandem mass spectrometry is described,
allowing the detection of carboxy-finasteride for up to 94 hours in urine specimens collected
after an oral administration of 5 mg of finasteride [07097].

Finasteride (FIN), a widely used medication for the treatment of androgen-dependent
diseases, blocks the conversion of testosterone to a more potent androgen,
dihydrotestosterone (DHT). In one study, it was investigated a dosing time-dependent effect
and safety of FIN in rats. Androgen receptor (AR) mRNA and nuclear protein levels exhibited
clear daily rhythms with the peak during the dark period in the prostate and during the light
period in the liver. Repeated oral administration of FIN (5 or 100 mg/kg) at 3 h after lights on
(HALO) for 2 weeks decreased serum DHT concentration throughout a 24-h period, whereas
the dosing of the agent at 15 HALO decreased its level only transiently even in the higher
dose group. FIN caused laboratory abnormalities in the 3 HALO group but not in the 15
HALO group. However, the effect of FIN on the prostate weight was not influenced by the
dosing time. These results suggest that the safety, but not effect, of FIN depends on its
dosing time in rats. The dosing of FIN in the active period might be a rational dosage
regimen, which is needed to be confirmed in human subjects [11331].

Aromatase inhibitors

Aromatase is the rate-limiting enzyme in estrogen biosynthesis. As a cytochrome P450, it
utilizes electrons from NADPH-cytochrome P450 reductase (CPR) to produce estrogen from
androgen. Estrogen is a key factor in the promotion of hormone-dependent breast cancer
growth. Aromatase inhibitors (AIs) are drugs that block estrogen synthesis, and are widely
used to treat estrogen-dependent breast cancer. Structure-function experiments have been
performed to study how CPR and AIs interact with aromatase to further the understanding of
how these drugs elicit their effects. Studies have revealed a strong interaction between
aromatase and CPR, and that the residue K108 is situated in a region important to the interaction of aromatase with CPR. The published X-ray structure of aromatase indicates that the F221, W224 and M374 residues are located in the active site. The site-directed mutagenesis experiments confirm their importance in the binding of the androgen substrate as well as AIs, but these residues interact differently with steroidal inhibitors (exemestane) and non-steroidal inhibitors (letrozole and anastrozole). Furthermore, the results predict that the residue W224 also participates in the mechanism-based inhibition of exemestane, as time-dependent inhibition is eliminated with mutation on this residue. Together with previous research from our laboratory, the study confirms that W224, E302, D309 and S478 are important active site residues involved in the suicide mechanism of exemestane against aromatase [11335].

Aromatase inhibitors are a rapidly growing class of drugs including both steroidal and nonsteroidal mechanism-based inhibitors. The steroidal agents are mostly androstenedione analogs like testolactone, formestane (Lentaron), exemestane (Aromasin), and atamestane. The nonsteroidal agents are fadrozole, letrozole (Femara), anastrozole (Arimidex), vorozole (Rivizor), and finrazole [06127].

Aromatase inhibitors are a class of drugs used in the treatment of breast cancer and ovarian cancer in postmenopausal women. They may also be used off-label to treat or prevent gynaecomastia in men. Aromatase is the enzyme which synthesizes estrogen. As breast and ovarian cancers require estrogen to grow, AIs are taken to either block the production of estrogen or block the action of estrogen on receptors. Aromatase inhibitors work by inhibiting the action of the enzyme aromatase, which converts androgens into estrogens by a process called aromatization. As breast tissue is stimulated by estrogens, decreasing their production is a way of suppressing recurrence of the breast tumor tissue. The main source of estrogen is the ovaries in premenopausal women, while in post-menopausal women most of the bodies estrogen is produced in the conversion of androgens to estrogen by the aromatase enzyme in peripheral tissues (outside the CNS), and also a few CNS sites in various regions within the brain. Estrogen is produced and acts locally via action of the aromatase enzyme in these tissues, but any circulating estrogen, which exerts systemic estrogenic effects in men and women, is the result of estrogen escaping local metabolism and spreading to the circulatory system.

The purpose of this study was to determine the effects of an alleged aromatase and 5-alpha reductase inhibitor (AI) on strength, body composition, and hormonal profiles in resistance-trained men. Thirty resistance-trained men were randomly assigned in a double-blind manner to ingest 500 mg of either a placebo or AI once per day for 8 wk. Participants participated in a 4-d/wk resistance-training program for 8 wk. At Weeks 0, 4, and 8, body composition, 1-repetition-maximum (1RM) bench press and leg press, muscle endurance, anaerobic power, and hormonal profiles were assessed. Significant Group × Time interaction effects occurred over the 8-wk period for percent body fat, total testosterone, and bioavailable testosterone. Significant main effects for time were noted for bench- and leg-press 1RM, lean body mass, and estradiol. No significant changes were detected among groups for Wingate peak or mean power, total body weight, dihydrotestosterone, hemodynamic variables, or clinical safety data. The authors concluded that 500 mg of daily AI supplementation significantly affected percent body fat, total testosterone, and bioavailable testosterone compared with a placebo in a double-blind fashion [10461].

Exemestane
The representative of aromatase inhibitors referred to as exemestane and particularly its major metabolite 17β-hydroxyexemestane were implemented in routine doping controls using a modified GC-MS-based method [12016].

Exemestane is an irreversible aromatase inhibitor used for anticancer therapy. Unfortunately, this drug is also misused in sports to avoid some adverse effects caused by steroids administration. For this reason exemestane has been included in World Anti-Doping Agency prohibited list. Usually, doping control laboratories monitor prohibited substances through their metabolites, because parent compounds are readily metabolized. Thus metabolism studies of these substances are very important. Metabolism of exemestane in humans is not clearly reported and this drug is detected indirectly through analysis of its only known metabolite: 17β-hydroxyexemestane using liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) and gas chromatography coupled to mass spectrometry (GC-MS). This drug is extensively metabolized to several unknown oxidized metabolites. For this purpose LC-MS/MS has been used to propose new urinary exemestane metabolites, mainly oxidized in C6-exomethylene and simultaneously reduced in 17-keto group. Urine samples from four volunteers obtained after administration of a 25mg dose of exemestane were analyzed separately by LC-MS/MS. Urine samples of each volunteer were hydrolyzed followed by liquid-liquid extraction and injected into a LC-MS/MS system. Three unreported metabolites were detected in all urine samples by LC-MS/MS. The postulated structures of the detected metabolites were based on molecular formulae composition obtained through high accuracy mass determination by liquid chromatography coupled to hybrid quadrupole-time of flight mass spectrometry (LC-QTOF MS) (all mass errors below 2 ppm), electrospray (ESI) product ion spectra and chromatographic behavior [11452].

**Anastrozole and exemestane**

Anastrozole (2,2’-[5-(1H-1,2,4-triazol-1-ylmethyl)-1,3-phenylene]bis(2-methylpropionitrile)) and exemestane (6-methylenandrostan-1,4-diene-3,17-dione) are therapeutically used to treat hormone-sensitive breast cancer in postmenopausal women. For doping purposes they may be used to counteract adverse effects of an extensive abuse of anabolic androgenic steroids (gynaecomastia) and to increase plasma testosterone concentrations. Excretion study urine samples and spot urine samples from women suffering from metastatic breast cancer, being treated with anastrozole or exemestane, were collected and analyzed to develop/optimize a detection system for anastrozole and exemestane to allow the identification of athletes who do not comply with the internationally prohibited use of these cancer drugs. The assay was based on liquid-liquid extraction after enzymatic hydrolysis following liquid chromatography/tandem mass spectrometry (LC/MS/MS). Anastrozole, exemestane and its main metabolite (17-dihydroexemestane) were identified in urine by comparison of mass spectra and retention times with respective reference substances. An assay validation for the analysis of anastrozole and exemestane was performed regarding lower limits of detection (anastrozole: 0.02 ng/mL; exemestane: 3.1 ng/mL; and dihydroexemestane: 0.5 ng/mL) [06128].

**Formestane**

Aromatase is the enzyme that synthesizes estrogen. Aromatase inhibitors (AIs) are a class of drugs used in the treatment of breast cancer and ovarian cancer in postmenopausal women. AIs may also be used off-label to treat or prevent gynaecomastia in men. The aromatase inhibitor formestane (4-hydroxy-androst-4-ene-3,17-dione) is prohibited in sports by the World Anti-Doping Agency (WADA). Formestane possesses only weak androgenic properties and is presumed to be employed in order to suppress estrogen production during
the illicit intake of anabolic steroids by athletes. Former studies additionally showed that formestane is an endogenous steroid produced in low amounts. According to the regulations of WADA, urinary concentrations above 100 ng/mL are assumed to be due to ingestion of formestane. To distinguish between endogenous or exogenous sources of urinary formestane, isotope ratio mass spectrometry (IRMS) is the method of choice. Therefore, a method to determine the carbon isotope ratio (CIR) of formestane in urine samples was developed and validated. Routine samples (n=42) showing concentrations of formestane above 5 ng/mL were investigated and enabled elucidation of the CIR of endogenous formestane and subsequent the calculation of a reference limit. A reference population encompassing (n=90) males and females was investigated regarding endogenous concentrations of formestane. An excretion study with one male volunteer was conducted to test and validate the developed method and to identify possible impact of formestane administration on other endogenous steroids. By CIR determination of formestane it is clearly possible to elucidate its endogenous or exogenous source. Taking into account the CIR of other target analytes like testosterone, a differentiation between formestane and androstenedione intake is possible. In 2011, the first exogenous formestane below the WADA threshold could be detected by means of the developed IRMS method [12196].

**Metabolism of keto and hydroxy steroids**

4-OH-androstenedione (formastane)

4-Hydroxy-androst-4-ene-3,17-dione (formestane) is an aromatase inhibitor and has shown anti-tumour activity in post-menopausal cancer. It is prohibited in sports by WADA and classified as an anti-estrogenic agent, and intensively subjected to phase I metabolism. Among the major identified metabolites are 4-hydroxy-testosterone, 3,17-dihydroxy-androstan-4-ones; 3alpha,4beta-dihydroxy-5alpha-androstane-17-one, 3beta,4beta-dihydroxy-5alpha-androstane-17-one, 4beta-hydroxy-5alpha-androstan-3,17-dione and 3beta-hydroxy-5alpha-androstan-4,17-dione. Formestane itself was also identified as a metabolite of androst-4-ene-3,17-dione [06004].

4-OH-testosterone

4-Hydroxy-testosterone (17beta,4-dihydroxy-4-androstene-3-one) is a steroid sold as a nutritional supplement in the United States (Testobol®) and regarded as a prohibited substance by WADA. This substance is excreted as the parent compound as well as 4-hydroxy-androst-4-ene-3,17-dione [06004].

6-Oxo-androstenedione

6-Oxo-androstenedione (androst-4-ene-3,6,17-trione) is marketed as an aromatase inhibitor and sold as a nutritional supplement. Analysis of urine samples collected after administration of 6-oxo-androstenedione resulted in the detection of the parent compound, 6alpha-OH-testosterone (minor metabolite), 6alpha-OH-etiocholanolone and 6alpha-OH-androstenedione (major metabolites). The parent compound was excreted 88 percent glucuronidated and the other metabolites were exclusively excreted as glucuronides [06004].

7-Keto-dehydroepiandrosterone

7-Keto-dehydroepiandrosterone has been characterized as a metabolite of dehydroepiandrosterone in in vitro studies and was detected in human urine samples. 7-Keto-dehydroepiandrosterone and 3-acetyl-7-keto-dehydroepiandrosterone have been marketed as nutritional supplements as part of a replacement therapy to increase androgen concentrations and improve the feeling of well being in males and females of advanced age. In vivo, 7-keto-dehydroepiandrosterone and 3-acetyl-7-keto-dehydroepiandrosterone are
metabolised to 7beta-hydroxy-epiandrosterone and 7alpha-hydroxy-epiandrosterone. Additionally, elevated concentrations of 7-keto-dehydroepiandrosterone and 7-keto-androsterone as well as 7epsilon-hydroxy-androstenedione were also found [06004].

**Oxabolone**

Oxabolone (4,17beta-dihydroxyestr-4-en-3-one cyclopentylpropionate) is a cyclopentylpropionate ester of 4-hydroxy-19-nortestosterone. The myotropic:androgenic dissociation of the unesterified steroid is 4.5, but with a smaller duration of activity than the esterified analogue, which has a myotropic:androgenic dissociation of 6.0. The main metabolite of 4-hydroxy-nortestosterone has been identified as 4-hydroxy-norandrostenedione (4-hydroxy-estr-4-ene-3,17-dione). Besides this major metabolite and 4-hydroxy-19-nortestosterone, several other metabolites including 4-hydroxy-estra 3,17-dione, 3alpha,4-dihydroxy-5alpha-androstan-17-one, 3alpha,4-dihydroxy-5beta-estran-17-one and 3beta,4-dihydroxy-5alpha-estran-17-one were detected [06004].

**Testolactone**

Testolactone (D-homo-17alpha-oxa-androsta-1,4-diene-3,17-dione) a prohibited substance according to the International Olympic Committee in the class of anabolic steroids. However, evidence of its anabolic activity is lacking and under the current WADA-regulations testolactone is classified as an aromatase inhibitor. The A-ring of testolactone is particularly subjected to intensive metabolism and several metabolites have been identified of which 4,5-dihydrotestolactone seems to be the most prominent one [06004].

**Dehydrogenase inhibitor**

All redox reactions take place in the extramembranous portion of NADH dehydrogenase. NADH initially binds to NADH dehydrogenase, and transfers two electrons to the flavin mononucleotide (FMN) prosthetic group of complex I, creating FMNH2. The electron acceptor – the isoalloxazine ring – of FMN is identical to that of FAD. The electrons are then transferred through the second prosthetic group of NADH dehydrogenase via a series of iron-sulfur (Fe-S) clusters, and finally to coenzyme Q (ubiquinone). Despite more than 50 years of study of NADH dehydrogenase, no inhibitors blocking the electron flow inside the enzyme have been found. Hydrophobic inhibitors like rotenone or piericidin most likely disrupt the electron transfer between the terminal FeS cluster N2 and ubiquinone. It has been shown that long-term systemic inhibition of complex I by rotenone can induce selective degeneration of dopaminergic neurons. NADH dehydrogenase is also blocked by adenosine diphosphate ribose – a reversible competitive inhibitor of NADH oxidation by binding to the enzyme at the nucleotide binding site. Both hydrophyllic NADH and hydrophobic ubiquinone analogs act at the beginning and the end of the internal electron-transport pathway, respectively. 17beta-Hydroxysteroid dehydrogenase type 2 (17beta-HSD2) catalyzes the oxidation of the highly potent steroids: the estrogen estradiol (E2) and the androgen testosterone (T) to the less active estrone and androstenedione, respectively. Inhibition of this enzyme may help maintain the local E2 level in bone tissue when the circulating E2 level drops and is therefore a novel and promising approach for the treatment of osteoporosis. In this work, a series of new nonsteroidal and achiral 17beta-HSD2 inhibitors, namely N-benzyl-diphenyl-3(or 4)-carboxamide and N-benzyl-5-phenyl-thiophene-2-carboxamide was designed and the compounds were synthesized in a two to three steps reaction. A small library was built applying parallel synthesis. Highly potent 17beta-HSD2 inhibitors could be identified in the thiophene-2-carboxamide class with IC50 in the low nanomolar range. These compounds also showed a good selectivity profile toward 17beta-HSD1 and toward the estrogen receptors alpha and beta. The most interesting 17beta-HSD2 inhibitor identified in
this study is the 5-(2-fluoro-3-methoxyphenyl)-N-(3-hydroxybenzyl)-N-methylthiophene-2-carboxamide 6 week displaying an IC$_{50}$ of 61 nM and a selectivity factor of 73 toward 17beta-HSD1 [11454].

**Transsexuality**

Sex segregation in competitive sports is regarded as fair. Before puberty boys and girls do not differ in height, muscle and bone mass. Testosterone exposure during puberty leads to an ultimate average greater height in men of 12-15 cm, longer and larger bones and muscle mass and strength and higher hemoglobin levels. Postpubertal androgen ablation reverses, at least in part, previous anabolic effects of testosterone on muscle, bone mineral density and hemoglobin but the long bones remain longer and wider. Testosterone administration dose dependently increases muscle mass and maximal voluntary strength. Therefore, exogenous androgens, being performance enhancing drugs, are banned for all athletes. An issue is the participation in competitive sports of people with errors of sexual differentiation and particularly transsexuals who have been sex-reassigned. In view of the effects of testosterone a clear demarcation is whether sex reassignment has taken place before or after hormonal puberty. Pubertal effects of testosterone are in part reversible but there is no reliable evidence as to its completeness. The International Olympic Committee (IOC) has taken an inevitably arbitrary decision with regard to participation of sex-reassigned transsexuals in elite sports: sex reassignment must have taken place at least two years earlier, hormone treatment must be appropriate for the reassigned sex and the reassigned sex must be legally recognized. The IOC policy is not binding for other organisations [08155].
SELECTIVE ANDROGEN RECEPTOR MODULATOR (SARM)

The elucidation of the metabolism of new therapeutics is a major task for pharmaceutical companies and of great interest for drug testing laboratories. The latter in particular need to determine the presence or absence of drugs or their metabolic products in urine to test for a misuse of these compounds. Commonly, in vitro or animal models are used to mimic the human metabolism and produce potential targets in amounts allowing for method development. Selective androgen receptor modulators (SARMs) have become a major field of clinical research enabling the tissue-selective stimulation of androgen receptors. The treatment of debilitating diseases, osteoporosis and frailty are primary goals and promising results have been obtained from clinical trials.

Androgen receptor (AR) plays a critical role in the function of several organs including primary and accessory sexual organs, skeletal muscle, and bone, making it a desirable therapeutic target. Selective androgen receptor modulators (SARMs) bind to the AR and demonstrate osteo- and myo-anabolic activity; however, unlike testosterone and other anabolic steroids, these nonsteroidal agents produce less of a growth effect on prostate and other secondary sexual organs. SARMs provide therapeutic opportunities in a variety of diseases, including muscle wasting associated with burns, cancer, or end-stage renal disease, osteoporosis, frailty, and hypogonadism [08196].

The selective androgen receptor modulators represent a novel class of drugs with tissue-specific agonistic and antagonistic properties, but are prohibited in sports from January 2008 according to the World Anti-Doping Agency. Preventive approaches to restrict the use of SARMs include early implementation of target analytes into doping control screening assays. Five model SARMs were synthesized, four of which are analogs to prostate-specific androgen receptor antagonists with a 5,6-dichloro-benzimidazole nucleus. The fifth SARM is a muscle-tissue specific agonist with a bicyclic hydantoin structure (BMS-564929). Dissociation pathways after negative electrospray ionization were studied using an LTQ-Orbitrap mass analyzer, and diagnostic product ions and common fragmentation patterns were employed to establish a screening procedure that target the intact SARMs as well as putative metabolic products. Sample preparation based on solid-phase extraction and subsequent LC-MS/MS measurement allowed for detection limits of 1-20 ng/mL, intra- and interday precisions of between 2.4 and 13.2 percent and between 6.5 and 24.2 percent, respectively. Recoveries varied from 89 to 106 percent, and tests for ion suppression or enhancement effects were negative for all analytes [08197].

Nonsteroidal selective androgen receptor modulators (SARMs) are an emerging class of drugs for treatment of various diseases including osteoporosis and muscle wasting as well as the correction of age-related functional decline such as muscle strength and power. Several SARMs, which have advanced to preclinical and clinical trials, are composed of diverse chemical structures including arylpropionamide-, bicyclic hydantoin-, quinoline-, and tetrahydroquinoline-derived nuclei. Since January 2008, SARMs have been categorized as anabolic agents and prohibited WADA. Suitable detection methods for these low-molecular weight drugs were based on mass spectrometric approaches, which necessitated the elucidation of dissociation pathways in order to characterize and identify the target analytes in doping control samples as well as potential metabolic products and synthetic analogs. Fragmentation patterns of representatives of each category of SARMs after electrospray ionization and collision-induced dissociation (CID) as well as electron ionization (EI) have been discussed The complexity and structural heterogeneity of these drugs is a daunting challenge for detection methods [08198].
Androgen receptor (AR) ligands are important for the development and function of several tissues and organs. However, the poor oral bioavailability, pharmacokinetic properties, and receptor cross-reactivity of testosterone, coupled with side effects, place limits on its clinical use. Selective AR modulators (SARMs) elicit anabolic effects in muscle and bone, sparing reproductive organs like the prostate. However, molecular mechanisms underlying the tissue selectivity remain ambiguous. It was performed a variety of in vitro studies to compare and define the molecular mechanisms of an aryl propionamide SARM, S-22, as compared with dihydrotestosterone (DHT). Studies indicated that S-22 increased levator ani muscle weight but decreased the size of prostate in rats. Analysis of the upstream intracellular signaling events indicated that S-22 and DHT mediated their actions through distinct pathways. Modulation of these pathways altered the recruitment of AR and its cofactors to the PSA enhancer in a ligand-dependent fashion. These studies reveal novel differences in the molecular mechanisms by which S-22, a nonsteroidal SARM, and DHT mediate their pharmacological effects [08199].

Selective androgen receptor modulators represent an emerging class of therapeutics to counteract various diseases such as osteoporosis and muscle wasting. Numerous drug candidates have been developed and investigated including a group that comprises a tricyclic tetrahydroquinoline nucleus such as 2-methyl-2-(8-nitro-3a,4,5,9b-tetrahydro-3H-cyclopenta[c]chinolin-4-yl)propan-1-ol. Due to their novelty and medicinal purpose, these compounds also possess great potential for misuse in sports, and studies on the mass spectrometric behavior of three synthesized model substances and drug candidates were conducted to provide information on typical dissociation pathways following electrospray ionization and collision-induced dissociation. Product ion mass spectra derived from protonated molecules were studied using high resolution/high accuracy orbitrap mass spectrometry, and characteristic fragmentation routes and product ions were elucidated. Major and general findings include the elimination of a hydroxyl radical from [M+H](+)+, the elimination of the 2-substituted side chain, and the gas-phase rearrangement of the investigated tricyclic tetrahydroquinolines to 6-nitroquinoline yielding a common product ion at m/z 175. Knowledge of these dissociation pathways supports the identification of related substances as well as metabolic products, which is of utmost importance to drug testing laboratories. The compounds were implemented into existing screening procedures, and detection limits (0.2-0.6 ng/mL), recoveries (92-97 %), and intraday and interday precision (<22 %) have been evaluated [08200].

The potential for misuse of SARMs in sport is great and drug testing methods based on liquid chromatography were established for different classes including arylpropionamide-, 2quinolinone- and bicyclic hydantoin-derived compounds. As gas chromatography and mass spectrometry (GC-MS) are still important analytical tools in sports drug testing, a method to determine 2-quinolinone- and bicyclic hydantoin-derived SARMs established. Spiked urine samples were subjected to routine doping control protocols including enzymatic hydrolysis, liquid-liquid extraction, concentration and derivatisation to trimethylsilylated analogues followed by GC-MS analysis. The method was validated for the items specificity, lower limit of detection (0.2-10 ng/mL), recovery (83-85 %), intraday and interday precision (9-15 % and 13-18 %, respectively), which demonstrates the suitability of conventional GC-MS systems to determine representatives of an emerging class of compounds in doping control specimens [08201].

Anabolic hormones, including testosterone, have been suggested as a therapy for aging-related conditions, such as osteoporosis and sarcopenia. These therapies are sometimes associated with severe androgenic side effects. The past decade has witnessed an unprecedented discovery effort to develop selective androgen receptor modulators (SARMs)
that improve physical function and bone health without adversely affecting the prostate and cardiovascular outcomes. SARMs have the potential to mimic the desirable central and peripheral androgenic anabolic effects of testosterone without having its side effects. In this study we evaluated the effects of LGD2941, in comparison to testosterone, on mRNA expression of selected target genes in whole blood in an non-human model. The regulated genes can act as potential blood biomarker candidates in future studies with androgen receptor ligands. Cynomolgus monkeys (Macaca fascicularis) were treated either with testosterone or LGD2941 for 90 days in order to compare their effects on mRNA expression in blood. Blood samples were taken before SARM application, on day 16 and on day 90 of treatment. Gene expression of 37 candidate genes was measured using quantitative real-time RT-PCR (qRT-PCR) technology. Our study shows that both testosterone and LGD2941 influence mRNA expression of 6 selected genes out of 37 in whole blood. The apoptosis regulators CD30L, Fas, TNFR1 and TNFR2 and the interleukins IL-12B and IL-15 showed significant changes in gene expression between control and the treatment groups and represent potential biomarkers for androgen receptor ligands in whole blood [09143].

One review described the historical evolution, the rationale for SARM development, and the mechanisms of testosterone action and SARM selectivity. Although steroidal SARMs have been around since the 1940s, a number of nonsteroidal SARMs that do not serve as substrates for CYP19 aromatase or 5alpha-reductase, act as full agonists in muscle and bone and as partial agonists in prostate are in development. The differing interactions of steroidal and nonsteroidal compounds with androgen receptor (AR) contribute to their unique pharmacologic actions. Ligand binding induces specific conformational changes in the ligand-binding domain, which could modulate surface topology and protein-protein interactions between AR and coregulators, resulting in tissue-specific gene regulation. Preclinical studies have demonstrated the ability of SARMs to increase muscle and bone mass in preclinical rodent models with varying degree of prostate sparing. Phase I trials of SARMs in humans have reported modest increments in fat-free mass [09144].

It was described the discovery of ACP-105 (1), a novel and potent nonsteroidal selective androgen receptor modulator (SARM) with partial agonist activity relative to the natural androgen testosterone. Compound 1 was developed from a series of compounds found in a HTS screen using the receptor selection and amplification technology (R-SAT). In vivo, 1 improved anabolic parameters in a 2-week chronic study in castrated male rats. In addition to compound 1, a number of potent antiandrogens were discovered from the same series of compounds whereof one compound, 13, had antagonist activity at the AR T877A mutant involved in prostate cancer [09145].

Hundreds of steroidal analogs have been prepared with a superior oral bioavailability, which should also possess reduced undesirable effects. However, only a few entered the pharmaceutical market due to severe toxicological incidences that were mainly attributed to the lack of tissue selectivity. Prominent representatives of anabolic-androgenic steroids (AAS) are for instance methyltestosterone, metandienone and stanozolol, which are discussed as model compounds with regard to general pharmacological aspects of synthetic AAS. Recently, nonsteroidal alternatives to AAS have been developed that selectively activate the androgen receptor in either muscle tissue or bones. These so-called selective androgen receptor modulators (SARMs) are currently undergoing late clinical trials (IIb) and were prohibited by the World Anti-Doping Agency from January 2008. Their entirely synthetic structures are barely related to steroids, but particular functional groups allow for the tissue-selective activation or inhibition of androgen receptors and, thus, the stimulation of muscle growth without the risk of severe undesirable effects commonly observed in steroid replacement therapies. Hence, these compounds possess a high potential for misuse in sports and will be the subject of future doping control assays [10097].
Selective androgen receptor modulators (SARMs) are potent anabolic agents with tissue-selective properties. Due to their potential misuse in elite sport, the World Anti-Doping Agency (WADA) has prohibited SARMs since 2008, and although no representative drug candidate has yet received full clinical approval, recent findings of SARMs illegally sold via the internet have further supported the need to efficiently test for these compounds in doping controls. In one communication, the mass spectrometric characterization of urinary metabolites of the SARM Andarine (also referred to as S-4) compared with earlier in vitro and animal studies is reported. Liquid chromatography interfaced to high-resolution/high-accuracy (tandem) mass spectrometry was used to identify phase I and II metabolites, confirming the predicted target analytes for sports drug testing purposes including the glucuronic acid conjugates of the active drug, its monohydroxylated and/or deacetylated product, the hydrolysis product resulting from the removal of the compound’s B-ring, as well as the sulfate of the monohydroxylated and the deacetylated phase I metabolite. The obtained data will support future efforts to effectively screen for and confirm the misuse of the non-approved drug candidate Andarine [10348].

Glucocorticoids are the most widely used antiinflammatory drugs in the world. However, prolonged use of glucocorticoids results in undesirable side effects such as muscle wasting, osteoporosis, and diabetes. Skeletal muscle wasting, which currently has no approved therapy, is a debilitating condition resulting from either reduced muscle protein synthesis or increased degradation. The imbalance in protein synthesis could occur from increased expression and function of muscle-specific ubiquitin ligases, muscle atrophy F-box (MAFbx)/atrogen-1 and muscle ring finger 1 (MuRF1), or decreased function of the IGF-I and phosphatidylinositol-3 kinase/Akt kinase pathways. It was examined the effects of a nonsteroidal tissue selective androgen receptor modulator (SARM) and testosterone on glucocorticoid-induced muscle atrophy and castration-induced muscle atrophy. The SARM and testosterone propionate blocked the dexamethasone-induced dephosphorylation of Akt and other proteins involved in protein synthesis, including Forkhead box O (FoxO). Dexamethasone caused a significant up-regulation in the expression of ubiquitin ligases, but testosterone propionate and SARM administration blocked this effect by phosphorylating FoxO. Castration induced rapid myopathy of the levator ani muscle, accompanied by up-regulation of muscle atrophy F-box and muscle ring finger 1 and down-regulation of IGF-I, all of which was attenuated by a SARM. The results suggest that levator ani atrophy caused by hypogonadism may be the result of loss of IGF-I stimulation, whereas that caused by glucocorticoid treatment relies almost solely on up-regulation of muscle atrophy F-box and muscle ring finger 1. The studies provide the first evidence that glucocorticoid- and hypogonadism-induced muscle atrophy are mediated by distinct but overlapping mechanisms and that SARMs may provide a more effective and selective pharmacological approach to prevent glucocorticoid-induced muscle loss than steroidal androgen therapy [10349].

An alternative route based on electrochemical reactions of drugs was reported to allow for the generation of selected metabolites. The utility of this approach for doping control purposes was demonstrated with a novel class of anabolic agents termed selective androgen receptor modulators (SARMs). An arylpropionamide- derived drug candidate was subjected to electrochemical "metabolism" and a major phase-I- metabolite, resulting from the elimination of a substituted phenol residue as identified in in vitro experiments, was generated and characterised using liquid chromatography/nuclear magnetic resonance spectroscopy and high resolution/high accuracy mass spectrometry. The metabolite was included in routine doping control procedures based on liquid chromatography/tandem mass spectrometry and has served as a reference compound for 5000 doping control specimens [08202].
Selective androgen receptor modulators (SARMs) represent an emerging class of drugs likely to be abused in sport. For clinical applications, these substances provide a promising alternative to testosterone-replacement therapies and their advantages include oral bioavailability, androgen receptor specificity, tissue selectivity, and the absence of steroid-related side effects. Although not yet commercially available, since January 2008 SARMs have been included on the prohibited list issued yearly by the World Anti-Doping Agency (WADA), so control laboratories need to update their procedures to detect either the parent drugs or their metabolites. Within this context, two quinolinone SARM models were synthesized and automatically characterized to update the existing routine screening procedures. The conditions for the new target analytes are compatible with the existing laboratory protocols used for both in-competition and out-of-competition controls and can be included in them. Validation parameters according to ISO 17025 and WADA guidelines were successfully determined. For analytical determinations, spiked urine samples were hydrolyzed and extracted at pH 9.6 with 10 mL of tert-butyl methyl ether. Then, the analytes were subsequently converted into trimethylsilyl derivatives and detected by gas chromatography-mass spectrometry. The absence of interferents, together with excellent repeatability of both retention times and the relative abundances of diagnostic ions, allowed proper identification of all SARM analytes. The analytes' quantification was linear up to 500 ng/mL and precision criteria were satisfied (coefficient of variation less than 25 percent at 10 ng/mL). The limits of detection were 1 ng/mL for both SARMs, whereas recovery values were between 96 and 99 percent. The validated method can be efficiently used for urine screening of the 2-quinolinone-derived SARMs tested [11111].

Selective androgen receptor modulators (SARM) are a prominent group of compounds for being misused in sports owing to their advantageous anabolic properties and reduced side effects. To target the preventive doping control analysis in relevant compounds, the challenge is to predict the metabolic fate of a new compound. For aryl-propionamide-derived SARM, an in vitro assay employing microsomal and S9 human liver enzymes was developed to simulate phase-I and phase-II metabolic reactions. In vitro metabolic profiles and the structure-metabolic relationship were compared between four structurally modified substrates. Accurate mass measurements were used to characterize the synthesized metabolites, and also collision-induced dissociation was examined to suggest the methodological approach to monitor the prohibited use of aryl-propionamide-derived drug candidates. Subsequent phase-I and phase-II metabolic reactions were successfully combined in one in vitro assay. The main routes of phase-I modifications involved the hydrolysis of ether linkage, monohydroxylation, and hydrolytic cleavage of the amide bond. Nitro-reduction and deacetylation were reactions observed for substrates possessing the corresponding functionality. SARM metabolites were analyzed in negative ion electrospray ionization and detected as deprotonated species [M-H](−). The main metabolic modifications were observed to occur in the B-ring side, and collision-induced dissociation resulted in the product ions originating from the A-ring side of the compound. These structure-specific ions may be monitored as target ions in the routine doping control [07099].

New anabolic agents termed selective androgen receptor modulators (SARMs) have a structural diversity (they encompass at least six chemical categories). It has necessitated the extension of doping control assays through the introduction of new target analytes as well as precursor ion scanning in order to make sure that this emerging class of drugs is comprehensively screened for. Detection assays for arylpropionamide-derived SARMs were reported for between 1 and 50 ng per mL of urine. Screening assays are of particular importance in doping controls, as they provide the information necessary to consider a sample suspicious for drug abuse. They have been updated and extended frequently based on new requirements as well as new findings, such as additional long-term metabolites for
improved retrospectives, as recently reported for methandienone. However, the requirements of obligatory confirmation analyses are strict and have also led to the development of alternative sample preparation procedures for LC-MS/MS measurements that are specifically optimized for just a few analytes [07050].

Selective androgen receptor modulators (SARMs) represent a class of emerging drugs with high potential for misuse in sports, and therefore members of this group are banned as anabolic agents by the World Anti-Doping Agency. Preventive approaches to restrict their use include early implementation of target analytes into doping control screening assays and evaluation of the mass spectrometric behavior of these drugs to allow their unequivocal identification as well as the characterization of structurally related compounds and metabolic products. Four model SARMs with the 6-alkylamino-2-quinolinone structure, including the advanced drug candidate LGD-2226, were synthesized. Fragmentation pathways after positive electrospray ionization and collision-induced dissociation were studied using an LTQ Orbitrap mass analyzer, and diagnostic product ions and common dissociation pathways were employed to establish a screening procedure targeting intact quinolinone-based SARMs as well as putative metabolic products such as dealkylated analogues. Therefore, features of a triple quadrupole mass analyzer such as multiple reaction monitoring and precursor ion scanning were utilized. Sample preparation based on commonly employed liquid-liquid extraction and subsequent liquid chromatographic/tandem mass spectrometric measurement allowed for detection limits of 0.01-0.2 ng/mL, and intra- and interday precisions between 3.2 and 8.5 percent and between 6.3 and 16.6 percent, respectively. Recoveries varied from 81 to 98 percent, and tests for ion suppression or enhancement effects were negative for all analytes [07100].

Selective androgen receptor modulators (SARMs) bind to the androgen receptor and demonstrate anabolic activity in a variety of tissues; however, unlike testosterone and other anabolic steroids, these nonsteroidal agents are able to induce bone and muscle growth, as well as shrinking the prostate. The potential of SARMS is to maximise the positive attributes of steroidal androgens as well as minimising negative effects, thus providing therapeutic opportunities in a variety of diseases, including muscle wasting associated with burns, cancer, end-stage renal disease, osteoporosis, frailty and hypogonadism. One review summarised androgen physiology, the current status of SARMS and potential therapeutic indications for this emerging class of drugs [06129].

The androgen receptor mediates the androgenic and anabolic activity of the endogenous steroids testosterone and 5alpha-dihydrotestosterone. Current knowledge of the androgen receptor protein structure, and the molecular mechanisms surrounding the binding properties and activities of agonists and antagonists has led to the design and development of novel nonsteroidal ligands with selected tissue-specific androgen receptor agonist and antagonist activities. The activity of these compounds, termed selective androgen receptor modulators (SARMs), is directed toward the maintenance or enhancement of anabolic effects on bone and muscle with minimal androgenic effects on prostate growth. SARMs are of potential therapeutic value in the treatment of male hypogonadism, osteoporosis, frailty and muscle wasting, burn injury and wound healing, anemia, mood and depression, benign prostatic hyperplasia and prostate cancer [06130].

Among the class of non-steroidal anabolic agents, selective androgen receptor modulators (SARMs) were studied regarding their in vitro as well as in vivo metabolism. The urgency of these studies was underlined by reports demonstrating once more the easy availability of authentic SARMs via Internet-based suppliers despite the fact that SARMs have not yet received clinical approval [12016].
Anabolic agents have been top-ranked for many years among statistics of adverse analytical findings compiled by the World Anti-Doping Agency (WADA). Besides archetypical anabolic-androgenic steroids (AAS), alternative substances with similar effects concerning bone and muscle anabolism have been therapeutically pursued. A prominent emerging class of drugs is the chemically heterogeneous group of selective androgen receptor modulators (SARMs), some of which have been detected in doping control samples between 2009 and 2012 despite missing clinical approval. In order to support the momentum of expanding the preventive and proactive measures among anti-doping laboratories, the analytical characterization of substances with misuse potential is of great importance. In the present study, the SARM drug candidates RAD140 (comprising a 5-phenyloxadiazole nucleus) and ACP-105 (bearing an N-substituted tropanol pharmacophore) were studied regarding their mass spectrometric behavior under ESI-MS(ESI/MS) and EI-MS(ESI/MS) conditions. Reference material was synthesized according to established protocols and dissociation pathways of RAD140 and ACP-105 were elucidated with liquid chromatography/electrospray ionization quadrupole/time-of-flight or iontrap/orbitrap and gas chromatography/electron ionization quadrupole/time-of-flight high resolution/high accuracy mass spectrometry. Fragmentation pathways to diagnostic product ions of RAD140 (e.g., m/z 223 and 205 using ESI-MS/MS and m/z 421 and 349 using EI-MS/MS) and ACP-105 (such as m/z 233 and 193 or 231 and 217 for ESI-MS/MS and EI-MS/MS measurements, respectively) were proposed as substantiated by determined elemental compositions and MS(n) experiments as well as comparison to spectra of a structural analog. Notably, for the formation of the characteristic fragment ion at m/z 421 of RAD140, the comparably seldom intramolecular migration of a trimethylsilyl residue triggered by electron ionization was suggested as corroborated by all of the above-mentioned analytical means. The obtained data will support future sports drug testing methods and facilitate and accelerate the implementation of this analyte and related compounds or metabolites in both GC/MS(ESI/MS) and LC/MS(ESI/MS)-based routine doping control procedures [13268].
compounds or metabolites in both GC/MS/(MS)- and LC/MS/(MS)-based routine doping control procedures [13269].

It was concluded that the obtained data will support future sports drug testing methods and facilitate and accelerate the implementation of this analyte and related compounds or metabolites in both GC/MS/(MS)- and LC/MS/(MS)-based routine doping control procedures [13270].

Background

Androgens are essential for male development and the maintenance of male secondary characteristics, such as bone mass, muscle mass, body composition, and spermatogenesis. Testosterone and structurally related anabolic steroids have been used to treat hypogonadism, muscle wasting, osteoporosis, cancer cachexia, and anemia, and been used for male contraception, and hormone replacement therapy in aging men or age-related frailty; while antiandrogens may be useful for treatment of conditions like acne, alopecia (male-pattern baldness), hirsutism, benign prostatic hyperplasia (BPH) and prostate cancer. However, the clinical application of the steroidal AR ligands has been limited by poor oral bioavailability, potential hepatotoxicity, lack of tissue selectivity, and occasionally, cross reaction with other steroid receptors. Also, structural modification of the steroidal ligands is somewhat limited by the steroid skeleton. Therefore, nonsteroidal AR ligands with improved pharmacological and pharmacokinetic properties have been developed to overcome these problems. The known AR ligands can be classified as steroidal or nonsteroidal based on the structure or as agonist and antagonist (antiandrogen) based on their ability to activate or inhibit transcription of AR target genes. Endogenous androgens, including testosterone and dihydrotestosterone (DHT), are steroidal agonists. Structural modifications of the endogenous steroids led to the development of various synthetic steroids, including agonists and antagonists. Nonsteroidal ligands were also proposed to achieve high AR specificity,
improved oral bioavailability, improved tissue selectivity, and more flexible structural modifications. Nonsteroidal AR ligands with improved pharmacological and pharmacokinetic properties have been developed to overcome these problems. One review focused on the pharmacokinetics, metabolism, and pharmacology of clinically used and emerging nonsteroidal AR ligands, including antagonists, agonists, and selective androgen receptor modulators [06049].

**Steroidal ligands and their clinical applications**

Testosterone and DHT are endogenous androgens. There are three modes of action of testosterone. It may directly act through AR in target tissues where 5alpha-reductase is not expressed, be converted to 5alpha-DHT (5-10 %) by 5alpha-reductase before binding to AR, or be aromatized to estrogen (0.2 %) and act through the estrogen receptor. DHT binds to AR with higher affinity, and has two to ten fold higher potency than testosterone in androgen-responsive tissues. On the other hand, estrogen plays a major role in regulating metabolic processes, mood and cognition, cardiovascular disease, sexual function including libido, and bone turnover in men. Testosterone is the major androgen that acts in FDHT-independent tissues, such as skeletal muscle, where 5alpha-reductase is not expressed or expressed at a very low level and it directly regulates skeletal muscle growth, bone formation, fat distribution, and sexual function. Following oral administration, the plasma half life of testosterone is less than 30 min, due to extensive metabolism. Approximately 90 percent of an oral dose of testosterone is metabolized before it reaches the systemic circulation. To improve the bioavailability, most of the testosterone preparations are delivered through transdermal patch or intramuscular injections. Alkylation or esterification at the 17 position was widely used in structural modification of the steroid skeleton to markedly slow down the hepatic metabolism and increase the oral bioavailability or duration of testosterone action. However, 17alpha-alkylated steroidal androgens are more likely to cause hepatotoxicity, the most serious side effect of the synthetic steroids. On the other hand, complete separation of androgenic and anabolic activity has not been accomplished with synthetic steroids. The androgenic activities of the synthetic steroids often cause undesirable side effects during therapy. Due to the structural similarity in the steroid skeleton, steroidal AR ligands also tend to cross react with other steroid receptors, which is also associated with adverse effects (i.e. gynecomastia) [06049].

Classically, testosterone is used to treat male hypogonadism, protein wasting diseases associated with cancer, burns, traumas, or Acquired Immunodeficiency Syndrome (AIDS), anemia secondary to chronic renal failure, aplastic anemia, hereditary angioedema, or as a component of hormonal male contraception. Recently, hormone replacement therapy (HRT) in aging males has also been proposed to improve body composition, bone and cartilage metabolism, certain domains of brain function, and even decrease cardiovascular risk. For most clinical applications, testosterone is usually given as longer acting esters through intramuscular injections, surgical implantation for implants and pellets, or transdermal delivery, such as patches and gels. In general, these administration routes are not very convenient, and are sometimes associated with fluctuation in serum testosterone levels, skin rashes and irritation. Pharmacologically, exogenous testosterone works well for male hypogonadism related to deficiency of endogenous hormone production, including primary (testicular), secondary (hypothalamic or pituitary), and age-related hypogonadism. However, when testosterone is used for age-related hypogonadism (HRT in aging men), the potential risk in the prostate becomes a major concern of long term treatment. Besides hypogonadism, testosterone is mainly used for the treatment of disease related muscle wasting and male hormonal contraception. When supraphysiologic concentrations of testosterone is used for
male contraception, steroid-related side effects, including decreases in HDL cholesterol, increases in hematologic parameters such as hemoglobin and hematocrit, increased body weight, and acne, are the major drawbacks of the treatment. Androgen can also be used as anabolic reagent to treat muscle wasting. Commonly used anabolic steroids include nandrolone decanoate and oxandrolone, although nandrolone decanoate is known to be associated with hepatotoxicity and side effects on the blood lipid profile. Muscle is not the only anabolic tissue. It has also been proposed that testosterone can be used as an anabolic reagent to treat osteoporosis, since androgens seem to have direct anabolic effects in bone, and the anabolic effects in skeletal muscle mass and strength could also be beneficial to the treatment of osteoporosis. However, the anabolic effects associated with most steroidal androgens become major concerns for therapy, particularly in aging men and women. On the other hand, both antiandrogens and 5alpha-reductase inhibitors are used to block androgen action in prostate cancer, BPH, and acne. The application of these steroidal antiandrogens, like cyproterone acetate and spironolactone, has been limited by the weak antagonist activities or crossreaction with other steroid receptors. Also, due to the lack of tissue selectivity, complete androgen blockage with antiandrogens also cause severe side effects related to androgen deficiency (e.g. loss of libido, hot flashes, impotence, and increased incidence of osteoporosis). In summary, steroidal AR ligands, including agonists and antagonists, are used in the treatment of a variety of androgen disorders. However, the side effects related to the lack of tissue selectivity, hepatotoxicity, and inconvenience of delivery limits the more widespread therapeutic applications of androgens. Several structural classes of nonsteroidal AR antagonists have been discovered. In summary, the development of nonsteroidal AR ligands will continue, with particular focus on the search for ligands that are AR specific, metabolically stable, safe, and tissue selective. A better understanding of the mechanism of action of the known nonsteroidal AR ligands will help design the next generation of ligands with improved target specificity and tissue selectivity that could greatly benefit the treatment of many diseases [06049].

**Arylpropionamide-based SARMs**

Drugs that promote anabolic processes with limited undesirable effects are of considerable therapeutic interest; some notable examples include those for the treatment of cancer cachexia and muscle-wasting diseases. Anabolic properties are not only therapeutically beneficial to critically ill and debilitated patients, but are also desirable to athletes seeking artificial enhancements in endurance, strength and accelerated recovery. The use of anabolic agents in the clinical setting is being reconsidered with the emergence of a new class of drugs referred to as SARMs (selective androgen receptor modulators). SARMs have the potential to complement or even replace anabolic androgenic steroidal use with the benefit of a reduction of the undesirable side effects associated with steroid administration alone. Arylpropionamide-based SARMs such as andarine (S-4) and S-22 have shown promising therapeutic properties and have attracted the interest of elite and amateur athletes despite the absence of clinical approval, and evidence for trafficking and misuse in sport has been obtained by doping control authorities. In this communication, the elucidation of urinary metabolites of the SARM drug candidate S-22 is compared with earlier in vitro metabolism studies. Following oral administration of illicit S-22, urine samples were collected after 62 and 135 h and analyzed for the active drug and its major metabolic products. Liquid chromatography interfaced with high-resolution/high-accuracy (tandem) mass spectrometry was used to identify and/or confirm the predicted target analytes for sports drug testing purposes. S-22 was detected in both specimens accompanied by its glucuronic acid conjugate. This was the B-ring hydroxylated derivative of S-22 plus the corresponding glucuronide (with the phase-II metabolites being the more abundant analytes). In addition,
the samples collected 62 h post-administration also contained the phase-I metabolite hydroxylated at the methyl residue (C-20) and the B-ring depleted degradation product “dephenylated” S-22) together with the corresponding carboxy analog that was previously reported for canine metabolism. The obtained data supports future efforts to effectively screen for and confirm the misuse of the non-approved S-22 drug candidate in doping controls [11334].

**SARMs produced by fungus**

Selective androgen receptor modulators (SARMs) are a group of substances that have potential to be used as doping agents in sports. Being a relatively new group not available on the open market means that no reference materials are commercially available for the main metabolites. In one study, the in vitro metabolism of SARMs by the fungus Cunninghamamella elegans has been investigated with the purpose of finding out if it can produce relevant human and equine metabolites. Three different SARMs, S1, S4 and S24, were incubated for 5 days with C. elegans. The samples were analysed both with and without sample pretreatment using ultra performance liquid chromatography coupled to high resolution mass spectrometry. All the important phase I and some phase II metabolites from human and horse were formed by the fungus. They were formed through reactions such as hydroxylation, deacetylation, O-dephenylation, nitro-reduction, acetylation and sulfonation. 4.

The study showed that the fungus produced relevant metabolites of the SARMs and thus can be used to mimic mammalian metabolism. Furthermore, it has the potential to be used for future production of reference material [13271].

**Andarine**

Selective androgen receptor modulators (SARMs) are a relatively new class of non-steroidal compounds that possess potent anabolic activity. They were developed following the identification of androgen receptor antagonists such as bicalutamine in 1998, as an alternative to anabolic steroids for treating a wide range of clinical conditions including cancer cachexia, muscle wasting, osteoporosis, androgen deficiency, and prostate cancer. SARMs are a heterogeneous group of compounds that are usually classified based on core structures such as aryl propionamide, quinolinone, tetrahydroquinoline, bicyclic hydantoin, and numerous others. SARMs have high muscle and bone tissue selectivity and are not substrates for alpha-reductase and aromatase enzymes. This results in less androgenic and estrogenic effects compared to anabolic steroids. Indeed, preclinical animal studies have demonstrated that SARMs can prevent bone loss and reduce body fat with fewer undesirable anabolic steroid side-effects. Although none of the SARMs have been approved for human use, a limited number have completed or are currently being evaluated in multicentre clinical trials. S-4 [Andarine, S-3-(4-acetylamino-phenoxy)-2-hydroxy-2-methyl-N-(4-nitro-3-trifluoromethyl-phenyl)-propionamide] a member of the aryl propionamide class of SARMs was evaluated in a phase I clinical trial, but the study had to be stopped due to adverse side-effects involving visual disturbances. S-22 (Ostarine®, GTx-024, enobosarm), another SARM in this class, is currently undergoing phase III clinical trials in patients with non-small lung cancer. Given the potential for misuse by athletes in power and strength sports, SARMs were placed on the World Anti-Doping Agency (WADA) list of prohibited substances in 2008. Although they are not available legally for medical purposes, a few SARMs have made their way on to the black market. For instance, S-4 is available for purchase in the United States via the internet. The S-22 SARM is also available via the Internet and has recently been identified in the urine of a 37-year-old male who exercises regularly. It is concerning that
someone would consider using these substances before they have been rigorously evaluated for safety in clinical trials. In the case of S-4, the adverse side-effects are known and should discourage anyone from using this substance. S-22 is still being evaluated and has common side-effects that include fatigue, anaemia, nausea, diarrhoea, headache, back pain, decreased total serum testosterone, and elevations in liver enzymes [13272]. Selective androgen receptor modulators (SARMs) comprise a new class of molecules that induce anabolic effects with fewer side effects than those of other anabolic agents. It was previously reported that the novel SARM S-101479 had a tissue-selective bone anabolic effect with diminished side effects in female animals. However, the mechanism of its tissue selectivity is not well known. In one report, it was shown that S-101479 increased alkaline phosphatase activity and androgen receptor (AR) transcriptional activity in osteoblastic cell lines in the same manner as the natural androgen ligand dihydrotestosterone (DHT); conversely, stimulation of AR dimerization was very low compared with that of DHT (34%). S-101479 increased bone mineral content in ovariectomized rats without promoting endometrial proliferation. Yeast two-hybrid interaction assays revealed that DHT promoted recruitment of numerous cofactors to AR such as TIF2, SRC1, beta-catenin, NCoA3, gelsolin and PROX1 in a dose-dependent manner. SARMs induced recruitment of fewer cofactors than DHT; in particular, S-101479 failed to induce recruitment of canonical p160 coactivators such as SRC1, TIF2 and notably NCoA3 but only stimulated binding of AR to gelsolin and PROX1. The results suggest that a full capability of the AR to dimerize and to effectively and unselectively recruit all canonical cofactors is not a prerequisite for transcriptional activity in osteoblastic cells and resulting anabolic effects in bone tissues. Instead, few relevant cofactors might be sufficient to promote AR activity in these tissues [13273].

New SARM compounds

A novel selective androgen receptor modulator scaffold was discovered as a byproduct obtained during synthesis of our earlier series of imidazolidin-2-ones. The resulting oxazolidin-2-imines are among the most potent SARMs known, with many analogues exhibiting sub-nM in vitro potency in binding and functional assays. Despite the potential for hydrolytic instability at gut pH, compounds of the present class showed good oral bioavailability and were highly active in a standard rodent pharmacological model [09146].

Laboratory techniques

Selective androgen receptor modulators (SARM) are a prominent group of compounds for being misused in sports owing to their advantageous anabolic properties and reduced side effects. To target the preventive doping control analysis in relevant compounds, the challenge is to predict the metabolic fate of a new compound. For aryl-propionamide-derived SARM, an in vitro assay employing microsomal and S9 human liver enzymes was developed to simulate phase-I and phase-II metabolic reactions. In vitro metabolic profiles and the structure-metabolic relationship were compared between four structurally modified substrates. Accurate mass measurements were used to characterize the synthesized metabolites, and also collision-induced dissociation was examined to suggest the methodological approach to monitor the prohibited use of aryl-propionamide-derived drug candidates. Subsequent phase-I and phase-II metabolic reactions were successfully combined in one in vitro assay. The main routes of phase-I modifications involved the hydrolysis of ether linkage, monohydroxylation, and hydrolytic cleavage of the amide bond. Nitro-reduction and deacetylation were reactions observed for substrates possessing the
corresponding functionality. SARM metabolites were analyzed in negative ion electrospray ionization and detected as deprotonated species [M-H](-). The main metabolic modifications were observed to occur in the B-ring side, and collision-induced dissociation resulted in the product ions originating from the A-ring side of the compound. These structure-specific ions may be monitored as target ions in the routine doping control [07101].

Anabolic agents have been among the most frequently detected drugs in amateur and professional sport. A novel class of therapeutics presumably complementing anabolic steroids in the near future includes so-called selective androgen receptor modulators (SARMs) that have been under clinical investigations for several years. Although not yet commercially available, their potential for misuse in sports is high. Four aryl-propionamide-derived SARMs were synthesized in order to establish a fast and robust screening procedure using liquid chromatography/electrospray ionization tandem mass spectrometry. Synthesized compounds were characterized by high-resolution/high-accuracy mass analysis employing a linear ion trap-Orbitrap hybrid mass spectrometer while routine analyses were conducted on a triple-quadrupole mass spectrometer. Characteristic product ions obtained by collision-induced dissociation were found at m/z 289 and 261 as well as m/z 269 and 241 representing the bisubstituted aniline residues of selected model compounds. Assay validation was performed regarding lower limit of detection (1 ng/mL), recovery (85-105 %), intraday precision (7.6-11.6 %) and interday precision (9.9-14.4 %), and precursor ion scan experiments on diagnostic product ions enabled the detection of a structurally related compound at 50 ng/mL [06131].
ESTROGENS AND FEMALE SPORTS

Women are at greater risk than men of sustaining certain kinds of injury and diseases of collagen-rich tissues. To determine whether a high level of oestradiol has an acute influence on collagen synthesis in tendons at rest and in response to exercise, one-legged kicking exercise was performed for 60 min at 67 percent of maximum power by healthy, young oral contraceptive (OC) users when circulating synthetic (ethinyl) oestradiol was high (n=11) and compared to similar women who had never used OCs when circulating endogenous oestrogen was low (n=12). Interstitial fluid was collected 24 h post-exercise through microdialysis catheters placed anterior to the patellar tendon in both legs and subsequently analysed for the amino-terminal propeptide of type I collagen (PINP), a marker of tendon collagen synthesis. To determine the long-term effect of OC usage, patellar tendon cross-sectional area (CSA) was measured by magnetic resonance imaging (MRI). A lower exercise-induced increase in tendon collagen synthesis was observed at higher than at lower levels. Furthermore, serum and the interstitial peritendinous tissue concentrations of insulin-like growth factor I (IGF-I) and IGF-binding proteins showed a reduced bioavailability at higher compared with results lower levels. No difference in patellar tendon CSA was observed between groups. In conclusion, the selective increase in tendon collagen synthesis when circulating endogenous oestrogen was low but not when circulating synthetic (ethinyl) oestradiol was high 24 h post-exercise is consistent with the hypothesis that oestradiol inhibits exercise-induced collagen synthesis in human tendon. The mechanism behind this is either a direct effect of oestradiol, or an indirect effect via a reduction in levels of free IGF-I. However, the data did not indicate any long-term effect on tendon size associated with chronic oral contraceptive use [08203].

The female hormones, estrogen and progesterone, fluctuate predictably across the menstrual cycle in naturally cycling eumenorhhoic women. Other than reproductive function, these hormones influence many other physiological systems, and their action during exercise may have implications for exercise performance. Although a number of studies have found exercise performance - and in particular, endurance performance - to vary between menstrual phases, there is an equal number of such studies reporting no differences. However, a comparison of the increase in the estrogen concentration (E) relative to progesterone concentration (P) as the E/P ratio (pmol/nmol) in the luteal phase in these studies reveals that endurance performance may only be improved in the mid-luteal phase compared with the early follicular phase when the E/P ratio is high in the mid-luteal phase. Furthermore, the late follicular phase, characterized by the pre-ovulatory surge in estrogen and suppressed progesterone concentrations, tends to promote improved performance in a cycling time trial and future studies should include this menstrual phase. Menstrual phase variations in endurance performance may largely be a consequence of changes to exercise metabolism stimulated by the fluctuations in ovarian hormone concentrations. The literature suggests that estrogen may promote endurance performance by altering carbohydrate, fat and protein metabolism, with progesterone often appearing to act antagonistically. Details of the ovarian hormone influences on the metabolism of these macronutrients are no longer only limited to evidence from animal research and indirect calorimetry but have been verified by substrate kinetics determined with stable tracer methodology in eumenorrhhoic women. One review thoroughly examined the metabolic perturbations induced by the ovarian hormones and, by detailed comparison, proposes reasons for many of the inconsistent reports in menstrual phase comparative research. Often the magnitude of increase in the ovarian hormones between menstrual phases and the E/P ratio appear to be important factors determining an effect on metabolism. However, energy demand and nutritional status may be confounding variables, particularly in carbohydrate metabolism. The review
specifically considers how changes in metabolic responses due to the ovarian hormones may influence exercise performance. For example, estrogen promotes glucose availability and uptake into type I muscle fibres providing the fuel of choice during short duration exercise; an action that can be inhibited by progesterone. A high estrogen concentration in the luteal phase augments muscle glycogen storage capacity compared with the low estrogen environment of the early follicular phase. However, following a carbo-loading diet will super-compensate muscle glycogen stores in the early follicular phase to values attained in the luteal phase. Estrogen concentrations of the luteal phase reduce reliance on muscle glycogen during exercise and although not as yet supported by human tracer studies, estrogen increases free fatty acid availability and oxidative capacity in exercise, favouring endurance performance. Evidence of estrogen's stimulation of 5'-AMP-activated protein kinase may explain many of the metabolic actions of estrogen. However, both estrogen and progesterone suppress gluconeogenic output during exercise and this may compromise performance in the latter stages of ultra-long events if energy replacement supplements are inadequate. Moreover, supplementing energy intake during exercise with protein may be more relevant when progesterone concentration is elevated compared with menstrual phases favouring a higher relative estrogen concentration, as progesterone promotes protein catabolism while estrogen suppresses protein catabolism [10098].

It was shown that isoflavones and exercise improve total and abdominal fat mass (FM) to a greater extent than does exercise alone in postmenopausal women, but not other cardiovascular disease (CVD) risk factors. Fat-free mass (FFM) showed a wide variability of responses, with 60 percent of women having increased FFM and 40 percent having decreased FFM. It was thus wondered if women who had decreased FFM could be considered as nonresponders (NRs) to exercise and if this masked a potential synergistic effect of phytoestrogens (PHY) and exercise. The aim of one study was to verify if PHYs enhance the response obtained after aerobic and resistance exercises in CVD risk profile in exercise responders. Among 21 women who participated in a 6-month exercise program and received PHY or placebo (PLA), 14 were exercise responders (PHY, n=8; PLA, n=6) whereas 7 were NRs. Body weight, waist circumference, FM, and FFM were assessed (dual-energy x-ray absorptiometry). Plasma glucose, insulin, sex hormone-binding globulin, and testosterone levels were obtained after a 12-hour overnight fast. Total energy intake was measured with a 3-day dietary record. All measurements were performed before and after the intervention. After exercise training, the PHY and PLA groups, but not the NR group, had significantly increased FFM. On the other hand, body weight, FM, and systolic and diastolic blood pressure decreased in the PHY group only. Furthermore, plasma insulin level and homeostasis model assessment significantly decreased while plasma sex hormone-binding globulin increased after training in the PHY group, whereas energy intake remained unchanged in both groups after the intervention. It was concluded PHYs combined with exercise compared with exercise alone seem to improve body composition and CVD risk profile in exercise-responder women [10350].

The identification of subtle menstrual cycle disturbances requires daily hormone assessments. In contrast, the identification of severe menstrual disturbances, such as amenorrhea and oligomenorrhea, can be established by clinical observation. The primary purpose of one study was to determine the frequency of subtle menstrual disturbances, defined as luteal phase defects (LPD) or anovulation, in exercising women, with menstrual cycles of 26-35 days, who engage in a variety of sports, both recreational and competitive. Secondly, the prevalence of oligomenorrhea and amenorrhea was also determined via measurement of daily urinary ovarian steroids rather than self report alone. Menstrual status was documented by daily measurements of estrone and pregnanediol glucuronide and luteinizing hormone across two to three consecutive cycles and subsequently categorized as ovulatory (Ovu), LPD, anovulatory (Anov), oligomenorrheic (Oligo) and amenorrheic (Amen).
in sedentary (Sed) and exercising (Ex) women. Among the menstrual cycles studied in the Sed group, the prevalence of subtle menstrual disturbances was only 4 percent; 96 percent of the observed menstrual cycles were ovulatory. This finding stands in stark contrast to that observed in the exercising group where only 50 percent of the observed menstrual cycles were ovulatory and as many as 50 percent were abnormal. Of the abnormal cycles in the exercising group, 29 percent were classified as LPD (short, inadequate or both) and 21 percent were classified as Anov. Among the cycles of exercising women with severe menstrual disturbances, 4 percent of the cycles were Oligo and 34 percent were Amen. No cycles of Sed women (0/20) displayed either Oligo or Amen. This study suggests that approximately half of exercising women experience subtle menstrual disturbances, i.e. LPD and anovulation, and that one third of exercising women may be amenorrheic. Estimates of the prevalence of subtle menstrual disturbances in exercising women determined by the presence or absence of short or long cycles does not identify these disturbances. In light of known clinical consequences of menstrual disturbances, these findings underscore the lack of reliability of normal menstrual intervals and self report to infer menstrual status [10099].

The continuous introduction of new products used as growth promoters in animal husbandry, for sports doping and as products for body-building requires residue laboratories to initiate research on developing a strategy for the identification of 'unknown' components. In this study, a strategy is presented for elucidating the identity, the structure and the possible effects of illegal estrogenic compounds in an unidentified water-based solution. To obtain complete information on the composition and activity of the unidentified product, a multidisciplinary approach was needed. A case-study is described with a “solution X” found during a raid. First, in vivo techniques (animal trials with mice, anatomical and histological research) were combined with in vitro techniques (the yeast estrogenic screen (YES)). In a later stage of the investigation, HPLC-fractionation, liquid chromatography-multiple mass spectrometry (LC-MSn) and gas chromatography-multiple mass spectrometry (GC-MSn) were used. Finally, the identity of “solution X” was confirmed in a very low concentration range (10 ng/L estrone and 400 ng/L ethinyloestradiol) [06132].

In contrast to age-matched men, endurance exercise training is not consistently associated with enhanced endothelial function in estrogen-deficient postmenopausal women. It was determined whether endurance exercise training improves endothelial function in postmenopausal women treated with estrogen. In a substudy, it was determined if oxidative stress is mechanistically linked to endothelial function adaptations to endurance exercise training. Brachial artery flow-mediated dilation (FMD) was measured in 36 sedentary, estrogen-deficient postmenopausal women (45-65 years) at study entry (baseline), after 12 weeks of either placebo, oral (1 mg/d) estradiol, or transdermal estradiol (0.05 mg/d) (randomized), and after an additional 12 weeks of continued estradiol or placebo treatment with concurrent endurance exercise training. In subgroups of women, FMD also was measured during the infusion of ascorbic acid at baseline and following estradiol/placebo plus endurance exercise training, and in seven habitually endurance-trained estrogen-deficient controls. FMD increased in the estrogen-treated groups after 12 weeks and remained unchanged in placebo. FMD further increased following 12 weeks of endurance exercise training in estrogen-treated, but not placebo-treated women. In the substudy, baseline FMD was similar between sedentary and endurance-trained controls. Ascorbic acid increased FMD at baseline in sedentary women and endurance-trained controls, and following endurance exercise training in placebo-treated, but not in estrogen-treated women. It was concluded that estrogen status appears to play an important modulatory role in improvements in endothelial function with endurance exercise training in postmenopausal women. The restored endurance exercise training adaptation in estrogen-treated postmenopausal women may be related to mitigation of oxidative stress [13277].
Ethnic variations

Previous studies have suggested that estrogen levels may be higher in African-American women (AAW) compared with Caucasian women (CW), but none have systematically examined estrogen secretion across the menstrual cycle or in relation to other reproductive hormones. The objective of one study was to compare estradiol (E2), progesterone (P), gonadotropins, androstenedione (a’dione), inhibins, and SHBG levels between AAW and CW across the menstrual cycle. Daily blood samples were collected from regularly cycling AAW (n=27) and CW (n=27) for a full menstrual cycle, and serial ultrasounds were performed. AAW and CW were of similar age (27) and body mass index (22.7 ± 0.4 kg/m²). All subjects grew a single dominant follicle and had comparable cycle (25-35 d) and follicular phase (11-24 d) lengths. E2 levels were significantly higher in AAW compared with CW with the most pronounced differences in the late follicular phase, midluteal phase, and late luteal phase. Although LH, FSH, inhibins A and B, P, a’dione, and SHBG were not different between the two groups, the a’dione to E2 ratio was lower in AAW. Estradiol is higher in AAW compared with CW across the menstrual cycle. Higher estradiol in the face of similar androstenedione and FSH levels suggests enhanced aromatase activity in AAW. Such differences may contribute to racial disparities in bone mineral density, breast cancer, and uterine leiomyomas [11455].

Urinary estrogens and androgens during pregnancy

Alterations in the maternal excretion of steroids during pregnancy are not restricted to the production of progesterone and estriol by the fetoplacental unit. Although there is a lack of longitudinal data on urinary androgen concentrations during pregnancy, some studies revealed that modifications in the excretions of androgens might be significant. Recently, several testosterone metabolites excreted as cysteine conjugates have been reported in human urine. It was conducted a longitudinal study on androgens conjugated with cysteine and major androgens and estrogens excreted as glucuronides in three pregnant women by mass spectrometric techniques. The urinary concentrations obtained in samples weekly collected during each of the three trimesters and samples collected before pregnancy were compared. Results showed a significant increase in urinary estrogens and norandrosterone and a moderate decrease in the urinary concentrations for most of the androgens. The most significant exception to this behavior was the rise observed for epitestosterone glucuronide when comparing basal levels with the first trimester. Cysteinyl conjugates of testosterone metabolites showed a different behavior. Whereas 4,6-androstanedione remained almost constant through the three trimesters, and delta6-testosterone decreased as the majority of androgens, the excretion profile of 1,4-androstanedione notably increased, reaching a maximum at the third trimester. Alterations in the steroid profile are used in doping control analysis for the screening of endogenous anabolic androgenic steroid misuse. In the study, the main parameters proposed for doping control have been determined for basal samples and samples collected in the first trimester and they have been compared. In spite of the limited number of cases, significant variations have been found in all pregnancies studied. These alterations have to be taken into consideration if anabolic steroids are included into the Athlete Biological Passport [13284].

Endogenous versus exogenous estrogens
Estrogens were prohibited in the food producing animals by European Union (96/22/EC directive) and added to the Report on Carcinogens in United States since 2002. Due to very low concentration in serum or urine (pg/mL), the method of control its abuse had not been fully developed. The endogenous estrogens were separated from urines of 18 adult men and women. The exogenous estrogens were chemical reference standards and over the counter preparations. Two patients of dysfunctional uterine bleeding (DUB) administered exogenous estradiol and the urines were collected for 72 h. The urinary estrogens were separated by high-performance liquid chromatography (HPLC) and confirmed. The exogenous and exogenous estrogens were analyzed by gas chromatography combustion isotope ratio mass spectrometry (GC-C-IRMS) to determine the $^{13}$C/$^{12}$C ratio. Stable carbon isotope analysis could distinguish the endogenous and exogenous urinary estrogen in humans [13285].

Sex-hormone binding globulin

A generic high-throughput bioaffinity liquid chromatography-mass spectrometry (BioMS) approach was developed and applied for the screening and identification of known and unknown recombinant human sex hormone-binding globulin (rhSHBG)-binding designer steroids in dietary supplements. For screening, a semi-automated competitive inhibition binding assay was combined with fast ultrahigh-performance-LC-electrospray ionization-triple-quadrupole-MS (UPLC-QqQ-MS). 17β-Testosterone-D3 was used as the stable isotope label of which the binding to rhSHBG-coated paramagnetic microbeads was inhibited by any other binding (designer) steroid. The assay was performed in a 96-well plate and combined with the fast LC-MS, 96 measurements could be performed within 4 h. The concentration-dependent inhibition of the label by steroids in buffer and dietary supplements was demonstrated. Following an adjusted bioaffinity isolation procedure, suspect extracts were injected into a chip-UPLC(NanoTile)-Q-time-of-flight-MS system for full-scan accurate mass identification. Next to known steroids, 1-testosterone was identified in three of the supplements studied and the designer steroid tetrahydrogestrinone was identified in a spiked supplement. The generic steroid-binding assay can be used for high-throughput screening of androgens, estrogens, and gestagens in dietary supplements to fight doping. When combined with chip-UPLC-MS, it is a powerful tool for early warning of unknown emerging rhSHBG bioactive designer steroids in dietary supplements [13277].

Testosterone

To examine the androgen response to exercise in women under conditions of high (H) and low (L) estrogen (E2) levels 10 exercise trained eumenorrheic women (20 years, 59 kg, 22 % body fat, VO$_{2}$max 51 mL/kg/min) completed a 60 min treadmill run at about 70 percent of VO$_{2}$max during both the mid-follicular (L-E2, 70 % VO$_{2}$max) and mid-luteal (H-E2, 68 % VO$_{2}$max) phases of their menstrual cycle. Blood samples were taken pre-exercise (PRE), immediately post (POST), and 30 min into recovery (30R) from exercise and analyzed for total testosterone using ELISA assays. Statistical analysis of testosterone response indicated no significant interaction existed between high and low estrogen conditions across the blood sampling times. However, a main effect occurred for exercise with the post-testosterone concentration being greater than pre, although pre versus 30R was not different. All testosterone hormonal concentrations immediately post-exercise greatly exceeded the level of hemoconcentration observed during the L-E2 and H-E2 exercise sessions. Thus, prolonged aerobic exercise induces short-term elevations in testosterone in trained eumenorrheic women, which appears unrelated to estrogen levels and menstrual cycle phase. These increases may occur due to either increased androgen production and/or
decreased degradation rates of the hormone, and are not solely the result of plasma fluid shifts from the exercise [13278].

In hypopituitary men, oral delivery of unesterified testosterone in doses that result in a solely hepatic androgen effect enhances protein anabolism during GH treatment. In one study, it was aimed to determine whether liver-targeted androgen supplementation induces protein anabolism in GH-replete normal women. Eight healthy postmenopausal women received 2-week treatment with oral testosterone at a dose of 40 mg/day (crystalline testosterone USP). This dose increases portal concentrations of testosterone, exerting androgenic effects on the liver without a spillover into the systemic circulation. The outcome measures were whole-body leucine turnover, from which leucine rate of appearance (LRa, an index of protein breakdown) and leucine oxidation (Lox, a measure of irreversible protein loss) were estimated, energy expenditure and substrate utilization. It was measured the concentration of liver transaminases as well as of testosterone, SHBG and IGF1. Testosterone treatment significantly reduced LRa by 7.1 ± 2.5 percent and Lox by 14.6 ± 4.5 percent. The concentration of liver transaminases did not change significantly, while that of serum SHBG fell within the normal range by 16.8 ± 4.0 percent and that of IGF1 increased by 18.4 ± 7.7 percent. The concentration of peripheral testosterone increased from 0.4 ± 0.1 to 1.1 ± 0.2 nmol/l, without exceeding the upper normal limit. There was no change in energy expenditure and fat and carbohydrate utilization. It was concluded that hepatic exposure to unesterified testosterone by oral delivery stimulates protein anabolism by reducing protein breakdown and oxidation without inducing systemic androgen excess in women. It was conclude that a small oral dose of unesterified testosterone holds promise as a simple novel treatment of protein catabolism and muscle wasting [13279].

**Prolonged aerobic exercise**

It was examined the androgen response to exercise in women under conditions of high (H) and low (L) estrogen (E2) levels. Ten exercise trained eumenorrheic women (mean ± SD: 20.0 ± 2.2 years, 58.7 ± 8.3 kg, 22.3 ± 4.9 % body fat, VO2max 50.7 ± 9.0 mL/kg/min) completed a 60 min treadmill run at about 70 percent of VO2max during both the mid-follicular (L-E2, 69.7 ± 7.3 % VO2max) and mid-luteal (H-E2, 67.6 ± 7.9 % VO2max) phases of their menstrual cycle. Blood samples were taken pre-exercise (PRE), immediately post (POST), and 30 min into recovery (30R) from exercise and analyzed for total testosterone using ELISA assays. Results were analyzed using repeated measures ANOVA. Testosterone responses were (mean ± SD: L-E2, pre = 1.41 ± 0.21, post = 1.86 ± 0.21, 30R = 1.75 ± 0.32 nmol/L; H-E2, pre = 1.27 ± 0.23, post = 2.43 ± 0.56, 30R = 1.69 ± 0.34 nmol/L). Statistical analysis indicated no significant interaction existed between high and low estrogen conditions across the blood sampling times. However, a main effect occurred for exercise with the post-testosterone concentration being greater than pre, although pre versus 30R was not different. All testosterone hormonal concentrations immediately post-exercise greatly exceeded the level of hemoconcentration observed during the L-E2 and H-E2 exercise sessions. It was concluded that prolonged aerobic exercise induces short-term elevations in testosterone in trained eumenorrheic women, which appears unrelated to estrogen levels and menstrual cycle phase. These increases may occur due to either increased androgen production and/or decreased degradation rates of the hormone, and are not solely the result of plasma fluid shifts from the exercise [13280].

**Urinary steroids in exercise**

Some studies suggest that performing strength training may cause alterations on the hypothalamic pituitary axis, resulting in steroid hormone variations. Intense training has been associated to slow the concentrations of estrogens and progesterone in women. The main
The purpose of this study was to evaluate the effects of strength training on the urinary steroid concentrations across the menstrual cycle phases. Twenty healthy women, regularly menstruating and not using pharmacologic contraceptives, performed a strength training during 8 weeks. Participants worked out 3 sets × 10 repetitions, with 2 min recovery time between sets, at 70-75 % of one maximum strength repetition. Urine samples were taken in three different phases of the menstrual cycle (menstrual, follicular and luteal) and they were collected both before and after training. Testosterone, DHEA, cortisol, cortisone, estradiol and progesterone concentrations were determined by gas chromatography-mass spectrometry. The results showed a significant decline after training in the urinary excretion of estradiol, during the menstrual and follicular phase, and progesterone, during the menstrual and luteal phase. No significant difference was observed for other steroid hormones. These data demonstrated that strength training can play an important role in the estrogen and progesterone metabolism in women, decreasing their levels across the menstrual cycle [13281].

**Salivary testosterone in exercise**

Testosterone has been related to improved acute neuromuscular performance in athletic populations. It is a contention that testosterone may also contribute to improved volitional motivation and, when monitored longitudinally, may provide one proxy marker for readiness to perform. Twelve female netball players provided saliva samples prior to five standardized training sessions in which they completed a maximal-distance medicine ball throw, and then 3 sets of bench press and then back squat using a self-selected load perceived to equal a 3-repetition maximum load. Additional repetitions were encouraged when possible and total voluntary workload was calculated from the product of the load lifted and repetitions performed. Relative salivary testosterone levels as a group were correlated with bench press and squat self-selected workload, as well as maximal medicine ball throw performance. It was concluded that individual salivary testosterone, when viewed relatively over time, demonstrated strong relationships with self-selected workloads during an in-season training period in female netball players. As such, daily variations in testosterone may provide information regarding voluntary training motivation and readiness to perform in elite athletic populations. Psychological and behavioral aspects of testosterone may have the potential to enhance training adaptation by complementing the known anabolic and permissive properties of testosterone [13282].

**Hyperandrosteronism in women**

International sports governing bodies such as the International Association for Athletics Federation and the International Olympic Committee have recently revised their policies for inclusion of athletes competing in women’s international sports competitions. Previously, the focus was on verification of gender or femininity. The mishandling of Caster Semanya’s case brought the complex issues of fairness with regard to athletes with disorders of sexual development or hyperandrogenism into both public and private debates. The new International Association for Athletics Federation and International Olympic Committee policies for inclusion in women’s sporting events rest largely on the serum testosterone level, mandating that it be less than the lower limit of normal for men as the defining criteria. This report provides an overview of past problems and an update of the newly adopted policies for eligibility for competition in women’s events. Endocrinologists will play a key role in the evaluation and treatment of women athletes who have elevated androgen levels, regardless of the underlying cause [12200].
**Effects of menstrual cycle**

Anabolic androgenic steroids (AAS), synthetic testosterone derivatives that are used for ergogenic purposes, alter neurotransmission and behaviors mediated by GABA(A) receptors. Some of these effects may reflect direct and rapid action of these synthetic steroids at the receptor. The ability of other natural allosteric steroid modulators to alter GABA(A) receptor-mediated currents is dependent upon the phosphorylation state of the receptor complex. Here it was shown that phosphorylation of the GABA(A) receptor complex immunoprecipitated by beta2/beta3 subunit-specific antibodies from the medial preoptic area (mPOA) of the mouse varies across the estrous cycle; with levels being significantly lower in estrus. Acute exposure to the AAS, 17alpha-methyltestosterone (17alpha-MeT), had no effect on the amplitude or kinetics of inhibitory postsynaptic currents in the mPOA of estrous mice when phosphorylation was low, but increased the amplitude of these currents from mice in diestru, when it was high. Inclusion of the protein kinase C (PKC) inhibitor, calphostin, in the recording pipette eliminated the ability of 17alpha-MeT to enhance currents from diestrous animals, suggesting that PKC-receptor phosphorylation is critical for the allosteric modulation elicited by AAS during this phase. In addition, a single injection of 17alpha-MeT was found to impair an mPOA-mediated behavior (nest building) in diestru, but not in estrus. PKC is known to target specific serine residues in the beta3 subunit of the GABA(A) receptor. Although phosphorylation of these beta3 serine residues showed a similar profile across the cycle, as did phosphoserine in mPOA lysates immunoprecipitated with beta2/beta3 antibody (lower in estrus than in diestru or proestru), the differences were not significant. These data suggest that the phosphorylation state of the receptor complex regulates both the ability of AAS to modulate receptor function in the mPOA and the expression of a simple mPOA-dependent behavior through a PKC-dependent mechanism that involves the beta3 subunit and other sites within the GABA(A) receptor complex [12161].

One study examined the effects of menstrual cycle phase (MCP) upon sprinting and recovery as well as upon metabolic responses to such exercise. Eight females performed a repeated 30-s sprint on a non-motorised treadmill interspersed with a 2-min rest in three phases of the MCP, follicular (low 17beta-estradiol and progesterone), just prior to ovulation (midcycle trial, highest 17beta-estradiol concentration and low progesterone) and in the luteal phase (high 17beta-estradiol and high progesterone). MCP was verified later by radioimmunoassay of 17beta-estradiol and progesterone. Peak power output (PPO) and mean power output (MPO) were unaltered due to MCP for follicular, midcycle and luteal trials. Similarly, percentage recovery of PPO and MPO (the PPO or MPO during sprint 2 expressed as a percentage of the PPO or MPO during sprint 1) was also unchanged. Blood lactate, blood pH and plasma ammonia after sprinting and estimated plasma volume were also unaltered by MCP. These findings suggest that hormonal fluctuations due to MCP do not interfere with maximal intensity whole body sprinting and the metabolic responses to such exercise [10351].

Numerous studies from our and other laboratories have shown that women have a lower respiratory exchange ratio (RER) during exercise than equally trained men, indicating a greater reliance on fat oxidation. Differences in estrogen concentration between men and women likely play a role in this sex difference. Differing estrogen and progesterone concentrations during the follicular (FP) and luteal (LP) phases of the female menstrual cycle suggest that fuel use may also vary between phases. The purpose of the current study was to determine the effect of menstrual cycle phase and sex upon glucose turnover and muscle glycogen utilization during endurance exercise. Healthy, recreationally active young women (n=13) and men (n=11) underwent a primed constant infusion of [6,6-2H]glucose with muscle
biopsies taken before and after a 90-min cycling bout at 65 percent peak $O_2$ consumption. LP women had lower glucose rate of appearance rate of disappearance and metabolic clearance rate at 90 min of exercise and lower proglycogen macroglycogen and total glycogen utilization during exercise compared with FP women. Men had a higher RER glucose $Ra$, $Rd$, and $MCR$ during exercise compared with FP women, and men had a higher RER at 75 and 90 min of exercise, glucose $Ra$, $Rd$, and $MCR$ and a greater PG utilization compared with LP women. It was concluded that gender, and to a lesser extent menstrual cycle, influence glucose turnover and glycogen utilization during moderate-intensity endurance exercise [06133].

The purpose of one project was to compare the impact of the menstrual cycle on short-term, high intensity (power) performance in active females who either had normal menstrual cycles (NOC) or who were using oral contraceptives (OC). Subjects (7 NOC, 17 OC) completed a Margaria-Kalamen staircase test and a Wingate cycle test on 3 occasions: one for familiarization and the other two trials (random order) during menses (MEN) or luteal (LUT) phase. Phase was documented by urinary luteinizing hormone for the NOC. There were no significant differences between MEN and LUT in the NOC group on the Wingate test ($n=7$) for any of the following: peak power, peak power per kg body weight, anaerobic capacity, anaerobic capacity per kg body weight, power decline, power decline per kg body weight. Also there were no significant differences in power for the Margaria-Kalamen test ($n=6$). There were no significant differences between MEN and LUT in the OC group for any of the following variables calculated from the subjects’ performance on the Wingate test ($n=17$): peak power, peak power per kg body weight, anaerobic capacity, anaerobic capacity per kg body weight, power decline, power decline per kg body weight. Also there were no significant differences in power for the Margaria-Kalamen test ($n=11$). It was concluded that for a moderately active group of women, anaerobic power performance was not influenced by menstrual cycle phase in either NOC or OC users [06134].

**Effects of exercise on the female reproductive system and sex hormones**

The excess in physical activity could be closely linked to considerable negative consequences on the whole body. These dysfunctions called as "female athlete triad" by the American College of Sports Medicine (ACSM) include amenorrhea, osteoporosis and disorder eating. The female athlete triad poses serious health risks, both on the short and on the long term, to the overall well-being of affected individuals. Sustained low energy availability can impair health, causing many medical complications within skeletal, endocrine, cardiovascular, reproductive and central nervous system. On the contrary, several studies have shown, that physical activity improves cardiovascular risk factors, hormonal profile and reproductive function. These improvements include a decrease in abdominal fat, blood glucose, blood lipids and insulin resistance, as well as improvements in menstrual cyclicity, ovulation and fertility, decreases in testosterone levels and Free Androgen Index (FAI) and increases in sex hormone binding globulin (SHBG). Other studies reported that physical activity improved self-esteem, depression and anxiety. Thus, the aim of one review was to elucidate the effect of physical exercise on female reproductive system and viceversa the impact of hormonal status on physical activity and metabolism. In addition this review supports the idea that physical exercise is a helpful tool for the management of obesity, prevention of cardiovascular, metabolic diseases and female reproductive organs related diseases (e.g. breast cancer). When the excess in physical activity leads up to the female athlete triad, it is imperative to treat each component of the triad by employing both pharmacological and non pharmacological treatments [13286].
**Effects of strength training**

Some studies suggest that performing strength training may cause alterations on the hypothalamic pituitary axis, resulting in steroid hormone variations. Intense training has been associated to slow the concentrations of estrogens and progesterone in women. The main purpose of one study was to evaluate the effects of strength training on the urinary steroid concentrations across the menstrual cycle phases. Twenty healthy women, regularly menstruating and not using pharmacologic contraceptives, performed a strength training during 8 weeks. Participants worked out 3 sets × 10 repetitions, with 2 min recovery time between sets, at 70-75 percent of one maximum strength repetition. Urine samples were taken in three different phases of the menstrual cycle (menstrual, follicular and luteal) and they were collected both before and after training. Testosterone, DHEA, cortisol, cortisone, estradiol and progesterone concentrations were determined by gas chromatography-mass spectrometry. The results showed a significant decline after training in the urinary excretion of estradiol, during the menstrual and follicular phase, and progesterone, during the menstrual and luteal phase. No significant difference was observed for other steroid hormones. These data demonstrated that strength training can play an important role in the estrogen and progesterone metabolism in women, decreasing their levels across the menstrual cycle [12198].

**Comparison of baseline free testosterone between elite and non-elite female athletes**

To compare the baseline free testosterone (T) and cortisol (C) concentrations of elite and non-elite female athletes 18 females from different sports (track and field, netball, cycling, swimming, bob skeleton) were monitored over a 12-week period. Baseline measures of salivary free T and C concentrations were taken weekly prior to any training. The elites (n=9) and non-elites (n=9) were classified as international and national level competitors, respectively, with both groups matched by sport. The pooled free T concentrations of the elites (87 pg/ml) were significantly higher than the non-elites (41 pg/ml) and consistently so across all weekly time points. Pooled free C concentrations were also greater in the elite group (2.90 ng/ml) than the non-elites (2.32 ng/ml) (P < 0.01). It was concluded that the pooled baseline T and C measures were higher in elite female athletes than non-elites. Higher free T and C concentrations could indicate a greater capacity for physical performance at higher work rates, which is commensurate with the demands of elite sport. Speculatively, the T differences observed could influence female behavior and thereby help to regulate sporting potential [12199].

**Effect of stretching**

The aim of one study was to investigate whether variation in estrogen levels during the menstrual cycle influences susceptibility to exercise-induced muscle damage after stretch-shortening cycle exercise. Physically active women (n=18; age 20 years) participated in the research. The subjects performed one session of 100 maximal drop jumps on day 1 or 2 of the follicular phase and another identical session on day 1 or 2 of the ovulatory phase; the order of the sessions was randomized. Quadriceps femoris muscle peak torque evoked by electrical stimulation and maximal voluntary contraction, muscle pain, and CK activity were measured before and at various times up to 72 h after exercise. It was found that the high estrogen level during the ovulatory phase might be related to an earlier return to baseline muscle strength after strenuous stretch-shortening cycle exercise in that phase compared with the follicular phase. The estrogen effect appears to be highly specific to the damaged
site because the differences in most EIMD markers (CK, soreness, and low-frequency fatigue) between the two menstrual cycle phases were small [13287].

**Effect of estrogens on muscle regeneration**

Skeletal muscle regeneration efficiency declines with age for both men and women. This decline impacts on functional capabilities in the elderly and limits their ability to engage in regular physical activity and to maintain independence. Aging is associated with a decline in sex hormone production. Therefore, elucidating the effects of sex hormone substitution on skeletal muscle homeostasis and regeneration after injury or disuse is highly relevant for the aging population, where sarcopenia affects more than 30 percent of individuals over 60 years of age. While the anabolic effects of androgens are well known, the effects of estrogens on skeletal muscle anabolism have only been uncovered in recent times. Hence, the purpose of this review is to provide a mechanistic insight into the regulation of skeletal muscle regenerative processes by both androgens and estrogens. Animal studies using estrogen receptor (ER) antagonists and receptor subtype selective agonists have revealed that estrogens act through both genomic and non-genomic pathways to reduce leukocyte invasion and increase satellite cell numbers in regenerating skeletal muscle tissue. Although animal studies have been more conclusive than human studies in establishing a role for sex hormones in the attenuation of muscle damage, data from a number of recent well controlled human studies is presented to support the notion that hormonal therapies and exercise induce added positive effects on functional measures and lean tissue mass. Based on the fact that aging human skeletal muscle retains the ability to adapt to exercise with enhanced satellite cell activation, combining sex hormone therapies with exercise may induce additive effects on satellite cell accretion. There is evidence to suggest that there is a 'window of opportunity' after the onset of a hypogonadal state such as menopause, to initiate a hormonal therapy in order to achieve maximal benefits for skeletal muscle health. Novel receptor subtype selective ligands and selective estrogen and androgen receptor modulators (SERMs, SARMs) promise to reduce health risks associated with classical hormonal therapies, whilst maintaining the positive effects on muscle repair. Dietary supplements containing compounds with structural similarity to estrogens (phytoestrogens) are increasingly used as alternatives to classical hormone-replacement therapies (HRT), but the effects on skeletal muscle are currently largely unknown. Research has started to investigate the combined effects of exercise and alternative HRTs, such as soy isoflavones, on skeletal muscle regenerative processes to provide safer and more efficient therapies to promote muscle regeneration and maintenance of muscle mass and strength in the aging population [13282].

**Influence of IGF-1**

The aim of one study was to determine the relationships of bone mineral density (BMD) and content (BMC) with insulin-like growth factor-1 (IGF-1), IGF-binding protein-3 (IGFBP-3) and estradiol in pubertal female athletes. The participants were 170 healthy adolescent girls (13-15 years) who participated in competitive extramural athletic programs, i.e., sports games (n=49), track sprinting (n=24), rhythmic gymnastics (n=23), swimming (n=24) and cross-country skiing (n=17). The control group (n=33) consisted of girls who took part only in compulsory physical education classes at school. The whole-body BMD and femoral neck and lumbar spine BMD and BMC were measured using DXA, and the volumetric BMD was calculated. Venous blood samples to determine the concentration of IGF-1, IGFBP-3 and estradiol were drawn after an overnight fasting. After adjusting for age, body height and body
mass, the relationships among BMD variables, IGF-1 and the IGF-1/IGFBP-3 molar ratio remained significant only in the rhythmic gymnast group. BMDs at the femoral neck and lumbar spine were also significantly related to estradiol levels only in the rhythmic gymnast group. No relationships were found among the measured BMD, IGF axis and estradiol in other athletic groups. Only BMC at the femoral neck remained associated with the IGF-1/IGFBP-3 molar ratio in the rhythmic gymnast group after adjusting for age, body height and body mass. Stepwise multiple regression analysis indicated that IGF-1 and estradiol together explained 43 percent of total variance in the femoral neck BMD and IGF-1 alone 35 percent of the total variance in the femoral neck BMC only in the rhythmic gymnast group. It was concluded that femoral neck and lumbar spine BMD correlated with IGF-1, IGF-1/IGFBP-3 molar ratio and estradiol in rhythmic gymnasts. No relationships were found between bone parameters and the hormones used in other athletic groups [09139].

Influence of age on muscle mass in women

Menopause is associated with a natural decline in estrogen, that increases visceral fat mass, decreases bone mass density, muscle mass, and strength. One review examined the role of menopause transition and associated decrease in hormonal status with regards to those changes. Studying changes in muscle mass associated with menopause is important, because of the high number of postmenopausal women in developed countries and the related risk of physical incapacity. Among modifiable factors, low physical activity and protein intakes are the best contributors to sarcopenia and the loss of strength in postmenopausal women. On the other hand, some biological factors, namely oxidative stress, inflammation, estrogen and other hormone deficiency are predictors of these phenomena. Interestingly, some methods have the potential to attenuate the loss of muscle mass and strength such as exercise, and supplement intake [09140].

Gestrinone

Gestrinone is a synthetic steroid hormone with anti-estrogenic and anti-progesterone properties. It is used to treat endometriosis, shrink uterine fibroids and reduce menorrhagia; besides, it has been investigated for use as contraceptive. Also, due to its anabolic effects, it has been included in the banned list of performance enhanced drugs in sport. Polyclonal antibodies raised against bovine serum albumin coupled to gestrinone 3-carboxymethyloxime (3OCMO-G) were used to develop two highly sensitive and specific enzyme-linked immunosorbent assays for gestrinone. One of them, based on direct format, shows a detection limit (LD) of 0.09 +/- 0.03 ng/L. The second assay, hapten-protein coating format, can detect until (LD) 0.14 +/- 0.05 ng/L. Both immunoassays were also highly specific, showing negligible or no cross-reactivity to other anabolic steroids. The developed ELISAs detected lower amounts of gestrinone than those determined by the reference chromatographic HPLC/MS/MS methods. The direct format was applied to quantify this steroid in spiked human urine without sample pre-treatment, with recovery values between 76 and 122 percent [10464].

Estrogen blockers

Estrogen blockers include antiestrogens such as steroidal and nonsteroidal drugs that block estrogen receptor action and aromatase inhibitors that block the enzymatic synthesis of estradiol. The original class of estrogen blockers was antiestrogens. These are drugs that
bind to and block estrogen receptor-alpha and/or -beta. The original antiestrogens were the nonsteroidal drugs clomiphene (Clomid) and tamoxifen (Nolvadex). Subsequently newer estrogen receptor blockers have been developed as a class of partial or mixed estrogen agonists, often described by the marketing term specific estrogen receptor modulator (SERM). These agents display a mixture of estrogen agonist and antagonist properties that differ between tissues and between drugs [06127].

Effects in men

There are no valid clinical indications for estrogen blockers in men. Accepted off-label use for estrogen blockers would be limited to men with breast cancer, an exceptionally rare tumor. Some limited experimental uses for estrogen blockade in men have included delayed puberty, short stature, gynecomastia, spinal growth, and idiopathic male infertility. Given the lack of convincing evidence established for any of these experimental indications, it is unlikely that TUE for estrogen blockers in men would be justified, apart from exceptional circumstances. Because there are no proven or likely indications for estrogen blockers in men, there are few clinical studies on the effects of modern estrogen blockers in men. There is, however, abundant and consistent evidence that estrogen blockers increase blood testosterone concentrations in men. However, it is well established that in normal men antiestrogens such as clomiphene, tamoxifen, and raloxifene cause a reflex rise in pituitary gonadotrophin secretion and consequently in blood testosterone concentrations. This is attributable to their inhibition of testosterone-negative feedback on the hypothalamus, a process that involves local aromatization of testosterone within the brain. A similar increase in blood testosterone concentrations ranging from 5 to 20 nmol/L is reported with aromatase inhibitors such as testolactone, exemestane, and anastrozole. By virtue of their common mechanism of action in inhibiting that part of testosterone’s negative hypothalamic feedback due to aromatization, it is highly likely that all estrogen blockers would have similar class-wide effects, proportional to their estrogen-blocking effectiveness [06127].

It is notable that blood testosterone concentrations are markedly increased in mice with complete inactivation of aromatase (63) or estrogen receptors-α (64) but not -β (65), with consequences for androgen receptor-mediated effects on bone (65), prostate (63), and smooth muscle (66, 67), although skeletal muscle effects have not yet been reported. This predicts that more effective estrogen blockade in men would produce significant and sustained elevations of blood testosterone concentrations and likely myotrophic and ergogenic effects in men treated with such drugs. Hence, these observations make a strong case to ban estrogen blockers in men due to their class-wide ability to provoke reflex increase in endogenous pituitary LH and endogenous testosterone secretion [06127].

Experimental

Several combinations of effective treatments have been used in the search for higher response rates or more rapid responses than monotherapy to diminish treatment-resistant depression. One strategy is to combine olanzapine plus antidepressant drugs. In preclinical studies in male rats, olanzapine combined with fluoxetine produce antidepressant-like actions and increase the allopregnanolone levels in the brain. 17-beta estradiol also produces antidepressant-like actions by increasing allopregnanolone levels. However, the effects of combining olanzapine with 17-beta estradiol in the forced swimming test have not been tested before. Thus, systemic injections of vehicle plus olanzapine, or fluoxetine (20.0 mg/kg; 25.0 mg/kg) or 17-beta estradiol (10.0 microg/rat; 20.0 microg/rat) reduced immobility by increasing active behaviors, which were cancelled by finasteride (finasteride was used to
block the endogenous production of allospregnolone by the brain) in ovariectomized rats forced to swim. Subthreshold doses of olanzapine (2.5 mg/kg) combined with subthreshold doses of 17-beta estradiol (5.0 microg/rat) produced antidepressant-like actions, as did the combination subthreshold dose of olanzapine (2.5 mg/kg) plus the subthreshold dose of fluoxetine (15.0 mg/kg). Finasteride cancelled the antidepressant-like actions of the several combinations used. It is concluded that olanzapine alone or combined with fluoxetine or estradiol reduced immobility by increasing swimming. In conclusion, olanzapine produces antidepressant-like actions alone or in combination with estradiol. These antidepressant-like actions of this combination were cancelled by finasteride [09141].

**Oral contraceptives**

Oral contraceptive (OC) treatment has an inhibiting effect on protein synthesis in tendon and muscle connective tissue. It was aimed to investigate whether OC influence myofibrillar protein turnover in young women. OC-users (24 ± 2 years; Lindynette® n=7, Cilest® n=4) and non-OC-users (controls, 24 ± 4 years, n=12) performed one-legged kicking exercise. The next day, the myofibrillar protein fractional synthesis rate (FSR) was measured using stable isotopic tracers (13C-proline) while the subjects were fed standardized nutrient drinks. Simultaneously, a marker for myofibrillar protein breakdown, 3-methyl-histidine (3-MH), was measured in the interstitial fluid of the vastus lateralis. Measurements were performed in both legs. In general, myofibrillar protein FSR was significantly lower in OC-users (two-way analysis of variance), although the difference seemed to depend on the OC type. Interstitial 3-MH in the skeletal muscle was not different between groups and did not vary by OC type. Exercise did not change myofibrillar protein FSR or 3-MH concentrations. Serum androstenedione and bioavailability of testosterone were lower in OC-users. In conclusion, the results indicate that the use of OC has an inhibiting effect on myofibrillar protein synthesis and the magnitude of the effect may depend on the type of OC. In contrast, there was no effect of OC on myofibrillar protein breakdown in the fed state [09138].

Some reports suggest variation in physiological responses and athletic performance, for female athletes at specific phases of the menstrual cycle. However, inconsistent findings are common due to the inappropriate verification of menstrual cycle phase, small subject numbers, high intra- and interindividual variability in estrogen and progesterone concentration, and the pulsatile secretion of these hormones. Therefore, the oral contraceptive (OC) cycle may provide a more stable environment in which to evaluate the acute effect of reproductive hormones on physiological variables and exercise performance. To date, most of the OC research has compared differences between OC use and nonuse, and few researchers have examined within-cycle effects of the OC. It is also apparent that OC use is becoming far more prevalent in athletes; hence the effect of the different exogenous and endogenous hormonal profiles on athletic performance should be investigated. Research to date identifies potential for variation in aerobic performance, anaerobic capacity, anaerobic power and reactive strength throughout an OC cycle [09142].
In general, myofibrillar protein FSR was significantly lower in OC-users although the difference seemed to depend on the OC type. Interstitial 3-MH in the skeletal muscle was not different between groups and did not vary by OC type. Exercise did not change myofibrillar protein FSR or 3-MH concentrations. Serum androstenedione and bioavailability of testosterone were lower in OC-users. In conclusion, the results indicate that the use of OC has an inhibiting effect on myofibrillar protein synthesis and the magnitude of the effect may depend on the type of OC. In contrast, there was no effect of OC on myofibrillar protein breakdown in the fed state [11112].

The purpose of one study was to examine whether common team sport performance variables (anaerobic power, reactive strength and repeat sprint ability) are affected by acute hormonal fluctuation within a monophasic oral contraceptive (OC) cycle. Ten female team sport athletes completed performance tests at three time points of a single OC cycle, during the consumption phase (CONS), early (WITH1) and late in the withdrawal phase (WITH2). Tests included drop jumps (30 cm and 45 cm heights), a counter movement jump, a 10s cycle sprint test and a 5x 6s repeated sprint cycle test. Resting endogenous serum estradiol and progesterone concentrations were also measured. No significant differences were observed between phases for the counter movement jump and cycle tests (total work and peak power). Reactive strength measured from the 30cm drop height was significantly lower during WITH2 compared to both CONS and WITH1. Reactive strength measured from the 45cm drop height was significantly higher in CONS compared to both WITH1 and WITH2. Serum estradiol levels were greater during WITH2 compared to both WITH1 and CONS but there was no difference in serum progesterone levels. The results demonstrate that for female team sport athletes, only reactive strength varied significantly throughout an OC cycle, possibly due to the action of hormones on neuromuscular timing and the stretch-shortening cycle [07102].

The purpose was to examine effects of oral contraceptive (OC) use on plasma growth hormone (GH) responses to heavy resistance exercise. Sixty untrained women were placed into one of two groups: currently using OC (Ortho Tri-Cyclen) (n=25) or not currently using OC (NOC) (n=35). Participants performed an acute heavy resistance exercise test (AHRET; six sets of 10 repetition squats; 2min rest between sets) during days 2-4 of the follicular phase (NOC group) or of inactive oral contraceptive intake (OC group). Plasma was obtained before and immediately after AHRET and subsequently fractionated based on apparent molecular weight (>60kD, 30-60kD, and <30kD). GH was determined in unfractionated plasma and each plasma fraction using 4 methods. GH increased significantly in all fractions post-AHRET. OC use augmented immunological GH response to AHRET in unfractionated plasma and >60kD molecular weight subtraction. However, OC use only increased biological activity of GH in one of two bioassays. These data demonstrated that GH concentrations at rest and following exercise are assay-dependent [07103].

Thirteen female cyclists/triathletes using a monophasic oral contraceptive (OC) performed an endurance test (1-h cycle) at three time points of an OC cycle. Testing times were during the OC consumption phase (CONS), early in the OC withdrawal phase (WITH1) and late in the OC withdrawal phase (WITH2). Resting endogenous serum oestradiol and progesterone concentrations were measured. Power output, heart rate (HR), ventilation (Ve), oxygen consumption (VO2), respiratory exchange ratio (RER), rating of perceived exertion (RPE), blood lactate and blood glucose were measured throughout the 1-h test. Serum oestradiol levels were significantly greater during WITH2 compared to the CONS. No significant differences were present between the testing times for mean power output, HR, VO2, RER, RPE, and blood glucose concentration. Greater mean ventilation and oxygen consumption values were measured during CONS compared to WITH1 and WITH2 respectively and blood lactate values compared to WITH1 only. Despite variation in some physiological variables,
there was no difference in endurance performance throughout an OC cycle in endurance trained female athletes [07104].

It is now estimated that the prevalence of oral contraceptive use in athletic women matches that of women in the general population. The oral contraceptive pill (OCP) reduces cycle-length variability and provides a consistent 28-day cycle by controlling concentrations of endogenous sex hormones. The OCP is administered in three different forms that differ widely in chemical constitution and concomitant effects on the human body. As fluctuation in sex steroids are believed to be a possible causal factor in performance and exercise capacity, it is imperative to understand the effect of administering the various types of OCP on women. However, the research into oral contraceptives and exercise performance is not consistent. The type of OCP administered (monophasic, biphasic or triphasic), as well as the type and dose of estrogen and progestogen within, will have varying effects on exercise. To date, research in the area of oral contraceptives and exercise capacity is sparse and much has been plagued by poor research design, methodology and small sample size. It is clear from the research to date that more randomised clinical trials are urgently required to assess the array of OCP formulations currently available to women and their concomitant effect on health and exercise capacity. Therefore, the purpose of one article was to critically appraise the literature to date and to provide a current review of the physiological scientific knowledge base in relation to the OCP and exercise performance. In addition, methodological control, design and conduct will be considered with future areas of research highlighted [07105].

**Effect of bone mass**

To determine the effect of oral contraceptives (OC) on bone mass and stress fracture incidence in young female distance runners. One hundred fifty competitive female runners ages 18-26 yr were randomly assigned to OC (30 microg of ethinyl estradiol and 0.3 mg of norgestrel) or control (no intervention) for 2 years. Bone mineral density (BMD) and content (BMC) were measured yearly by dual x-ray absorptiometry. Stress fractures were confirmed by x-ray, magnetic resonance imaging, or bone scan. Randomization to OC was unrelated to changes in BMD or BMC in oligo/amenorrheic (n=50) or eumenorrheic runners (n=100). However, treatment-received analyses (which considered actual OC use) showed that oligo/amenorrheic runners who used OC gained about 1 percent per year in spine BMD and whole-body BMC, amounts similar to those for runners who regained periods spontaneously and significantly greater than those for runners who remained oligo/amenorrheic. Dietary calcium intake and weight gain independently predicted bone mass gains in oligo/amenorrheic runners. Randomization to OC was not significantly related to stress fracture incidence, but the direction of the effect was protective in both menstrual groups (hazard ratio 0.57) and the effect became stronger in treatment-received analyses. The trial's statistical power was reduced by higher-than-anticipated noncompliance. OC may reduce the risk for stress fractures in female runners, but our data are inconclusive. Oligo/amenorrheic athletes with low bone mass should be advised to increase dietary calcium and take steps to resume normal menses, including weight gain; they may benefit from OC, but the evidence is inconclusive [07106].

**Influence of oral conceptives on tendons and ligament**

Sex differences exist with regards to ligament and tendon injuries. Lower collagen synthesis has been observed in exercising women vs. men, and in users of oral contraceptives (OC) vs. nonusers, but it is unknown if OC will influence tendon biomechanics of women undergoing regular training. Thirty female athletes (handball players, 18-30 years) were recruited: 15 long-term users of OC (7.0 ± 0.6 years) and 15 nonusers (>5 years).
Synchronized values of patellar tendon elongation (obtained by ultrasonography) and tendon force were sampled during ramped isometric knee extensor maximum voluntary contraction to estimate mechanical tendon properties. Furthermore, tendon cross-sectional area and length were measured from MRI images, and tendon biopsies were obtained for analysis of tendon fibril characteristics and collagen cross-linking. Overall, no difference in tendon biomechanical properties, tendon fibril characteristics, or collagen cross-linking was observed between the OC users and nonusers, or between the different phases of the menstrual cycle. In athletes, tendon cross-sectional area in the preferred jumping leg tended to be larger than that in the contralateral leg, and a greater absolute and normalized tendon stiffness, as well as a lower strain, were observed in the jumping leg compared with the contralateral leg. The results indicate that long-term OC use or menstrual phases does not influence structure or mechanical properties of the patellar tendon in female team handball athletes [13283].

Influence of SERMs on steroid metabolism

In a comparable line of investigation, the alteration of steroid profile data by selective estrogen receptor modulators (SERMs, category S4.2) was studied. Although relatively straightforward in detection, the effect of tamoxifen, toremifene, and clomiphene on T, 5alpha-androstane-3α,17β-diol (ADIOL), 5beta-androstane-3alpha,17beta-diol (BDIOL), EpiT, 4-androstenedione, A, and etiocholanolone (E), LH and follicle-stimulating hormone (FSH) were studied. Significant effects were observed for T, EpiT, and 4-androstenedione in males; all other parameters were found unaffected [13012].

Folinic acid supplementation

Although there are numerous benefits to women from athletic participation, a complex combination of endocrine and metabolic factors exaggerates risk for a serious health concern: the female athlete triad. The purpose of one article was to provide updates on new issues related to the triad, specifically the relationship between athletic-associated amenorrhea and endothelial dysfunction-a potential fourth component to the triad that is a concern for future cardiovascular risk, public health issues, and athletic performance. Folic acid should be considered a potential safe and inexpensive therapeutic treatment to restore endothelial-dependent vasodilation [11336].

Laboratory techniques

Estrogens were prohibited in the food producing animals by European Union (96/22/EC directive) and added to the Report on Carcinogens in United States since 2002. Due to very low concentration in serum or urine (pg/mL), the method of control its abuse had not been fully developed. The endogenous estrogens were separated from urines of 18 adult men and women. The exogenous estrogens were chemical reference standards and over the counter preparations. Two patients of dysfunctional uterine bleeding (DUB) administered exogenous estradiol and the urines were collected for 72h. The urinary estrogens were separated by high-performance liquid chromatography (HPLC) and confirmed. The exogenous and exogenous estrogens were analyzed by gas chromatography combustion isotope ratio mass spectrometry (GC-C-IRMS) to determine the $^{13}$C/$^{12}$C ratio (delta$^{13}$C‰). The delta$^{13}$C‰ values of reference standard of E1, E2, and E3 have been defined. Two DUB patients’ urinary estradiol delta$^{13}$C‰ values was depleted to -28 after the administration. The
progesterone, 17α-hydroxyprogesterone, pregnanediol, as well as desogestrel and ethinylestradiol from contraceptives were also determined. Stable carbon isotope analysis can distinguish the endogenous and exogenous urinary estrogen in human [12197].

Selective estrogen receptor modulator (SERM)

It was discussed the capabilities of liquid chromatography coupled to mass spectrometry with a time-of-flight system with accurate mass measurement for the detection and characterisation of drug metabolites in biological samples for anti-doping purpose. Urinary excretion samples of three selective oestrogen receptor modulators (SERMs) with a common triphenylethylene structure: clomiphene, toremifene, and tamoxifen, obtained after oral administration of a single dose of each drug, were analysed using a time-of-flight system, after automatic tuning and calibration of the equipment, in positive full scan mode using an electrospray ionisation source. Following this approach we detected most of all significant metabolites reported by others and postulated new metabolites, especially for toremifene, have been characterised: N-demethyl-3-hydroxy-4-methoxy-toremifene and 3-hydroxy-4-methoxy-toremifene; in additiona to this, in the urinary excretion samples of toremifene some metabolites, without the characteristic chlorine isotope pattern, discarded in previous studies, that are also metabolites of tamoxifen, were identified. The lack of certified reference materials does not allow an accurate determination of the limit of detection (LODs) of all metabolites; however an estimation taking into account the response factor of similar compounds allows to estimate that all metabolites are clearly detectable in a range of concentration comprised between 10 ng/mL and 30 ng/mL [08207].

One study was performed to investigate the influence of the intake of selective oestrogen receptor modulators on the urinary endogenous steroids profile. For this purpose the circadian variability of luteinizing hormone, follicle-stimulating hormone, testosterone, 5alpha-androstan-3alpha,17beta-diol, 5beta-androstan-3alpha,17beta-diol, epitestosterone, 4-androstenedione, androsterone and etiocholanolone were measured on eight subjects (four males and four females) by gas chromatography-mass spectrometry and chemiluminescent immunometric assay techniques before and after oral administration of multiple doses of either tamoxifen (80 mg for 2 days) or toremifene (120 mg for 2 days) or clomiphene (100 mg for 2 days). The individual baseline variability of the steroids studied was set up by collecting the urine samples every 3 h, for 3 days prior to the treatment; whereas the evaluation of the effects of the oral administration of multiple doses of selective oestrogen receptor modulators on the steroid urinary profile was assessed by collecting urine samples every three hours for at least five days from the first administration. The results of the measurements showed that, only in male subjects, the relative urinary concentrations of testosterone, epitestosterone and 4-androstenedione were significantly altered generally after the second day of drug administration. While no significant effects were recorded in both sexes on the luteinizing hormone, follicle-stimulating hormone, androsterone, etiocholanolone, 5alpha-androstan-3alpha,17beta-diol and 5beta-androstan-3alpha,17beta-diol urinary levels and on testosterone/epitestosterone, 5alpha-androstan-3alpha,17beta-diol/5beta-androstan-3alpha,17beta-diol and androsterone/etiocholanolone ratios [11113].

The alteration of steroid profile data by selective estrogen receptor modulators (SERMs) was studied. Although relatively straightforward in detection, the effect of tamoxifen, toremifene, and clomiphene on testosterone, 5alpha-androstan-3alpha,17beta-diol, 5beta-androstan-3alpha,17beta-diol, epitestosterone, 4-androstenedione, and etiocholanolone, LH and follicle-stimulating hormone (FSH) were studied. Significant effects were observed for testosterone, epitestosterone, and 4-androstenedione in males; all other parameters were found
unaffected [12017].

**Toremiphene**

Toremifene is a selective estrogen receptor modulator included in the list of prohibited substances in sport by the World Anti-doping Agency. The aim of one study was to investigate toremifene metabolism in humans in order to elucidate the structures of the most abundant urinary metabolites and to define the best marker to detect toremifene administration through the analysis of urine samples. Toremifene (Fareston®) was administered to healthy volunteers and the urine samples were subjected to different preparation methods to detect free metabolites as well as metabolites conjugated with glucuronic acid or sulphate. Urinary extracts were analyzed by LC-MS/MS with triple quadrupole analyzer using selected reaction monitoring mode. Transitions for potential metabolites were selected by using the theoretical [M+H]^+ as precursor ion and m/z 72 or m/z 58 as product ions for N,N-dimethyl and N-desmethyl metabolites, respectively. Toremifene and 20 metabolites were detected in excretion study samples, excreted free or conjugated with glucuronic acid or sulphate. Structures for most abundant phase I metabolites were proposed using accurate mass measurements performed by QTOF MS, based on fragmentation pattern observed for those metabolites available as reference standards. Several metabolic pathways including mono- and di-hydroxylation, N-desmethylation, hydroxymethylation, oxidation, dehalogenation and combinations were proposed. All metabolites were detected up to one month after toremifene administration; the most abundant metabolites were detected in the free fraction and they were metabolites resulting from dehalogenation. Several of the metabolites elucidated in this work have not been reported until now in the scientific literature [11114].

In the present study, toremifene urinary excretion studies were evaluated in order to examine main metabolic reactions and to select target metabolites in doping control analysis. Urine samples from three female subjects were collected every 3 h for at least 15 days after the oral administration of a single dose of Fareston® (60 mg). The elemental compositions of the compounds detected were determined by liquid chromatography-mass spectrometry using a time-of-flight system with accurate mass measurement. More detailed structure elucidation was obtained by monitoring the presence or absence of structure-specific ions, using product ion scan and neutral loss acquisition modes, whereas the metabolites urinary profiles were evaluated in selected reaction monitoring acquisition mode. The results showed that the main routes of phase-I modifications involved carboxylation of the chlorinated side chain, N-demethylation and hydroxylation in different positions. Fifteen metabolites were found in all subjects studied, most of them were detected for more than 10 days in the free, glucuronide and sulphate fractions, with a maximum of excretion generally after 9-22 and 34-47 h from drug administration. These metabolites can be divided in two groups: metabolites with the characteristic chlorine isotope pattern and metabolites without the characteristic chlorine isotope pattern. The most abundant and long-term compounds were the carboxylated metabolites followed by the hydroxylated metabolites. Their product ions originating after collision-induced dissociation were observed to occur prevalently in the dimethylaminoethoxy and in the chlorinated side chains. These structure-specific ions were used to design screening and confirmation procedures to positively identify toremifene administration in doping control analysis [11220].

**Raloxiphene**

A selective, sensitive, accurate and precise liquid chromatography-tandem mass spectrometry (LC-MS/MS) method for determination of raloxifene and its three glucuronides:
raloxifene-6-beta-glucuronide (M1), raloxifene-4’-beta-glucuronide (M2), raloxifene-6,4’-diglucuronide (M3) in urine samples is presented in this paper. The developed analytical method is the first fully validated method capable of simultaneous determination of raloxifene and its glucuronides in real urine samples. Moreover, for the first time a method for determination of raloxifene diglucuronide in relevant biological samples was introduced. Metabolites were obtained by a bioconversion process of raloxifene to its glucuronides using the microorganism Streptomyces sp. and were used as standards for validation. Urine samples were introduced to a simple solid phase extraction prior to the analysis by LC-MS/MS. The method was linear in a wide range with high determination coefficient. The limits of quantification achieved were 1.01, 1.95, 2.83 and 4.69nM for raloxifene, M1, M2 and M3, respectively. The recoveries were higher than 93 percent, the accuracy was within 100 ± 9 percent and the precision was better than 12 percent for all compounds. The developed method was successfully applied to the real urine samples and showed to be appropriate for use in further research of still not completely discovered raloxifene pharmacokinetics. Furthermore, the presented method could also serve for a potential application in anti-doping analysis [11115].

Raloxifene is one of the selective estrogen receptor modulators and is often used to prevent and treat osteoporosis in postmenopausal women. Because of the indirect impact on serum testosterone levels and the potential ability for performance enhancement, it is banned by the World Anti-Doping Agency (WADA). This study established a fast, sensitive and selective liquid chromatography-tandem mass spectrometry method to quantify total raloxifene (unchanged and glucuronidated) in human urine for doping analysis. Urines from six healthy volunteers were collected 240 h after taking a single dose of raloxifene. The concentrations of urinary raloxifene were analyzed by the established method after sample preparation, including hydrolysis with β-glucuronidase. The lowest limit of quantification was 0.5 ng/mL. Linearity was observed for raloxifene concentrations ranging from 0.5 to 100 ng/mL, with a correlation coefficient of 0.999. The recoveries were >93 percent. Inaccuracies were below ±5 percent, and precisions varied from 2.18 to 5.37 percent. The results showed that urinary raloxifene was immediately detectable within 4 h after the administration of only a single dose of raloxifene. Such a result indicates a violation of the WADA rules. Furthermore, ingesting raloxifene would be detectable after 6 days in the urine of males or >10 days in the urine of female [13800].

Laboratory techniques
A selective, sensitive, accurate and precise liquid chromatography-tandem mass spectrometry (LC-MS/MS) method for determination of raloxifene and its three glucuronides: raloxifene-6-β-glucuronide (M1), raloxifene-4'-β-glucuronide (M2), raloxifene-6,4'-diglucuronide (M3) in urine samples is presented in one paper. The developed analytical method is the first fully validated method capable of simultaneous determination of raloxifene and its glucuronides in real urine samples. Moreover, for the first time a method for determination of raloxifene diglucuronide in relevant biological samples was introduced. The developed method was successfully applied to the real urine samples and showed to be appropriate for use in further research of still not completely discovered raloxifene pharmacokinetics. Furthermore, the presented method could also serve for a potential application in anti-doping analysis [11337].
AROMATASE INHIBITORS

Androgens can increase muscular mass and strength and remain the most frequently abused and widely available drugs used in sports doping. Banning the administration of natural or synthetic androgens has led to a variety of strategies to circumvent the ban of the most effective ergogenic agents for power sports. Among these, a variety of indirect androgen doping strategies aiming to produce a sustained rise in endogenous testosterone have been utilized. These include oestrogen blockade by drugs that act as oestrogen receptor antagonists (antioestrogen) or aromatase inhibitors [08204].

The detection of metabolites of the anti-estrogenic substance cyclofenil, listed on the World Anti-Doping Agency Prohibited List since 2004 is described. Target substances are hydroxylated metabolites, bearing an aliphatic hydroxyl group either in the 2-, 3- or 4-position of the aliphatic ring, in addition to the phenolic functions on the aromatic rings. Structural identification used NMR as well as high-resolution mass spectrometry after nano-electrospray ionisation (ESI). Unambiguous detection of all three synthesised cyclofenil metabolites M1-M3 was done using gas chromatography for separation and electron ionisation mass spectrometry for detection of the per-silylated compounds in comparison with a reference urine deriving from an excretion study within the WADA 2007 Educational Programme [08205].

Tamoxifene

Different liquid chromatographic/tandem mass spectrometric (LC/MS/MS) scanning techniques were considered for the characterization of tamoxifene metabolites in human urine for anti-doping purpose. Five different LC/MS/MS scanning methods based on precursor ion scan (precursor ion scan of m/z 166, 152 and 129) and neutral loss scan (neutral loss of 72 Da and 58 Da) in positive ion mode were assessed to recognize common ions or common losses of tamoxifene metabolites. The applicability of these methods was checked first by infusion and then by the injection of solution of a mixture of reference standards of four tamoxifene metabolites available in a laboratory. The data obtained by the analyses of the mixture of the reference standards showed that the five methods used exhibited satisfactory results for all tamoxifene metabolites considered at a concentration level of 100 ng/mL, whereas the analysis of blank urine samples spiked with the same tamoxifene metabolites at the same concentration showed that the neutral loss scan of 58 Da lacked sufficient specificity and sensitivity. The limit of detection in urine of the compounds studied was in the concentration range 10-100 ng/mL, depending on the compound structure and on the selected product ion. The suitability of these approaches was checked by the analysis of urine samples collected after the administration of a single dose of 20 mg of tamoxifene. Six metabolites were detected: 4-hydroxytamoxifen, 3,4-dihydroxytamoxifen, 3-hydroxy-4-methoxytamoxifen, N-demethyl-4-hydroxytamoxifen, tamoxifen-N-oxide and N-demethyl-3-hydroxy-4-methoxytamoxifen, which is in conformity to our previous work using a time-of-flight (TOF) mass spectrometer in full scan acquisition mode [10203].

A molecular imprinted polymer (MIP) has been synthesized in order to specifically extract tamoxifen, a nonsteroidal antiestrogen, and its metabolites from urine by solid-phase extraction (SPE) before HPLC-UV analysis. Clomiphene, a chlorinated tamoxifen analogue, was selected as template for MIP synthesis. Polymerisation was achieved by thermal polymerisation of methacrylic acid (MAA) as functional monomer, ethylene glycol
dimethacrylate (EDMA) as cross-linking agent and acetonitrile as porogen. The efficient elimination of the urinary matrix has been obtained by MIP-SPE but the elution recovery of tamoxifen was initially too low (approximately 14 %). This problem has been overcome following two ways. At first, a preliminary HLB-SPE of the urine has enabled to discard endogenous salts and to percolate an organic sample through the MIP cartridge. Extraction recoveries are equal to 56 and 74 percent for tamoxifen and 4-hydroxytamoxifen, respectively. Then, a second MIP has been prepared with styrene and MAA as functional co-monomers. Strong pi-pi interactions occurring between phenyl groups of styrene and tamoxifen promote rebinding of the analyte by the specific sites. The enhanced hydrophobic character of the imprinted polymer has enabled the direct percolation of urine through MIP-SPE and the easy elimination of endogenous salts from urine with only one aqueous washing step. HPLC-UV analysis has confirmed high extraction recoveries (85 %) for tamoxifen and its metabolite with an enrichment factor of 8. This analytical protocol can selectively detect the presence of tamoxifen metabolites in urines and be useful as a proof of doping in competitive sports [08206].

In men, the stimulation of GH and inhibition of LH secretion by testosterone requires aromatization to estradiol. Tamoxifen, a selective estrogen receptor modulator (SERM), possesses central estrogen antagonistic effect but peripheral hepatic agonist effect, lowering IGF-I. Thus, tamoxifen is likely to perturb the neuroendocrine regulation of GH and gonadal axes. Raloxifene, a SERM, is used for therapy of osteoporosis in both sexes. Its neuroendocrine effects in men are poorly understood. It was conducted a randomized, open-label crossover study. Ten healthy men were randomized to 2-wk sequential treatment with tamoxifen (10 and 20 mg/d) and raloxifene (60 and 120 mg/d), with a 2-wk intervening washout period. Tamoxifen, but not raloxifene, significantly reduced IGF-I levels by 25 ± 6 percent and increased SHBG levels by 20 ± 7 percent at the higher therapeutic dose. There was a nonstatistically significant trend toward a reduction in the GH response to arginine with both SERMs. Both drugs significantly increased LH, FSH, and testosterone concentrations. The mean increase in testosterone and LH was significantly greater with tamoxifen than with raloxifene treatment. It was concluded that tamoxifen, but not raloxifene, reduces IGF-I levels. Both SERMs stimulate the gonadal axis, with tamoxifen imparting a greater effect. We conclude that in therapeutic doses, raloxifene perturbs the GH and gonadal axes to a lesser degree than tamoxifen [10463].

One study was performed to investigate the influence of the intake of selective oestrogen receptor modulators on the urinary endogenous steroids profile. For this purpose the circadian variability of luteinizing hormone, follicle-stimulating hormone, testosterone, 5alpha-androstan-3alpha,17beta-diol, 5beta-androstan-3alpha,17beta-diol, epitestosterone, 4-androstenedione, androsterone and etiocholanolone were measured on eight subjects (four males and four females) by gas chromatography-mass spectrometry and chemiluminescent immunometric assay techniques before and after oral administration of multiple doses of either tamoxifen (80 mg for 2 days) or toremifene (120 mg for 2 days) or clomiphene (100 mg for 2 days). The individual baseline variability of the steroids studied was set up by collecting the urine samples every 3 h, for 3 days prior to the treatment; whereas the evaluation of the effects of the oral administration of multiple doses of selective oestrogen receptor modulators on the steroid urinary profile was assessed by collecting urine samples every three hours for at least five days from the first administration. The results of the measurements showed that, only in male subjects, the relative urinary concentrations of testosterone, epitestosterone and 4-androstenedione were significantly altered generally after the second day of drug administration. While no significant effects were recorded in both sexes on the luteinizing hormone, follicle-stimulating hormone, androsterone, etiocholanolone, 5alpha-androstan-3alpha,17alpha-diol and 5beta-androstan-3alpha,17beta-diol urinary levels and on
testosterone/epitestosterone, 5alpha-androstan-3alpha,17beta-diol/5beta-androstan-3alpha, 17beta-diol and androsterone/etiocholanolone ratios [11456].

One study was performed to investigate the influence of the intake of selective oestrogen receptor modulators on the urinary endogenous steroids profile. For this purpose the circadian variability of luteinizing hormone, follicle-stimulating hormone, testosterone, 5alpha-androstan-3alpha, 17beta-diol, 5beta-androstan-3alpha,17beta-diol, epitestosterone, 4-androstenedione, androsterone and etiocholanolone were measured on eight subjects (four males and four females) by gas chromatography-mass spectrometry and chemiluminescent immunometric assay techniques before and after oral administration of multiple doses of either tamoxifen (80 mg for 2 days) or toremifene (120 mg for 2 days) or clomiphene (100 mg for 2 days). The use of selective oestrogen receptor modulators has been prohibited since 2005 by the World Anti-Doping Agency regulations. As they are extensively cleared by hepatic and intestinal metabolism via oxidative and conjugating enzymes, a complete investigation of their biotransformation pathways and kinetics of excretion is essential for the anti-doping laboratories to select the right marker(s) of misuse. This work was designed to characterize the chemical reactions and the metabolizing enzymes involved in the metabolic routes of clomiphene, tamoxifen and toremifene. To determine the biotransformation pathways of the substrates under investigation, urine samples were collected from six subjects (three females and three males) after oral administration of 50 mg of clomiphene citrate or 40 mg of tamoxifen or 60 mg of toremifene, whereas the metabolizing enzymes were characterized in vitro, using expressed cytochrome P450s and uridine diphosphoglucuronosyltransferases. The separation, identification and determination of the compounds formed in the in vivo and in vitro experiments were carried out by liquid chromatography coupled with mass spectrometry techniques using different acquisition modes. Clomiphene, tamoxifen and toremifene were biotransformed to 22, 23 and 18 metabolites respectively, these phase I reactions being catalyzed mainly by CYP3A4 and CYP2D6 isoforms and, to a lesser degree, by CYP3A5, CYP2B6, CYP2C9, CYP2C19 isoforms. The phase I metabolic reactions include hydroxylation in different positions, N-oxidation, dehalogenation, carboxylation, hydrogenation, methoxylation, N-dealkylation and combinations of them. In turn, most of the phase I metabolites underwent conjugation reaction to form the corresponding glucuron conjugated mainly by UGT1A1, UGT1A3, UGT1A4, UGT2B7, UGT2B15 and UGT2B17 isoenzymes [13274].

**Exemestane**

The renamed category S4 (Hormone and metabolic modulators) includes five sub-groups, of which the class of aromatase inhibitors (4.1) lists exemestane that was subjected to human in vivo metabolism studies. Four metabolites formerly not reported were discussed and
structures were assigned and proposed based on LC-MS and LC-MS/MS (with accurate mass) data. The metabolites include bis-hydroxylated exemestane bearing the two hydroxyl functions at C-6 and the C-6-linked methylene unit, as well as 6-hydroxyandrost-1,4-diene-17β-ol-3-one and two isomers of 6-hydroxyandrost-1,4-diene-3,17-dione. Since the proposed compositions are not yet supported by chemical (or enzymatic) synthesis or available reference material, the suggested products have to be considered tentative but nevertheless useful for screening purposes [13012].

Aminoglutethimide

Aminoglutethimide is an anti-steroid drug marketed under the tradename Cytadren by Novartis around the world. It blocks the production of steroids derived from cholesterol and is clinically used in the treatment of Cushing’s syndrome and metastatic breast cancer. It is also used by body builders. Aminoglutethimide has two mechanisms of action: it blocks aromatase in the generation of estrogens from androstenedione and testosterone and it blocks the conversion of cholesterol to pregnenolone by inhibiting the enzyme P450scc and consequently decreases synthesis of all hormonally active steroids. At low doses, aminoglutethimide is only an effective inhibitor of aromatase, but at higher doses, it effectively blocks P450scc as well. Following an alternate analytical approach, the utility of metallic plasmonic nanoparticles for the isolation and detection of aminoglutethimide (S4.1) with surface-enhanced Raman spectroscopy and plasmon resonance was presented. By means of colloidal silver triangular nanoprisms, a LOD of 0.13 ng/mL was accomplished, demonstrating the high sensitivity of the employed approach; however, the limitation to one particular drug and the unknown specificity under routine doping control conditions might not allow to consider the assay fit-for-purpose [13012].

Formestan

Formestane (F, androst-4-en-4-ol-3,17-dione) is an irreversible aromatase inhibitor with the ability to suppress the estrogen production from anabolic steroids. Consequently, F is mentioned on the World Anti-Doping Agency (WADA) prohibited list and because studies have shown that F is produced endogenously in small amounts, a threshold for urinary excreted F of 150 ng/mL was introduced. Lower concentrations could be due to endogenous production and need further investigation to prove the exact origin through determination of the carbon isotope ratio. However, because the current screening methods are a lot more sensitive, F is detected in practically every urine sample. A strict implementation of this WADA rule would imply that almost every urine sample needs additional investigation to verify an exogenous or endogenous origin. The main aim of this study was to propose and introduce a lower concentration limit of 25 ng/mL beneath which the detected F is considered as being endogenous and no further investigation is needed. The data presented in this paper suggests that this threshold provides a good balance between a sufficiently large detection window and not having to perform isotope ratio mass spectrometry (IRMS) analyses on negative urine samples [13275].

The class of hormone and metabolic modulators of the 2013 WADA Prohibited List comprises five categories. Among the explicitly mentioned aromatase inhibitors (S4.1), particularly formestane was subject of research projects within the past 12 months, arguably due to its known natural occurrence and the resulting analytical challenge in doping controls. Sensitive and specific steroid profiling has demonstrated that formestane is ubiquitous to human urine samples and consequently, analytical approaches were assessed for the determination of the formestane origin. The strategies were similar to those employed for the
detection and discrimination of natural/endogenous anabolic agents from synthetic analogs with the desire of reasonable effort. Levels of 100 ng/mL and later 150 ng/mL were suggested to be indicative for formestane administration and trigger follow-up analyses by IRMS [13009].

Formestane (F, androst-4-en-4-ol-3,17-dione) is an irreversible aromatase inhibitor with the ability to suppress the estrogen production from anabolic steroids. Consequently, F is mentioned on the World Anti-Doping Agency (WADA) prohibited list and because studies have shown that F is produced endogenously in small amounts, a threshold for urinary excreted F of 150 ng/mL was introduced. Lower concentrations could be due to endogenous production and need further investigation to prove the exact origin through determination of the carbon isotope ratio. However, because the current screening methods are a lot more sensitive, F is detected in practically every urine sample. A strict implementation of this WADA rule would imply that almost every urine sample needs additional investigation to verify an exogenous or endogenous origin. The main aim of one study was to propose and introduce a lower concentration limit of 25 ng/mL beneath which the detected F is considered as being endogenous and no further investigation is needed. The data presented in this paper suggests that this threshold provides a good balance between a sufficiently large detection window and not having to perform isotope ratio mass spectrometry (IRM) analyses on negative urine samples [13276].
BLOOD DOPING

Overviews

As science marches on, athletes and coaches march close behind. Researchers have long been interested in how red cell mass and blood volume affect exercise capacity. Interest in blood doping soared after the 1968 Mexico City Olympics. Studies in the 1970s and 1980s suggested that transfusing red cells could speed endurance performance. Diverse athletes of the time were accused of blood doping. In the late 1980s, recombinant human erythropoietin (EPO) began to supplant transfusion for doping. EPO use is a suspect in nearly 20 deaths in 4 years in European cyclists. In the 1998 Tour de France, a team was ejected for using EPO and six other teams quit the race. Tests for detecting artificial blood also exist, but it seems it will take widespread, year-round, unannounced, out-of-competition testing and stern penalties to deter blood doping [07107].

WADA describes blood doping as the use of drugs or any technique to increase red blood cell mass: this enables a greater O₂ transport to tissues thereby increasing aerobic capacity and endurance. In clinical practice, patients suffering from chemotherapy induced anaemia, with a haemoglobin concentration below 10 g/dL, benefit from erythropoietin (EPO) therapy, which currently provides an alternative to red blood cell transfusion. Autologous blood transfusion is popular among sports people who engage in doping because its detection is also very difficult, in contrast to the homologous type which can be detected by flow cytometry [12011].

Blood doping practices in sports have been around for at least half a century and will likely remain for several years to come. The main reason for the various forms of blood doping to be common is that they are easy to perform, and the effects on exercise performance are gigantic. Yet another reason for blood doping to be a popular illicit practice is that detection is difficult. For autologous blood transfusions, for example, no direct test exists, and the direct testing of misuse with recombinant human erythropoietin (rhEpo) has proven very difficult despite a test exists. Future blood doping practice will likely include the stabilization of the transcription factor hypoxia-inducible factor which leads to an increased endogenous erythropoietin synthesis. It seems unrealistic to develop specific test against such drugs (and the copies hereof originating from illegal laboratories). In an attempt to detect and limit blood doping, the World Anti-Doping Agency (WADA) has launched the Athlete Biological Passport where indirect markers for all types of blood doping are evaluated on an individual level. The approach seemed promising, but a recent publication demonstrates the system to be incapable of detecting even a single subject as "suspicious" while treated with rhEpo for 10-12 weeks. Sad to say, the hope that the 2012 London Olympics should be cleaner in regard to blood doping seems faint. It was proposed that WADA strengthens the quality and capacities of the National Anti-Doping Agencies and that they work more efficiently with the international sports federations in an attempt to limit blood doping [12223].

Among doping practices, blood doping has become an integral part of endurance sport disciplines over the past decade. The term "blood doping" or "blood boosting," earlier known as "induced erythrocythemia," usually refers to methods or substances administered for non-medical reasons to healthy athletes with the aim of increasing maximal aerobic power and thereby improving aerobic performance. The definition of blood doping therefore must include methods or substances administered for non-medical reasons to healthy athletes for improving aerobic performance. It includes all means aimed at producing an increased or more efficient mechanism of oxygen transport and delivery to peripheral tissues and muscles.
The World Anti-Doping Agency (WADA) defines blood doping as “the misuse of certain techniques and/or substances to increase one’s red blood cell mass, which allows the body to transport more $O_2$ to muscles and therefore increase stamina and performance.” Prohibited procedures include the use of synthetic $O_2$ carriers, the transfusion of red blood cells (RBCs), the infusion of hemoglobin (Hb), and the artificial stimulation of erythropoiesis. Several paragraphs of the “2011 Prohibited List” of the WADA are relevant as regards blood doping. First, under “Prohibited Substances” (“S2. Peptide hormones, growth factors and related substances”), several erythropoiesis-stimulating agents (ESAs) are itemized: erythropoietin (Epo), darbepoetin-alfa, hypoxia-inducible factor (HIF) stabilizers, methoxy-polyethylene glycol-epoetin (CERA), and peginesatide (Hematide; Affymax). Second, under “Prohibited Methods” forbidden blood products are specified (“M1. Enhancement of oxygen transfer”). Furthermore, intravenous infusions (unless clinically legitimated) and the sequential withdrawal, manipulation and reinfusion of whole blood are prohibited (“M2. Chemical and physical manipulation”). Finally, genetic interventions with the potential to enhance sport performance are defined (“M3. Gene doping”), including “the transfer of nucleic acids or nucleic acid sequences, the use of normal or genetically modified cells, and the use of agents that directly or indirectly affect functions known to influence performance by altering gene expression” [11116].

The wide-spread assumption that doping with erythropoietin or blood transfusion is only effective by increasing arterial blood $O_2$ content because of rising hematocrit is not self-evident. “Natural blood dopers” (horses, dogs) increase both hematocrit and circulating blood volume during exercise by releasing stored erythrocytes from the spleen. Improvement of aerobic performance by augmenting hemoglobin concentration may be expected until the optimal hematocrit is reached; above this value maximal cardiac output declines due to the steep increase of blood viscosity. Therefore an enlarged blood oxygen content might only be useful if the normal hematocrit of man during exercise is suboptimal. However, recent studies suggest that cardiac power rises after erythropoietin allowing an unchanged cardiac output in spite of increased viscosity. Other factors underlying improved performance after blood doping might be: augmented diffusion capacity for oxygen in lungs and tissues, increased percentage of young red cells with good functional properties (after erythropoietin), increased buffer capacity, increase of blood volume, vasoconstriction, reduced damage by radicals, mood improvement by cerebral effects of erythropoietin. Also the importance of placebo is unknown since double-blind studies are rare. It is suggested that blood doping has multifactorial effects not restricted to the increase in arterial oxygen content [10309].

Many innovative methods for blood doping have been tested and proven efficient in other fields of medicine, for example criminology. Another strategy that has been suggested recently is the use of a hematologic passport, which is based on the sequential evaluation of some hematological and biochemical parameters. An athlete’s hematologic profile should be fairly stable over time. Using proper sequential determinations, individual reference ranges can be defined for both hemoglobin and hematocrit. The International Ski Federation decided to pursue athletes with hemoglobin values above 175 g/l for men and 155 g/l for women, whereas the International Cycling Union disqualified athletes with hematocrit values exceeding 50 percent for men and 47 percent for women when reticulocytes were above 2 percent. Thus far, the hematologic passport appears to be a feasible solution to identify athletes with non-physiological variations within a global strategy to deter blood doping, but it has not been approved, nor is it being incorporated into developing antidoping policies [10353].

Blood and urine samples can be taken in-competition and out-of competition. With respect to
reservations that a venipuncture is a medical intervention and may violate the tenets of
certain religious or cultural groups, the WADA has stated that there is no basis for such
provisos [11428].

Oxygen is essential for life, and the body has developed an exquisite method to collect
oxygen in the lungs and transport it to the tissues. Hemoglobin contained within red blood
cells (RBCs), is the key oxygen-carrying component in blood, and levels of RBCs are tightly
controlled according to demand for oxygen. The availability of oxygen plays a critical role in
athletic performance, and agents that enhance oxygen delivery to tissues increase aerobic
power. Early methods to increase oxygen delivery included training at altitude, and later,
transfusion of packed RBCs. A breakthrough in understanding how RBC formation is
controlled included the discovery of erythropoietin and cloning of the EPO gene. Cloning of
the EPO gene was followed by commercial development of recombinant human Epo
(rHuEpo). Legitimate use of this and other agents that affect oxygen delivery is important in
the treatment of anaemia (low Hb levels) in patients with chronic kidney disease or in cancer
patients with chemotherapy-induced anaemia. However, competitive sports was affected by
illicit use of rHuEpo to enhance performance. Testing methods for these agents resulted in a
cat-and-mouse game, with testing labs attempting to detect the use of a drug or blood
product to improve athletic performance (doping) and certain athletes developing methods to
use the agents without being detected [08208].

Optimum performance in aerobic sports performance requires an efficient delivery to, and
consumption of, oxygen by the exercising muscle. It is probable that maximal oxygen uptake
in the athlete is multifactorial, being shared between cardiac output, blood oxygen content,
muscle blood flow, oxygen diffusion from the blood to the cell and mitochondrial content. Of
these, raising the blood oxygen content by raising the haematocrit is the simplest acute
method to increase oxygen delivery and improve sport performance. Legal means of raising
haematocrit include altitude training and hypoxic tents. Illegal means include blood doping
and the administration of EPO (erythropoietin). The ability to make EPO by genetic means
has resulted in an increase in its availability and use, although it is probable that recent
testing methods may have had some impact. Less widely used illegal methods include the
use of artificial blood oxygen carriers (the so-called "blood substitutes"). In principle these
molecules could enhance aerobic sports performance; however, they would be readily
detectable in urine and blood tests. An alternative to increasing the blood oxygen content is
to increase the amount of oxygen that haemoglobin can deliver. It is possible to do this by
using compounds that right-shift the haemoglobin dissociation curve (e.g. RSR13). There is a
compromise between improving oxygen delivery at the muscle and losing oxygen uptake at
the lung and it is unclear whether these reagents would enhance the performance of elite
athletes. However, given the proven success of blood doping and EPO, attempts to
manipulate these pathways are likely to lead to an ongoing battle between the athlete and
the drug testers [08209].

Owing to the continuous progress of technology, biology, and sport medicine, blood doping is
still a controversial issue that will remain a major challenge for years to come. Blood doping
is unfair and not always detectable by current antidoping strategies; the potential risks for
health outweigh any potential benefit. As long as it is proceed further in the understanding of
the intricate molecular mechanisms that regulate erythropoiesis, innovative and revolutionary
therapeutic resources will become commercially available. As occurred earlier for other
performance-enhancing substances, the side effects of these therapeutic agents when used
by athletes will become apparent in the future. The long history of doping in sports teaches
us how eagerly people will reach for premature technology, with little fear of potential side
effects or complications. Athletes may take advantage of many innovative therapies to
improve athletic performance, and genetic doping is presently the most attractive method.
Staying ahead in the fight against the use of blood doping involves staying ahead in basic and clinical research. There is growing evidence of unsuspected and previously undetected agents being used, and the potential list appears to be endless. Awareness of this emerging problem involves the need for cooperation among manufacturers, sport federations, antidoping agencies, and laboratory professionals to ensure that methods for the detection of putative doping agents are available at the time of product release. Scientists should be aware that the continued integrity of sports competition and athletes’ health both depend on their ability to outpace the efforts of dopers; this calls for on-going development and the application of reliable detection strategies [10353].

The World Anti-Doping Agency (WADA) defines blood doping as “the misuse of certain techniques and/or substances to increase one’s red blood cell mass, which allows the body to transport more $O_2$ to muscles and therefore increase stamina and performance.” Prohibited procedures include the use of synthetic $O_2$ carriers, the transfusion of red blood cells (RBCs), the infusion of hemoglobin (Hb), and the artificial stimulation of erythropoiesis. Several paragraphs of the “2011 Prohibited List” of the WADA are relevant as regards blood doping. First, under “Prohibited Substances” (“S2. Peptide hormones, growth factors and related substances”), several erythropoiesis-stimulating agents (ESAs) are itemized: erythropoietin (Epo), darbepoetin-alfa, hypoxia-inducible factor (HIF) stabilizers, methoxy polyethylene glycol-epoetin (CERA), and peginesatide (Hematide®; Affymax®). Second, under “Prohibited Methods” forbidden blood products are specified (“M1. Enhancement of oxygen transfer”). Furthermore, intravenous infusions (unless clinically legitimated) and the sequential withdrawal, manipulation and reinfusion of whole blood are prohibited (“M2. Chemical and physical manipulation”). Finally, genetic interventions with the potential to enhance sport performance are defined (“M3. Gene doping”), including “the transfer of nucleic acids or nucleic acid sequences, the use of normal or genetically modified cells, and the use of agents that directly or indirectly affect functions known to influence performance by altering gene expression.” Hemoglobin mass is a key factor for maximal exercise capacity. Some athletes apply prohibited techniques and substances with intent to increase hemoglobin mass and physical performance, and this is often difficult to prove directly. Autologous red blood cell transfusion cannot be traced on reinfusion, and also recombinant erythropoietic proteins are detectable only within a certain timeframe. Novel erythropoietic substances, such as mimetics of erythropoietin (Epo) and activators of the Epo gene, may soon enter the sports scene. In addition, Epo gene transfer maneuvers are imaginable. Effective since December 2009, the World Anti-Doping Agency has therefore implemented “Athlete Biologic Passport Operating Guidelines,” which are based on the monitoring of several parameters for mature red blood cells and reticulocytes. Blood doping may be assumed, when these parameters change in a nonphysiologic way. Hematologists should be familiar with blood doping practices as they may play an important role in evaluating blood profiles of athletes with respect to manipulations, as contrasted with the established diagnosis of clinical disorders and genetic variations [11428].

During the last 30 years, the artificial increase of red blood cell volume ("blood doping") has changed the level of performance in all endurance sports. Many doping scandals have shown the extent of the problem. The detection of blood doping relies on two different approaches: the direct detection of exogenous manipulating substances (erythropoietic stimulants) or red cells (homologous transfusion) and the indirect detection, where not the doping substance or technique itself, but its effect on certain biomarkers is measured. Whereas direct detection using standard laboratory procedures such as isoelectric focusing can identify erythropoietic stimulants, homologous blood transfusion is identified through mismatches in minor blood group antigens by flow cytometry. Indirect methods such as the athlete biological passport are the only means to detect autologous transfusion and may also be used for the detection of erythropoietic stimulants or homologous transfusion. New
techniques to unmask blood doping include the use of high-throughput “omics” technologies (proteomics/metabolomics) and the combination of different biomarkers with the help of mathematical approaches. Future strategies should aim at improving the use of the available data and resources by applying pattern recognition algorithms to recognize suspicious athletes and, on the basis of these findings, use the appropriate testing method. Different types of information should be combined in the quest for a forensic approach to anti-doping.

Blood doping in sports has been a hot topic of present. Longitudinal follow up of hematological parameters in different endurance sports, during the 1990s and early 2000s, has provided considerable suspicions about extensive blood manipulation, with performance enhancing effects. Recent doping revelations in the media also prove that blood doping is not an anticipated myth but it is, in fact, real. Erythropoiesis stimulating agents and autologous blood transfusions are used in synergy with substantial effect on the maximum oxygen uptake and delivery to muscles. Whilst both methods of blood manipulation represent a potential health hazard, in the context of an elevated hematocrit, nevertheless despite a number of suspicious deaths amongst athletes, this has not yet been fully documented. A reliable test for detection of recombinant human erythropoietin was implemented in 2000, but this is probably circumvented by microdose regimens. The Athlete's Biological Passport represents the progeny of the idea of an indirect approach based on long term monitoring of hematological parameters, thus making it possible to detect autologous blood doping and erythropoietin use after the substance is excreted. Nevertheless with advances in anti-doping measures it is possible that the levels of excretion of substances used can be masked. Clearly more sensitive and specific diagnostic tools and research/development in these areas of major concern are warranted, which, combined with changes in the athlete's attitude, will help in reaching the vision of fair play.

Blood doping is based on the use and administration of any illicit substance or procedure aimed at increasing and optimising oxygen delivery to the exercising muscles and, therefore, includes blood transfusions, administration of erythropoiesis-stimulating substances (namely hormones and growth factors), blood substitutes and artificial altitude facilities, possibly mixed and/or combined. The use of blood transfusions, either autologous or homologous, is an effective strategy for increasing oxygen delivery to the muscles and can be used immediately before a single competition or even during long-lasting sporting events to maintain a stable haemoglobin (Hb) concentration, especially when a natural decrease is expected as a result of physiological adaptation to endurance exercise. The procedure is not new, since it became popular nearly 40 years ago, but then suddenly declined due to its inclusion among the list of prohibited methods issued by the International Olympic Committee (IOC). Another reason that contributed greatly to the sudden decay of popularity of blood transfusions among elite athletes was the cloning of the erythropoietin gene and subsequent development of recombinant erythropoietin (rHuEpo) and its introduction among the armamentarium of illicit ergogenic aids. The great success of rHuEpo and analogues (erythropoiesis-stimulating agents, ESA) was mainly the consequence of the remarkable biological and technical advantages that these substances had over traditional means of increasing the red cell mass, such as blood transfusions. These advantages include easier supply (from healthcare facilities as well as from the “black market”), more comfortable administration (small subcutaneous doses) and the sharp and long-lasting effects on erythropoiesis (i.e. “blood boosting”). Once the concentration of Hb has been raised through ESA administration, the high concentration can be maintained by weekly administered microdoses of ESA which have a detection window of only 12-18 hours, for rHuEpo, compared to 3 days for regular doses. The subsequent development and implementation of (more or less) reliable electrophoretic techniques to screen for rHuEpo misuse caused a sudden resurgence of blood transfusions, which also took advantage of new procedures for
collecting and storing the erythrocytes (e.g. freezing), allowing their use over a very long period of time as well as their harvesting during rest periods, thus avoiding a decline of Hb and aerobic sport performance during the competitive season [13290].

The oxygen carrying capacity of the organism has been addressed as performance limiting in most endurance sport disciplines. From basic physiology, it is known that the oxygen transport of the body is mediated through cardiac output and hemoglobin, both entities being key factors in the Fick principle, which defines oxygen uptake. VO$_{2\text{max}}$, the maximum oxygen uptake, and total hemoglobin (tHb) are both well-established determinants for aerobic exercise capacity. Possible ways to manipulate VO$_{2\text{max}}$ can be examined by Fick’s principle: 

\[ \text{VO}_{2\text{max}} = \text{CO} \left( \text{CaO}_2 - \text{CvO}_2 \right) \]

where CO is cardiac output, CaO$_2$ is arterial oxygen content and CvO$_2$ is venous oxygen content. Systematic endurance training increases cardiac output through increased plasma volume (PV) and eccentric hypertrophy of the heart. Induced hypervolemia with dextran or other plasma volume expanders increases CO and VO$_{2\text{max}}$ in untrained individuals, but the VO$_{2\text{max}}$ remains unchanged in athletes, with only a small increase in CO. This is due to a lower diastolic reserve capacity, which does not compensate for the reduction in CaO$_2$. Arteriovenous difference is already high in the working muscle. Oxygen extraction has been measured to 85 percent in a maximum intensity setting with a one legged knee extensor exercise with supramaximal blood flow, hence reducing the capillary transit time further than with two legged exercises. CaO$_2$ on the other hand can easily be modified by elevating the hemoglobin level either by ESA or blood transfusions, thus increasing VO$_{2\text{max}}$ [13005].

One of the prime training targets for endurance athletes is therefore to increase their oxygen uptake and thereby increase their cardiac output and the oxygen carrying capacity of the blood. It is well known that regular endurance training leads to enlargement of the cardiac cavities and thus cardiac output and, on the other hand, induces an increase in red cell volume, which will improve the oxygen transport. However, these adaptations are slow, require dedicated training over many years, and there is a high interindividual difference in the ability to adapt to training. Thus, athletes and coaches have searched for possibilities to bypass these natural adaptations. It is well known that hypoxia will accelerate red cell production and thus increase red cell volume so that altitude training and different other types of hypoxic interventions are nowadays standard training strategies for most elite athletes competing in endurance events. In light of the inventive spirit of human nature, it was clear that sooner or later athletes would seek artificial means to increase their oxygen transport capacity without having to go through the cumbersome and time-consuming process of hypoxic training. From a scientific point of view, the experiments laying the base for a beneficial effect of increased red cell mass stem from military investigations, which demonstrated that the infusion of red cells had the same physiological effects as the adaptation of the erythropoietic system to the hypoxia of altitude and that the “tolerance” of hypoxia (measured through heart rate response to exercise) was improved in the transfused subjects. In the following decades, this topic was further developed with additional investigations that showed a beneficial effect of increased red cell volume on endurance performance. The positive effect of increased red cell volume depended on the amount of transfused red cells with increases in VO$_{2\text{max}}$ of up to 17 percent [13006].

Based on testimonies and confiscated diaries, it has been revealed a doping regimen where a cyclist “mobilizes” with EPO during the low season and “harvests” blood after one month. The blood is retransfused just before completion or even during longer stage races and then withdrawn after the finish. In research early investigators of autologous blood transfusions could not support a performance enhancing effect. When whole blood is stored at 4 °C the red blood cell count is reduced by 33 percent after 4 weeks. Eventually, when red blood cells were stored with cryoprotective agents like glycerol, a number of studies have proven a
correlation between blood transfusions and improved VO$_{2\text{max}}$ or work capacity. The increase in maximal oxygen uptake is typically around 5-10 percent with a dose dependent pattern. 10,000 m time for "highly trained" male runners has been reduced by one minute after retransfusion of 400 ml red blood cells. The increase in VO$_{2\text{max}}$ is correlated to the increase in hemoglobin. Thus, the result is more dependent on dosage than method. The blood volume is not affected by either method and the performance enhancing effect is solely due to elevated Hb [13005].

During the last 30 years, the artificial increase of red blood cell volume ("blood doping") has changed the level of performance in all endurance sports. Many doping scandals have shown the extent of the problem. The detection of blood doping relies on two different approaches: the direct detection of exogenous manipulating substances (erythropoietic stimulants) or red cells (homologous transfusion) and the indirect detection, where not the doping substance or technique itself, but its effect on certain biomarkers is measured. Whereas direct detection using standard laboratory procedures such as isoelectric focusing can identify erythropoietic stimulants, homologous blood transfusion is identified through mismatches in minor blood group antigens by flow cytometry. Indirect methods such as the athlete biological passport are the only means to detect autologous transfusion and may also be used for the detection of erythropoietic stimulants or homologous transfusion. New techniques to unmask blood doping include the use of high-throughput "omics" technologies (proteomics/metabolomics) and the combination of different biomarkers with the help of mathematical approaches. Future strategies should aim at improving the use of the available data and resources by applying pattern recognition algorithms to recognize suspicious athletes and, on the basis of these findings, use the appropriate testing method. Different types of information should be combined in the quest for a forensic approach to anti-doping [13006].

Blood doping in sports has been a hot topic of present. Longitudinal follow up of hematological parameters in different endurance sports, during the 1990s and early 2000s, has provided considerable suspicions about extensive blood manipulation, with performance enhancing effects. Recent doping revelations in the media also prove that blood doping is not an anticipated myth but it is, in fact, real. Erythropoiesis stimulating agents and autologous blood transfusions are used in synergy with substantial effect on the maximum oxygen uptake and delivery to muscles. Whilst both methods of blood manipulation represent a potential health hazard, in the context of an elevated hematocrit, nevertheless despite a number of suspicious deaths amongst athletes, this has not yet been fully documented. A reliable test for detection of recombinant human erythropoietin was implemented in 2000, but this is probably circumvented by microdose regimens. The Athlete's Biological Passport represents the progeny of the idea of an indirect approach based on long term monitoring of hematological parameters, thus making it possible to detect autologous blood doping and erythropoietin use after the substance is excreted. Nevertheless with advances in anti-doping measures it is possible that the levels of excretion of substances used can be masked. Clearly more sensitive and specific diagnostic tools and research/development in these areas of major concern are warranted, which, combined with changes in the athlete's attitude, will help in reaching the vision of fair play [13005].

Relevant for doping controls is the hemoglobin mass (Hb$_{\text{mass}}$). It represents an attractive complement to established markers for the detection of autologous blood doping due to its independence from plasma volume; however, factors such as its within-subject variability (e.g. resulting from reduced training or altitude exposure) as well as technical aspects necessitated in-depth investigations. In one study, a total of 130 athletes (rowing, swimming, running, cycling, kayaking, and football) were tested on approximately 6 occasions within one year using the standard CO-rebreathing method. The within-subject coefficient of variation
was found as high as 4 percent, which was considered to be of limited applicability in sports drug testing if used as single parameter only. In combination with other markers, potential utility was nevertheless recognized. Reduced training volumes showed substantial influence on Hb_{mass} as explicitly demonstrated in a follow-up study with nine triathletes. Within a period of 30 days of detraining, a significant decrease of Hb_{mass} accounting for 3.1 percent was measured, corroborating the need to consider numerous individual factors when applying Hb_{mass} as an anti-doping measure. It was also drawn comparable conclusions from a study with 21 individuals mimicking a 42 weeks cycling season. The athletes underwent ten CO-rebreathing tests for Hb_{mass} determination during the period of the investigation. At the 99 percent specificity level, 10 out of 11 "doped" persons returned positive test results; however, one false positive outcome was recorded as well. Increasing the specificity level to 99.9 percent eliminated the false positive finding but reduced the sensitivity to 73 percent, enabling the detection of 8 out of 11 "doped" volunteers. In order to minimize the impact of technical issues on the variability of Hb_{mass} measurements, the influence of different spectrophotometers on the analytical result as well as the impact of quality controls were assessed, identifying the hemoximeters as a major contributor to inter-laboratory variations, which was minimized with adequate corrections via standardized calibrator samples [13012].

**Prevalence of blood doping**

By using similar models as in the biological passport, but with lower specificity it is possible to estimate the prevalence of doping. Analyses of blood values from the contestants of the 2001 Nordic World Ski Championships revealed that 50 percent of the medal winners and 33 percent of 4th to 10th positions had highly abnormal blood profiles. In comparison only 3 percent of the competitors who finished 41-50 had a highly abnormal blood profile. When comparing individuals, hematocrit and thereby Hb is significantly correlated to VO_{2max} in the untrained. It has also been researched the development of hemoglobin concentrations in Finnish and Swedish cross country skiers from 1987 to 1999. In the beginning the athletes were below the average for the general population in accordance with the compensatory plasma volume expansion of training. In the 1990s the average hemoglobin concentration increased with over 1.0 g/100 mL. The highest individual values were almost 20.0 g/100 mL for both sexes, higher than what is found in permanent mountain dwellers. In that time period, cross country skiers refined the use of altitude training. However, this cannot explain the rise in Hb alone. Still, there is only a handful of studies documenting an effect of altitude training because there is a large interindividual variation of response. When Fédération Internationale de Ski (FIS) issued a regulation for maximum Hb values in 1996 (18.5 g/100 mL for males and 16.5 g/100 ml for females), the maximum values were reduced by 1.5 and 4.2 g/100 mL in males and females. This regulation exists today in different sports federations, but the upper limits are reduced to a Hct or Hb of 0.50 and 17.0 g/100 mL for males and 0.47 and 16.0 g/ 100 mL for females [13005].

It was also compared blood samples from the late 1990s to 2007 in international cross country skiers. The average Hb value fell initially from about 16.2 to a nadir in 2002–2003 of 14.8 g/100 ml. During this time period the EPO test was introduced and FIS announced a strengthening of the anti-doping program. From 2001 to 2007 the average Hb reached the highest values in the Olympic seasons 2001-2002 and 2005-2006. In 2006 the hemoglobin values increased significantly (1.0 g/100 mL in females) in just one week before the Olympics. Samples collected at 1200 m above sea level were in general only 0.15 g/100 mL higher than samples collected below 600 m over sea level in females. In cycling, one can identify some of the trends from cross country skiing like the significant reduction in number of reticulocytes after 2002. In autologous blood doping, reticulocytes increase after phlebotomy and decrease to below pre value after reinfusion. With EPO the opposite is true.
There should be no between season variations since samples are drawn throughout the season for all consecutive years. The current Hb limit of 17.0 g/100 mL is arbitrary. In one study 3.9 percent of the blood donors and 10.4 percent of male elite rowers were found to exceed the limit. This retrospective study confirms violation of the Hb and Hct regulation does not automatically mean doping. However, it does not prove that more athletes have a natural elevated hemoglobin concentration than the normal population because the subjects were not controlled for blood doping. The blood doping prevalence is probably skewed between nations. In the early 2000s the prevalence of blood doping in track and field endurance athletes estimated with the ABPS model ranged from 1 to 48 percent between different nations The average prevalence was 18 percent [13005].

**Biochemical markers of hypoxia**

Although tissues may exist regardless of reduced oxygen pressure, this requires glycolytic ATP generation, which is very expensive from the energetic viewpoint. Hypoxia is defined as the condition in which oxygen pressure is reduced at the level of bodily tissues. There are many clinical situations during which decreased tissue oxygenation may occur. It may be transient or chronic, as well as systemic or local. An emergent need exists for monitoring and diagnosis with respect to numerous possible clinical circumstances leading to hypoxia and its life-threatening consequences. The assessment of global oxygen homeostasis relies on blood gas analysis and lactate concentration, but such an approach does not fully reflect the local oxygenation of tissues. Oxygen needle microelectrode measurements reveal great differences in tissue pO$_2$ levels. Local pO$_2$ levels depend on many factors, among which the most important are: the distance to the nearest capillary, the extracellular and intracellular fluid diffusion rates and intracellular measurements of the number and activity levels of mitochondria. Thus, nowadays, it is impossible to establish an accurate normal value ranges for local tissue pO$_2$. Oxygen deficiency is an important gene regulator. A sequence-specific DNA-binding factor, the hypoxia induced factor (HIF), is the fundamental hypoxia response protein. 70 genes identified so far have been found to be HIF-dependent. They are responsible for increased oxygen delivery, i.e. by boosting angiogenesis due to vascular endothelial growth factor (VEGF) release and the enhancement of red blood cell production by erythropoietin (EPO). VEGF-induced angiogenesis is one of several key hypoxia adaptations. An enhanced vascular bed in response to hypoxia affects almost every bodily tissue and organ. This was observed particularly in skeletal muscles as well as in the brain. The expression of a few hypoxia markers does not require HIF activation. An especially interesting member of this group is osteopontin (OPN), whose synthesis increases during hypoxia. OPN was originally linked to bone remodeling, but currently it seems to posses an important role in immunity, inflammation and tumor pathogenesis. Quantification of hypoxia is clinically essential both for therapy and prognosis. Taking account of the fact that the concept of oxygen pressure at the tissue level is not quantitative (norms do not exist, results are incomparable), biochemical markers are preferable. Particularly significant in this context are hypoxia-induced proteins such as HIF, EPO, VEGF or potentially OPN [12224].

**Theoretical aspects on energy transfer in the body**

The time course of energy metabolism during moderate exercise involves primarily the phosphagen system (for the first 10 to 15 s), followed by anaerobic glycolysis for the next 1 to 2 min and aerobic metabolism for physical activities lasting more than 2 min. ATP molecules normally present within muscle cells can be promptly used to sustain muscle
contraction; phosphocreatine is an additional reserve of energy that can be used to rapidly synthesize ATP. Both systems provide energy at a very rapid rate, but when a muscle fiber is undergoing a sustained contraction, these energy reserves are quickly exhausted. When muscle fibers are actively contracting, each thick filament breaks down roughly 2500 ATP molecules/s. Because even a small skeletal muscle contains thousands of muscle fibers, the ATP demands are enormous and, therefore, skeletal muscles must rely on alternative mechanisms to supply energy. Most cells generate ATP through aerobic metabolism in mitochondria and glycolysis in the cytoplasm. Aerobic metabolism normally provides up to 95 percent of the energy demand of a resting cell. In this process, mitochondria absorb oxygen, adenosine diphosphate (ADP), phosphate ions, and organic substrates that enter the tricarboxylic acid cycle (also known as the citric acid cycle or the Krebs cycle). While carbon atoms are released as carbon dioxide, hydrogen is shuttled to respiratory enzymes in the inner mitochondrial membrane where their electrons are removed. After a series of intermediate steps, protons and electrons are combined with oxygen to form water. By this process, a large amount of energy is efficiently produced, as each organic molecule fed to the tricarboxylic acid cycle generates 17 ATP molecules. During extensive physical exercise, the demand for energy, along with mitochondrial ATP production, progressively increase to a maximum rate that is determined by the availability of oxygen, which cannot diffuse into the muscle fiber fast enough to enable the mitochondria to fulfill the on-going energy expenditure. At peak levels of exertion, mitochondrial activity can provide only about one-third of the ATP required. Therefore, oxygen becomes progressively depleted, and muscles cannot get sufficient amounts to perform at their optimal potential, in terms of both power and resistance. Such a relative gap between oxygen demand and availability is conventionally called “oxygen debt.” Owing to the relative depletion of oxygen to produce ATP via traditional mechanisms, muscle tissue is compelled to shift to the anaerobic pathway, culminating in ATP production through conversion of pyruvic acid, provided by the enzymatic pathway of glycolysis, to lactic acid. Therefore, the process of anaerobic glycolysis enables the generation of additional energy when mitochondria are unable to fulfill the current energy demand. However, anaerobic energy production has its drawbacks. Although nearby 80% of the lactate produced diffuses from the muscles and is transported to the liver for conversion to glucose or glycogen, in conditions of extensive training, it cannot be completely cleared and lactate gradually accumulates at both the site of synthesis and in the blood. As the relative concentration of intracellular lactate can become extremely elevated in muscles, this process can persist for several minutes after the end of the exercise. As the progressive accumulation of lactate lowers the intracellular pH and alters the functional characteristics of key enzymes, the overall efficiency of the muscular contraction finally declines, producing the characteristic symptoms of fatigue, pain, and muscle soreness that may develop several hours or even days after particularly strenuous or unaccustomed exercise. Lactic acidosis typically occurs when the concentration of lactate in blood exceeds 4 mmol/l. Highly trained athletes have maximal oxygen uptakes that may be double those of sedentary people and that permits greater muscular activity coupled to a reduced production and accumulation of lactic acid. Oxygen is carried to peripheral tissues and muscles by two efficient delivery systems: 3 percent is carried in solution (plasma), whereas the remaining 97 percent is bound to hemoglobin, the main protein in red blood cells. Practices that are aimed at producing an increase in hemoglobin in blood or a more efficient mechanism of oxygen transport and delivery are associated with improved energy production, allowing the muscles to become more fatigue resistant and to perform better [10353].

Carotid body arterial chemoreceptors are essential for a normal hypoxic ventilatory response (HVR) and ventilatory acclimatization to hypoxia (VAH). However, recent results show that O2-sensing in the brain is involved in these responses also. O2-sensing in the rostral ventrolateral medulla, the posterior hypothalamus, the pre-Bötzinger complex and the nucleus tractus solitarius contribute to the acute HVR. Chronic hypoxia causes plasticity in
the brain that contributes to VAH and represents another time domain of central O$_2$-sensing. The cellular and molecular mechanisms of acute O$_2$-sensing in the brain remain to be determined but they appear to involve O$_2$-sensitive ion channels and heme oxygenase-2, which acts by a different mechanism than has been described for the carotid body. It is not known if plasticity in such mechanisms of acute central O$_2$-sensitivity contributes to VAH. However, O$_2$-sensitive changes in gene expression in the brain do contribute to VAH and demonstrate another mechanism of O$_2$-sensing that is important for ventilatory control. This time domain of O$_2$-sensing in the brain involves gene expression under the control of hypoxia inducible factor-1$\pm$ (HIF-1$\pm$ and potentially several HIF-1$\pm$ targets, such as erythropoietin, endothelin-1, heme oxygenase and tyrosine hydroxylase [09147].

Human muscle operates along a continuum of power output, which is set through bioenergetic and anatomical principles. In turn, environmental and intrinsic factors during contractile work exert pronounced control over muscle performance by instructing muscle remodelling. This phenotypic control is specifically indicated with intense exercise at altitude, when extra strain is put on energy supply and the temperature-dependent mechanical efficiency of contraction. While it is classically thought that chronic exposure to hypoxia is maladaptive, repeated short episodes of reduced oxygenation alone or in combination with intense endurance work is now understood to preserve exercise performance when atmospheric oxygen levels are low. Endurance training at moderate altitude exploits the temperature-dependent malleability of energy supply that may maximize metabolic flux at altitude. The contribution of genomic mechanisms is important to the plasticity of metabolic pathways in exercised muscle. This is highlighted by the association of distinct gene polymorphisms in master governors of mitochondrial and vascular growth with exercise phenotypes. Feedforward control of human locomotor muscle by exercise involves the transient upregulation of transcript expression for metabolic processes. The response of the mitochondrial transcriptome to intense exercise is graded with respect to mitochondrial content and deoxygenation during muscle work and reflects exercise-induced mitochondrial biogenesis. This supports the notion that genome-mediated muscle malleability is under feedback control by design constraints of the pathway of oxygen. Thus, activity-dependent and genetic mechanisms contribute to the interindividual difference in the metabolic bottlenecks in athletes performing in exceptional environmental conditions [09148].

In a comparative study on erythrocytes (RBCs) drawn from mountaineers before and after a high-altitude stay, it was observed that upon returning to sea level, their RBCs displayed a senescent-like phenotype as indicated by their density and the partial loss of membrane proteins which are shed by ageing RBCs. The aim of one study was therefore to investigate possible changes in the membrane skeleton of these RBCs and to compare them with pathological RBCs. It was analysed the proteins of RBC ghosts obtained from the subjects before and after returning to sea level by two-dimensional electrophoresis and mass spectrometry. It was observed lower expression and fragmentation of beta-actin after exposure to hypoxia. This suggested an alteration in membrane skeleton structure, which was confirmed by beta-actin release in cell lysates during ghost preparation. It was observed a similar actin fragmentation and release in RBC lysates from beta-thalassaemic patients. In conclusion, these results indicate that after exposure to hypoxia, RBCs display a modification of their actin and cytoskeleton instability [09149].

**Hemoglobin mass and physical performance**

In aerobic sport disciplines, such as long-distance running, cycling, or cross-country skiing, the main factors determining performance are a high delivery of O$_2$ to the exercising skeletal muscles and its use. The rate of maximal O$_2$ uptake ($O_2$ max) is dependent on a high cardiac output (Q) and a wide difference for arterialvenous O$_2$ (a-vO$_2$), that is, the Fick equation.
Because $Q_{\text{max}}$ is difficult (if not impossible) to manipulate to higher values during competitions, the distribution of $Q$ during maximal exercise to the working skeletal muscles is close to 80 percent, and arterial $O_2$ extraction is already in the range of approximately 90 percent at maximal exercise, the only variable that remains open for manipulations in regards to increasing exercise performance is the arterial $O_2$ content. Accordingly, in a given person, changes in Hb concentration by either RBC transfusion or hemodilution will increase or decrease $O_{2\text{max}}$, respectively. On the group basis, however, concentration of hemoglobin is not predictive of $O_{2\text{max}}$, whereas the total mass of Hb ($H_{\text{mass}}$) correlates very well with $O_{2\text{max}}$. Indeed, a somewhat reduced hemoglobin concentration is sometimes, but not always, observed among athletes, whereas $H_{\text{mass}}$ is usually increased compared with normal healthy persons. The first experiments with blood transfusions and exercise performed demonstrated that the transfusion of 450 mL of whole blood on 4 consecutive days decreases submaximal exercise heart rate (in hypoxia) for several weeks, and hence predicted that exercise performance would be increased. Accordingly, it was calculated in a recent review that a change of 1 g in $H_{\text{mass}}$ will produce a change in $O_{2\text{max}}$ of 4 mL/min whereas the effects on submaximal exercise performance are probably variable according to competition distance. It should also be noted here that volume loading (i.e. plasma volume expansion) in itself does not lead to an improved exercise performance in elite athletes, again highlighting the role of $H_{\text{mass}}$. If, however, a plasma volume expander is administrated simultaneously with increments in $H_{\text{mass}}$, then performance will probably increase more than when just augmenting the total red cell volume [11428].

**Erythropoiesis**

Erythropoiesis is part of the large process of haematopoiesis, which involves the production of mature cells found in the blood and lymphoid organs. Haematopoiesis is continuously required because of the normal turnover in the cell populations in the blood and lymphoid organs. In the normal adult human, the daily turnover of erythrocytes exceeds $10^{11}$ cells. During periods of increased erythrocyte loss, due to haemolysis or haemorrhage, the production of erythrocytes increases rapidly and markedly. However, overproduction of erythrocytes does not occur, even after the most severe loss of erythrocytes. In haematopoiesis, a few pluripotent haematopoietic stem cells in the bone marrow proliferate and differentiate to give rise to all the cellular components of the blood and the lymphoid system. During this process, an individual haematopoietic cell undergoes an apparently random process called commitment. When a cell undergoes commitment, its potential to proliferate becomes limited and its potential to develop into multiple types of mature cell is also restricted. Thus, these haematopoietic cells are termed committed, lineage specific progenitor cells. The major stages of differentiation in mammalian erythropoiesis are as follows. The most immature stage of committed erythroid progenitors is the burst forming unit-erythroid (BFU-E). The next major stage of erythroid progenitor cell development is the colony forming unit-erythroid (CFU-E). A continuum of erythroid progenitor stages exists between the BFU-E and CFU-E, with decreasing proliferative potential as the progenitors approach the CFU-E stage. The descendant cells of the CFU-E are termed erythroid precursor cells. These erythroid precursors are proerythroblasts, basophilic erythroblasts, polychromatophilic erythroblasts, and orthochromatic erythroblasts. The orthochromatic erythroblasts do not divide, but they enucleate, forming the nascent erythrocyte called the reticulocyte [06145].

*Effects of marathon*
In marathon runners changes in red blood cell count, haematocrit and haemoglobin in relation to haemodilution have been reported. Moreover, it has been hypothesized that strenuous exercise induces oxidant stress through several different mechanisms. One study investigated the haematological variables, iron status and oxidative indices before, immediately and 48 h after a race in 8 healthy trained males aged 33-44 years running a 21-km marathon in 79 ± 3 min. The haematological parameters were determined by standard procedures. Erythropoietin and soluble-transferrin receptor were evaluated immunoenzymatically. Nontransferrin-bound iron (NTBI) was assayed by high-performance liquid chromatography after nitrilotriacetic acid chelation. Malonyldialdehyde (MDA) concentration was assayed colorimetrically. The total number of reticulocytes rose significantly after the run with a significant increase in the high-RNA-content fraction. Erythropoietin rose by 26 percent and by 25 percent immediately and 48 h after the race, respectively. Serum iron and serum ferritin remained unchanged but NTBI and serum MDA increased significantly immediately after running. Significant positive correlations at any time between MDA and polymorphonuclear neutrophils, MDA and NTBI, polymorphonuclear neutrophils and NTBI, and between lactate dehydrogenase and NTBI were observed. It was concluded that the erythropoietic changes observed in marathon runners are the results of several interacting mechanisms that involve either the haemopoietic system per se or erythrocyte haemolysis and oxidative stress [06146].

Effects of training in juniors

During the world junior speed skating championship 2002 all athletes (60 males, 56 females) were subjected to hematologic blood testing one day before the competition as requested by International Skating Union (ISU). This study aimed to obtain hematologic reference values for junior athletes, whilst the influence of endurance training on hematologic variables of young athletes was studied. Hematologic results of athletes were compared to results of non-athletes matched by age and gender (14 males, 17 females). The blood analysis was done on an ADVIA 120. To compare measurement of ferritin, erythropoietin, and soluble transferrin receptor in serum as well as in EDTA-plasma, serum and EDTA-blood was obtained from the control group. In hemoglobin and hematocrit it was found no significant difference between the two groups, whereas the number of erythrocytes was lower in athletes. The mean corpuscular volume was higher in athletes, whilst the corpuscular hemoglobin content was only marginally higher in athletes than in non-athletes. Consequently corpuscular hemoglobin concentration mean was lower in athletes than in non-athletes. There was no difference of erythropoietin and soluble transferrin receptor, whilst in ferritin we found a difference between the groups. Endurance training does not change the values of hemoglobin and hematocrit. Increased mean corpuscular volume and decreased corpuscular hemoglobin concentration mean could be a result of changed properties of red blood cell-membrane caused by acidosis and higher osmolality during the training. In junior athletes we did not find an iron overload as described in some adult athletes [06147].

Red blood cells

Red blood cells (RBCs) during microcirculation, aging and storage, lose N-acetylenuraminic acid (NANA) and other biomaterials thereby altering cell structures, some properties and functions. Such cell damage very likely underlies the serious adverse effects of blood transfusion. However, a controversy has remained since 1961-1977 as to whether with aging, the RBCs, suffering loss of NANA, do have a decreased charge density. Any correlation between the changes in the cell properties with cell aging is also not clear. Therefore, to remove the ambiguity and uncertainty, it was carried out multiparametric
studies on Percoll fractions of blood of 38 volunteers (lightest-young-Y-RBCs, densest-old-O-RBCs, two middle fractions). It was found that there were striking differences between the properties of Y-RBCs and O-RBCs. The potential of Y-RBCs decreased gradually with aging. Studies in parallel on RBC fractions incubated with both positively charged quantum dots and SNA-FITC along with their potentials provide for the first time direct visual evidence about the lesser amount of charge density and NANA on O-RBCs, and a collinear decrease in their respective potentials. Close correlation was found between the surface charge on an aging RBC and its structure and functions, from the cell morphology, the membrane deformability to the intracellular Hb structure and oxidation ability. This quantitative approach not only clarifies the picture but also has implications in biology and medicine [11120].

Hematological parameters are used for monitoring health status of athletes, to prevent sports’ anemia and also for suspecting blood doping. It is important to monitor professional athletes during the training and competitive season, because some modifications of the hematological parameters are induced from long-lasting and continuous exercise, although these variations are not usually clinically relevant and fall into reference intervals described for general population. Moreover, hematological parameters are integrated in formulae used in the anti-doping context for screening the athletes. The reference intervals applied to athletes are usually those found in the general population. The erythrocyte (RBC) mass is often considered the most important parameter for evaluating the training effectiveness. The RBC mass should be related to whole body mass, inducing also gender differences evidenced by different reference intervals usually proposed for males and females. However, in athletes the gender difference on VO$_{2max}$ is principally related to the cardiac size, measured as left ventricular mass, accounting for 68 percent of the difference. The lack of correlation between BMI and Hb in the whole group of athletes indicates that in a population with consistent number of subjects the body characteristics do not apparently influence the Hb concentration. Athletes are thought to be physically normal and healthy by definition, but high training workload and psychophysical stress from competitions can modify their homeostasis, inducing apparently pathological biochemical and hematological results. In general, similar reference intervals for hematological parameters are described in athletes’ population and general population, but some differences exist. Regardless of exercise and possible related effects, the reference intervals in athletes should take into account also the anthropometrical characteristics of the subjects that can markedly differ among sports disciplines. It was pointed out the need of considering body mass index (BMI) in evaluating and interpreting serum creatinine data in athletes, when a correlation between this parameter and BMI. The relation between mass and hematological parameters has been not extensively studied. Therefore, it was investigated the relation between hematological parameters and BMI in 126 top-level male athletes: 32 rugby players of Italian National team, nine triathletes of Italian National team, 27 football players of a Italian Second Division team, 24 cyclists of a ProTour team, 21 sailors of a America’s Cup yacht, 11 basketball players of a Italian First Division team, and two ice dancers of Italian National team. The age range was 17-35 years. The BMI was calculated as weight/(height)$^2$ and supplied by teams’ physicians. The blood drawings were performed at rest in the morning before the start of the training and competitive season. An informed consent for blood drawings has been obtained. The correlation between BMI and hematological parameters in the whole group of athletes gave significant result for erythrocytes (RBC), but not for hemoglobin (Hb) and reticulocytes (Ret). The correlation between mean values of the considered parameters in groups of athletes competing in different sports and BMI, gave non-significant data for RBC and Ret, and a weak correlation for Hb. The lack of correlation between BMI and Hb and between BMI and Ret represents an important finding for the use of the parameters in antidoping context. The relative stability of the parameters in athletes, together with the absence of relation with BMI, reinforce the integration of Hb and Ret in formulae applied in antidoping context. In conclusion, the type of sport discipline and body mass characteristics can influence in part
Hb and RBC, but not Ret. Thus, the interpretation of Ret values is not influenced by anthropometrical characteristics and could be identical in different sports disciplines [07108].

The analysis of the cytosolic red blood cell (RBC) proteome is negatively affected by the high intracellular amount of hemoglobin complicating the detection of low-abundant cytosolic proteins. In this study, an alternative approach for the preparation of hemoglobin-depleted RBC lysates is presented, which was established in combination with downstream 2D PAGE analysis and Orbitrap MS. Hemoglobin removal was accomplished by using HemoVoid® depletion reagent, which enabled a very efficient enrichment of low-abundant proteins by simultaneously reducing the hemoglobin concentration of the sample. After defining selected sample preparation protocol characteristics including specificity/selectivity, precision and linearity, a 2D reference map (pH 4-7) of the cytosolic RBC proteome was generated and a total of 189 different proteins were identified. Thus, the presented approach proved to be highly suitable to prepare reproducible high-resolution 2D protein maps of the RBC cytosol and provides a helpful tool for future studies investigating disease- or storage-induced changes of the cytosolic RBC proteome [12225].

In recent years, multivariate statistical models have been validated as reliable approaches to detect recombinant human erythropoietin (r-huEPO) during current use (ON-model), as well as after recent use (OFF-model). Later research has focused only on the OFF-model, which is based on Hb concentrations and Ret%, because it has been claimed able to specifically detect recent blood doping practices, that are more likely to be discovered in unannounced anti-doping or intra-competition testing. Because of the variations in Hb and Ret%, the calculated OFF-score showed a consistent decrease from the resting value to T2 and a slight increase towards T3, however, still lower than the baseline value. From a medical point of view, despite the statistical significance of some variations, not all of them necessarily play a physiologically relevant role. Indeed, it is unlikely that the significant variations observed in WBC (12-14 %), MCV (0.2-1.0 %), MCH (0.5-1.0 %), MCHC (1.0-3.0%), and platelets (3.9-8.1 %) have any physiological importance. On the other hand, the variation in RBC, Hb, Ht, and Ret count indicated noticeable adaptive modifications in the bone marrow microenvironment in response to the elevated metabolic demand [13296].

**Effects of iron on performance**

It was investigated the iron-related haematological parameters in both male and female athletes participating in different sporting disciplines necessitating different metabolic energy demands. A total of 873 athletes (514 males and 359 females) were divided according to gender and to the predominant energy system required for participation in sport (aerobic, anaerobic or mixed) and haematological and iron-related parameters were measured. For both male and female athletes, significant differences related to the predominant energy system were found at a general level. According to the ferritin cutoff value of 35 microg/L, whole body iron and sTfr significantly differed in all three groups of male and female athletes. The percentage of hypochromic erythrocytes in male athletes was significantly higher only in those who required an anaerobic energy source, whilst in the females hypochromic erythrocytes and hemoglobin were significantly different only in anaerobic and mixed energy source athletes. According to the ferritin cutoff value of 22 microg/L, in females, whole body iron, sTfr and hypochromic erythrocytes were significantly higher in all three groups of athletes than those below the aforementioned cutoff value. It was concluded that the predominant energy system required for participation in sport affects hematological parameters. sTfr and body iron proved to be reliable parameters for monitoring the dynamics of iron metabolism and could contribute to successful iron-deficiency prevention [11121].
Testing of blood

Full blood counts are now used as evidence that athletes have used banned blood doping. This has led to legal scrutiny of the efficacy of preanalytical procedures such as specimen homogenisation. To characterise the impact of different mixing strategies on whole-blood homogeneity manual inversion, mechanical mixing and automatic mixing performed by the Sysmex XT-2000i were evaluated. Automated mixing by the instrument, or 1 min of mechanical mixing, thoroughly homogenised specimens even for tubes that had been refrigerated and left undisturbed for 36 h. Manual inversions were almost as effective, provided that specimens were first allowed to equilibrate to ambient temperatures. It was concluded that current sport guidelines that mandate at least 15 min of mechanical mixing are excessive. Except where specimens are presented to the instrument manually, mechanical mixing is redundant in the context of full blood counts [12233].

Freezing red blood cells

Red blood cells undergo structural and biochemical aging-related changes during storage, and therefore, the conventional storage of blood at 4°C is allowed for only 5 to 7 weeks depending on storage solution. Because the recovery of reinfused RBCs in the circulation is inversely proportional to their storage period, the period of storage at 4°C becomes a compromise between the recovery of reinfused RBCs after reinfusion and the in vivo resynthesis of RBCs during the storage period to compensate for the donated RBCs. Adding glycerol to RBCs minimizes the ice crystal formation in the RBCs during freezing. This allows the RBC storage for up to 10 years at −20°C or −80°C. However, a drawback with freezing blood is the additional loss of RBCs during the freeze-thaw-wash process. Different storage procedures yield different amounts of transfused hemoglobin and hence influence the sensitivity of any new test based on blood markers. It is well recognized that the reinfusion of RBCs results in considerable posttransfusion hemolysis of up to 25% within the first 24 hours after reinfusion. Therefore, a sensitivity of 35 percent would apply only during the first minutes to hoursafter reinfusion and thereafter decreases as in vivo hemolysis would occur. Using the frozen storage procedure would reduce the amount of reinfused hemoglobin and, thereby, the sensitivity [12009].

Effect of endurance training on erythrocyte deformability

Higher erythrocyte deformability may reduce the risk of circulatory diseases by enhancing oxygen delivery and reducing the load on the cardiovascular system. The effect of endurance training on erythrocyte deformability is not clear. One study explored the impact of endurance training on erythrocyte deformation and shape and investigated the underlying mechanisms of hemorheological alterations. Forty male Wistar rats were randomly divided into two groups: sedentary (S; n=21) and exercised (E; n=19). Hematological indices and erythrocyte shape were measured at the end of the 11th week. The gene expression of erythropoietin (Epo) and the Epo receptor (EpoR) was quantified using reverse transcription-PCR (RT-PCR), and Epo protein expression was analyzed using Western blotting. Endurance training significantly decreased the abnormality ratio of erythrocyte shape. The deformability indicator (DI) of red blood cells was lower in the E group than in the S group. Eleven weeks of endurance training increased Epo mRNA and protein expression in the kidney, EpoR mRNA expression in the bone marrow, and relative circulating Epo compared to the sedentary group. The decrease in the erythrocyte morphological index and the maximum of deformability indicator were associated with an increase in relative circulating Epo. In conclusion, 11 weeks of endurance training increased erythrocyte deformability. Epo and
EpoR may contribute to the decreased morphological index and deformability indicator in erythrocytes during endurance training in rats [13297].

**Hemoglobin and hematocrit**

There is limited information regarding the optimal hemoglobin level for physical activity and most studies followed relatively few participants. The object of this study was to assess iron storage levels in a population of healthy young males and their impact on physical fitness. Blood samples were drawn from 358 consenting infantry recruits for hemoglobin, iron, ferritin, transferrin, folic acid, and B₁₂ levels. A detailed medical and nutritional history was noted. Recruits performed a field fitness test including a 2,000-m run. Mean hemoglobin was 13.8 ± 1.0 g/dL. Level of hemoglobin lower than 14 and 12 g/dL were found in 54 percent and 5 percent of the recruits, respectively. Mean ferritin was 57 ± 34 ng/ml, with 15 percent of the recruits under 25 ng/ml. On multivariate analysis, after adjusting for pre-induction sports activity, intermediate pre-induction hemoglobin level (12-14 g/dL) was associated with significantly faster 2,000-m running time (than both the lower hemoglobin group (n=16) and the higher hemoglobin group (n=166). The subjects in this study were non-athletic healthy young men. The high rate of abnormally low hemoglobin and ferritin values probably indicates a nutritional deficit in this population. The slower running results in the group with hemoglobin below 12 g/dL are in line with previous work, indicating the need for iron supplementation. The decrease in running ability with increased hemoglobin above 14 g/dL is surprising and will need further evaluation [07109].

Hemoglobin (Hb) and reticulocytes (Ret) are measured as indirect markers of doping in athletes. It was studied the diurnal variation, the impact of exercise, fluid intake and ambient temperature in athletes on these parameters. Hourly venous blood samples were obtained from 36 male athletes of different disciplines (endurance (END) and non-endurance (NON-END)) over 12 h during a typical training day. Seven inactive subjects served as controls (CON). Hb and Ret were determined. A mixed model procedure was used to analyse the data. At baseline, Hb was similar for all groups, END showed lower Ret than NON-END and CON. Exercise showed a significant impact on Hb (+0.46 g/dL), the effect disappeared approximately 2 h after exercise. Hb decreased over the day by approximately 0.55 g/dL. There was no relevant effect on Ret. Fluid intake and ambient temperature had no significant effect. Hb shows significant diurnal- and exercise related variations. In an anti-doping context, most of these variations are in favour of the athlete. Blood samples taken after
exercise might therefore provide reliable results and thus be used for the longitudinal monitoring of athletes if a timeframe for the re-equilibration of vascular volumes is respected [10101].

**Regulation of red blood cell mass**

One article reviewed the regulation of production of RBCs at several levels. It was focused on the regulated expansion of burst-forming unit-erythroid erythroid progenitors by glucocorticoids and other factors that occur during chronic anemia, inflammation, and other conditions of stress. It was also highlighted the rapid production of RBCs by the coordinated regulation of terminal proliferation and differentiation of committed erythroid colony-forming unit-erythroid progenitors by external signals, such as erythropoietin and adhesion to a fibronectin matrix. It was discussed the complex intracellular networks of coordinated gene regulation by transcription factors, chromatin modifiers, and miRNAs that regulate the different stages of erythropoiesis [11458].

**Circadian rhythm**

In the fight against doping in sports, indirect detection methods using Hb and Hct are starting to play a more and more important role. The goal of this investigation was to quantify the changes in plasma volume (PV) during a 2 week study of endurance exercise simulating a cycling stage race and to test for PV changes relative to the circadian rhythm of the athlete. Fifteen endurance trained triathletes and cyclists performed a standardised 3 day taper (no exercise), followed by a 9 day cycling stage race simulation. Hb showed a mean increase of 4 percent during the 3 day taper period which was caused by a reduction in PV. During the exercise phase Hb dropped by 1.5 g/dL or 11 percent, which relates to an average expansion of PV by 0.6 l or 16 percent. The fluctuations in morning PV showed a wide inter-subject variability. The smallest change was 493 ml (10 %), which was accompanied with a drop in Hb from 14.8 g/dl to 13.7 g/dl. The largest increase was 1277 mL (or 25 %). The corresponding Hb values for this subject dropped from 15.8 g/dL to 13.1 g/dL. The Hb concentration of the morning and evening samples showed a mean difference of approximately 0.6 g/dL or 3.7 percent, which was observed both during the taper (without exercise) and stage race phases. This study showed that exercise induced changes of PV in healthy trained endurance athletes can be up to 1277 mL or 25 percent when tested at the same time of the day. This fact needs to be considered in the interpretation of blood profiles as this value might even be higher if the test was to be performed at different times of the day. In the study it was able to demonstrate that the circadian rhythm of Hb concentration remains stable even under maximal PV expansion and reaction to exercise. This finding could be implemented in the athlete biological passport model to help reduce the variation of biological markers [11459].

**Seasonal variations of hemoglobin**

The influence of training and competition workloads is crucial for evaluation of longitudinal hematological data in athletes. There are only a few papers on the variation of aematological parameters during long-lasting periods and, especially, during an entire competitive season. It was summarized that some hematological parameters can be influenced by long-term training and competition periods. Hemoglobin (Hb) and hematocrit (Ht) are decreased during the more intense periods of training, throughout the season. In different sport disciplines, the decline of Hb ranges from 3 to 8 percent during the competition season, while the range of reticulocytes (Ret%) varies from 5 to 21 percent. Reticulocytes are also decreased after long periods of training and competitions, but their variation is not necessarily associated with that
of Hb. The qualitative variations (trend of modifications) of haematological parameters are roughly independent of the sport discipline, but quantitatively (amount of modifications) dependent on sport discipline. The modifications are more evident in cycling, running, swimming than they are in football and rugby. The variations of haematological parameters within the same sport discipline are qualitatively concordant and quantitatively different among separate but consecutive competitive seasons. These findings are described in aerobic and team sports sportsmen. The definition of reliable reference ranges in sportsmen would only be possible by following the best laboratory practices. For antidoping purposes more studies investigating hematological modifications during the season are advisable [11117].

**Stability of hemoglobin under testing conditions**

With the setting up of the newly Athlete's Biological Passport antidoping programme, novel guidelines have been introduced to guarantee results beyond reproach. It was investigated in this context, the effect of storage time on the variables commonly measured for the haematological passport. It was also wanted to assess for these variables, the within and between analyzer variations. Blood samples were obtained from top level male professional cyclists (27 samples for the first part of the study and 102 for the second part) taking part to major stage races. After collection, they were transported under refrigerated conditions (2 °C <T<12 °C), delivered to the antidoping laboratory, analysed and then stored at approximately 4 °C to conduct analysis at different time points up to 72 h after delivery. A mixed-model procedure was used to determine the stability of the different variables. As expected haemoglobin concentration was not affected by storage and showed stability for at least 72 h. Under the conditions of the investigation, the reticulocytes percentage showed a much better stability than previous published data (> 48 h) and the technical comparison of the haematology analyzer demonstrated excellent results. In conclusion, the data clearly demonstrate that as long as the World Anti-Doping Agency's guidelines are followed rigorously, all blood results reach the quality level required in the antidoping context [11118].

Hematologic parameters are commonly utilized in sports medicine and antidoping testing. However, there are no universally accepted methodologies for comparing the performance of automated blood analyzer systems. To address this problem, it was selected and examined 19 studies from a review of literature published from 2000 to 2010. Meaningful discrepancies were found between measurements obtained with different analytical systems. Because harmonization and clear standardization of methods are lacking, the analytical variability often largely exceeds intra- and inter-individual biological differences, producing equivocal test results unreliable for clinical and antidoping testing. A central criticality to applying the Bayesian approach is analytical variability, but the use of different analytical technologies precludes the comparison of inter-methods for determining the robustness of blood variables and their clinical significance. Therefore, future multicenter studies are needed to compare analytical methodologies and blood analyzer systems, and to establish worldwide-accepted standards and quality control protocols [11119].

**Statistical models for blood cell survival**

The aim of one work is to compare different labelling methods that are commonly used to estimate the lifespan of red blood cells (RBCs), e.g. in anaemia of renal failure, where the effect of treatment with erythropoietin depends on the lifespan of RBCs. A previously developed model for the survival time of RBCs that accounts for plausible physiological processes of RBC destruction was used to simulate ideal random and cohort labelling methods for RBCs, as well as the flaws associated with these methods (e.g. reuse of label...
and loss of the label from the surviving RBCs). Random labelling with radioactive chromium and cohort labelling using heavy nitrogen were considered. Blood sampling times were determined for RBC survival studies using both labelling methods by applying the theory of optimal design. It was assessed whether the underlying parameter values of the model are estimable from these studies, and the precision of the parameter estimates were calculated. In theory, parameter estimation would be possible for both types of ideal labelling methods without flaws. However, flaws associated with random labelling are significant and not all parameters controlling RBC survival in the model can be estimated with good precision. In contrast, cohort labelling shows good precision in the parameter estimates even in the presence of reuse and prolonged incorporation of the label. A model based analysis of RBC survival studies is recommended in future to account for limitations in methodology as well as likely causes of RBC destruction [11460].

Preanalytical mixing of whole-blood specimens

Full blood counts are now used as evidence that athletes have used banned blood doping. This has led to legal scrutiny of the efficacy of preanalytical procedures such as specimen homogenisation. To characterise the impact of different mixing strategies on whole-blood homogeneity manual inversion, mechanical mixing and automatic mixing performed by the Sysmex XT-2000i were evaluated. Automated mixing by the instrument, or 1 min of mechanical mixing, thoroughly homogenised specimens even for tubes that had been refrigerated and left undisturbed for 36 h. Manual inversions were almost as effective, provided that specimens were first allowed to equilibrate to ambient temperatures. Current sport guidelines that mandate at least 15 min of mechanical mixing are excessive. Except where specimens are presented to the instrument manually, mechanical mixing is redundant in the context of full blood counts [11583].

Blood parameters during endurance exercise

Hematological assessment is crucial for evaluating athletes healthy status. Professional athletes experience physiological modifications during competitions and over a season: the risk of sports anaemia is high. Few descriptions of hematological parameters behaviour during a 3-weeks cycling stage race have been published. It was studied nine professional cyclists engaged in the 2011 Giro d'Italia stage race. Pre-analytical and analytical phases tightly followed academic and anti-doping authorities’ recommendations. Hematological and iron metabolism parameters were measured days -1 (pre-race), 12 and 22 during the race. Hemoglobin, red blood cells and hematocrit decreased during the race with a stabilisation in the second half, but final values were lower than baseline. Reticulocytes did not modify, whilst the immature reticulocyte fraction increased. No differences were found in red blood cells volume and corpuscular haemoglobin content, neither in iron metabolism markers. The acute phase proteins, haptoglobin and C-reactive protein, both increased over the race, while haemoglobin and haptoglobin were inversely related. These data are important for improving the knowledge of physiological modifications in hematological and iron metabolism parameters of professional athletes during highly demanding competitions [12232].

During flights

WADA's biological passport uses Hb and Ret% as markers for detection of blood doping. Athletes often have to travel long distances when they go for competition or training camps. Thus it is a legitimate discussion if the influence of travelling has a significant impact on these markers. For that reason the aim of this study was to investigate Hb and Ret% before and after a day of travelling including a flight of 8 h. Fifteen male endurance athletes
performed a 14 h journey including an 8 h flight. Hydration status, bodyweight and fluid intake was controlled. Blood was sampled in the morning and evening of day 1 and day 2 for interday comparisons and to control if intraday fluctuations are a result of travelling or circadian rhythm. Day 1. The subject’s bodyweight did not show a significant difference between the two timepoints of day 1, with 72.9 ± 5.9 kg in the morning and 72.5 ± 5.8 kg in the evening. The subjects showed a positive fluid balance of 982 ± 780 ml. Hb showed a significant decrease from 14.5 ± 0.6 g/dL to 14.0 ± 0.6 g/dL while Ret% remained unchanged (1.09 ± 0.25 % vs 1.03 ± 0.29 %). Day 2. The bodyweight of the subjects was 71.9 ± 5.8 kg in the morning and 72.9 ± 5.7 kg in the evening. The fluid balance was 407 ± 908 mL. The high SD is a sign that some of the subjects had a negative fluid balance, which was the case for four subjects. Hb showed a significant decrease from 14.9 ± 0.6 g/dL to 14.2 ± 0.5 g/dL while Ret% remained unchanged (1.03 ± 0.30 % vs 1.06 ± 0.32 %). The homeostasis of the human body regarding its fluid balance and hydration remains stable during changing environmental conditions which occur at a typical travel day including an 8 h flight. It was concluded that an 8 h flight does not change the haematological variables used in the biological passport in a bigger range than by circadian fluctuations. Thus blood samples after flights up to 8 h can be used for the interpretation in antidoping [11461].

**Total hemoglobin mass**

Training and hypoxia-associated changes in maximal oxygen uptake are mediated by different blood adaptations. Training increases blood volume because of plasma and red cell volume expansion, resulting in increased cardiac output, whereas hypoxia increases only red cell volume, leading to increased hemoglobin concentration and oxygen transport capacity. Blood doping mimics the altitude effects, however, by far exceeding its magnitude [10102].

Determination of total haemoglobin mass (Hb\text{mass}) via carbon monoxide (CO) depends critically on repeatable measurement of percent carboxyhaemoglobin (%HbCO) in blood with a hemoximeter. The main aim of one study was to determine, for an OSM3 hemoximeter, the number of replicate measures as well as the theoretical change in percent carboxyhaemoglobin required to yield a random error of analysis (Analyser Error) of ≤1 percent. Before and after inhalation of CO, nine participants provided a total of 576 blood samples that were each analysed five times for percent carboxyhaemoglobin on one of three OSM3 hemoximeters; with approximately one-third of blood samples analysed on each OSM3. The error of analysis was calculated for the first two (duplicate), first three (triplicate) and first four (quadruplicate) measures on each OSM3, as well as for all five measures (quintuplicates). Two methods of CO-rebreathing, a 2-min and 10-min procedure, were evaluated for error of analysis. For duplicate analyses of blood, the Analyser Error for the 2-min method was 3.7, 4.0 and 5.0 percent for the three OSM3s when the percent carboxyhaemoglobin increased by two above resting values. With quintuplicate analyses of blood, the corresponding errors reduced to .8, .9 and 1.0 percent for the 2-min method when the percent carboxyhaemoglobin increased by 5.5 above resting values. In summary, to minimise the error of analysis to about 1 percent or less on an OSM3 hemoximeter, researchers should make ≥5 replicates of percent carboxyhaemoglobin and the volume of CO administered should be sufficient increase percent carboxyhaemoglobin by ≥5.5 above baseline levels [10356].

The purpose of one study was to determine the reliability of total hemoglobin mass (Hb\text{mass}) measurement in the field and to establish the variability of Hb\text{mass} during a cycling race, to assess its viability as an additional antidoping detection parameter in a control-matched longitudinal study in a International Cycling Union’s (UCI) ProTour stage race in 6
professional cyclists and 5 recreationally active controls. Seventy-two Hb\text{mass} tests using the optimized carbon monoxide rebreathing method were performed over 7 consecutive days, before and throughout the tour. Fasted venous blood was obtained for measurement of hematocrit (Hct) and hemoglobin concentration [Hb] in the morning before stages 1, 3, and 6 (D1, D3, and D6). Reliability of Hb\text{mass} measurement was established using typical error calculated from 2 baseline measures. Individual change scores and coefficients of variation were used to assess stability during racing. Typical error for Hb\text{mass} was 1.3 percent (95 % confidence limits 0.9 to 2.5 %). Calculated 95 percent and 99.99 percent confidence interval for percent change in Hb\text{mass} were ± 3.6 percent and ± 7.2 percent, respectively. Mean Hb\text{mass} remained within ± 1.9 percent of baseline in cyclists and ± 0.5 percent in controls. In all cases, individual change scores for both cyclists and controls fell within the 95 percent confidence interval. There was a decrease in Hct (8.1 % ± 2.8 %) and [Hb] (9.7 % ± 3.2 %) throughout the tour in cyclists but not in controls. It was demonstrated that Hb\text{mass} can be measured reliably via CO-rebreathing during a cycling tour. Unlike concentration of hemoglobin and hematocrit, total hemoglobin mass remains stable over 6 days of racing in professional cyclists and may have potential in an antidoping context [10103].

The purpose of one study was to reveal erythropoietin doping. It was recently suggested that the assessment of total haemoglobin mass (tHb) by means of the carbon monoxide rebreathing technique should be implemented in anti-doping work. Since erythropoietin may increase the hemoglobin concentration [Hb] simply by reducing plasma volume it was injected eight human subjects with epo for 15 weeks and directly tested the feasibility hereof. Erythropoietin treatment increased [Hb] in all subjects at all time points (range 3.8-18.8 %). In approximately half the subjects this was mainly the consequence of an increased tHb, but in the remaining subjects the change was the result of a decrease in the plasma volume. After the initial epo "boosting" period the assessment of tHb could not detect epo injections in 50 percent of the subjects in the remaining "maintenance" period. In the authors’ opinion the variability observed over time when assessing tHb is not justifiable in an anti-doping setting [10104].

The aims of one study were to evaluate total hemoglobin mass (tHb\text{mass}) in international field hockey players, to examine the correlation between tHb\text{mass} and maximum oxygen uptake (VO\text{2max}); and to assess influences of iron status on tHb\text{mass} and on VO\text{2max}. The players of the German women's (n=17, aged 21-31 years) and men's (n=17, aged 19-32 years) national field hockey team were investigated. tHb\text{mass} was measured by an optimized carbon monoxide rebreathing method. The following parameters were measured in venous blood: Hemoglobin concentration (Hb\text{conc}), hematocrit (Hct), number and percentage of reticulocytes, reticulocyte hemoglobin content, serum iron, serum ferritin, serum transferrin, unsaturated iron-binding capacity, and serum soluble transferrin receptor concentration. VO\text{2max} was determined in a treadmill test. tHb\text{mass} correlated to VO\text{2max} in women and in men, whereas Hb\text{conc} and Hct did not. The investigated parameters of iron status showed no association to tHb\text{mass} or to VO\text{2max}. In conclusion, tHb\text{mass} can be used as an indicator for endurance capacity in elite field hockey players, whereas Hb\text{conc} may not. tHb\text{mass} or VO\text{2max} were not influenced by the actual iron status of the investigated athletes [10105].

To evaluate total hemoglobin mass (tHb\text{mass}) in international field hockey players; to examine the correlation between tHb\text{mass} and maximum oxygen uptake (O\text{2max}); and to assess influences of iron status on tHb\text{mass} and on O\text{2max}. The players of the German women's (n=17) and men's (n=17) national field hockey team were investigated. tHb\text{mass} was measured by an optimized carbon monoxide rebreathing method. Total hemoglobin mass correlated to O\text{2max} in women and in men, whereas hemoglobin concentration and hematocrit did not. The investigated number and percentage of reticulocytes, reticulocyte hemoglobin content, serum iron, serum ferritin, serum transferrin, unsaturated iron-binding
capacity, and serum soluble transferrin receptor concentration showed no association to tHbmass or to $O_{2\text{max}}$. In conclusion, total hemoglobin mass can be used as an indicator for endurance capacity in elite field hockey players, whereas hemoglobin concentration may not. Total hemoglobin mass or $O_{2\text{max}}$ were not influenced by the actual iron status of the investigated athletes [09150].

Total haemoglobin mass (tHb) as a direct parameter of the blood system and ultimate target of all blood transfusions has not been evaluated for its post-transfusion survival and stability. Therefore, the purpose of one study was to investigate the latter which may also be relevant from an anti-doping perspective as autologous blood transfusions remain impossible to detect. The tHb was determined by the CO rebreathing method prior to and after donation of 1 unit of whole blood, as well as prior to and after reinfusion (weekly up to 56 days) of the erythrocyte concentrate in 10 men. The mean tHb content of the derived erythrocyte concentrate was $60 \pm 3$ g, while the net tHb increases after transfusion of $51$ g ($95 \%$ confidence intervals $33-69$ g) permitted proof of an elevated tHb for at least 56 days after transfusion. It was concluded that the results show that an elevated tHb induced by autologous transfusion allowed continuous identification although, as expected, a slow decrease of tHb has been revealed in the observation period. In reference to anti-doping, CO rebreathing permits proof of a supraphysiologically elevated tHb but possibly only if a stable baseline value is known [09151].

The assessment of total hemoglobin mass (tHb-mass) with the optimized carbon monoxide-rebreathing procedure (oCOR) is discussed as a promising method to detect blood doping. The method requires repeated measurements of the carboxyhemoglobin fraction (%HbCO) using spectrophotometers (CO oximeters). In order to determine whether %HbCO measurements with different spectrophotometers yield similar tHb-masses, the results of 57 tHb-mass calculations from simultaneous %HbCO measurements with two different spectrophotometers were analyzed. For the comparison of longitudinal tHb-mass alterations (deltaHb-mass), 3 tHb-mass measurements were obtained at 6-month intervals (33-37 subjects). Apparently, the analytical variation in tHb-mass determination with oCOR increases considerably with the use of different spectrophotometers. Therefore, agreement on the use of one spectrophotometer that accurately measures low %HbCO values is needed if oCOR should be used in an anti-doping setting [11122].

Determination of total haemoglobin mass (Hbmass) via carbon monoxide (CO) depends critically on repeatable measurement of percent carboxyhaemoglobin (%HbCO) in blood with a hemoximeter. The main aim of one study was to determine, for an OSM3 hemoximeter, the number of replicate measures as well as the theoretical change in percent carboxyhaemoglobin required to yield a random error of analysis (Analyser Error) of $\leq 1$ percent. Before and after inhalation of CO, nine participants provided a total of 576 blood samples that were each analysed five times for percent carboxyhaemoglobin on one of three OSM3 hemoximeters; with approximately one-third of blood samples analysed on each OSM3. The Analyser Error was calculated for the first two (duplicate), first three (triplicate) and first four (quadruplicate) measures on each OSM3, as well as for all five measures (quintuplicates). Two methods of CO-rebreathing, a 2-min and 10-min procedure, were evaluated for Analyser Error. For duplicate analyses of blood, the Analyser Error for the 2-min method was 3.7, 4.0 and 5.0 percent for the three OSM3s when the percent carboxyhaemoglobin increased by two above resting values. With quintuplicate analyses of blood, the corresponding errors reduced to .8, .9 and 1.0% for the 2-min method when the percent carboxyhaemoglobin increased by 5.5 above resting values. In summary, to minimise the analyser error to $\leq 1\%$ on an OSM3 hemoximeter, researchers should make $\geq 5$ replicates of percent carboxyhaemoglobin and the volume of CO administered should be sufficient increase percent carboxyhaemoglobin by $\geq 5.5$ above baseline levels [11123].
An increase of hemoglobin (Hb) mass is the key target of blood doping practices to enhance performance as it is a main determinant of maximal oxygen uptake. Although detection methods exist for doping with recombinant EPO and homologous blood transfusions, autologous transfusions remain virtually undetectable. In this context, the most sensitive parameter would be a determination of Hb mass itself. The purpose of one study therefore was to establish whether Hb mass measurements by the optimized CO-rebreathing method allow screening for the withdrawal and reinfusion of autologous red blood cells. The optimized CO-rebreathing method was used for evaluation of Hb mass in two groups at three time points (duplicate measurements: baseline, after donation, and after reinfusion). Group I (n=6) was to donate and receive 1 unit of packed red cells (PRC) in contrast to two PRC in group II (n=4). The time span between withdrawal and reinfusion was 2 days. The mean Hb content of the blood units was 59 ± 4 g (group I) and 108 ± 1 g (group II). Hb mass decreased significantly after blood and increased significantly after reinfusion (group I: 70 ± 16 g; group II: 90 ± 9 g) but was still lower than at baseline. The total error of measurements for the duplicate measures ranged between 0.8 and 3.1 percent (Hb mass: 6-22 g). It was concluded that Hb mass determination with the optimized CO-rebreathing method has sufficient precision to detect the absolute differences in Hb mass induced by blood withdrawal and autologous reinfusion. Thus, it may be suited to screen for artificially induced alterations in Hb mass [07110].

Hemoglobin mass is a main determinant of maximal oxygen uptake. Blood doping aims at increasing this variable. Limits for hematocrit and hemoglobin concentration are used as indicators of blood doping. However, these variables are measures of concentration, do not represent total hemoglobin mass and are altered by vascular volumes shifts. Direct estimation of hemoglobin mass could improve blood tests. It is unknown if physical exercise alters hemoglobin mass. The purpose of one study was to investigate the reaction of hemoglobin mass and other vascular compartments to heavy exercise in athletes. Hemoglobin mass and vascular compartments were evaluated using the optimised CO rebreathing method in 7 elite cyclists during a stage race. Simultaneously, hemoglobin concentration and hematocrit were analysed. Hemoglobin mass (pre-race 958 ± 123 g, end race 948 ± 106 g) and red cell volume did not change significantly over the study period, while plasma volume and blood volume tended to increase. Hematocrit (pre-race 44.1 ± 2.5 %, end race 40.9 ± 1.59 %) and hemoglobin concentration (pre-race 15.8 ± 0.9 g/dL, end race 14.7 ± 0.7 g/dL) decreased. During the study, a plasma volume expansion as adaptation to prolonged exercise occurred. Hemoglobin concentration and aematocrit decreased accordingly, whereas hemoglobin mass remained stable. Hemoglobin mass might therefore be a suitable screening tool for blood manipulations [07111].

A high hemoglobin mass (Hbmass) is associated with a high maximum aerobic power (VO2max), however, the extent to which Hb(mass) is influenced by training is currently unclear. Accordingly, this study monitored changes in Hbmass and VO2max in 12 previously untrained adults (aged 18-25 years) following 40 days of regular physical activity. Hbmass and VO2max were assessed at the start and end of a 40-day physical activity program, which comprised of approximately 40 min of daily, moderate-intensity physical activity. Relative VO2max increased by 11 percent, yet there was no significant change in relative Hbmass (1.7 %) and body mass (0.2 %) during the 40-day period. There was a significant correlation between Hbmass and VO2max at the start of the study but not between the change in relative VO2max and the change in relative Hbmass. The results support the concept of relative stability in Hbmass with approximately 1 month of moderate-intensity physical activity suggesting that Hbmass may be used for talent identification and possibly for anti-doping purposes [12226].
Hemoglobin mass (Hbmass) is another parameter independent of plasma volume shifts. Hbmass is the total amount of circulating hemoglobin level in the blood. Because of its lower variability compared with Hb, it has been suggested as a potential candidate for the hematologic module of the Athlete Biological Passport. The hematologic module of the Athlete Biological Passport consists of longitudinal monitoring of Hb and OFF-hr and other RBC indices of blood manipulation that aims to identify suspicious values and profiles. Hbmass has been measured for more than a century by the use of carbon monoxide (CO) by the indicator dilution principle. Hemoglobin level mass would be an advantageous parameter in detecting ABT especially during longer periods of strenuous exercise, that is, during the Tour de France, where Hbmass is stable but Hb decreases because of plasma volume expansion. In a noncompetition setting, relatively stable Hb values would be considered normal, but when observed during such strenuous events such as the Tour de France, they must be considered indicative of blood transfusions. The WADA recommends in the Operating Guidelines for the Biological Passport that a value or sequence exceeding the 99.9 percent specificity level should be reviewed by a panel of experts. This implies 1 false positive for every thousand analyses. Nevertheless, individual antidoping organizations are allowed to use lower specificity levels before further scrutinization is performed [12009].

It was quantified the changes of hemoglobin mass (Hbmass) and maximum oxygen consumption (VO2max) after 22 days training at 1300-1800 m combined with nightly exposure to 3000-m simulated altitude. It was hypothesized that with simulated 3000-m altitude, an adequate beneficial dose could be as little as 10 h/24 h. Fourteen male collegiate runners were equally divided into 2 groups: altitude (ALT) and control (CON). Both groups spent 22 days at 1300-1800 m. ALT spent 10 h/night for 21 nights in simulated altitude (3000 m), and CON stayed at 1300 m. VO2max and Hbmass were measured twice before and once after the intervention. Blood was collected for assessment of percent reticulocytes (%retics), serum erythropoietin (EPO), ferritin, and soluble transferrin receptor (sTfR) concentrations. Compared with CON there was an almost certain increase in absolute VO2max (8.6 %, 90 % confidence interval 4.8 to 12.6 %) and a likely increase in absolute Hbmass (3.5 %; 90 % confidence interval 0.9 to 6.2%) at postintervention. The %retics were at least very likely higher in ALT than in CON throughout the 21 nights, and sTfR was also very likely higher in the ALT group until day 17. EPO of ALT was likely higher than that of CON on days 1 and 5 at altitude, whereas serum ferritin was likely lower in ALT than CON for most of the intervention. Thus, together the combination of the natural and simulated altitude was a sufficient total dose of hypoxia to increase both Hbmass and VO2max [13292].

One study sought to quantify the effects of reduced training, surgery and changes in body mass on haemoglobin mass (Hbmass) in athletes. Hbmass of 15 athletes (6 males, 9 females) was measured 9 ± 6 times over 162 ± 198 days, during reduced training following injury or illness. Additionally, body mass (n=15 athletes) and episodes of altitude training (n=2), iron supplementation (n=5), or surgery (n=3) were documented. Training was recorded and compared with pre-injury levels. Analysis used linear mixed models for ln(Hbmass), with Sex, Altitude, Surgery, Iron, Training and log(Body Mass) as fixed effects, and Athlete as a fixed and random effect. Reduced training and surgery led to 2.3 and 2.7 percent decreases in Hbmass, respectively. Altitude and iron increased Hbmass by 2.4) and 4.2 percent, respectively. The effect of changes in body mass on Hbmass was not statistically significant. The estimates for the effects of surgery and altitude on Hbmass should be confirmed by future research using a larger sample of athletes. These estimates could be used to inform the judgements of experts examining athlete biological passports, improving their interpretation of Hbmass perturbations, which athletes claim are related to injury, thereby protecting innocent athletes from unfair sanctioning [13293].
Within-subject variation in hemoglobin mass

Illicit autologous blood transfusion to improve performance in elite sport is currently undetectable, but the stability of longitudinal profiles of an athlete’s hemoglobin mass ($H_{\text{b mass}}$) might be used to detect such practices. The aim of one study was to quantify within-subject variation of $H_{\text{b mass}}$ in elite athletes, and the effects of potentially confounding factors such as reduced training or altitude exposure. A total of 130 athletes (43 females and 87 males) were measured for $H_{\text{b mass}}$ an average of six times during a period of approximately 1 year using carbon monoxide rebreathing. Linear mixed models were used to quantify within-subject variation of $H_{\text{b mass}}$ and its associated analytical and biological components for males and females, as well as the effects of reduced training and moderate altitude exposure in certain athletes. The maximum within-subject coefficient of variation (CV) for $H_{\text{b mass}}$ was 3.4 percent for males and 4.0 percent for females. The analytical CV was about 2.0 percent for both males and females, and the long-term biological CV, after allowing for analytical variation, was 2.8 percent for males and 3.5 percent for females. On average, self-reported reduced training resulted in a 2.8 percent decrease in $H_{\text{b mass}}$ and altitude exposure increased $H_{\text{b mass}}$ by 1.5% to 2.9%, depending on the duration and type of exposure. It was concluded that the within-subject CV for $H_{\text{b mass}}$ of about 4 percent indicates that athletes may experience changes up to about 20 percent with a 1-in-1000 probability. Changes of this magnitude for measures taken a few months apart suggest that $H_{\text{b mass}}$ has a limited capacity to detect autologous blood doping. However, changes in $H_{\text{b mass}}$ may be a useful indicator when combined with other measures of blood manipulation [12227].

Influence of exercise

It was investigated whether 12 months of chronic endurance training would affect hematology, CD4(+) lymphocyte transferrin receptor (CD71) expression, CD4(+) intracellular iron and the incidence of upper respiratory tract illnesses (URTI) in Ironman triathletes compared with untrained men. Resting venous blood samples were taken from 15 Ironman triathletes (TR) and 12 untrained men (UT) every 4 weeks for 12 months. Erythrocyte, leukocyte and platelet concentration, haematocrit, haemoglobin (Hb) and mean corpuscular haemoglobin (MCHC) were measured with a full blood count. CD4(+) lymphocytes were analysed for changes in transferrin receptor (CD71) expression (CD4(+)CD71(+)), and intracellular iron (Fe$^{3+}$), by flow cytometry. The TR group had significantly lower Hb, MCHC, and platelets for 10, 9 and 11 months, respectively; lower CD4(+)CD71(+) (3 months) and Fe(3+) (1 month), respectively; higher CD4(+)CD71(+) (1 month); a higher lymphocyte count for 4 months. There were no between-group differences in other variables. In both groups haematology and lymphocytes increased during spring, early summer and winter and decreased during late summer/late winter, with an inverse relationship between CD4(+)CD71(+) and Fe$^{3+}$. The TR group reported significantly fewer URTI than the UT. Low Hb and MCHC suggest an iron deficiency which may affect triathlete performance. Monthly changes in lymphocytes, CD4(+)CD71(+) and Fe(3+) suggested that spring, summer and late autumn are associated with CD4(+) proliferation. There may be seasonal relationships between haematology and lymphocyte function, independent of endurance training, possibly affecting performance but not the incidence of URTI [10357].

Exercise in humans augments the mobilization of circulating hematopoietic progenitor cells (CD34(+)) from the bone marrow. It was investigated the effect of inflammation on erythroid marrow activity by mobilization of erythroid progenitor cells (EPIs) along with soluble markers of erythropoiesis. Ten healthy athletes who participated in an ultradistance foot race participated in the study. Peripheral blood mononuclear cells were isolated, before (phase I),
at the end (phase II), and at 48 h post-race (phase III). EPs were detected as burst colony forming units (BFU-e) and colonies were scored at day 14. Markers of inflammation (C-reactive protein, serum amyloid-A, interleukin-6, ferritin and S100B) and bone marrow activity (erythropoietin, soluble transferrin receptor and lipocalin-2) were assessed. An approximately three-fold decrease in BFU-e number was observed at phase II. sTfR concentrations were also decreased at phase II and remained decreased at phase III. However, EPO and lipocalin-2 concentrations reached a maximum value at phase II, with a tendency to decrease at phase III. These findings indicate that exercise-induced inflammation modulates bone marrow homeostasis leading to an increase in leukocyte turnover and a decrease in erythroid compartment. It appears that lipocalin-2 is the main factor that regulates the production and mobilization of EPs [10106].

Erythropoietin (Epo) treatment increases hematocrit (Htc) and, consequently, arterial O₂ content. This in turn improves exercise performance. However, because elevated blood viscosity associated with increasing Htc levels may limit cardiac performance, it was suggested that the highest attainable Htc may not necessarily be associated with the highest attainable exercise capacity. To test the proposed hypothesis that an optimal Htc in acute and chronic Epo-treated mice exists – i.e. the hematocrit that facilitates the greatest O₂ flux during maximal exercise – hematocrit levels of wild-type mice were acutely elevated by administering novel erythropoiesis-stimulating protein (NESP; wtNESP). Furthermore, in the transgenic mouse line tg6 that reaches Htc levels of up to 0.9 because of constitutive overexpression of human Epo, the Htc was gradually reduced by application of the hemolysis-inducing compound phenylhydrazine (PHZ; tg6PHZ). Maximal cardiovascular performance was measured by using telemetry in all exercising mice. Highest maximal O₂ uptake (VO₂max) and maximal time to exhaustion at submaximal exercise intensities were reached at Htc values of 0.58 and 0.57 for wtNESP, and 0.68 and 0.66 for tg6PHZ, respectively. Rate pressure product, and thus also maximal working capacity of the heart, increased with elevated Htc values. Blood viscosity correlated with VO₂max. Apart from the confirmation of the Htc hypothesis, we conclude that tg6PHZ adapted better to varying Htc values than wtNESP because of the higher optimal Htc of tg6PHZ compared to wtNESP. Of note, blood viscosity plays a critical role in limiting exercise capacity [10107].

**Influence of injury and training on hemoglobin mass**

One study sought to quantify the effects of reduced training, surgery and changes in body mass on haemoglobin mass (Hbmass) in athletes. Hbmass of 15 athletes (6 males, 9 females) was measured 9 ± 6 (mean ± SD) times over 162 ± 198 days, during reduced training following injury or illness. Additionally, body mass (n=15 athletes) and episodes of altitude training (n=2), iron supplementation (n=5), or surgery (n=3) were documented. Training was recorded and compared with pre-injury levels. Analysis used linear mixed models for ln(Hbmass), with gender, altitude, surgery, iron, training and log(Body Mass) as fixed effects, and athlete as a fixed and random effect. Reduced training and surgery led to 2.3 and 2.7 percent decreases in Hbmass, respectively. Altitude and iron increased Hbmass by 2.4 and 4.2 percent, respectively. The effect of changes in body mass on Hbmass was not statistically significant. The estimates for the effects of surgery and altitude on Hbmass should be confirmed by future research using a larger sample of athletes. These estimates could be used to inform the judgements of experts examining athlete biological passports, improving their interpretation of Hbmass perturbations, which athletes claim are related to injury, thereby protecting innocent athletes from unfair sanctioning [13295].

**Total hemoglobin mass in endurance-trained**

To evaluate differences in total haemoglobin mass (tHb mass) and in red blood cell profile between elite endurance-trained (END) and non-endurance-trained (nEND) male and female adolescent athletes, tHb mass (CO rebreathing) and specific variables of red blood cell
profile (haemoglobin concentration, haematocrit, erythrocyte indices) were determined in 59 elite junior athletes (29 END, 30 nEND). It was hypothesized that at the age of 15-17 years, regular endurance training might induce a significant increase in tHb mass and changes in red blood cell profile. Therefore, all parameters were again determined after 6, 12 and 18 months in a subset of 27 subjects (17 END, 10 nEND). In END, tHb mass related to body weight was about 15 percent greater than in nEND whereas no significant differences were observed for the red blood cell profile. In both groups, tHb mass related to body weight and the variables of red blood cell profile had not changed significantly after 6, 12 and 18 months of regular training. In conclusion, in elite junior athletes, differences in tHb mass between END and nEND were similar, however, smaller compared with previously in adult athletes reported values. At the age of 15-17 years, 18 months of regular training did not induce significant changes in tHb mass beyond alterations explained by physical growth and also variables of red blood cell profile did not change significantly [11462].

**Influence of acute hard training**

Sensitivity of the Athlete Blood Passport for blood doping could be improved by including total haemoglobin mass (Hb_mass), but this measure may be unreliable immediately following strenuous exercise. It was examined the stability of Hb_mass following ultra-endurance triathlon (3.8 km swim, 180 km bike, 42.2 km run). Twenty-six male sub-elite triathletes, 18 racers and 8 controls, were tested for Hb_mass using CO re-breathing, twice 1-5 days apart. Racers were measured before and 1-3 h after the triathlon. Controls did no vigorous exercise on either test day. Serum haptoglobin concentration and urine haemoglobin concentration were measured to assess intravascular haemolysis. There was a 3.2 percent increase in Racers' Hb_mass from pre-race (976 g ± 14.6 %) to post-race (1 007 g ± 13.8 %), as opposed to a -0.5 percent decrease in controls (pre-race 900 g ± 13.9 %, post-race 896 g ± 12.4 %). Haptoglobin was -67 percent reduced in racers (pre-race 0.48 g/L ± 150 %, post-race 0.16 g/L ± 432 %), compared to -6 percent reduced in controls (pre-race 1.08 g/L ± 37 %, post-race 1.02 g/L ± 37 %). Decreased serum haptoglobin concentration in racers, which is suggestive of mild intravascular blood loss, was contrary to the apparent Hb_mass increase post-race. Ultra-endurance triathlon racing may confound the accuracy of post-exercise Hb_mass measures, possibly due to splenic contraction or an increased rate of CO diffusion to intramuscular myoglobin [12228].

**In detraining**

Haemoglobin mass (Hb_mass) determination using CO rebreathing may assist to detect illegal blood doping practices, however variations in Hbmass with periods of intensive training and detraining must be quantified. This study aimed to determine the effect of a 30-day period of detraining on Hb_mass in ultra-endurance triathletes. Nine male recreational triathletes (29-44 years) participated in the study. Hb_mass was assessed using CO rebreathing 30 days and 10 days before an ultra-endurance triathlon and after about 10, 20 and 30 days of detraining following the race. VO2max was assessed 10 days before the race and also after the 30-day detraining period, which consisted of an 87 percent reduction in training hours. After 30-days of detraining there was a 3.1 percent decrease in mean Hb_mass from 868 ± 99 to 840 ± 94 g, and a 4.7 percent decrease in mean VO2max from 4.83 ± 0.29 to 4.61 ± 0.41 L/min as well as a 2.8 percent increase of body mass from 75.1 ± 6.4 to 77.1 ± 6.1 kg and a 28 percent increase in skinfold total from 43.9 ± 14.2 to 55.1 ± 14.0 mm. Individual decreases in Hb_mass following detraining would need to be considered if using Hb_mass for anti-doping purposes [12229].

**A stable parameter**

A high hemoglobin mass (Hb_mass) is associated with a high maximum aerobic power (VO2max),
however, the extent to which Hb mass is influenced by training is currently unclear. Accordingly, one study monitored changes in Hb mass and VO2max in 12 previously untrained adults (aged 18-25 years) following 40 days of regular physical activity. Hb mass and VO2max were assessed at the start and end of a 40-day physical activity program, which comprised of approximately 40 min of daily, moderate-intensity physical activity. Relative VO2max increased by 11 percent, yet there was no significant change in relative Hb mass (1.7 %) and body mass (0.2 %) during the 40-day period. There was a significant correlation between Hb mass and VO2max at the start of the study, but not between the change in relative VO2max and the change in relative Hb mass. The results support the concept of relative stability in Hb mass with approximately 1 month of moderate-intensity physical activity suggesting that Hb mass may be used for talent identification and possibly for anti-doping purposes [11125].

Influence of travelling

Dehydration, fluid shifts or changes in coagulation occurring during air travel can trigger distinct reactions in the haematological system. Athletes are concerned that these effects might impair sporting performance, increase the risk of thrombosis or cause abnormalities in blood values that might be mistaken for doping in the 'Athlete's biological passport' (ABP) a longitudinal monitoring of haematological variables in antidoping. The aim of one study was to investigate key variables of the ABP before and after a long-haul flight in athletes. Fifteen endurance athletes were submitted to ABP blood samples in the morning before and after arrival of an 8 h flight. Two additional samples were obtained in the morning and the evening 3 days after the travel. Twelve nontravelling subjects served as controls. Hemoglobin concentration was higher before than after travel in athletes (+0.5 g/dL), a similar pattern was observed 3 days after the travel. No difference was observed in the control group. Reticulocyte percentage did not show any significant changes in neither of the groups. It was concluded that the observed changes are in line with normal diurnal variations. There is no indication that travel will affect haematological variables in way that might be mistaken for blood doping [12230].

Influence of erythropoietin

In healthy subjects, administration of recombinant human erythropoietin (rHuEpo) increases haemoglobin concentration not only by the well known increase in red blood cell mass but also by a decrease in plasma volume. The decrease in plasma volume, which precedes the increase in red cell mass, appears to be a rapid responding mechanism regulated by the renin-angiotensin-aldosterone system to control haematocrit. Theoretically, normal human red blood cells can persist in the circulation for approximately 17 weeks. However, neocytolysis, the selective hemolysis of young circulating red blood cells which contributes to the regulation of red cell mass, seems to appear during specific conditions that cause a rapid decrease in erythropoietin levels such as spaceflight, high altitude exposure or blood doping. Little is known about the time course of these mechanisms post rHuEpo administrations. Recombinant human erythropoietin (rHuEpo) increases haemoglobin mass (Hb(mass)) and maximal oxygen uptake (VO2max). One study defined the time course of changes in Hb(mass), VO2max as well as running time trial performance following 4 weeks of rHuEpo administration to determine whether the laboratory observations would translate into actual improvements in running performance in the field. Nineteen trained men received rHuEpo injections of 50 IU/kg body mass every two days for 4 weeks. Hb(mass) was determined weekly using the optimized carbon monoxide rebreathing method until 4 weeks after administration. VO2max and 3,000 m time trial performance were measured pre, post administration and at the end of the study. Relative to baseline, running performance significantly improved by 6 percent after administration and remained significantly enhanced
by 3 percent 4 weeks after administration, while VO₂_max was also significantly increased post administration and remained significantly increased 4 weeks after rHuEpo. Hb(mass) was significantly increased at the end of administration compared to baseline. The rate of decrease in Hb(mass) toward baseline values post rHuEpo was similar to that of the increase during administration but Hb(mass) was still significantly elevated 4 weeks after administration compared to baseline. It was concluded that running performance was improved following 4 weeks of rHuEpo and remained elevated 4 weeks after administration compared to baseline. These field performance effects coincided with rHuEpo-induced elevated VO₂_max and Hb(mass) [13294].

**Laboratory technique**

The assessment of total hemoglobin mass (tHb-mass) with the optimized carbon monoxide-rebreathing procedure (oCOR) is discussed as a promising method to detect blood doping. The method requires repeated measurements of the carboxyhemoglobin fraction (%HbCO) using spectrophotometers (CO oximeters). In order to determine whether %HbCO measurements with different spectrophotometers yield similar tHb-masses, the results of 57 tHb-mass calculations from simultaneous %HbCO measurements with two different spectrophotometers (RapidLab, OSM3) were analyzed. For the comparison of longitudinal tHb-mass alterations (delta tHb-mass), 3 tHb-mass measurements were obtained at 6-month intervals (33-37 subjects). Because of significant differences in %HbCO measurements, the limits of agreement for tHb-mass (OSM3) and tHb-mass(RapidLab) were 11 percent (95 % reference range -6.8 to +15.6 %) and the correlation of deltahHb-masses as determined with the two spectrophotometers over two time intervals was weak. In only about 70 percent of all deltahHb-mass estimations did deltahHb-mass(OSM3) and deltahHb-mass(RapidLab) show the same direction of change. Apparently, the analytical variation in tHb-mass determination with oCOR increases considerably with the use of different spectrophotometers. Therefore, agreement on the use of one spectrophotometer that accurately measures low %HbCO values is needed if oCOR should be used in an anti-doping setting [12231].

The sensitivity of the athlete blood passport to detect blood doping may be improved by the inclusion of total hemoglobin mass (Hb_mass), but the comparability of Hb_mass from different laboratories is unknown. To optimize detection sensitivity, the analytical variability associated with Hb_mass measurement must be minimized. The aim of one study was to investigate the efficacy of using quality controls to minimize the variation in Hb_mass between laboratories. Three simulated laboratories were set up in one location. Nine participants completed three carbon monoxide (CO) re-breathing tests in each laboratory. One participant completed two CO re-breathing tests in each laboratory. Simultaneously, quality controls containing Low (1-3 %) and High (8-11 %) concentrations of percent carboxyhemoglobin (%HbCO) were measured to compare hemoximeters in each laboratory. Linear mixed modeling was used to estimate the within-subject variation in Hb_mass, expressed as the coefficient of variation, and to estimate the effect of different laboratories. The analytic variation of Hb_mass was 2.4 percent when tests were conducted in different laboratories, which reduced to 1.6 percent when the model accounted for between-laboratory differences. Adjustment of Hb_mass values using quality controls achieved a comparable analytic variation of 1.7 percent. The majority of between-laboratory variation in Hb_mass originated from the difference between hemoximeters, which could be eliminated using appropriate quality controls [11124].

**Reticulocytes**

Reticulocytes (Ret) are a key variable in the emerging concept of the athlete's biological
The ratio between the amount of hemoglobin in the mature erythrocyte population and the passport and the longitudinal monitoring of biological parameters in the field of anti-doping. In this context, knowledge on the variability of Ret in athletes and the influence of exercise is necessary. The aim of one study was to evaluate longitudinal variation in Ret and the influence of short- and long-term exercise. Ret% in 793 samples of 238 athletes were determined and analyzed in different study parts for inter- and intra-individual variation and the impact of long- (competitive season) and short-term (all out) exercise. Median Ret% was 0.9 (99.5 % confidence interval 0.4 to 2.7). Intra-individual variation for Ret% was 0.0118; inter-individual variation 0.0124. During periods of intensive exercise Ret% was slightly but significantly lower (mean - 0.1 %). After a short, all-out exercise bout, Ret% was increased (+0.5 %). Athletes mostly display similar Ret% than the normal population; however, intra-individual variation in athletes is higher. During the competitive season of endurance athletes, Ret% is slightly decreased. After short bouts of intense exercise Ret% is increased [10466].

Reticulocytes are the transitional cells from erythroblasts to mature erythrocytes. Reticulocytes are present in blood for a period of 1-4 days and can be recognized by staining with supravital dyes, such as new methylene blue, or fluorescent markers, which couple residual nucleic acid molecules, a hallmark of the immature forms of erythrocytes. Although reticulocytes could be counted through a microscope (there is a standard of International Committee for Standardisation in Haematology for manual counting), this method is reported to be time consuming, inaccurate and imprecise. The integration of the reticulocyte count in automated hematology systems allowed the widespread use of these parameters, although the lack of calibration material and different markers, technologies and software used in automated systems could engender discrepancies among data obtained from different analytical systems. The importance of reticulocytes in sports medicine derives from their sensitivity, the highest among haematology parameters, in identifying the bone marrow stimulation, especially when recombinant human erythropoietin is fraudulently used. Automated systems are also able to supply information on volume, density and the haemoglobin content of reticulocytes. Some of the related parameters are also used in algorithms for identifying abnormal stimulation of bone marrow as reticulocytes haematocrit. The pre-analytical variability of reticulocytes (transportation, storage, biological variability) should be taken into account in sports medicine also. Reticulocytes remain stable for almost 24 hours at 4 degrees C from blood drawing, they are affected by transportation, and biological variability is not high in general. It could be remarked, however, that the intra-individual variability is high when compared with other haematological parameters such as haemoglobin and haematocrit. The intervals of data reported in athletes are very similar to reference intervals characterizing the general population. The reticulocyte count shows some modifications after training and during the competition season. The variability induced by exercise cannot be overlooked since the so-called haematological passport, a personal athlete's document in which haemoglobin and other parameters are registered, may be introduced by sports federations. Exposure to naturally high altitude and "living high – training low" programmes determined contentious results on reticulocytes. Simulated high altitude induced by intermittent hypobaric hypoxia does not modify reticulocytes, despite an increase in erythropoietin serum concentration. The variability among athletes competing in different sport disciplines is apparently limited. The knowledge of the behaviour of reticulocytes in training and competitions is crucial for defining their role in an antidoping control context. It is important for sport physicians and clinical pathologists to know the reticulocyte variability in the general population and in athletes, the pre-analytical warnings, the different methodologies for counting reticulocytes and the derived parameters automatically available, and, finally, the possible influence of training, competitions, type of sport and altitude [08210].

The ratio between the amount of hemoglobin in the mature erythrocyte population and the
reticulocytes (RBCHb:RetHb ratio) has previously been suggested as a marker to screen for erythropoietin-abuse. It was speculated that the reinfusion of blood would lead to a marked increase in this ratio, making it a valuable parameter in the screening for autologous blood doping. Three bags of blood (approximately 201 ± 11 g of Hb) were withdrawn from 16 males and stored at either -80 degrees C (n=8) or +4 degrees C (n=8) and reinfused 10 weeks or 4 weeks later, respectively. Seven subjects served as controls. Different erythrocyte parameters were measured on a hematological analyzer serially throughout and during a 4 week wash-out period. By using RBCHb:RetHb ratio cut-off limits of 146 (1:100) ("suspicious") and 183 (1:1000) ("positive"), 35 percent (-80 T) and 20 percent (+4 T) of all samples obtained during a 4 week wash-out period were identified as "suspicious", and 19 percent (-80 T) and 4 percent (+4 T) as "positive". In total, 7 out of 16 (44 %) subjects had at least one sample exceeding 183. Compared to the currently used indirect parameters, the RBCHb:RetHb ratio is the best indicator of autologous blood doping after reinfusion, and the parameter could be used in a testing setting, once stability validation has been performed [09153].

Automated haematological analysers still represent the gold standard for the study of reticulocyte maturation even if this technique is based on structural properties and staining affinity rather than on functional aspects. On the contrary, flow cytometry allows the simultaneous analysis of multiple cellular characteristics including functional features. The aim of one study was now to investigate whether simultaneous analysis of different reticulocyte parameters using flow cytometry may add functional information when considering their pattern of maturation. Thirty-nine healthy donors and 31 haemodialysed patients on treatment with rHuEpo were analysed. TO/CD71 scattergraph reticulocyte analysis designed a peculiar distribution which was similar among the same group of subjects (H or HDT), but different between healthy donors and haemodialysed patients. Distribution of the percentage of reticulocytes in low, medium and high boxes did not show any difference between healthy donors and haemodialysed patients groups, while the analysis using flow cytometry pointed out statistically significant differences between healthy donors and haemodialysed patients groups in the three boxes where the TO(+)/CD71(+) reticulocytes were localized. The present study suggests that TO/CD71 analysis was reproducible and could detect different pattern of maturation of a particular clinical setting [09154].

The role of reticulocytes (Ret) in sports medicine became clear when the count of immature erythrocytes was introduced in protocols used for anti-doping purposes. Because specific research regarding seasonal variations in Ret is lacking, it was assessed Ret (and [Hb]) in top-level male and female skiers during four consecutive competitive seasons. A significant difference between males and females was found for [Hb] and Ret values: [Hb] was lower and Ret was higher in females. The difference was maintained across all four competitive seasons. Marked within-subject differences in [Hb], Ret and immature reticulocyte fraction values were noted; the within-subject variability was greater than the between-subject variability in both genders. For instance, a difference for Ret was consistently shown between first and second blood drawings, i.e. between basal value, before the start of training and competition, and the value at middle of season, when training workload was at highest level. Unlike Ret%, the analysis of variance showed significant changes in [Hb] values across competitive seasons for both genders. Comparison between consecutive seasons (e.g. 2005-2006 vs 2006-2007) showed significant differences for both parameters. The behaviour of [Hb] and Ret during the various seasons was parallel in females, whereas a discrepancy existed in males. In general, inter-individual variability is quite high, thus, Ret and [Hb] modifications should be referred only to the single athlete. It was thus confirm the validity of the use of Ret counts for anti-doping purposes [10111].
Hemoglobin concentration and percent reticulocytes were analyzed in blood samples taken pre-competition, post-competition, and during out of competition testing in elite speed skaters. Percent reticulocytes during screening was not different from the values obtained post-race, and no significant gender difference was found. Mean hemoglobin concentration both in males and females was slightly but significantly higher at 1425 m altitude compared to <750 m altitude (0.23 g/dl increase in males and 0.48 g/dl increase in females). Mean percent reticulocytes at 1425 m altitude is significantly higher (0.24 % in males and 0.27 % in females, respectively) compared to blood sampled <750 m altitude. The distribution of percent reticulocytes shows 11 out of 11 500 samples with percent reticulocytes below 0.4 percent. From the 171 samples with a values >2.4 percent in 52 skaters at least two consecutive samples yielded a percent reticulocytes above 2.4 percent. In 50 individuals with generally normal values but at least in two consecutive samples values above 2.4 percent the pattern required additional testing. In conclusion, percent reticulocytes are a robust hematological parameter, including acute exercise [10112].

Automated haematological analysers still represent the gold standard for the study of reticulocyte maturation even if this technique is based on structural properties and staining affinity rather than on functional aspects. On the contrary, flow cytometry allows the simultaneous analysis of multiple cellular characteristics including functional features. Aim was to investigate whether simultaneous analysis of different reticulocyte parameters using flow cytometry may add functional information when considering their pattern of maturation. Thirty-nine healthy donors (H) and 31 haemodialysed patients on treatment with rhHuEpo (HDT) were analysed. Reticulocyte counts and their stages of maturation were studied both with ADVIA 2120 and by flow cytometry. TO/CD71 scattergraph reticulocyte analysis designed a peculiar distribution which was similar among the same group of subjects (H or HDT), but different between H and HDT. Distribution of the percentage of reticulocytes in low, medium and high boxes calculated by ADVIA 2120 did not show any difference between H and HDT groups, while the analysis using flow cytometry pointed out statistically significant differences between H and HDT groups in the three boxes where the TO+/CD71+ reticulocytes were localized. The present study suggests that TO/CD71 analysis was reproducible and could detect different pattern of maturation of a particular clinical setting [10113].

Reticulocytes (Ret) are a key variable in the emerging concept of the athlete's biological passport and the longitudinal monitoring of biological parameters in the field of anti-doping. In this context, knowledge on the variability of Ret in athletes and the influence of exercise is necessary. The aim of one study was to evaluate longitudinal variation in Ret and the influence of short- and long-term exercise. Reticulocytes in 793 samples of 238 athletes were determined and analyzed in different study parts for inter- and intra-individual variation and the impact of long- (competitive season) and short-term (all out) exercise. Median percentage of reticulocytes was 0.9 (95 % confidence interval 0.4 to 2.7). Intra-individual variation for Ret% was 0.0118; inter-individual variation 0.0124. During periods of intensive exercise Ret% was slightly lower (mean - 0.1 %). After a short, all-out exercise bout, Ret% was increased (+0.5 %). Athletes mostly display similar Ret% than the normal population; however, intra-individual variation in athletes is higher. During the competitive season of endurance athletes, Ret% is slightly decreased. After short bouts of intense exercise Ret% is increased. These data can be used for the interpretation of blood profiles in athletes [10355].

The Sysmex R-500 (R-500) Hematology Analyzer is a bench-top system appropriate for the analysis of limited batches of blood samples. The R-500 provides percentage proportional (RET%), absolute reticulocyte (RET#), and absolute red blood cell (RBC#) counts. The system was validated, according to the International Committee for Standardization in Hematology, International Standards Organization (ISO/IEC) 17025, and World Antidoping
Agency (WADA) specifications. The instrument calibration was performed according to the manufacturer and validation parameters comprised linearity, precision, uncertainty (intermediate and long-term precision), comparability, effect of drift, carryover, stability, and accuracy. The linearity and the comparability studies for RET#, RET%, and RBC# were expressed in regression factors (R2) and coefficients of correlation, respectively. For the precision studies, the coefficients of variation for RET#, RET%, and RBC# were 9.5 percent, 9.8 percent, and <1.5 percent, respectively. For the intermediate precision studies, the coefficients of variation for RET#, RET%, and RBC# were 3.1 percent, 3.6 percent, and 0.6 percent, respectively. Carryover was found to be negligible. Sample stability was demonstrated at both room temperature and at 4 degrees C over a 24-hour period. Comparability studies for the R-500 were performed using a Sysmex SE-9500. The total evaluation led to the conclusion that the R-500 is an accurate and precise analyzer and because of to its relatively limited size, it can be considered a portable instrument, capable to be used in sports competition and training sites, where doping control and health tests are conducted. The analytical methodology of RET% measurement by the R-500 has been incorporated into the Doping Control Laboratory of Athens' Scope of Accreditation according to the ISO/IEC 17025 and WADA specifications [07112].

The role of reticulocytes (Ret) in sports medicine became important when the count of immature erythrocytes has been introduced in protocols used and officially approved for anti-doping purposes. The use of modern automated analysers, which allow the easy count and the description of characteristics of reticulocytes, increased the possible use of these parameters in sports medicine. It was studied the behavior of Ret and immature reticulocyte fraction (IRF) in top-level athletes practising rugby, ski, soccer and cycling, throughout a competitive season. It was aimed at increasing the knowledge of physiological characteristics of these sportsmen and supplying valuable suggestions to trainers and sports physicians. It was observed a stability of Ret counts, also during training and competitions, although some modifications, namely decrease during competitions periods in cyclists, and in rugby and soccer players, occurred. No significant correlation was found between Ret count and Hb in each sport discipline. IRF values tend to be high in athletes owing to continuous bone marrow stimulation linked to haemolysis, typical of sports activities. It was confirmed the validity of the use of Ret counts for antidoping purposes and also for evaluating health status and iron metabolism of sportsmen [07113].

The percentage of reticulocytes has been investigated such as the injection of the granulocyte colony-stimulating factor (G-CSF), for which anecdotal evidence existed as to its abuse in elite sport. In a controlled study, the repeated administration of therapeutic dosages of G-CSF (10 microg/kg/day) over a period of 5 days resulted in a statistically significant increase of %reticulocytes while all volume-dependent parameters such as red blood cell count, haematocrit and haemoglobin were found decreased [13009].

Reticulocytes (Ret), immature precursors of erythrocytes, contain nucleic acid (RNA) residues, are larger in volume than mature red blood cells (RBCs) but have a lower hemoglobin (Hb) concentration. All enucleated RBCs with two blue-stained subparticles are counted as Ret and related to 1000 erythrocytes in the same field. Automatic counting methods rely on staining the particles with classical dyes (new methylene blue, brilliant cresyl blue, or similar) or with fluorophores (acridine orange) which bind the RNA residues, making them recognizable and numerable. Automation combines simultaneous enumeration of stained particles and recording of particle size with the advantage of high precision, since a high number of events are collected for each count and better throughput [13009].

Produced by thered bone marrow from mature erythroblasts that undergo enucleation, they still retain RNAresidues. After a brief period in the bone marrow, they are released into the
blood stream where they remain for up to 4 days until they mature into erythrocytes. Their lifetime is much shorter than that of mature RBCs, which have a mean lifetime of 120 days. While circulating in the bloodstream, Ret undergo several rapid changes as they mature: membrane remodeling, volume change, and extrusion of organelles. Reticulocytes develop from erythroblasts and circulate in the bloodstream for about 1-4 days before maturing into erythrocytes. With the introduction of reticulocyte count in equations and statistical models for detecting suspected blood doping, its application to sports medicine has attracted growing interest in reticulocyte behavior during training and competition seasons in athletes and experimental blood doping treatment in healthy volunteers. An update on recent publications is therefore needed to improve the interpretation of reticulocyte analysis and its variability in sportsmen. Reticulocyte count constitutes a robust parameter during the preanalytical phase, but cell stability can be assured only if blood samples are kept at constantly cold temperatures (4 degrees C) and test results will differ depending on the blood analyzer system used. Marked intraindividual variability is the principal finding to be evaluated when exercise-induced changes are observed or illicit procedures suspected. Furthermore, reticulocyte variability is greater than that of other hematological parameters such as hemoglobin or hematocrit. Ideally, any variation should be interpreted against long-term time series for the individual athlete: values obtained from large athlete cohorts ought to be used only for extrapolating outliers that deserve further examination. Reticulocyte distribution in athletes is similar to that found in the general population, and a gender effect in some sports disciplines or selected athlete groups may be seen. Reticulocyte variability is strongly influenced by seasonal factors linked to training and competition schedules and by the type of sports discipline. Published experimental data have confirmed the high sensitivity of reticulocyte analysis in identifying abnormal bone marrow stimulation by either erythropoietin administration or blood withdrawal and reinfusion [13298].

Extended intervals between sample collection and analyses render athlete's whole-blood specimens collected in the field for antidoping purposes susceptible to storage degradation. The aim of this study was to characterize the stability of key blood variables under different storage durations and temperatures. It was evaluated stability of full blood count indices (plus reticulocytes) in individual tubes left undisturbed during 36, 48, 72, 96, 120, 144 and 168 h of storage at approximately 4, 6 and 12°C. Samples were measured on a Sysmex XT-2000i instrument. The two key variables in the context of antidoping (haemoglobin concentration, reticulocytes) were stable for at least 168 h, except under 12°C (stable 48 h only). Volume-dependent variables changed in a predictable manner that enabled a nomogram to be generated to predict original values provided storage duration and temperature were known. It was concluded that key blood results can be relied upon for at least 7 days if storage temperature is kept at 4-6°C [13299].

Sports anemia

Reticulocyte evaluation in sportsmen is important because of its usefulness in monitoring athletes’ health, as, for example, in detecting sports anemia. Professional athletes are particularly prone to developing this condition in which Hb loss is accompanied by an increase in Ret count. Sport-induced anemia is associated with various causes, but erythrocyte destruction due to intravascular hemolysis is the major one responsible for continuous stimulation of bone marrow which can be monitored by Ret count. Sports anemia is evidenced by marked changes in blood cell count and iron-associated parameters during periods of intense training or, even more accentuated, at the start of the training season, and it is frequently encountered in endurance athletes. It is a transient condition, with only 8 percent of elite athletes presenting frank anemia (Hb concentration below reference limits: 135 g/L in males and 120 g/L in females). Training induces an increase in plasma volume
which, through hormonal (e.g., Epo) and osmotic responses, stimulates erythropoiesis, inducing augmentation of the red cell mass, including RBC and immature erythroid forms (e.g., reticulocytes). While the plasma volume may rise by over 20 percent, the increase in red cell mass will range between 10 and 18 percent, with a final relative decrease in hematocrit. The advantages of these changes are that plasma expansion decreases blood viscosity and improves blood flow in large vessels, while the greater deformability of newly formed erythrocytes increases capillary flow. It is unlikely, however, that such exercise-induced hematological variations will be exclusively due to hemodilution. For instance, microcytosis in endurance athletes is secondary to reactive reticulocytosis due to intravascular hemolysis. Hemolysis may result from the breakdown of erythrocytes in exercising muscles (swimmers, weightlifters, rowers) or from the impact with the ground (runners). Within this context, it is useful for sports physicians and clinical pathologists to understand the effect various conditions (type of sport and training, competition schedules, altitude) can have on Ret values. Ret measurement in sports medicine attracted attention after Ret count began being applied for antidoping purposes [13298].

**Influence of erythropoietin**

It has been reported the effect of rhEpo administration in healthy subjects on the Ret values to highlight the physiological response to hormone stimulation. In detail, bolus rhEpo injections (150 U or 300 U/kg body weight) increase the immature reticulocyte fraction (IRF) starting 36 h after a single dose of rhEpo, peak after 3-4 days, and normalize within 7 days. rhEpo transiently increases the lifespan of circulating Ret from a baseline value of 1.7-3.4 days and increases Ret values twofold by inducing increased Ret release from the bone marrow and prolonging the maturation time of circulating Ret. After frequent weekly injections for 14 days and a concomitant doubling in reticulocyte percentage (Ret%), Ret% returned to basal levels even with weekly rhEpo injections and continuously high, suggesting a decreased sensitivity to prolonged rhEpo treatment [13298].

**Blood drawing**

Accuracy and rigorous standardization of blood collection techniques are needed to avoid spurious changes in hematological parameters and of Ret in particular. According to a study on 36 athletes, the use of different sampling techniques (cannula or syringe) had no significant impact on Ret% measurement when carried out over a day, during different days of a year with equal timing of sampling days to preclude the effect of climatic extremes, nor did the environmental temperature modify the Ret% values [13298].

**Measurement**

Reticulocytes are the most sensitive index available to authorities who seek to sanction athletes for blood doping based on deviations beyond individual reference ranges. Because such data comprise longitudinal results that are generated by different laboratories, the comparability of reticulocyte counts from different instruments is of crucial importance. To enhance between-instrument comparability of reticulocyte counts reported by the Sysmex XT-2000i automated haematology analyser it was optimised recalibration of instruments towards assigned values of control material (e-CHECK) in tandem with fresh blood verification. In terms of reticulocyte counts reported as a percentage of all cells in a fresh blood sample, it was possible to recalibrate all three test instruments so that the mean of 10 samples was within 0.1 percent of the comparative instrument’s mean value. This approach provides a straightforward means of reducing between-instrument differences in reticulocyte counts generated by the Sysmex XT-2000i [13300].
**Diurnal variation**

Reticulocytes count shows a physiological circadian rhythm with an acrophase occurring at 01:00 a.m. (95% confidence interval between 07:48 p.m. and 04:28 a.m.), reflecting the diurnal variations in serum erythropoietin that peaks at 01:00 a.m. These variations in circulating Ret constitute 37 percent of the total variability encountered over a day. The intraindividual daily range is 130 percent, with the highest value expressed as a percent of the lowest. The sleep/wake cycle is responsible for synchronizing the body’s biological clock, and resetting it can take up to 42 days. After intercontinental flights across time zones, athletes involved in competitions worldwide often experience circadian rhythm disruption [13298].

**Biological variability**

Ashenden reported three different values for analytical variation with regard to reticulocytes: as 9.1, 7.6, and 5.9 percent for low, medium, and high Ret%. Intraindividual variability was found to be greater than interindividual variability in both genders among top-level ski athletes. The within-subject variance for Ret in 793 samples obtained from 238 athletes was 0.0118, the between-subject variance was 0.0124. The intraindividual CV calculated on 500 samples from 43 subjects was 8.37 ± 1.64 percent in endurance athletes, 8.08 ± 2.27 percent in nonendurance athletes, and 7.4 ± 1.12 percent in nonathletes. These values suggest an enhanced stimulation of bone marrow in the athletes, although the differences among the groups were not significant. By comparison, the coefficient of variation of Hb in the same individuals was 2.65 ± 0.67, 3.0 ± 0.79, and 2.36 ± 0.42 percent, respectively. High intraindividual variability among elite athletes was reported in a large group of speed skaters, especially on precompetition screening when very high values for some athletes (>3.0 %) were measured. Thus Ret intraindividual variability is higher in athletes than in nonathletes. Moreover, Ret variations should be interpreted against long-term time series in the individual athlete; values obtained from large athlete cohorts should only be used for extrapolating outliers which deserve further examination [13298].

**Kinetics of reticulocytes production in humans**

RBCs are produced in the bone marrow; their formation involves a vast variety and number of cells at different stages of maturation, starting with the first stem cell progeny committed to erythroid differentiation and ending with the mature circulating RBC. Under normal conditions, the rate of RBC production is such that the red cell mass in the body is regulated and constant. It takes approximately from 12 to 15 days for a cell at the burst-forming unit-erythroid stage to mature into an erythroblast. Within 6-8 days, a cell in this stage proliferates and differentiates into a colony-forming unit-erythroid, which needs another 5-7 days to proliferate and develop into basophilic erythroblasts after the nucleus has been extruded, the cell is referred to as a Ret, an immature RBC larger in volume than erythrocytes by about 24 percent, with a lower Hb concentration (about 17 %) and a similar Hb content. Ret lifetime is much shorter than that of erythrocytes (1-4 vs 120 days) [13298].

**Reported reticulocyte values in athletes**

Recent studies have confirmed that reticulocytes are not normally distributed. The data were recorded in athletes before the competition season. The differences in Ret values could have been due to different training workloads. It should be remarked that the results are similar for different groups of athletes (endurance and anaerobic athletes), when presented as median
and percentiles (25th–75th). Conversely, different results were recorded in athletes practicing the same discipline (triathlon) probably due to different workloads. Elite speed skaters showed values clearly higher than those measured in athletes practicing other disciplines: a specific cluster could be recognized, but the particular methodology could also be cited to explain this difference. Ret values are not influenced by body mass index (BMI) of athletes. In a study on a heterogeneous group of male professional athletes (n=126) practicing different sports and characterized by a wide range in BMI (22-28 kg/m²), no correlation was found. BMI partially influenced Hb and erythrocyte values, reinforcing the robustness of Ret as a parameter for evaluating the hematological status in athletes. From an analysis of studies investigating seasonal variability of hematological parameters in athletes, it appears that variations in Ret and Hb are unrelated. However, there are no apparent differences between athletes and sedentary people when athletes are at rest. Differences eventually emerge for small groups of athletes during the competitive season, and controls as endurance athletes could have higher or lower values than the general population, depending on the phase of training [13298].

**Gender effects on reticulocytes**

Gender could be a source of variation in Ret distribution. Higher Ret values were described for female Alpine ski athletes during four consecutive seasons. The differences between genders were confirmed in all seasons; however, the trends of Ret changes within each season and between consecutive seasons ran parallel in both genders. Differences in Ret% between genders and a high between-subject variability were observed. Within gender analysis revealed that although the values remained stable in the males (no period or season-related effect), differences between periods within seasons were noted in the females. In contrast, no gender-related influence on reticulocytes distribution was observed in endurance athletes. In a large group (n=873) of athletes practicing different sports disciplines, the Ret values were higher for the females. Thus a gender effect may be observed in some sports disciplines or selected groups of athletes [13298].

**Stability of reticulocytes**

Instability is defined as an absolute difference, quotient, or percentage deviation from results obtained from measurement at time 0 and after a given period of time. It has been found that reticulocytes are less stable than Hb, but stability depends on the counting method applied. Storage at cold temperatures (ideally 4°C) is essential to guarantee the stability of Ret values [13298].

**Effects of exercise on reticulocytes**

Ret% increased after short-term exhaustive exercise as demonstrated in 23 Caucasian endurance athletes (19 males, 4 females; age range, 18-56 years). Blood samples were drawn immediately before and within 10 min after the end of a standardized incremental test until exhaustion on a treadmill or cycling ergometer (duration, 30-45 min). The increase in Ret was low (mean, 0.05 %) but evident in nearly all subjects. Thus, depending on its intensity, acute exercise can modify Ret count. However, exercise intensity is a key factor for determining Ret changes: no increase was observed by the same authors over a day in 36 male athletes, 20 endurance (cycling, triathlon), and 16 nonendurance (ball disciplines) mainly training at moderate intensity. In professional triathletes out-of-competition observed over a period of 63 days, a significant decrease in Ret% was found only at the end of the study (between day 49 and days 56 and 63), while no change in MCV was noted. A decrease in Ret after long periods of training and competition was observed, but its variation
was not necessarily associated with that of Hb. In a review article, the authors also compared the differences in Ret-related parameters between athletes practicing different sports at different levels and controls as measured on different automated systems. Generally, no variations in all Ret-related parameters (Chr, RetHb, and MCVr) were found between the athletes and the controls. Thus, training and competitions influence Ret values during a season; Ret decrease can be seen during the more intense phase of the season, but this effect is not always evident. The differences between consecutive seasons are greater than within season differences for Ret in the same group of athletes; the differences are gender specific. Average Ret values decrease in the past decade in elite athletes. Ret changes during a season are not always parallel to changes in Hb. Qualitative variations in Ret are mainly independent of the sports discipline, but quantitatively dependent on the sports discipline. Ret is influenced by exposure to altitude, level of altitude, and especially the duration of exposure to hypoxia are crucial for determining Ret changes [13298].

Reticulocytes in doping

Ret is a crucial parameter for suspecting and discovering the illicit use of substances and/or procedures which can enhance oxygen transfer to muscles. The use of Ret for detecting suspected recombinant erythropoietin (rHuEpo) abuse has been widely described. A study on the use of different rHuEpo treatment schemes involved 24 healthy male volunteers divided into three groups of eight subjects each. Two groups received rHuEpo injections (65 U/kg) for a 4-week period (2 weeks “boosting” phase plus 2 weeks “maintenance”). During the boosting phase, the subjects were injected with the hormone every second day (4 injections/week) and during the maintenance period, they had one injection per week. The injection period was followed by a 3-week washout period. The third group received rHuEpo (60 U/kg) for 10 weeks, with 3 weeks of boosting (the frequency of injections was the same as for the other two groups), followed by 7 weeks of maintenance, with one injection per week and 1 week of washout. Ret increased in all treated subjects during the boosting period; the increase was more pronounced in the two groups treated with 2 weeks of boosting and 2 weeks of maintenance. Ret values were higher than the highest cutoff (2.4%) in 8 out of 24 subjects during the boosting period, 4 from the groups treated for 2 weeks, and 4 from the group treated for 3 weeks. During the maintenance period, only one subject, treated for 2 weeks, had Ret >2.4 percent. No subjects had Ret <0.2 percent during the entire observation period. Ret was the most sensitive parameter for discovering the rHuEpo treatment. Blood manipulation can also be performed by expanding and diluting plasma to mask increased enhancement of Hb and erythrocytes. In a study the testing of desmopressin-induced hemodilution in eight physically active males was studied. After desmopressin treatment, a significant decrease in Hkr, Hb, and OFFhr was found. The mean Ret value before and after desmopressin treatment was 0.8 ± 0.2 and 0.6 ± 0.2 percent, respectively. Desmopressin abuse is an effective method for diluting blood. Ret behavior during blood manipulation by withdrawal and reinfusion (autotransfusion) has been recently investigated in studies involving adults or athletes to define variations in hematological parameters when high quantities of blood are drawn, stored, and then reinfused in healthy subjects. In a study involving seven male triathletes for a 63-day period, from day 1 to day 21, the training workload was progressively increased up to a regular weekly training of 5 h. No significant differences between consecutive measurements of Ret and MRV were found; the final values at 5 and 12 days after reinfusion differed significantly from the value measured after blood withdrawal. The authors stated that some absolute variations in hematological parameters in a period of 15 days could be used for detecting suspected blood manipulation: 6 percent for Hkr%, 4 percent for Hb, and 20 percent for OFFhr. These values, however, are lower than possible changes induced by training and competitions. Ret remains constant during blood withdrawal. Its decrease during recovery and after reinfusion is more informative. However, if the amount of blood withdrawn is high, that is, three blood bags over
a period of 2 weeks or two blood bags in 1 week, Ret will increase due to the natural stimulation of bone marrow to release new erythrocytes. This increase is followed by a decrease, with a normalization of values during the recovery period, and then an additional decrease after reinfusion which inhibits bone marrow activity. In conclusion, Ret is a valid parameter for detecting suspected blood doping as Ret is a specific and sensitive parameter for detecting suspected rhHuEpo abuse. Ret is also a sensitive parameter for detecting suspected blood manipulation by transfusion during the recovery phase after withdrawal and after reinfusion. Moreover, Ret changes during blood manipulation by transfusion depend on the quantity of blood drawn and reinfused and the time of testing [13298].

**Neocytolyis**

Neocytolyis, the selective hemolysis of young circulating red blood cells (RBCs), contributes to the physiologic control of red cell mass and to pathophysiologic phenomena such as anemia of renal disease, anemia after spaceflight, and blood doping by athletes. Progress in understanding the process is hampered by the lack of established markers to distinguish young from older RBC. Twelve potentially informative RBC surface markers were assayed by flow cytometry in normal blood samples, and 4 were preferentially expressed in young RBC. To create a model of neocytolyis, 3 normal volunteers had recombinant human erythropoietin (rhEpo) administered until mild erythrocytosis occurred, then were studied upon rhEpo withdrawal. Neocytolyis ensued that most evident from a rapid rise in serum ferritin as the iron from young RBC was transferred back to stores. Five additional volunteers had surface markers monitored during and after rhEpo administration. Three subjects with marginal baseline iron stores had blunted response to rhEpo, no significant neocytolyis, and no change in RBC surface marker expression. Two subjects with adequate baseline iron stores developed erythrocytosis followed by neocytolyis. Decreased expression of CD44 (homing-associated cell adhesion molecule) and CD71 (transferrin receptor) seemed to correlate best with neocytolyis; CD35 (complement receptor) less so. Of note, further studies are needed to determine if these changes are causative of red cell destruction. Thus, this study begins to establish a human model of neocytolyis, to establish markers differentiating young and old RBC, and to establish a basis for better definition of the process. Although the study is preliminary, the results support the possibility that flow could be useful to detect blood doping because neocytolyis should predictably occur in athletes who surreptitiously blood dope [09152].

The phenomenon of neocytolyis regulates sudden changes in erythropoietin concentrations in the body, inducing apoptosis of young RBCs. The reintroduction of old, but still efficient RBCs, cannot substantially influence the downregulation of RBC mass when it is excessive. Hence, neocytolyis can explain some of the potential pitfalls of autologous transfusion when the hemoglobin increase is lower than expected and serum bilirubin concomitantly increases. This may be due not to improper storage of the blood, but rather to excessive introduction of RBCs, stimulating a downregulation of erythrocyte release [06005].

**Polycytemia**

Polycytemia is defined by the increase of hematocrit and haemoglobin respectively. Possible causes might be neoplastic diseases like polycythemia vera with proliferation of a cell clone. More often one will find reactive forms resulting from chronic hypoxemia. A physiologic form of polycythemia can be found in highlanders and athletes training at high altitude. With increasing frequency erythropoietin and it's analoga are being used as doping substances to induce Polycytemia. Red cell proliferation induced by chronic hypoxemia is
the most common form in patients. In this instance the lung itself can be the cause (hypoxemia with hypocapnea in blood gas analysis) or hypoventilation caused by an insufficient respiratory pump (hypercapnea with hypoxemia in blood gas analysis) induces a compensatory Polycythemia. The former form can be treated with long term oxygen therapy and the latter by non-invasive ventilation, either approach corrects hypoxemia and reduces Polycythemia within some weeks [10470].

**Blood conservation and transfusions**

In 1628 the English physician William Harvey described the blood circulatory system. Shortly afterward, the first reported blood transfusion was attempted. Since then, substantial improvements have been made in the techniques employed for blood transfusion. Blood transfusions were originally used to support critically ill patients with severe forms of acute and chronic anemia. However, recent advances in biotechnology have allowed the separation of whole blood in its components. Because patients seldom require all of the components of whole blood, it makes sense to transfuse only that portion needed for a specific condition or disease. This treatment is conventionally referred to as “blood component therapy.” Typically, up to four components may be derived from 1 unit of blood: red blood cells (RBCs), platelets, plasma, and cryoprecipitated antihemophilic factor (AHF). RBCs may be stored under refrigeration for a maximum of 42 days, or they may be frozen for up to 10 years. Platelets must be stored at room temperature and may be kept for a maximum of five days. Fresh frozen plasma, mainly used for the therapy of acquired and congenital bleeding disorders, is stored frozen for usually up to one year. Cryoprecipitated AHF, which contains one or more specific clotting factors, is made from fresh frozen plasma and may be stored frozen for up to 1 year. Additional products manufactured from whole blood include albumin, immune globulin, specific immune globulins, and clotting factor concentrates. Blood transfusions can be traditionally classified as autologous, where the blood donor and transfusion recipient are the same, or as allogeneic, where the blood is transfused into someone other than the donor. The most common autologous donation is the preoperative donation of blood for possible re-transfusion up to six weeks before or following elective surgery. As a significant amount of iron is removed by each autologous donation, an adequate time for recovery of not less than 72 h from the last donation, and appropriate iron supplements, are usually required for patients undergoing autologous donations. An important step in ensuring the safety of allogeneic transfusions is the screening of donated blood for infectious diseases. Today, nine tests for infectious diseases are traditionally performed. Hepatitis B (HBV) and syphilis tests were in place before 1985. Since then, tests for human immunodeficiency virus (HIV-1 and HIV-2), human T-lymphotropic virus (HTLV-I and -II), and the hepatitis C virus (HCV) have been introduced. Current evidence suggests that blood transfusions are unlikely to be beneficial in the absence of active blood loss when the hemoglobin concentration exceeds 100 g/L (hematocrit > 30 %). The benefits arising from blood transfusions may exceed the risks when the hemoglobin concentration falls to 70 g/L (hematocrit < 21 %). Therefore, the majority of existing guidelines conclude that transfusion is rarely indicated when the hemoglobin concentration is greater than 100 g/l, and it is almost always indicated when it falls below a threshold of 60 g/L in healthy, stable patients or likely a higher threshold in older or sicker patients [10353].

Blood transfusion is an effective and unmediated means of increasing the number of red blood cells in the circulation in order to enhance athletic performance. Blood transfusion became popular in the 1970s among elite endurance athletes and declined at the end of the 1980s with the introduction of recombinant erythropoietin. The successive implementation in 2001 of a direct test to detect exogenous erythropoietin and in 2004 of a test to detect
allogeneic blood transfusion forced cheating athletes to reinfuse fully immunologically compatible blood. The implementation of indirect markers of blood doping stored in an Athlete's Biological Passport provides a powerful means to deter any form of blood transfusion [10109].

It was observed earlier that, in endurance sports such as cycling, triathlon, cross-country skiing, and marathon running, ways of boosting the blood's oxygen-carrying capacity can enhance performance by over 20 percent. The first clear evidence of blood doping through blood transfusion came from a controlled experiment carried out in 1947. Since then, transfusions have long been used for this purpose, as they are an extremely straightforward, simple, and effective method of increasing the oxygen carrying capacity of blood. There are two methods of doping through blood transfusions: autologous and allogeneic; for convenience and safety, the former is reportedly much more used. The traditional procedure of autologous blood transfusion begins by the withdrawal of 1 to 4 units of blood (1 unit = 450 ml of blood) several weeks before competition. The blood is centrifuged, the plasma components are immediately reinfused, and the corpuscular elements, principally RBCs, are stored refrigerated at 4°C or frozen at −80°C. As blood stored by refrigeration displays a steady decline in the number of RBCs, a substantial percentage, up to 40 percent, of the stored RBCs may not be viable. The freezing process, conversely, limits the aging of the cells, allowing the storage of the blood for up to 10 years with a 10-15 percent loss of RBCs. Stored RBCs are then reinfused, usually 1 to 7 days before a high-endurance event. When properly performed, this process increases hemoglobin and hematocrit levels by up to 20 percent, but it is not completely safe and free from side effects. A large infusion of RBCs may be associated with hyperviscosity syndrome, which is characterized by increased blood viscosity and decreased cardiac output and blood flow velocity and results in reduction of peripheral oxygen delivery. Additional complications may be phlebitis, septicemia, bacterial infection, and air/clot embolism. In addition, allogeneic transfusions may trigger transfusion reactions characterized by fever, urticaria, and anaphylactic shock and are significantly associated with transmission of blood-borne infectious diseases including hepatitis, acquired immunodeficiency syndrome, malaria, cytomegalovirus, and Creutzfeldt-Jacob disease. There are anecdotal reports of athletes (the 1984 United States Olympic cycling team and the Spanish cyclist Manzano among others) experiencing severe side effects from blood transfusions, and some of them nearly died after being injected with poorly stored blood. Earlier studies have shown that a greater than 5% increase in circulating hemoglobin is necessary to improve performance, suggesting that athletes would need to infuse at least 1 unit of blood to obtain a surreptitious athletic advantage [10353].

For the last decade, the only way to test for blood doping by allogeneic transfusion has been to assess the hematocrit or hemoglobin threshold; several sport federations banned athletes if random tests gave values over an arbitrary limit. Recently, a more reliable approach to the detection of blood transfusion in athletes has been proposed. The method is based on the quantification of antigenically distinct donor and recipient RBCs by flow cytometry, through the use of standard blood bank antisera in combination with a fluorescent-labeled secondary antibody directed against human immunoglobulin. This strategy allows detection of even a single unit of blood transfused, provided that there is at least one antigen mismatch between donor and recipient. As individual RBCs display an almost unique antigen pattern, which is under strict genetic regulation, the possibility of two blood samples matched for ABO and Rh factor being identical for the panel of 12 blood group antigens tested is less than 1:500. The test currently involves RBC phenotyping for the antigens C, c, E, e, K, k, Fya, Fyb, Jka, Jkb, S, and s. Therefore, flow cytometry appears to be the ideal technique for detecting allogeneic transfusion with a high degree of analytical efficiency. However, this test has some limitations. First, it does not detect autologous transfusion with blood donated and stored beforehand, as the RBCs surface antigens of the donor and recipient are identical. An
additional problem is the lack of an easy confirmatory test, such as DNA analysis. A final concern arises from persons who are blood group chimeras, as the identification of a second RBC population may indicate either a transient (allogeneic RBC transfusion) or static (life-long chimera) phenomenon. However, serial testing will enable discrimination between these two situations [10353].

Blood doping consists of any illicit means used to increase and optimize oxygen delivery to the muscles and includes blood transfusions, administration of erythropoiesis-stimulating substances, blood substitutes, natural or artificial altitude facilities, and innovative gene therapies. The use of blood transfusion, an extremely straightforward, practical and effective means of increasing an athlete’s red blood-cell supply in advance of competition, became rather popular in the 1970s, but it has suddenly declined following the widespread use of recombinant human erythropoietin among elite endurance athletes. Most recently, following implementation of reliable tests to screen for erythropoiesis-stimulating substances, blood transfusions have made a strong resurgence, as attested by several positive doping tests. Doping by blood transfusion can be classified as homologous, where the blood is infused into someone other than the donor, and autologous, where the blood donor and transfusion recipient are the same. The former case produces more clinically relevant side effects, but is easily detectable using current antidoping protocols based on erythrocyte phenotyping by flow cytometry and, eventually, erythrocyte genotyping by DNA testing. Since the donor and recipient blood are identical in autologous blood doping, this is less risky, though much more challenging to detect. Indirect strategies, relying on significant deviations from individual hematological profiles following autologous blood donation and reinfusion, are currently being investigated. For the time being, the storage of athletes' blood samples to allow testing and sanctioning of guilty athletes once a definitive test has been introduced may represent a reliable deterrent policy [06005].

Since the early 1960s it has been recognized that any means to increase and optimize oxygen delivery to the muscles would profoundly enhance an individual's athletic performance, especially for demanding physical exercise. Basically, this process, also known as induced erythrocythemia, blood boosting or, more recently, blood doping, consists of techniques administered to the athlete to “increase one’s red blood cell mass, which allows the body to transport more oxygen to muscles and therefore increase stamina and performance.”. Erythrocythemia induced by the infusion of 400–920 mL of packed red blood cells (RBCs) effectively enhances performance capacity in endurance track races, probably due to an increase in oxygen delivery to the working muscles. Reinfusion of 750 mL of RBCs substantially increases maximum oxygen consumption, although any performance improvement is not apparently associated with observed changes in the hematological profile. It is noteworthy that the maximum oxygen increase per gram change in hemoglobin is fairly comparable following either reinfusion of blood or recombinant human erythropoietin injections and persists for several weeks post-reinfusion, regardless of the return to baseline of the main hematological values. Increased performance for 3 h to 14 days following reinfusion of 1350 mL of autologous blood is also evident in cross-country skiers, based on improved race time over a specified distance. Significant improvements in treadmill endurance tests have also been reported following induced erythrocythemia . Apparently, blood transfusions also work for anaerobic sports, as the extra proton-buffering capacity of infused hemoglobin raises the lactate threshold and contributes to lower lactate generation during submaximal exercise. Hence, the great potential to improve athletic performance by blood transfusion is well-established [06005].

Consistent evidence shows that a greater than 5 percent increase in circulating hemoglobin is necessary to improve athletic performance, suggesting that athletes would need to infuse at least one unit of blood to obtain a surreptitious athletic advantage. The greater the amount
of blood transfused, the greater is the expected performance improvement; hence, larger infusions of either homologous or autologous RBCs may be associated with the hyperviscosity syndrome, characterized by increased blood viscosity, decreased cardiac output and blood flow velocity, finally resulting in a reduction in peripheral oxygen delivery [06005].

**Blood transfusions in general**

The widespread availability and relatively low cost of blood for transfusions are paramount needs for modern healthcare systems. Blood requirements for surgical and medical treatment are increasing steadily while the availability is stable or even decreasing, so that the demand is already exceeding the supply. Current technology and increasing knowledge on tissue and cell engineering, especially those based on the use of haematological stem cells to obtain mature and efficient blood particles, is opening appealing strategies and approaches for obtaining safe and disposable blood to be used for clinical purposes. RBC have been widely investigated in the past, and their metabolic pathways and mechanical properties have been exhaustively described and also reproduced in vitro. The production of biomaterial particles with similar (or even identical) chemical and physical properties as those of mature, functional RBC has been reported, so we have already alerted the scientific community as well as anti-doping authorities on the possible, surreptitious use of these bioengineering techniques for unfair and illicit purposes in sports [12234].

Blood doping is based on the use and administration of any illicit substance or procedure aimed at increasing and optimising oxygen delivery to the exercising muscles and, therefore, includes blood transfusions, administration of erythropoiesis-stimulating substances (namely hormones and growth factors), blood substitutes and artificial altitude facilities, possibly mixed and/or combined. The use of blood transfusions, either autologous or homologous, is an effective strategy for increasing oxygen delivery to the muscles and can be used immediately before a single competition or even during long-lasting sporting events to maintain a stable haemoglobin (Hb) concentration, especially when a natural decrease is expected as a result of physiological adaptation to endurance exercise. The procedure is not new, since it became popular nearly 40 years ago, but then suddenly declined due to its inclusion among the list of prohibited methods issued by the International Olympic Committee (IOC). Another reason that contributed greatly to the sudden decay of popularity of blood transfusions among elite athletes was the cloning of the erythropoietin gene and subsequent development of recombinant erythropoietin (rHuEpo) and its introduction among the armamentarium of illicit ergogenic aids. The great success of rHuEpo and analogues (erythropoiesis-stimulating agents, ESA) was mainly the consequence of the remarkable biological and technical advantages that these substances had over traditional means of increasing the red cell mass, such as blood transfusions. These advantages include easier supply (from healthcare facilities as well as from the "black market"), more comfortable administration (small subcutaneous doses) and the sharp and long-lasting effects on erythropoiesis (i.e. "blood boosting"). Once the concentration of Hb has been raised through ESA administration, the high concentration can be maintained by weekly administered microdoses of ESA which have a detection window of only 12-18 hours, for rHuEpo, compared to 3 days for regular doses. The subsequent development and implementation of (more or less) reliable electrophoretic techniques to screen for rHuEpo misuse caused a sudden resurgence of blood transfusions, which also took advantage of new procedures for collecting and storing the erythrocytes (e.g. freezing), allowing their use over a very long period of time as well as their harvesting during rest periods, thus avoiding a decline of Hb and aerobic sport performance during the competitive season. The predominant form of blood doping by transfusion is autologous blood transfusion, i.e. the blood donor and the recipient are the same. Homologous transfusions, in which the blood is drawn from a donor who is not the recipient, can also be
used, but the potential side effects and the easier identification by traditional red blood cell (RBC) phenotyping and flow cytometry substantially limit the use of this practice [12234].

**Autologous transfusion**

Autologous blood transfusions (ABTs) have been used by athletes for approximately four decades to enhance their performance. Although the method was prohibited by the International Olympic Committee in the mid 1980s, no direct detection method has yet been developed and implemented by the World Anti-Doping Agency (WADA). Several indirect methods have been proposed with the majority relying on changes in erythropoiesis-sensitive blood markers. Compared with the first methods developed in 1987, the sensitivity of subsequent tests has not improved the detection of blood doping. Nevertheless, the use of sophisticated statistical algorithms has assured a higher level of specificity in subsequent detection models, which is a crucial aspect of antidoping testing particularly to avoid “false positives.” Today, the testing markers with the best sensitivity/specificity ratio are the Hbmr model (an algorithm based on the total amount of circulating hemoglobin level [hemoglobin level mass] and percentage of reticulocytes) and the OFF-hr model (algorithm based on hemoglobin level concentration and percentage of reticulocytes). Only the OFF-hr model is currently approved by WADA. Recently, alternative indirect strategies for detecting blood doping have been proposed. One method is based upon a transfusion-induced immune-response resulting in specific changes in gene expression related to leukocytes such as T lymphocytes. Another method relies on detecting increased plasticizer metabolite levels in the urine caused by the leakage of plasticizers from the blood bags used during the blood storage. These methods need further development and validation across different types of transfusion regimes before they can be implemented. In addition, several research projects have been funded by WADA in recent years and are now under development. Although strategies to detect autologous blood transfusion have improved, a highly sensitive test to detect small volumes of transfused autologous blood has not yet been implemented [12009].

The use of blood doping is forbidden by the World Anti-Doping Agency. Several practices, such as blood transfusions are used to increase oxygen delivery to muscles and all of them are highly pursued. In this regard, the development of accurate methodologies for detecting these prohibited practices is one of the current aims of the anti-doping control laboratories. Flow cytometry methods are able to detect allogeneic blood transfusions but there is no official methodology available to detect autologous blood transfusions. One paper reviewed protocols, including the Athlete Biological Passport, that use indirect markers to detect misuse of blood transfusions, especially autologous blood transfusions. The methods of total haemoglobin mass measurements and the detection of metabolites of blood bags plasticizers in urine are reviewed. The latter seems to be an important step forward because it is a fast screening method and it is based on urine, a fluid widely available for doping control. Other innovative approaches to blood transfusion detection are also mentioned. A combination of the reported methodologies and the implementation of the Athlete Biological Passport is becoming a promising approach [12235].

Blood doping represents one main trend in doping strategies. Blood doping refers to the practice of boosting the number of red blood cells (RBCs) in the bloodstream in order to enhance athletic performance, by means of blood transfusions, administration of erythropoiesis-stimulating substances, blood substitutes, natural or artificial altitude facilities, and innovative gene therapies. While detection of recombinant EPO and homologous transfusion is already feasible through electrophoretic, mass spectrometry or flow cytometry-based approaches, no method is currently available to tackle doping strategies relying on autologous transfusions. It was exploited an in vitro model of autologous transfusion through a 1:10 dilution of concentrated RBCs after 30 days of storage upon appropriate dilution in
freshly withdrawn RBCs from the same donor. Western blot towards membrane Prdx2 and Percoll density gradients were exploited to assess their suitability as biomarkers of transfusion. Membrane Prdx2 was visible in day 30 samples albeit not in day 0, while it was still visible in the 1:10 dilution of day 30 in day 0 RBCs. Cell gradients also highlighted changes in the profile of the RBC subpopulations upon dilution of stored RBCs in the fresh ones. From this preliminary in vitro investigation it emerges that Prdx2 and RBC populations might be further tested as candidate biomarkers of blood doping through autologous transfusion, though it is yet to be assessed whether the kinetics in vivo of Prdx2 exposure in the membrane of transfused RBCs will endow a sufficient time-window to allow reliable anti-doping testing [12236].

There are two main strategies for doping by blood transfusion: autologous, whereby the blood donor and transfusion recipient are the same person, and homologous (allogeneic), whereby blood is transfused into someone other than the donor. The traditional procedure for autologous blood transfusion involves the withdrawal of 1 to 4 units of blood (1 units 450 mL of blood, corresponding to 225 mL of concentrated RBCs at a packed cell volume of 0.75) several weeks before competition to allow re-establishment of the RBC mass to the baseline level. The blood is immediately centrifuged, the plasma components are reinfused and the corpuscular elements (principally RBCs) are refrigerated at 4°C or frozen at -80°C. Stored erythrocytes are then traditionally reinfused into the athlete 1-7 days before a major endurance event [06005].

The drawing of blood for appropriate storage induces natural stimulation of the bone marrow by a complex mechanism that involves the hypoxia inducible factor (HIF) pathway. At the same time, administration of recombinant human erythropoietin at low, subtherapeutic doses increases bone marrow production. Recombinant human erythropoietin can be subcutaneously administered several weeks before competition or during resting periods, allowing the collection of up to 3-5 units of blood in a month, with minimal changes in hemoglobin concentrations, as clearly demonstrated by preoperative medicine. Blood reinfusion then increases the hemoglobin concentration, which is already raised by the exogenous hormone. At the time of competition, athletes finally show up with increased hemoglobin, but virtually undetectable erythropoietin in urine using the official electrofocusing technique. The success of the old technique of blood transfusion in hemodoping is also linked to the disappointing results of new technologies for inducing bone marrow to release RBC cohorts and increase hemoglobin [06005].

As if not complex enough for the anti-doping fight, biotechnology is offering new solutions for intensive care patients requiring blood transfusions, which in turn opens new flood gates for potential abuse. Examples of these new yet not approved/launched products are erythrocytes prepared ex vivo from hematopoietic stem cells as well as erythrocyte-mimicking synthetic biomaterial particles that might require complementary or extended doping control analytical strategies in the future. However, with the increasing knowledge and in-depth investigation of ex vivo stored erythrocytes and concomitantly occurring alterations at the proteome and metabolome levels, alternative (and possibly comprehensive) strategies might arise enabling the detection of different kinds of blood doping. Pilot studies were conducted concerning membrane proteins of red blood cells, using commonly accepted approaches such as 2D gel electrophoresis and iTRAQ labeling with LC-MS/MS quantitation. These studies yielded significant alterations of cytoskeletal-derived proteins such as spectrin beta, ankyrin-1, tropomodulin-1, beta adducin, and tropomyosin as well as transmembrane proteins including glycophorin C and aquaporin-1 with a minimum increase or decrease of at least a factor of 1.5. Focusing on cytosolic proteins and their changes under transfusion medicine-based ex vivo storage conditions, Walpurgis et al. employed 2D difference gel electrophoresis (2D DIGE) to accurately quantify alterations of protein amounts by respective
varying spot volumes, which are all individually corrected by their corresponding internal standard. Following identification of 14 protein candidates, their characterization was conducted by LC-MS/MS revealing transglutaminase 2, beta actin, and copper chaperone as potential marker proteins for storage-induced lesions of blood products and, thus, possibly for doping control purposes. The validity of the characterized proteins was cross-checked by western blot analysis. Despite the significant alterations of membrane and cytosolic proteins as determined in these two aforementioned studies, both approaches necessitate further evaluation since the dilution of these arguably indicative modifications might not remain detectable once the blood is re-infused [13009].

The predominant form of blood doping by transfusion is autologous blood transfusion, i.e. the blood donor and the recipient are the same. Homologous transfusions, in which the blood is drawn from a donor who is not the recipient, can also be used, but the potential side effects and the easier identification by traditional red blood cell (RBC) phenotyping and flow cytometry substantially limit the use of this practice. The detection of autologous blood transfusion is more challenging. A direct method based on the identification of plasticizers excreted in the urine as a result of autologous blood transfusion was recently proposed as a reliable approach to detect such transfusions in athletes, although it has shown several drawbacks and is not currently implemented as a doping detection tool. However, an indirect approach, based on the assessment of Hb concentration and reticulocyte percentage (Ret%) over time, can be used and also combined in the so-called OFF-score (i.e. Hb-60/Ret%). These parameters are introduced into a statistical programme (i.e. the Athlete’s Biological Passport), which is aimed to unmask non-physiological perturbations of blood homeostasis such as those following a blood transfusion (abnormal Hb increase and a decrease in Ret%) or withdrawal of blood for the purpose of storage and subsequent re-administration (abnormal Hb decrease combined with an increase in Ret%). Absolute values of Hb and Ret% along with other derived parameters (mean corpuscular volume, Ret%, Hb, etc) might also be used for screening for blood transfusions, but the results provided so far have been rather controversial, despite the fact that the high sensitivity of the passport approach for detecting blood transfusion has been unequivocally proven in a blinded experiment in healthy subjects. Although the passport approach is useful in the case of “regular” amounts of re-infused blood (3 units), its low sensitivity in detecting smaller amounts (1 unit) still represents a major limitation. The leading issue in detecting autologous blood transfusion is the potential dilution of intravenously administered RBC and their early, partial removal [13290].

Adverse events

Homologous blood transfusions may trigger reactions characterized by fever, urticaria, and anaphylactic shock, and are significantly associated with transmission of blood-borne infectious diseases, including hepatitis, acquired immunodeficiency syndrome, malaria, cytomegalovirus and Creutzfeldt Jakob disease. Occasionally, patients may develop phlebitis, septicemia, bacterial infection, air/clot embolism and transfusion-associated graft-versus-host disease (TAGVHD), a lethal complication of infusion of non-irradiated cellular blood components into a susceptible recipient [06005].

Both blood transfusion and rhEPO will increase the hematocrit unless masked with a plasma volume expander. When the hematocrit rises above 0.46, there is a documented risk for cardio-vascular disease (CVD) in the normal population. However, this might not reflect the truth in athletes which represent a highly selected and younger cohort. A number of suspicious deaths in cyclists have, however, been reported, but it has not been identified any true hazard analysis for CVD and blood doping in the literature. Blood transfusions are safe in a hospital setting but adverse events like allergic and hemolytic transfusion reactions
do occur. However, in blood doping the strict regulation for labeling and storage of the components are likely not followed leading to a greater risk for adverse events [13005].

**Plasma markers for testing**

Several authors have highlighted the impact of blood manipulation on iron metabolism. With iron being the major substrate for Hb synthesis, it is evident that iron-related variables will be affected by any manipulations of erythropoiesis. Ferritin, the iron storage protein, was addressed as a potential marker as early as the 1980s. However, the association to inflammation and its susceptibility to be influenced by external iron administration limits its specificity. Hepcidin was recently investigated as another potential marker in this context. This molecule regulates the iron absorption by the body and was found in several studies to be a potential marker for blood manipulation. However, more data on the natural variation and the impact of exercise and other confounding factors are necessary [13009].

The athlete biological passport for the fight against doping is currently based on longitudinal monitoring for abnormal changes in cellular blood parameters. Serum parameters related to altered erythropoiesis could be considered for inclusion in the passport. The aim of one study was to quantify the changes in such parameters in athletes during a period of intense exercise. Twelve highly trained cyclists tapered for 3 days before 6 days of simulated intense stage racing. Morning and afternoon blood samples were taken on most days and analysed for total protein, albumin, soluble transferrin receptor, and ferritin concentrations. Plasma volume was determined via total haemoglobin mass measured by carbon-monoxide rebreathing. Percent changes in means from baseline and percent standard errors of measurement (analytical error plus intra-athlete variation) on each measurement occasion were estimated with mixed linear modelling of log-transformed measures. Means of all variables changed substantially in the days following the onset of racing, ranging from -13 percent (haemoglobin concentration) to +27 percent (ferritin). After the second day, errors of measurement were generally twice those at baseline. Plasma variables were affected by heavy exercise, either because of changes in plasma volume (total protein, albumin, haemoglobin), acute phase/inflammatory reactions (ferritin) or both (soluble transferrin receptor). These effects need to be taken into consideration when integrating a plasma parameter into the biological passport model for athletes [13304].

**Combination of biomarkers**

The main scientific focus has been on finding single biomarkers that will detect certain doping techniques with acceptable sensitivity and good specificity. Future research should explore complementary paths using mathematical methods for the combination of the multitude of markers that often display a good sensitivity but may lack specificity. Approaches such as support vector machines and other classification techniques that are in use in many other domains of science might be helpful. In this context, information from different sources (e.g. urine tests, blood tests) should be combined, as also for urine test information, a longitudinal monitoring has been proposed. By these means, specificity could be increased and distinct patterns for certain doping interventions or the identification of suspicious and potentially doping athletes could be warranted, which would then trigger follow-up testing with more specific methods. This would help to save resources and make the fight against doping more efficient. In this context, the application of newer diagnostic tools relating to the ‘omics’ technologies such as transcriptomics, proteomics, and metabolomics will nurture this area in the years to come. Thus, it may be possible to identify the biological fingerprint of many potential doping substances which would allow athletes to present themselves to a competition with physiological values and profiles that fall within their own personal limits. Additionally, the scope of analyses could be expanded to
Screening for homologous blood transfusions

Blood groups
The plasma membrane of red blood cells expresses a wide series of blood group antigens that are actually complex oligosaccharides that differ mainly in their biochemical structure. In addition to the traditional AB antigen cluster, RBCs are characterized by the rhesus (Rh) polymorphic polypeptides and the associated glycoprotein RhAG. That blood group system is the most polymorphic of the human blood groups, including at least 45 independent antigens. Owing to the complex combination of AB and Rh antigens on the RBC surface, hematopoiesis in the bone marrow produces erythrocytes characterized by a genetically determined, virtually unique antigen pattern. An antidoping method implemented by WADA is based on the quantification of antigenically distinct donor and recipient erythrocytes by flow cytometry, using standard blood-bank antisera combined with a fluorescent-labeled secondary antibody directed against human immunoglobulin. This strategy allows the detection of small populations (about 5%) of cells that are antigenically distinct from an individual’s own RBCs with a degree of sensitivity, provided there is at least one antigen mismatch between the donor and recipient. The test is based on phenotyping for several RBC antigens, including C, c, E, e, K, k, Fya, Fyb, Jka, Jkb, S and s. The chance of detecting two identical samples by this screening strategy is reportedly less than 1:500. Transfused erythrocytes remain in the circulation for up to 120 days in sedentary individuals and for 60–90 days in elite athletes, because RBCs typically display shorter survival in physically active individuals. The identification of a second RBC population in persons who are blood group chimeras may indicate either a transient (homologous RBC transfusion) or a life-long chimera phenomenon. In such a case, serial testing easily allows discrimination between these two situations. In other cases, enlargement of the antigen panel by Rh50 glycoprotein, CD47, glycophorin B, Duffy, LW glycoprotein, and Band 3 testing may represent a reliable solution. An alternative strategy that may soon become faster and cheaper is to screen blood for these antigens using genomic DNA and the associated single-nucleotide polymorphisms (SNPs). DNA analysis displays limited diagnostic efficiency in populations of athletes characterized by a higher prevalence of non-expressed RHD. In addition, it is important to mention that PCR-based assays are prone to different types of errors than those observed with the traditional phenotyping techniques, such as contamination with amplified products and the identification of particular antigen genotypes that are not necessarily expressed on the RBC membrane.

Screening for autologous blood transfusions

The detection of autologous blood transfusion is more challenging. A direct method based on the identification of plasticizers excreted in the urine as a result of autologous blood transfusion was recently proposed as a reliable approach to detect such transfusions in athletes, although it has shown several drawbacks and is not currently implemented as a doping detection tool. However, an indirect approach, based on the assessment of Hb concentration and reticulocyte percentage (Ret%) over time, can be used and also combined in the so-called OFF-score (i.e. Hb-60√Ret%). These parameters are introduced into a statistical programme (i.e. the Athlete’s Biological Passport), which is aimed to unmask non-physiological perturbations of blood homeostasis such as those following a blood transfusion (abnormal Hb increase and a decrease in Ret%) or withdrawal of blood for the purpose of storage and subsequent re-administration (abnormal Hb decrease combined with an increase in Ret%). Absolute values of Hb and Ret% along with other derived parameters (mean corpuscular volume, Ret%, Hb, etc.) might also be used for screening for blood
transfusions, but the results provided so far have been rather controversial, despite the fact that the high sensitivity of the passport approach for detecting blood transfusion has been unequivocally proven in a blinded experiment in healthy subjects. Although the passport approach is useful in the case of "regular" amounts of re-infused blood (3 units), its low sensitivity in detecting smaller amounts (1 unit) still represents a major limitation. The leading issue in detecting autologous blood transfusion is the potential dilution of intravenously administered RBC and their early, partial removal. It may also be mentioned that the organisation and management of the collection and long-term storage of blood bags is difficult, especially outside healthcare facilities, so that this practice is mostly limited to high-profile, wealthy athletes [12234].

Neither homologous nor autologous blood transfusions could be detected directly until 2003, when it was presented a test for the detection of homologous transfusion that identifies mixed red blood cell (RBC) populations using antisera against minor blood group antigens. In this assay, 12 blood group antigens were selected to identify donor RBC populations in patients who received between one to three units of homologous blood with a lower limit of detection around 5 percent of the total red cell population. Transfused erythrocytes survive for an average of 94 days after storage for 42-49 days, giving the test a wide detection window. The methods were further validated and improved by using a panel of eight primary blood groups antigens. Applying the technique of signal amplification, the authors improved the separation of those antigens with weak or heterozygous expression resulting in an identification of mixed RBC populations in samples containing 0.3-2.0 percent of donor blood. It has also been presented forensic standards of doping analyses for homologous blood transfusions in a single-blind and single-site study. A specificity of 100 percent was described as no false-positive results were observed in the analysis of 140 blood samples containing different percentages (0-5 %) of a minor RBC population. The sensitivity of the method was 78 percent and most samples were unambiguously detected. With their approach, the ISO-17025 accreditation and validation requirements were fulfilled. Examples of single and double population fluorescence intensity histograms (using anti-Jk\textsuperscript{a} antibody and the mix of fluorescein isothiocyanate (FITC)-coupled secondary antibodies) have been presented. Several athletes tested positive for homologous blood transfusion on the basis of this test. Obviously, this method is inappropriate for the detection of autologous blood transfusions, which continue to be undetectable by direct means. From the time before 2000, when EPO was similarly undetectable by a direct test, indirect biomarkers have emerged as a method to deter blood doping and possibly limit the extent of manipulations. The use of indirect biomarkers of doping has culminated in the introduction of the so-called athlete biological passport (ABP) which can be regarded as the best approach [13006].

The donor
Studies in a small number of donors have demonstrated that a temporary decrease in RBC mass is well tolerated when donors give twice the usual amount (170-225 mL) of erythrocytes in a standard 405-495 mL donation, causing no detectable symptoms of reduced oxygen-carrying capacity, as confirmed by negligible changes in heart rate or systolic and diastolic blood pressure. Nevertheless, some physiologic adjustments of the hematopoietic response to the acutely reduced RBC mass can be recorded. These include a typical erythropoietin response (serum erythropoietin increases four-fold within 1 day, declining exponentially thereafter), changes in erythrocyte and hemoglobin synthesis (reticulocyte count increases rapidly by 2.4-fold after 7 days, remaining elevated for another 7 days, whereas hemoglobin values remain reduced on average by about 15 % for 2 weeks) and changes in iron metabolism (serum ferritin sharply decreases, while the soluble transferrin receptor concentration increases by 60 % by day 14). Blood donation of 450 mL from healthy blood donors also leads to an increase in hypochromic reticulocytes from day 1 or 2, peaking on day 9 and reaching a maximum increase of 178 percent. Hypochromic
n erythrocytes and soluble transferrin receptor increase within the same period, whilst transferring saturation decreases. The reticulocyte count increases substantially from the first day, with a maximum increment of 55 percent [06005].

The recipient
Reinfusion of 1350 mL of blood generally leads to hemoglobin increases of 8 percent from the pre-phlebotomy level and of 14 percent from the pre-infusion level, with simultaneous reduction in serum erythropoietin in 24 h and a sharp increase in serum iron and bilirubin. Blood reinfusion also significantly increases both hemoglobin and ferritin concentrations by up to 18 percent and 68 percent, respectively. Such changes are associated with a stable and marked decline, approaching 50 percent of the baseline concentration, of serum erythropoietin. Levels of reticulocytes and soluble transferrin receptor also decline progressively from day 7 to day 21 following transfusion [06005].

The use of blood markers
The first attempt to develop a test to detect the use of autologous blood transfusions (ABT) was performed by Berglund et al in 1987. A volume of 1350 mL of blood, corresponding to 3U of blood, was withdrawn from each subject, stored at 4°C for 4 weeks, and then reinfused into the donor. The reinfusion of blood resulted in a 60 percent reduction in serum EPO within the first 24 hours as well as a marked increase in Hb, serum ferritin, and serum bilirubin. From these data, a test based on absolute thresholds of Hb (>12.0 g/dL), bilirubin (>30 micromol/L), ferritin (>33 micromol/L), and EPO (<15 mU/mL) yielded a sensitivity of 50 percent within the first week of transfusion. Nevertheless, a general problem with using such absolute thresholds is the small within-subject to between-subject variability ratio found for most erythropoiesis-sensitive markers. Therefore, an alternative “2-sample procedure” was suggested by Berglund et al, where an increase in Hb greater than 5 percent and a concomitant decrease in serum EPO greater than 50 percent served as the limits. This algorithm also yielded a sensitivity of 50 percent but with the window of detection now extending to two weeks. Another important aspect when developing a test for the detection of ABT is the applicability of the test across different transfusion regimens. Historical evidence has shown that athletes and their physicians adjust their doping regimes whenever a new testing technology is introduced [12009].

During the 1990s, different sports federations implemented upper hematocrit and Hb thresholds to discourage athletes from manipulating their blood. In addition, reticulocyte analysis and thresholds were implemented, but the sensitivity of these thresholds to detect ABT was not examined before 2006. The withdrawal of blood results in a significant increase in percentage of reticulocytes reaching peak levels of 3.0 percent 1 week after withdrawal in tandem with a significantly decreased Hb. Withdrawal of blood is the only blood manipulation that results in this specific test result pattern and is therefore highly indicative of ABT. After RBC reinfusion, only a modest decrease in percentage of reticulocytes, from 1.3 to 0.8 percent, was observed. Individual Hb values apply to an absolute cutoff threshold of 17.0 g/dL, but only 1 of 10 subjects exceeds this limit [12009].

mRNA
Leuenberger et al. investigated a different angle of detecting blood transfusion by measuring the impact on cell-free microRNA (miRNA) in plasma. In a controlled transfusion study with blood stored for 42 days, three miRNAs namely miR-30b, miR-30c, and miR-26b were significantly increased up to one day post re-infusion. Combining data from miRNA with ‘conventional’ blood parameters such as EPO serum concentration (which was shown to
decrease in the same study) could provide a complementary tool to determine autologous blood doping [13009].

**DNA-based method for detecting homologous blood doping**

Homologous (or allogeneic) blood doping, in which blood is transferred from a donor into a recipient athlete, is the easiest, cheapest, and fastest way to increase red cell mass (hematocrit) and therefore the oxygen-carrying capacity of the blood. Although thought to have been rendered obsolete as a doping strategy by the increased use of rhEPO to increased hematocrits, there is evidence that athletes are still using this potentially dangerous method to improve endurance performance. Current testing for homologous blood doping is based on identification of mixed populations of red blood cells by flow cytometry. This paper proposes that homologous blood doping could also be tested for by high-resolution qPCR-based genotyping and demonstrates that assays could be developed that would detect second populations of cells even if the "donor" blood was depleted of 99 percent of the DNA-containing leukocytes. Issues of test specificity and sensitivity are discussed as well as some of the ethical considerations that would have to be addressed if athletes' genotypes were to be used by the anti-doping authorities to prevent, or detect, the use of prohibited ergogenic practices [13302].

Aiming at an alternative methodology for the detection of homologous blood doping, it was studied the applicability of DNA analysis from whole blood to assess whether the genetic material of one or more individuals is present in one sample. Employing the typical 16 loci as used in forensic analyses, the presence of more than 2 allele lengths (in at least 7 different loci with a minimum relative abundance of 100 RFU) was considered proof for the presence of donor blood in the specimen. The sensitivity, as assessed by different mixtures of donor and acceptor blood ex vivo, was estimated to be a low as 2.5 percent (of donor blood), hence, representing a methodology with the potential to complement the currently routinely used flow cytometry [13009].

Homologous (or allogeneic) blood doping, in which blood is transferred from a donor into a recipient athlete, is the easiest, cheapest, and fastest way to increase red cell mass (hematocrit) and therefore the oxygen-carrying capacity of the blood. Although thought to have been rendered obsolete as a doping strategy by the increased use of rhEPO to increased hematocrits, there is evidence that athletes are still using this potentially dangerous method to improve endurance performance. Current testing for homologous blood doping is based on identification of mixed populations of red blood cells by flow cytometry. This paper proposes that homologous blood doping could also be tested for by high-resolution qPCR-based genotyping and demonstrates that assays could be developed that would detect second populations of cells even if the "donor" blood was depleted of 99 percent of the DNA-containing leukocytes. Issues of test specificity and sensitivity are discussed as well as some of the ethical considerations that would have to be addressed if athletes' genotypes were to be used by the anti-doping authorities to prevent, or detect, the use of prohibited ergogenic practices [13303].

**DNA testing**

Homologous blood transfusion is an illicit practice used by athletes to improve the delivery of oxygen to tissues and, as such, it is banned in sports. The current method of detection is based on the flow cytofluorimetric phenotypic identification of red blood cells mismatch of minor blood group antigens between the donor and the recipient. The selectivity of this
method to clearly identify transfused samples is related to the number of blood group antigens tested. Despite the fact that several different antigens are investigated, two individuals sharing the expression of the same minor blood group antigens pattern cannot be distinguished. We tested the possibility to use a different approach based on DNA forensic human identification techniques. Analysis of the DNA short tandem repeats (STRs) demonstrated its suitability in detecting mixed whole blood samples simulating homologous blood transfusion in 100 percent of the samples tested, ensuring the capability of clearly detecting mixed blood cell populations also on samples where the fraction of the minoritary population is as low as 2.5 percent [13323].

Response to foreign erythrocytes

Another interesting approach arises from the analysis of erythrocytes. In a pilot project, it was analyzed proteomic data (e.g. from 2-DE gels) from two volunteers and showed that RBC membrane proteome changes during storage could provide biomarkers for the detection of autologous transfusion in the future. In a similar small study, it was shown that the marker oxidative stress-related protein peroxiredoxin 2 and the RBC population characterized by density separation significantly changed after mixture of stored RBCs with freshly withdrawn RBCs in vitro. In another project supported by WADA one group hypothesized that a systemic response towards a supra-physiological red cell volume induced by autologous transfusion might be assessable in vivo by measuring the differences in red cell distribution by continuous density gradients and flow cytometry characterization of erythrocytes. Furthermore, as several molecular changes occur in stored RBCs, commonly referred to as the “storage lesion”, it was hypothesized that autologous transfusion will lead to a sudden exposure of cell detritus to the immune system causing a cellular and molecular immune response. A distinct immune reaction was found on a transcriptional level in T lymphocytes using whole genome microarrays and qRT-PCR confirmation. This concept was reassessed by evaluation of the immune response of peripheral blood mononuclear cells using cellular fluorescence markers in vitro and in vivo [13006].

Stability of hemoglobin

The stability of the most crucial variables, i.e. haemoglobin concentration and percentage of reticulocytes, under the defined pre-analytical conditions has been established to be at least 36 h, requiring rapid and cooled transport of doping control blood samples to an accredited laboratory. Extending the storage time to 168 h at +4°C, +6°C, and +12°C as done in this study demonstrated that these parameters were not significantly altered if the temperature was kept at 4-6°C, hence allowing to rely on analytical data up to seven days after blood collection when adequately cooled. Physiologically, the percentage of reticulocytes can vary depending on factors such as seasonal stress (training, competition, and recovery), sport discipline, diseases, etc. However, intra-individually, the parameter has proved extraordinary informative and has thus become a major pillar of the ABP. In order to support the significance of values measured from individuals and the comparison of analyses conducted at different laboratories and/or on different analytical systems of the same instrument type, a study to improve the between-instrument comparability by optimizing the calibration was conducted. By means of a stabilized whole blood matrix used as a calibrant, mean values of “authentic” samples were within 0.1 percent among the test instruments, thus allowing an improvement in the commonly observed bias between systems still operating within the manufacturers' specifications [13009].

Effects of blood withdrawal and reinfusion on biomarkers

In the 2000s, athletes have been tested positive for allogeneic blood transfusion by means of
flowcytometry indicating a return to former blood transfusion practices. However, an unequivocal detection method revealing autologous transfusion is still not available. Since accelerated or inhibited erythropoiesis leads to characteristic changes in peripheral blood parameters, irrespectively of the stimulating agent, an indirect detection method of recombinant human erythropoietin (rHu-EPO) use based on changes in certain hematological parameters has been implemented by some international sport federations. Despite its use, data on the effect of blood withdrawal and reinfusion in these hematological parameters have never been reported in full. It was hypothesized that autologous blood manipulations produce large variations in currently used biomarkers of erythropoiesis making individual hematological profiles an effective tool identifying this manipulation. It was measured hemoglobin concentration [Hb], hematocrit, reticulocytes, serum EPO and sTfR concentrations in 10 healthy, male subjects at baseline and after the withdrawal of 20 ± 3 percent (1.3 ± 0.2 L) of the subjects' blood volume on day 0, 1, 3, 7, 14, 21 and 28 and after reinfusion of 0.8 ± 0.1 L of packed RBCs on day 0, 1, 3, 7, 14 and 21. To maintain blood volume after blood withdrawal, 1.3 L of hydroxyl-ethyl-starch (Voluven®) was infused. All subjects were given daily oral iron supplementation (100 mg). [Hb], hematocrit, reticulocytes was measured. Serum EPO and sTfR concentrations were determined by ELISA. The indirect OFF-hr blood models for rHu-EPO detection were applied. It was found that following blood withdrawal, [Hb] remained reduced on average by about 15 percent for 2 weeks. Accordingly, s-EPO increased 4-fold within a day, declining exponentially thereafter. Reticulocyte count increased rapidly by 2.4-fold after 7 days, remaining elevated for another 7 days whereas sTfR increased by 60 percent by day 14 and remained elevated until 3 days after blood reinfusion. Following blood reinfusion, [Hb] increased acutely by 8 percent returning to the initial baseline value after 2 days. s-EPO remained unchanged whereas reticulocyte count was reduced by 25-37 percent from day 7 to 21. sTfR declined progressively after reinfusion. The highest OFFhr score was 126 at day 2 during the polycytemic period corresponding to a 1 in 1000 cut-off threshold. Evidence indicates that the hematocrit within-subject biological and seasonal variation in man shows a maximal relative change of 15 percent within a 95 percent confidence interval i.e. a change from 0.42-0.48.5 Data of a wider range of sports also show within subject estimates of variance in [Hb] of 1.6 g/dL,6 which agree with a10 percent fluctuation found in soccer players.7 In the present study, however, all 10 subjects exceeded the normal variation, with [Hb] ranging from 19-39 percent. Even when the control [Hb] value was taken as the mean [Hb] value, 9 of 10 subjects exceeded their individual upper limit based on a 7.5 percent addition to their control [Hb] value (range 3.0-11.5 %). Importantly, alterations in other hematological biomarkers (s-EPO, reticulocytes and sTfR) were observed at all times through this investigation, suggesting that determination of these biomarkers could be used as supportive evidence for erythropoietic manipulations with acute [Hb] increases of more than 7.5%. At present, only two blood tests are available. To protect the health of the athlete, World Anti Doping Agency has implemented an upper limit of 17.0 g/dL, which – if exceeded – elicits a no start sanction. However, only one subject in this study showed [Hb] values higher than 17.0 g/dL. In conclusion, autologous blood procedures induce a clear pattern of accelerated erythropoiesis during the anemic period. Within the limitations of the study, it is suggested that variations in [Hb] exceeding 15 percent between samples obtained in top ranked endurance athletes during the anticipated anemic period and shortly before any major competition would be indicative of autologous blood manipulation [06152].

Laboratory problems

Antidoping testing is currently exclusively based on haematochemical analysis performed in specialized laboratories accredited by WADA (World Anti-Doping Agency). Many of the analytical methods used for the determination of the parameters considered, such as haematological parameters (haemoglobin, hematocrit and reticulocytes), proteins (soluble
transferrin receptor and hepcidin) and hormones (erythropoietin and growth hormone) are often affected by lack of clear standardization and harmonization. The observed incongruity of the data deriving from different laboratories often results in the risk of false positive results in athletes. One review wanted to provide additional proofs in support of the need to improve the antidoping methodology involving different research and clinical institutions and skills [10354].

Robustness of measurements after storage of blood

With the setting up of the newly Athlete’s Biological Passport antidoping programme, novel guidelines have been introduced to guarantee results beyond reproach. It was investigated in this context, the effect of storage time on the variables commonly measured for the haematological passport. It was also wanted to assess for these variables, the within and between analyzer variations. Blood samples were obtained from top level male professional cyclists (27 samples for the first part of the study and 102 for the second part) taking part to major stage races. After collection, they were transported under refrigerated conditions (between 2 degrees and 12 degrees C), delivered to the antidoping laboratory, analysed and then stored at approximately 4 degrees C to conduct analysis at different time points up to 72 h after delivery. A mixed-model procedure was used to determine the stability of the different variables. As expected haemoglobin concentration was not affected by storage and showed stability for at least 72 h. Under the conditions of the investigation, the reticulocytes percentage showed a much better stability than previous published data (> 48 h) and the technical comparison of the haematology analyzer demonstrated excellent results. In conclusion, the data clearly demonstrate that as long as the World Anti-Doping Agency’s guidelines are followed rigorously, all blood results reach the quality level required in the antidoping context [10308].

Two main blood storage procedures can be used for storing red blood cells: refrigeration and freezing. Nevertheless, the efficiency of these procedures measured as the increase in hemoglobin after reinfusion compared with baseline has never been examined. The main objective was to examine which storage procedure yielded the largest increase in circulating haemoglobin after reinfusion compared to baseline. Equal volumes of blood from 15 men were withdrawn and stored either frozen or refrigerated as packed red blood cells. Serial measures of circulating hemoglobin by carbon monoxide rebreathing provided an opportunity to monitor recovery from anaemia, as well as the net increase in circulating haemoglobin after transfusion. The post-thaw yield of hemoglobin in the bags was 72 percent after refrigerated storage compared with only 52 percent after freezing. Nevertheless, frozen storage allowed hemoglobin to fully recover before reinfusion, while the haemoglobin was 10 percent lower in the refrigerated group compared with baseline. After reinfusion, the hemoglobin levels were 12 percent higher than the baseline values in the group reinfused with frozen blood, while for the refrigerated group, hemoglobin levels were only 5 percent higher than baseline. The relatively larger recovery from anemia in the frozen group during storage more than compensated for the larger loss of hemoglobin during freezing and resulted in a larger net gain in hemoglobin. Based on the average 23 g per week recovery of hemoglobin, extending refrigerated storage to 7-8 weeks may yield sufficient time for patients to fully replenish harvested hemoglobin from three bags of blood without reliance on frozen storage of RBC [11136].

One review examined the science and methodology of blood conservation in modern anaesthetic and surgical practice. Blood transfusion is associated with increased morbidity and mortality in all surgical patients, and the reduction or even elimination of transfusion has been and continues to be the subject of much research. Blood substitutes, despite extensive investigation, have not been proved successful in trials to date, and none have entered
clinical practice. Pharmacological treatments include antifibrinolytic drugs (although aprotinin is no longer in clinical use), recombinant factor VIIa, desmopressin, erythropoietin and topical haemostatic agents, and the role of each of these is discussed. Autologous blood transfusion has recently fallen in popularity; however, cell salvage is almost ubiquitous in its use throughout Europe. Anaesthetic and surgical techniques may also be refined to improve blood conservation. Blood transfusion guidelines and protocols are strongly recommended, and repetitive audit and education are instrumental in reducing blood transfusion [09155].

It should be mentioned that the organisation and management of the collection and long-term storage of blood bags is difficult, especially outside healthcare facilities, so that this practice is mostly limited to high-profile, wealthy athletes. The widespread availability and relatively low cost of blood for transfusions are paramount needs for modern healthcare systems. Blood requirements for surgical and medical treatment are increasing steadily while the availability is stable or even decreasing, so that the demand is already exceeding the supply. Current technology and increasing knowledge on tissue and cell engineering, especially those based on the use of haematological stem cells to obtain mature and efficient blood particles, is opening appealing strategies and approaches for obtaining safe and disposable blood to be used for clinical purposes. RBC have been widely investigated in the past, and their metabolic pathways and mechanical properties have been exhaustively described and also reproduced in vitro [13290].

**Peroxiredoxin 2 as a marker during storage**

Employing a different strategy at the proteome level of red blood cells (RBCs), a considerable increase of peroxiredoxin 2 (Prdx2) was observed upon ex vivo storage of erythrocytes. The study did not include transfusion experiments and it remains to be clarified whether the increased Prdx2 levels can be visualized once the stored RBCs have circulated in the bloodstream for a certain period of time; however, experiments with stored blood diluted tenfold with freshly sampled specimens allowed for the detection of Prdx2 using 1D gel electrophoresis and Western blotting [13012].

**Whole blood transfusion**

Hemoglobin mass (Hb\textsubscript{mass}) is a key factor for maximal exercise capacity. In aerobic sport disciplines, such as long-distance running, cycling, or cross-country skiing, the main factors determining performance are a high delivery of O\textsubscript{2} to the exercising skeletal muscles and its use. The rate of maximal O\textsubscript{2} uptake (O\textsubscript{2}\textsubscript{max}) is dependent on a high cardiac output (Q) and a wide difference for arterial-venous O\textsubscript{2} (a-vO\textsubscript{2}), that is, the Fick equation:

\[
\text{Oxygen consumption} = (\text{cardiac output} \times \text{oxygen concentration of arterial blood}) - (\text{cardiac output} \times \text{oxygen concentration of venous blood})
\]

Because maximal cardiac output is difficult (if not impossible) to manipulate to higher values during competitions, the distribution of Q during maximal exercise to the working skeletal muscles is close to 80 percent, and arterial O\textsubscript{2} extraction is already in the range of approximately 90 percent at maximal exercise, the only variable that remains open for manipulations in regards to increasing exercise performance is the arterial O\textsubscript{2} content. Accordingly, in a given person, changes in Hb concentration by either red blood cell (RBC) transfusion or hemodilution will increase or decrease O\textsubscript{2}\textsubscript{max}, respectively. On the group basis, however, concentration of hemoglobin is not predictive of O\textsubscript{2}\textsubscript{max}, whereas the total mass of Hb correlates very well. Indeed, a somewhat reduced hemoglobin concentration is sometimes, but not always, observed among athletes, whereas Hb\textsubscript{mass} is usually increased compared with normal healthy persons. It has been calculated that a change of 1 g in Hb\textsubscript{mass}...
will produce a change in $O_{2\text{max}}$ of 4 mL/min whereas the effects on submaximal exercise performance are probably variable according to competition distance. It should also be noted here that volume loading (i.e. plasma volume expansion) in itself does not lead to an improved exercise performance in elite athletes, again highlighting the role of Hb mass. If, however, a plasma volume expander is administrated simultaneously with increments in Hb mass, then performance will probably increase more than when just augmenting the total red cell volume. Some athletes apply prohibited techniques and substances with intent to increase Hb mass and physical performance, and this is often difficult to prove directly. A test for detection of allogeneic blood transfusion doping was implemented in 2004. The test uses blood group antisera to identify mixed RBC populations in blood samples by flow cytometry. Autologous RBC manipulations can at present only be detected via indirect measures, which represent a major problem in antidoping efforts. The CO rebreathing technique for detecting nonphysiologic increases in Hb mass is still investigational, and besides practical difficulties related to this method, its potential inclusion in the blood passport may be problematic, because the margin of variation when assessing Hb mass (biologic and measurement errors) would still allow athletes to manipulate with blood volumes that would increase exercise performance considerably. Finally, it should also be considered that, from an athlete’s viewpoint, it may not be desirable to breathe CO shortly before a competition as this may limit exercise performance. Novel erythropoietic substances, such as mimetics of erythropoietin (Epo) and activators of the Epo gene may soon enter the sports scene. In addition, Epo gene transfer maneuvers are imaginable. Effective since December 2009, the World Anti-Doping Agency (WADA) has therefore implemented “Athlete Biological Passport Operating Guidelines”, which are based on the monitoring of several parameters for mature RBC and reticulocytes. Blood doping may be assumed, when these parameters change in a non-physiological way. Hematologists should be familiar with blood doping practices as they may play an important role in evaluating blood profiles of athletes with respect to manipulations, as contrasted to the established diagnosis of clinical disorders and genetic variations [11116].

Traditional antidoping analyses are based on the detection of a substance in biologic fluids (“Adverse analytical finding”). This approach has major limitations in regard to blood doping. Autologous blood cannot be detected, there is a plethora of ESAs, the detection window is limited, and there is urine manipulation. Some sports federations earlier introduced upper hemoglobin concentration and Hct limits to escape from this dilemma. Athletes tested above the limits were declared unfit for competition (“No-start rule”). However, hemoglobin concentration and Hct are influenced by external factors, such as body posture, exercise, or residence at altitude. In addition, “clean” athletes can have naturally high hemoglobin concentrations and Hct values. A large retrospective study on male blood donors in Denmark revealed that 3.9 percent of nonathletes and 10.4 percent of elite rowers had Hct values more than 0.51 (i.e. above the recommended limits for athletic competition). In addition, the adoption of upper [Hb] and Hct limits may paradoxically generate more blood doping because, by ESA misuse, [Hb] and Hct can be manipulated with the aim of approaching the target values without exceeding it. Hematologic parameters depend on ethnicity, age, and gender. Even [Hb] values differ. Hence, it has been suggested to use longitudinal blood profiles together with heterogeneous factors, such as ethnicity and age, to develop models with improved sensitivity to detect blood doping. Some blood parameters, such as the concentration of Epo and reticulocytes (Ret), increase on administration of ESAs (ON-score), whereas they decrease after RBC transfusion or after the cessation of ESA administration (OFF-score). The “Abnormal Blood Profile Score” (not presently used for the assessment of abnormal blood profiles based on the passport data) regards additional red cell parameters, including the mean corpuscular Hb concentration (MCHC), mean corpuscular volume (MCV), mean corpuscular Hb mass (MCH), Ret counts, serum Epo, and soluble transferrin receptor (sTfR). Having become effective in December 2009, the “Athlete Biologic Passport Operating
Guidelines" equip Anti-Doping Organizations with a framework in which to pursue antidoping rule violations in accordance with Article 2.2. of the World Anti-Doping (WAD) Code ("Use or Attempted Use by an Athlete of a Prohibited Substance or a Prohibited Method"). The guidelines include mandatory requirements for collection, transportation, analysis of blood samples, and results management. The following markers are considered in the Athlete Biologic Passport hematologic module: Hct, Hb, RBC count, reticulocyte percentage, reticulocyte number, MCV, MCH, and MCHC. In addition, parameters of interest can be the mean Ret cell volume (MCVr), Ret Hb concentration (MCHCr) and Ret Hb content (MCHr) [11116].

**RBC parameters associated with autologous transfusion**

The failure to obtain direct proof for autologous blood transfusion has prompted the search for indirect evidence. In a preliminary antidoping context it has been reported changes in hematologic parameters after blood withdrawal and reinfusion. Ten healthy men were subjected to withdrawal of 20 percent of their blood volume (and hence much more than common doping practice), which was replaced by 1.3 L of hydroxyl-ethyl starch. Circulating Epo increased 4-fold within a day, declining exponentially thereafter. Reticulocyte number increased 2.4-fold after 7 days, remaining elevated for another 7 days. Concentration of hemoglobin remained reduced on average by 15 percent for 2 weeks. Soluble transferrin receptor increased by 60 percent by day 14 and remained elevated until 3 days after reinfusion of 0.8 L of packed RBCs, which was performed one month later. Thereby, hemoglobin concentration increased acutely by 8 percent returning to the initial baseline value after 7 days. Epo concentrations remained unchanged, whereas reticulocyte numbers were reduced by approximately 30 percent from days 7 to 21. The loss of Hb\text{mass} of approximately 75 g (measured by CO rebreathing) after donation of 550 mL blood has been shown to be recovered after a mean of 36 days. After the retransfusion of one RBC unit Hb\text{mass} acutely increased by 51 g, showing a continuous decrease from week 2 until week 8, albeit Hb\text{mass} was still elevated compared with pre-reinfusion values. Based on the results of a retrospective longitudinal blinded study, the same group of investigators has reported that the use of an adaptive model incorporating hematologic measures allows for detection of autologous blood transfusion [11116].

Since no direct detection method for autologous blood transfusions exists, the most promising attempt is the Athlete Biological Passport (ABP) and its adaptive model that enables a longitudinal monitoring of hematologic measures to identify patterns of blood manipulations. The purpose therefore was to evaluate the performance of this adaptive model for the detection of autologous blood transfusions in a longitudinal blinded setting. Twenty-one subjects were divided into a doped group (multiple transfusions of 1-2 units of red blood cells, n=11) and a control group (n=10). The time course of a cycling season (42 weeks) was simulated including three major competitions (Classics, Grand Tour, World Championships). Up to 10 venous blood samples were ordered per subject by a blinded investigator mimicking the intelligent approach in obtaining hematologic data for the adaptive model (hemoglobin [Hb] concentration, reticulocyte percentage, OFF-score). Retrospective analysis allowed identification of four (probability >99 %) or three (probability >99.9 %) abnormal samples for Hb and eight (probability >99 %) or five (probability >99.9 %) abnormal samples for OFF-hr in doped subjects. Four doped subjects (36 %) presented an abnormal OFF-hr sequence and three doped subjects (27 %) an abnormal Hb sequence; there were no false-positive sequence results. The best possible sensitivity was 82 percent when a combination of all tests was used. The investigation provides evidence that the adaptive model allows detection of autologous blood transfusions with a good sensitivity. An intelligent testing approach and the adherence to World Anti-Doping Agency’s ABP operating guidelines are nevertheless determinants in the success [11135].
Detection of homologous blood transfusion

The aim of one study was to improve and validate a flow cytometric method for the detection of homologous blood transfusion in doping control analysis. A panel of eight different primary antibodies and two different phycoerythrin-conjugated secondary antibodies was used for the detection of different blood populations. The flow cytometer used in this study was the BD FACSArray instrument. Mixed red blood cell populations were prepared from phenotype known donors. Linearity, specificity, recovery, precision, robustness and interday-precision were tested for every primary antibody used in the presented assay. The technique of signal amplification was utilized for an improved separation of antigens with weak or heterozygous expression to improve the interpretation of histograms. The resulting method allowed to clearly identify mixed red blood cell populations in homologous blood transfusion samples containing 0.3-2.0 percent of donor blood [07114].

Subjects submitted to intravenous blood transfusions for medical reasons or blood doping to increase athletic performance are potentially exposed to the plasticizer di-(2-ethylhexyl)phthalate (DEHP) found in bags used for transfusens. Exposure to DEHP has been evaluated by measuring DEHP metabolites in selected groups of subjects. Urinary DEHP metabolites, mono-(2-ethylhexyl)phthalate, mono-(2-ethyl-5-hydroxyhexyl)phthalate (MEHHP), and mono-(2-ethyl-5-oxohexyl)phthalate (MEOHP) were measured in a control group with no explicit known exposure to DEHP (n=30), hospitalized patients receiving blood transfusions (n=25), nontransfused hospitalized patients receiving other medical care involving plastic materials (n=39), and athletes (n=127). Patients were tested in the periods 0 to 24 and 24 to 48 hours after exposition. Urinary concentrations of all three DEHP metabolites were significantly higher in patients receiving blood transfusion than in nontransfused patients and the control group, except for MEHHP and MEOHP in the period 24 to 48 hours. Samples from four athletes showed increased concentrations of DEHP metabolites comparable to urinary concentrations of patients receiving blood transfusion. It was concluded that elevated concentrations of urinary DEHP metabolites represent increased exposure to DEHP. High concentrations of DEHP metabolites present in urine collected from athletes may suggest illegal blood transfusion and can be used as a qualitative screening measure for blood doping [09156].

A test for detection of allogeneic blood transfusion doping was implemented in 2004. The test uses blood group antisera to identify mixed RBC populations in blood samples by flow cytometry. It has been applied antisera against 12 blood group antigens and demonstrated that the presence of allogeneic cells can be assessed in the blood of subjects who had previously received at least one unit of allogeneic blood. No false-positive results were obtained in an analysis of 140 blood samples containing different percentages (0-5 %) of a minor RBC population, indicating a 100 percent specificity of the method. Most samples containing a 1.5 percent minor RBC population were unambiguously detected, yielding a 78 percent sensitivity. The method proved to fulfill the ISO-17025 accreditation and validation requirements. Athletes making use of allogeneic blood transfusion are thus very likely to be caught if tested. Autologous RBC manipulations can at present only be detected via indirect measures, which represents a major problem in antidoping efforts. The CO rebreathing technique for detecting nonphysiologic increases in Hb\text{mass} is still investigational and besides practical difficulties related to this method, its potential inclusion in the blood passport may be problematic, because the margin of variation when assessing Hb\text{mass} (biologic and measurement errors) would still allow athletes to manipulate with blood volumes that would increase exercise performance considerably. Finally, it should also be considered that, from an athlete's viewpoint, it may not be desirable to breathe CO shortly before a competition as this may limit exercise performance [11428].
Plasticizers from transfused blood

Despite the promising results and deterrence generated by the ABP, additional information enforcing anti-doping efforts concerning blood doping are desirable. The detection of atypically high concentrations of plasticizers in urine samples of athletes can be considered as indication for blood transfusion as demonstrated in several studies in the past. In a controlled blood transfusion study with 25 volunteers, blood re-infusion was conducted after 14 or 28 days with 12 and 13 participants, respectively. In a time-dependent manner, longer storage prior to re-infusion yielded higher urinary levels of plasticizer (here di(2-ethylhexyl)phthalate) metabolites, which were significantly elevated for more than 24 h post-infusion. In order to estimate the intra-individual variability of these urinary metabolites influenced by residential, dietary, or environmental exposure, a pilot study with seven volunteers was conducted over a period of seven days. Although the collective of individuals was rather small, no urinary values near those observed after blood transfusion were observed, supporting the idea of employing plasticizers for improved targeted doping controls [13012].

A totally different approach to detect ABT was recently proposed. This approach relies on increased levels of metabolites of di-2-ethyl hexyl phthalate (DEHP) in the urine. The DEHP is a chemical added to plastics such as polyvinyl chloride (PVC) to increase flexibility. The DEHP exists in the PVC matrix as a semisolid and is widely used in medical devices such as blood storage bags. The DEHP molecules migrate out of the PVC matrix into the blood products when they are kept in the blood bags. Considering the largest source of DEHP exposure in humans (ingestion), once DEHP enters the gastrointestinal tract in contaminated foods, it is rapidly hydrolyzed in the small intestine to mono(2-ethylhexyl) phthalate (MEHP) and 2-ethylhexanol via pancreatic lipases. At low concentrations, most of the DEHP is absorbed as its metabolites, although at high doses, a limited amount of unmetabolized DEHP may also be absorbed. Intact DEHP that does cross into the bloodstream is rapidly converted by plasma and liver enzymatic actions to MEHP with a biologic half-life of less than 6 hours. Urinary concentrations of all 3 DEHP metabolites are significantly higher in patients receiving blood transfusions than in nontransfused patients and control subjects within the first 24 hours after transfusion. However, it must be recognized that the data collected are specific for a European population and might specifically reflect the commercial and regulatory trends in the European phthalate market. Another issue is the use of different blood products. Because of differences in solubility of DEHP in various blood products, an RBC unit would deliver more DEHP compared with a whole blood transfusion [12009].

Misuse of autologous blood transfusions in sports remains undetectable. The metabolites of the plasticizer di-(2-ethylhexyl)phthalate (DEHP) were recently proposed as markers of blood transfusion, based on high urinary concentrations of these compounds observed in patients subjected to blood transfusion. One study evaluated DEHP metabolites in urine for detecting autologous blood transfusion. One blood bag was drawn from moderately trained subjects and the red blood cells (RBCs) were reinfused after different storage periods. Group 1 (12 subjects) was reinfused after 14 days, and Group 2 (13 subjects), after 28 days of storage. Urine samples were collected before and after reinfusion for determination of the concentrations of three DEHP metabolites, mono-(2-ethylhexyl)phthalate, mono-(2-ethyl-5-hydroxyhexyl)phthalate, and mono-(2-ethyl-5-oxohexyl)phthalate. Concentrations of DEHP metabolites on the days before reinfusion were in agreement with those described after common environmental exposure. A few hours after the reinfusion a significant increase was observed for all metabolites in all volunteers. Concentrations 1 day later were still higher than before reinfusion. Variations in urine dilution supported normalization by specific gravity. Concentrations of DEHP metabolites tended to be higher after longer storage times of RBCs. It was concluded that autologous transfusion with RBCs stored in plastic bags provokes an
acute increase in the urinary concentrations of DEHP metabolites, allowing the detection of this doping malpractice. The window of detection is approximately 2 days. The method might be applied to urine samples submitted for antidoping testing [12237].

The category of illegal oxygen transfer enhancement includes several aspects such as various forms of blood doping and manipulation of oxygen uptake, transport, and delivery. Phthalate-derived plasticizers such as di(2-ethylhexyl)phthalate (DEHP) are commonly present PVC-based blood containers and released during storage into blood preparations. Upon infusion, DEHP blood concentrations increase causing elevated urine concentrations of DEHP metabolites, which were quantitatively assayed by means of isotope-dilution LC-MS/MS [12016].

Cytosolic red blood cell proteome analyze
The storage of packed red blood cells (RBCs) is associated with the development of morphological and biochemical changes leading to a reduced posttransfusion functionality and viability of the cells. Within this study, 2D DIGE and high-resolution/high-accuracy Orbitrap MS were used to analyze the storage-induced changes of the cytosolic RBC proteome and identify characteristic protein patterns and potential marker proteins for the assessment of RBC storage lesions. Leukodepleted RBC concentrates were stored according to standard blood bank conditions for 0, 7, 14, 28, and 42 days and analyzed by using a characterized and validated protocol. Following statistical evaluation, a total of 14 protein spots were found to be significantly altered after 42 days of ex vivo storage. Protein identification was accomplished by tryptic digestion and LC-MS/MS and three proteins potentially useful as biomarkers for RBC aging comprising transglutaminase 2, beta actin, and copper chaperone for superoxide dismutase were selected and validated by western blot analysis. These can serve as a basis for the development of a screening assay to detect RBC storage lesions and autologous blood doping in sports [12238].

Capillary electrophoretic separation
The use of autologous blood transfusions by endurance athletes has remained one of the most difficult doping practices to detect. The implementation of the Athlete's Biological Passport by some sporting bodies has proved to be effective; however, the analysis relies on the long-term monitoring of numerous biological markers, looking for abnormal variations in a number of biological markers to indicate doping. This work introduces an approach to identify autologous blood transfusions by examining the red blood cells (RBCs) directly. By using high-speed capillary electrophoretic separations, the relative distribution of the sizes of the RBCs in a sample can be established in under 3 min, following the preparation of the cells. As RBCs that have been stored for transfusions undergo vesiculation, the relative size of the transfused cells differs from the native cells. The capillary electrophoretic separation allows for a rapid examination of this distribution and the changes that are seen when transfused RBCs are mixed with native cells. In this work, the effectiveness of this approach is demonstrated in the identification of simulated (in vitro) autologous blood transfusions performed with blood samples from three highly trained cyclists; it was possible to rapidly identify when as little as 5% of the RBCs in the sample were from a simulated autologous transfusion [13073].

Intravascular hemolysis
Since the observation that mechanical stress causes red blood cell (RBC) destruction, foot-strike hemolysis has been used to explain sports anemia and RBC rejuvenation in athletes. Recently gained knowledge questions the importance of mechanical RBC trauma on RBC
hemolysis in athletes. Male athletes (n=90) and untrained male controls (n=58) were investigated for aerobic performance, hematological parameters, serum erythropoietin concentration (EPO), soluble transferrin receptor concentration (sTFR), and erythrocyte aspartate aminotransferase activity (eAST). On hard floor running disciplines (HFR, n=26, short- and long-distance runners, triathletes) showed a lower eAST and thus no younger RBC population than not on hard floor running athletes (NHFR, n=64, cyclists, soccer players, others) or the untrained control group (n=58). HFR had higher but still normal EPO and no higher sTFR. It was concluded that because intravascular hemolysis occurs in swimmers, cyclists, and runners, and mean RBC age is not reduced in runners, mechanisms other than foot-strike hemolysis have to be considered as well. Possible reasons are intramuscular destruction, osmotic stress, and membrane lipid peroxidation caused by free radicals released by activated leukocytes. Intravascular hemolysis can even be regarded as physiological means to provide heme and proteins for muscle growth [06148].

**Evaluation of blood parameters**

Information derived from blood analyses can assist in the detection and/or deterrence of blood doping in sport. It was investigated whether comparing an athlete's hematologic values against his or her own historical baseline rather than population-derived thresholds enhanced the ability to detect blood doping. It was developed an approach whereby an athlete's true baseline value could be estimated with just one prior blood test. It was also estimated a universal value for within-subject variability for key hematologic parameters using the highest value obtained among four separate cohorts of male athletes including 80 elite rowers, 124 endurance-trained or team-sport subjects, 288 professional football players and 630 athletes competing at national or international level. The (individual) baseline and (universal) variability were then incorporated so as to define expected thresholds for subsequent blood tests. The sensitivity of our approach was obtained by analyzing data from 49 recreational athletes administered either recombinant human erythropoietin (n=37) or placebo (n=12). It was found that removing within-subject variability by comparing new results against an historical baseline heightened the capacity to detect blood doping. It was possible to delineate the longitudinal changes in either hemoglobin (Hb) or the OFF-hr model score (an algorithm using both Hb and percent reticulocytes) caused by recombinant human erythropoietin treatment from the natural biological fluctuations found in subjects treated with placebo. The objective data supported the intuitive belief that longitudinal monitoring of athletes' blood profiles will help detect blood doping. This information could be used to instigate target-testing of suspicious athletes, or even warrant the exclusion from competition of athletes with aberrant variations in key hematologic values [06149].

Hematological manipulation to optimize aerobic performances is a serious problem in elite and professional sports and the approach to identify blood doping is as yet challenging. In most cases, the current strategy contemplates a first stage of analysis, based on the application of arbitrary threshold for hemoglobin or hematocrit, followed by second-generation blood tests, or the adoption of an individual hematological passport. To establish the influence of preanalytical variables on the athletes' hematological profile, we compared hemoglobin, hematocrit, and reticulocytes count in 27 male professional cyclists after a mean time of 2.30 ± 0.12 tourniquet holding. Statistically significant differences were observed for hematocrit (+ 2.4 %) and hemoglobin measurements (+ 1.4 %), but not for the reticulocytes count (- 1.9 %). In 4 out of 27 cases (15 %), the variability of the hematocrit measurement exceeded the 4.1 percent desirable analytical quality specification for total error. Results of the present investigation further highlight the risk that unfulfillment of rigorous and standardized procedures for collection of blood specimens might increase the number of false positive testing and might lead to inappropriate sanctioning of a minority of clean athletes with hematocrit or hemoglobin values naturally elevated. Owing to the minor
biological variability and the lesser susceptibility to variation of the preanalytical phase, the hemoglobin concentration might be a more suitable parameter than hematocrit for inclusion within laboratory testing to identify blood doping [06150].

Evaluation over time
It was assessed haematological parameters and possible modifications in elite rugby players throughout a competitive season for increasing the knowledge of physiological characteristics of these sportsmen. Blood samples were collected from the members of the Italian National rugby team at four consecutive training camps during a whole competitive season. Forty-four athletes were recruited for the first camp, 36 for the second, 30 for the third and 32 for the fourth. Due to turnover of the subjects during the season only 13 athletes could be examined at all four camps, and another six in the first three camps. Therefore, it was selected the data of these 19 athletes. Iron and transferrin saturation were stable, whilst ferritin increased at the end of the season. The modifications of the soluble transferrin receptor (sTFR) were linked to those of haematocrit: sTFR increased after training and during the competition period when haemoglobin and haematocrit decreased, and decreased at the end of the season. Haemoglobin and haematocrit showed slightly higher levels during the first part of the season and decreased in the second half, when physical demand was high, as demonstrated by biochemical additional tests. Leucocytes and platelets were stable throughout the season. Haematological and iron metabolism parameters in the elite rugby players examined during a whole season fall within physiological range of values. The variability of the parameters during the season is related to training and competition workload. Reticulocytes and sTFR are the most sensitive parameters for studying the iron metabolism of the athletes [06151].

Erythropoietin (EPO)

Overview
The synthesis of recombinant human erythropoietin has marked a turning point in the treatment of anaemia secondary to chronic kidney disease. However, the potentially fatal cardio- and cerebrovascular complications of the intake of high-doses of ESAs (erythropoiesis-stimulating agents), such as those observed in athletes who resort to doping, reason out the ever-prevalent debate concerning the balance between the risks and benefits of ESA administration for therapeutic purposes. Hence, there is still a discussion as to what values haemoglobin should ideally be maintained at. Additional concerns arise in cancer patients due to the ability of erythropoietin to act as an angiogenic and, in general, as a cell growth factor, because this might favour the progression of neoplastic disease. It was summarized the prominent points of the latest guidelines on the management of anaemia in nephropathic patients, also identifying the possible risks that may result from the tendency to aim at too low haemoglobin levels [13306].

Erythropoietin (EPO) is the main hormonal regulator of red blood cell production. Recombinant EPO has become the leading drug for treatment of anaemia from a variety of causes; however, it is sometimes misused in sport with the aim of improving performance and endurance. This paper presents an introductory overview of EPO, its receptor, and a variety of recombinant human EPOs/erythropoiesis stimulating agents (ESAs) available on the market (e.g. epoetins and their long acting analogs - darbepoetin alfa and continuous erythropoiesis receptor activator). Recent efforts to improve on EPO's pharmaceutical properties and to develop novel replacement products are also presented. In most cases, these efforts have emphasized a reduction in frequency of injections or complete elimination
of intravenous or subcutaneous injections of the hormone (biosimilars, EPO mimetic peptides, fusion proteins, endogenous EPO gene activators and gene doping). Isoelectric focusing (IEF) combined with double immunoblotting can detect the subtle differences in glycosylation/sialylation, enabling differentiation among endogenous and recombinant EPO analogues. This method, using the highly sensitive anti-EPO monoclonal antibody AE7A5, has been accepted internationally as one of the methods for detecting misuse of ESAs in sport [12241].

Erythropoietin (EPO) is a peptide hormone and another compound that is found in the blood. EPO occurs naturally in the human body. To boost the amount of EPO in the human body with the aim of improving endurance performance or to improve recovery from anaerobic exercise, some athletes (e.g. cyclists) may use recombinant EPO. Recombinant EPO is prohibited both in and out of competition under the World Anti-Doping Code Prohibited List, although raising endogenous EPO in an athlete's body through the method of high altitude training is not prohibited. Recombinant EPO use, traditionally difficult to detect in the athlete, has recently been successfully tested in athletes as a result of collaboration of WADA and the pharmaceutical companies in uncovering a molecular marker of the drug. This uncovering process helps differentiate naturally occurring EPO and those artificially introduced [12015].

Recombinant human erythropoietin (rhEPO) is arguably the most successful therapeutic application of recombinant DNA technology till date. Humoral regulation of hematopoiesis was first identified in 1906 and endogenous EPO was isolated in 1977, with its gene cloned in 1985. A series of initial clinical trials were performed to assess its effectiveness in correcting anemia of chronic kidney disease (CKD). After it proved to abrogate the transfusion requirements and improve the well-being of patients, it was granted license in 1988 as a therapeutic agent for CKD patients. Since then, it has found varied applications, especially in stimulating erythropoiesis in anemia due to chronic conditions like renal failure, myelodysplasia, infections like HIV, in prematurity, and in reducing peri-operative blood transfusions. EPO, a member of the type I cytokine superfamily, was first identified as the hormone that stimulates erythroid progenitors within the bone marrow to mature into erythrocytes. The main site of production of EPO is from the kidney and to a much lesser extent from the liver. In the kidney, certain interstitial fibroblasts appear to be a major source of EPO; however, other studies suggest an important role of proximal tubular cells as well. The human erythropoietin gene is located at chromosome 7q11-22, and consists of five exons and four introns, which produce a post-transcriptional single polypeptide backbone containing 193 amino acids. This undergoes post-translational modification with the addition of three N-glycosylation and one O-glycosylation sites and removal of 28 amino acids, resulting in a 165 amino acid polypeptide chain which is the primary structure of the mature EPO. The molecular mass of the polypeptide backbone and the glycosylated form of erythropoietin is estimated to be 18 and 30 kDa, respectively. EPO acts synergistically with other cytokines to promote the proliferation, differentiation, and survival of progenitor cells in the erythroid lineage and boosts the production of erythrocytes. It does not influence the fate of the pluripotent stem cell, but acts on the colony forming unit-erythroid (CFU-E) cells to prevent their apoptosis and induce expression of erythroid specific proteins. The EPO-R polypeptide is a 66-kDa membrane protein belonging to the cytokine receptor superfamily. The EPO binding to its receptor results in homodimerization of the receptor, followed by activation of several signal transduction pathways: JAK2/STAT5 system, G-protein (RAS), calcium channel, and kinases. A gain of function mutation in JAK2 has been reported in patients with polycythemia vera and other myeloproliferative diseases. EPO also acts on angiogenesis, vasculogenesis, regulation of vascular resistance, and neuroprotection. Various types of rhEPO are commercially available today with different dosage schedules and modes of delivery.
- erythropoietin alpha: Epoetin alpha is an isoform of recombinant DNA-derived erythropoietin (rEPO), synthesized in Chinese hamster ovary (CHO) cells. It differs from the beta isoform in its migration on isoelectric focusing (IEF) and in a range of lectin-binding assays.

- erythropoietin beta: Epoetin beta is also synthesized by CHO cell lines and differs from epoetin alpha in containing:
  - a greater proportion of more basic isoforms
  - a greater proportion of EPO binding to Erythrina cristagalli agglutinin
  - isoforms with higher in vivo: In vitro bioactivity

Their efficacy in stimulating erythropoiesis is dose dependent and differs according to the patient's disease and nutritional status. Apart from the generally recommended subcutaneous (sc) route of administration, intravenous (iv) and intraperitoneal routes have been used to administer EPO. With the increasing reports of pure red cell aplasia (PRCA) with SC route, the Department of Health in UK recommends a change EPO-alpha administration from subcutaneous to intravenous route. However, sc route has several advantages over iv route like ease of administration, non-requirement of venous access, and up to 30 percent reduction in weekly rhEPO dose on hemodialysis patients. Although patients on peritoneal dialysis may benefit from intraperitoneal route, a larger dose may be required to maintain the same hemoglobin level. Outside the uremic setting, both iv and sc rhEPO have been employed, but the sc route was used in the majority of the studies. However, there have been no studies to compare the efficacy of these routes. rhEPO can be given once, twice, or thrice weekly depending on the clinical status of the patient as per the level of hemoglobin maintained. EPO should be used carefully according to guidelines as unsolicited use can result in serious adverse effects. Because of its capacity to improve oxygenation, it has been abused by athletes participating in endurance sports and detecting this has proved to be a challenge [12242].

Stimulation of erythropoiesis is one of the most efficient ways of doping. This type of doping is advantageous for aerobic physical exercise and of particular interest to endurance athletes. Erythropoiesis, which takes place in bone marrow, is under the control of EPO, a hormone secreted primarily by the kidneys when the arterial oxygen tension decreases. In certain pathological disorders, such as chronic renal failure, the production of EPO is insufficient and results in anemia. The pharmaceutical industry has, thus, been very interested in developing drugs that stimulate erythropoiesis. With this aim, various strategies have been, and continue to be, envisaged, giving rise to an expanding range of drugs that are good candidates for doping. Anti-doping control has had to deal with this situation by developing appropriate methods for their detection. One article presented an overview of both the drugs and the corresponding methods of detection, and thus follows a roughly chronological order [12243].

Among the peptide hormone-derived therapeutics, ESAs and predominantly erythropoietin (EPO) have been subject of extensive studies concerning improved or newly established traceability as well as pure/fundamental research elucidating and later exploiting the small but significant differences between the natural human EPO and its recombinant analogs. In order to probe for the capability of routine doping control methodologies, i.e. isoelectric focusing polyacrylamide gel electrophoresis (IEF-PAGE) and sodium dodecyl sulfate-PAGE (SDS-PAGE), to detect epoetin kappa in human urine, an administration study was conducted. Three male volunteers received 3000 IU intravenously and urine samples were monitored for up to 48 h. Both approaches (IEF- and SDS-PAGE) allowed for the detection of epoetin kappa with SDS-PAGE being superior in terms of the detection window (24 h). While the benefits of SDS-PAGE concerning EPO analyses have been recognized several years
ago, its utility for third-generation EPO drugs was established only recently with the introduction of sarcosyl-PAGE (also referred to as SAR-PAGE). Using sarcosyl instead of SDS, enhanced antibody-antigen binding as well as improved band focusing was accomplished, which allowed for a significantly lowered detection limit of the prohibited compound in plasma and urine sports drug testing samples. The different electrophoretic behaviors of recombinant human EPO products and their natural analogs in serum and urine, which are essential to all routinely applied doping control methods, have been attributed to minor but analytically relevant modifications within the glycosidic moiety. Consequently, elucidating the nature of these modifications was of particular interest to research groups.

Focusing on recombinant human EPO, glycopeptides derived from enzymatic digests with trypsin and Glu-C were separated by capillary electrophoresis and analyzed by means of ESI-TOF MS. Here, comprehensive glycoform analysis was conducted for both N- and O-glycopeptides, allowing (among others) the identification of a sulfated sialoform of N83 in recombinant human EPO. As dictated by the employed analytical technique, only accurate masses (errors varied up to 30 ppm) of the protonated intact analytes, as well as respective adduct ions, served for characterization purposes. Following a different strategy, namely sequential deglycosylation by exoglycosidase treatment and subsequent SDS-PAGE analysis, human urinary and serum EPO as well as recombinant EPO were investigated concerning their glycosylation pattern. While EPO from all three sources was amenable to degradation by b-N-acetylglucosaminidase, the subsequent incubation with alpha- or betamannosidase did affect only recombinant EPO, demonstrating a distinct difference in the glycosidic moiety potentially offering a new angle for future doping control assays. Aiming at a fast alternative to conventional EPO doping control tests, the utility of the recently introduced membrane-assisted isoform immunoassay (MAIIA) combined with wheat germ agglutinin (WGA)-based chromatographic separation of recombinant as well as human urinary and serum EPO was evaluated. Employing immuno-magnetic beads-based extraction (IMBE) combined with capillary zone electrophoresis and deep UV laser-induced fluorescence detection, the highly resolved glycoform profiling of EPO was accomplished for pharmaceutical preparations. The approach can support studies concerning isoform composition studies in recombinant EPO products but the sensitivity was not found sufficient for the analysis of urine or serum and the method considered prone to matrix interference; hence, an introduction into sports drug testing programs is not expected [12017].

Due to the complexity of detecting and differentiating recombinant EPO from its natural analog in human urine or blood, alternative indirect approaches have been subject of various recent studies. One of these elucidated the impact of EPO administration on circulating and/or renally eliminated microRNAs (miRNA) and their potential as long-term biomarkers for ESA doping. Following the intravenous or subcutaneous administration of Mircera (200 mg), plasma samples were collected for up to 27 days and analyzed for miRNA affected in a statistically significant manner. Among a variety of marker candidates, miR-144 was the most influenced parameter, which was significantly elevated 27 days post-administration of Mircera and thus possibly representing a valuable alternative marker for illicitly administered ESAs. These preliminary findings will require in-depth elucidation and validation but possess the potential for expanded complementary doping control assays. Hepcidin has been considered as another potential marker for EPO administration due to its decreased serum concentration following subcutaneous EPO injections. Whether the effect also prevails upon i.v. applications of 50 IU/kg bodyweight was subject of another study. Despite significantly elevated (4 h post administration) and subsequently decreased (24 h post administration) serum hepcidin levels, the dynamics and variability of the marker essentially excluded its utility as indicator for doping control purposes [12017].

Erythropoietin (EPO) is the main hormonal regulator of red blood cell production. Recombinant EPO has become the leading drug for treatment of anaemia from a variety of
Erythropoietin (EPO) is the main hormonal regulator of red blood cell production. Recombinant EPO has become the leading drug for treatment of anaemia from a variety of causes; however, it is sometimes misused in sport with the aim of improving performance and endurance. This paper presents an introductory overview of EPO, its receptor, and a variety of recombinant human EPOs/erythropoiesis stimulating agents (ESAs) available on the market (e.g. epoetins and their long acting analogs – darbepoetin alfa and continuous erythropoiesis receptor activator). Recent efforts to improve on EPO's pharmaceutical properties and to develop novel replacement products are also presented. In most cases, these efforts have emphasized a reduction in frequency of injections or complete elimination of intravenous or subcutaneous injections of the hormone (biosimilars, EPO mimetic peptides, fusion proteins, endogenous EPO gene activators and gene doping). Isoelectric focusing (IEF) combined with double immunoblotting can detect the subtle differences in glycosylation/sialylation, enabling differentiation among endogenous and recombinant EPO analogues. This method, using the highly sensitive anti-EPO monoclonal antibody AE7A5, has been accepted internationally as one of the methods for detecting misuse of ESAs in sport [12240].

Although the concept of a humoral regulator of erythropoiesis was introduced more than 100 years ago, its existence was first firmly established a little more than 50 years ago. One review briefly describes the historical development of information about erythropoietin. It then describes our current understanding of where erythropoietin is produced; the factors that regulate its rate of production; how erythropoietin acts at the cellular level to stimulate erythropoiesis; and its role in the regulation of the rate of erythropoiesis. Finally, it discusses the clinical uses of erythropoietin in the diagnosis and therapy of hematopoietic diseases [09157].

A review covered landmarks or milestones in the development of erythropoietin (EPO). Thirty-nine landmark advances have been identified, which cover the period 1863-2003. Several reports are included that directly support these original landmark advances. The areas of EPO research updated are: sites of production; purification, assay and standardization; regulation; action; use in anemias; extraerythropoietic actions; adverse effects; and blood doping. The new reports on the use of EPO in the therapy of myocardial infarction; stroke and other neurological diseases; diabetic retinopathy and other retinal diseases are also covered [10467].

Erythropoietin. EPO, is a 165 amino acid, 34 kDa glycoprotein hormone produced by the kidney in response to low blood oxygenation which causes an increase in circulating red blood cells by stimulating the division and differentiation of erythroid progenitor cells in the
bone marrow. EPO consists of various isoforms which are made up of different complex sugars that are linked by a single polypeptide chain. The carbohydrate moieties make up 40 percent of its molecular weight. Epoetin, the recombinant human erythropoietin (rhEPO) was approved by the Food and Drug Administration for clinical use in 1989. The various EPO pharmaceutical preparations are based on differences in their carbohydrate moieties [07002].

To overcome the limitation of the currently adopted direct method to detect recombinant Human Erythropoietin (rHuEpo) abuse in sport, indirect analysis of blood parameters are increasingly used as part of the anti-doping strategies. The aim of one work was to identify whether immunophenotype modifications on erythroid cells may be indicative of previous rHuEPO administration. The study was conducted on dialyzed patients under treatment with rHuEPO (DPT). Dialyzed patients without rHuEPO therapy (DP) and volunteer donors (H) were used as controls. The analysis of erythroid cells immunophenotype, performed using a multiparametric flow cytometry technique, showed a peculiar pattern of CD71 expression following rHuEPO treatment. In particular CD71 showed an increased expression in mature and intermediate reticulocytes and a surprisingly decreased expression in immature reticulocytes. In conclusion, the analysis of reticulocyte maturation stages with TO/CD71 double staining may be considered as a valid alternative indirect method for the detection of rHuEPO abuse [07115].

Endogenous and exogenous erythropoietin (EPO) present in urine can be distinguished according to their isoelectric profiles. This methodology requires urine samples to be concentrated about 200 to 1000 times with manipulations that should remove most of the cells occurring in the original sample. In one study, it was tried to obtain DNA profiles from 10 ultrafiltered urines (retentates) in order to evaluate whether a formal genetic identification was technically feasible. No nuclear DNA profiles could be established from retentates, despite 34 PCR-cycles amplifications. Contrastingly, mitochondrial DNA (mtDNA) profiles were obtained for 9 out of the 10 retentates. Apart from some particularities, retentate mtDNA profiles were all distinct and matched mtDNA profiles of corresponding reference samples [07116].

Epo is a naturally occurring hormone. Its existence was suspected almost a century ago by Carnot and Deflandre, who postulated that a humoral factor, which they called “hemopoietine,” regulates RBC production. The definitive existence of Epo was demonstrated by Krumdieck in 1943. The sequence encoding for human Epo is located on chromosome 7. Human Epo, a 165-amino acid glycoprotein with a molecular weight of 34 kDa, is derived from a 193-amino acid transcript that has been modified by the cleavage of a 27-amino acid leader sequence and the loss of the carboxyl-terminal arginine by post-translational processing by an intracellular carboxypeptidase. After synthesis, N-linked carbohydrate chains with terminal sialic acids prevent the immediate hepatic clearance of the molecule. Despite few sequence homologies, the tertiary structure of Epo is similar to that of other growth hormones and cytokines such as growth hormone, prolactin, interleukin 6, and granulocyte colony-stimulating factor. The human erythropoietin gene was originally cloned in the mid 1980s, and rHuEpo was first approved for marketing in France in 1988. Its therapeutic use for the treatment of several forms of chronic anemia was shown to be effective and safe. Thus far, several mammalian Epo genes have been cloned, sequenced, and expressed. Epo is highly conserved among mammals, and there is a high degree of sequence homology in the coding region of the mature secreted protein. More than 63 percent of the molecule is composed of invariant amino acids (106 residues); human and monkey Epos display 94 percent and 91 percent sequence homology in nucleotides and amino acid composition, respectively. In contrast, human and mouse Epos are 76 percent identical in nucleotide sequence and 80 percent identical in amino acid sequence. There is also increasing evidence that many non-hematopoietic organs and tissues, such as stem
Genetically engineered erythropoietin (Epo) has been systematically administered to anemic chronic renal failure patients for the past 15 years. By the mid-1990s, it had also become clear that Epo was the drug of choice among endurance athletes seeking to improve performance. From a technical perspective, Epo has several advantages over blood transfusion, including no complex logistically challenging maneuvers such as blood withdrawal, storage, and reinfusion. In addition, there is no decay in performance or training after a period of blood withdrawal, and there is limited “detectability,” as Epo is a naturally occurring peptide hormone. A considerable amount of clinical evidence supported the use of rHuEpo for doping purposes, as it provided significant erythropoietic and ergogenic benefits due to substantial increases in hemoglobin, hematocrit, maximal oxygen uptake, and exercise endurance time. As testing strategies for Epo are as important as the development of reliable analytical procedures, detailed knowledge of the pharmacokinetic characteristics of rHuEpo is essential both for interpreting changes observed in indirect markers of administration and for planning suitable methods of testing for direct identification. Following subcutaneous administration, a “flip-flop” phenomenon can be observed; the pharmacokinetics appear to be linear from 50 to 1000 U/kg, but not for a lower dose of 10 U/kg. The mean half-life of 50 IU/kg daily repeated subcutaneous administration of rHuEpo is about 36 h, and the total clearance is 17 ml/h/kg. Remarkably, the total clearance appears nearly three times higher in athletes than in untrained subjects (6.5 ml/h/kg). The half-life is five times longer following subcutaneous than intravenous administration (from 4 to 7 h). The administration of rHuEpo is typically accompanied by a delayed increase in hemoglobin (up to 9.6 %), hematocrit (up to 8.3 %), reticulocytes, macrocytes, serum Epo, and soluble transferrin receptor (sTfr) concentrations. The increase of these markers becomes significant from the third to the tenth day following initial administration, and it is always followed by a negative and transitory feedback loop of endogenous Epo production, which can be interpreted as an indirect marker of rHuEpo administration. In clinical practice, rHuEpo administration produces a remarkable acceleration of the dynamic response of maximal oxygen uptake to submaximal exercise, increasing exercise capacity [10353].

Several variants of rHuEpo are currently available. The term “erythropoietin” conventionally refers to rHuEpo preparations that have an amino acid sequence homologous to that of the naturally occurring hormone, whereas the appropriate Greek letters, “alpha,” “beta,” “gamma,” and “delta” designate preparations that differ in composition and/or the nature of the carbohydrate moieties. Epoetin alfa (Epogen®, Eprex®, Epoxitin®, Erypo®, Espo®, Globuren®, Procrit®) and epoetin beta (Epogen®, Marogen®, NeoRecormon®, Recormon®), which are produced by transfected Chinese hamster ovary cells and are nearly biochemically and immunologically identical to their naturally occurring counterpart, display similar molecular and pharmacokinetic characteristics, although the latter has a higher molecular weight, a lower number of sialylated glycan residues, and, possibly, slight pharmacokinetic advantages, such as a longer terminal elimination half-life. Epoetin beta has been the subject of studies aimed at proving efficacy with a reduced administration frequency, but results are rather controversial. Epoetin gamma is produced in a different host cell than the other erythropoietic agents; therefore, its glycosylation pattern and pharmacokinetics are different. Small-scale clinical studies found epoetin gamma to be slightly more biologically active than epoetin alfa. Epoetin delta (Dynepo®) is a recently approved rHuEpo produced by human cells engineered to transcribe and translate the Epo gene under the control of a newly introduced regulatory DNA sequence. Epoetin delta has the same amino acid sequence and glycosylation pattern as human Epo. Because it has become available recently, only limited clinical data are available. The pharmacodynamic response to two to three times weekly 40 to 100 IU/kg epoetin delta administration appears to be consistent with known Epo cells; the embryo proper, including its developing nervous system; brain; uterus; and ovary express Epo [10353].
pharmacological activity and includes a dose-dependent increase in hematocrit (between 0.12 and 0.18 %/day), hemoglobin, reticulocytes, and RBCs for at least 3 to 4 weeks, followed by a decline toward baseline values with exposure cessation. A tendency for efficacy to fall with time, which may be associated with the development of neutralizing antibodies or tolerance, has been observed. The mean half-life of subcutaneous administration is 18 to 20 h, compared to 7 to 12 h following intravenous injection [10353].

As an increase in the carbohydrate content of Epo results in a longer plasma half-life and enhanced biological activity, more effective analogs have been developed. Darbepoetin alfa, a novel erythropoiesis-stimulating protein or NESP (Aranesp®), is a glycosylation analog of rHuEPO that has been synthesized using DNA technology. Its molecular weight is 38.5 kDa, and its total carbohydrate content is 52 percent. The amino acid sequence of NESP differs from that of native human Epo at five positions (Ala30Asn, His32Thr, Pro87Val, Trp88Asn, and Pro90Thr); this allows the attachment of additional oligosaccharides at asparagine residue positions 30 and 88. Therefore, NESP contains five N-linked oligosaccharide chains and 22 sialic acid residues, whereas native Epo contains three oligosaccharide chains and 14 sialic acid residues. NESP binds to the Epo receptor in the same fashion as native Epo and induces intracellular signaling. In comparing the pharmacokinetics of NESP and rHuEPO, the mean half-life for NESP is nearly two to three times longer than that of rHuEPO (25 and 49 h when administered intravenously and subcutaneously, respectively). Despite a similar volume of distribution of nearby 50 ml/kg, the clearance of NESP is significantly reduced as compared to that of rHuEPO (1.6 ± 0.3 versus 4.0 ± 0.3 ml/h/kg). Dosage requirements of darbepoetin do not differ between the intravenous and subcutaneous routes of administration. The less frequent administration of darbepoetin alfa in comparison to the other epoetins may reduce drug costs in the long term, but the variability in dosage or dosage frequency required within a single patient is much higher [10353].

CERA (continuous erythropoietin receptor activator) is the latest erythropoiesis-stimulating protein that has become commercially available. Administered at a considerably less frequent dosing (once every 3 or 4 weeks), CERA induces enhanced and sustained erythropoietic effects through continuous modulated stimulation of erythropoiesis and offers greater flexibility and convenience as compared to other conventional blood-boosting substances. Postulated mechanisms of action include a weaker binding to and a more rapid dissociation from the Epo receptor and an extended half-life in plasma, which has been reported to be seven-fold greater than that of standard epoetins. At doses of 5 to 8 microg/kg, CERA increases reticulocytes and hemoglobin by 262 percent and 16 to 23 g/L (over 50 % of patients had a response ≥ 20 g/L), respectively; these levels were maintained over the next 12 weeks. Levels of sTfr also increase in a dose-dependent manner, whereas serum ferritin and serum iron levels decrease, reaching a nadir 5 to 10 days after administration before returning to baseline. The mean elimination half-life is 133 to 137 h for both intravenous and subcutaneous administration. Side effects of CERA therapy are generally mild, and no serious adverse events have been reported thus far. CERA is currently in phase III clinical trials [10353].

Approximately 90 percent of endogenous Epo is produced by the kidney in response to tissue oxygen sensors that register oxygen depletion. The recent discovery of a novel family of proteins called “hypoxia inducible factors” (HIF) has increased our understanding of the complex mechanism of response to hypoxia and Epo production that occurs when the human body has to deal with increased oxygen demand, such as in hard-working muscles. Epo is the paradigm of oxygen-regulated genes controlled by transcription factor HIF-1, well recognized as the key regulator of cellular and systemic oxygen homeostasis. Despite its clinical effectiveness in selected clinical settings, concern has been expressed about complications and side effects of rHuEpo therapy. In both controlled and uncontrolled clinical
studies, the most frequent adverse events per 100 patient-years of exposure to epoetin delta were hypotension, muscle cramps, upper respiratory infections, headache, thrombosis, and hypertension. An important concern is that the cardiovascular system of an athlete misusing erythropoiesis-stimulating proteins may be in jeopardy. In some clinical trials, thrombotic events such as myocardial infarction, cerebrovascular disease, transient ischemic attack, and venous thromboembolism occurred at a rate of 0.04 events per patient-year. In addition, there have been occasional reports of serious or unusual thromboembolic events, including migratory thrombophlebitis, microvascular thrombosis, and thrombosis of the cerebral sinus, retinal artery, and temporal and renal veins. Endothelial activation, alterations of blood rheology (namely, increased blood viscosity), increased systolic blood pressure at submaximal exercise, and platelet reactivity were acknowledged as important mechanisms involved in the thrombotic potential of Epo. Although an unequivocal causal relationship with rHuEpo therapy has not been established yet, polycythemic conditions characterized by hematocrit values exceeding 60 percent, as were anecdotally achieved in the mid-1990s when rHuEpo abuse was largely uncontrolled, when compounded by dehydration, may have predisposed athletes to thromboembolic complications. Far more threatening is the onset of red cell aplasia, a rare congenital or acquired condition characterized by an arrest in RBC production. A final concern arises from the evidence that the Epo receptor pathway may be somehow involved in the growth, viability, and angiogenesis of malignant tumors. Increasing evidence has accumulated to show that Epo has pleotropic effects beyond regulation of the RBC mass. In the embryo, Epo acts as a major regulator of vascular formation and organ growth, and Epo receptors are found in almost every embryonic tissue.

As exogenous recombinant Epo is less negatively charged than the naturally occurring hormone, isoelectric focusing has emerged as a reliable approach for direct detection of rHuEpo and analogs in urine. Electropherograms from urinary rHuEpo differ substantially from those of endogenous Epo, as the former produce four or five bands in the basic region, whereas the latter gives rise to up to 14 bands that overlap with and are parallel to those of rHuEpo in the basic region but that are also clustered in the acidic region. A preliminary electrophoretic technique for discriminating rHuEpo from its endogenous counterpart in urine was described in 1995. The method was improved by using isoelectric focusing that reduced the non-specific binding traditionally accompanying immunoblotting. This isoelectric focusing technique detects rHuEpo in urine samples collected 3 days after nine doses of epoetin alfa with both 100 percent sensitivity and specificity. However, 7 days after the last dose, the overall sensitivity of the techniques falls to 50 percent. The indirect approach, based on multiple markers of enhanced erythropoiesis, appears to be a valid and reliable strategy when complemented by the urine confirmatory test. The combination of blood and urine tests represented the strategy implemented by the International Olympic Committee for detecting rHuEpo misuse at the Sydney Olympics. However, in analogy with other performance-enhancing drugs, during-competition testing has led to much wasted testing effort, as the pharmacodynamic properties of rHuEpo and its analogs discourage misuse near or at the time of competition. Thus, direct testing methods, such as the rHuEpo urine test or the ON-model, will likely fail due to the almost complete elimination of rHuEpo before the test and the return to baseline of most biochemical parameters of erythropoiesis, unless international sporting federations use the information gathered to assist in targeted out-of-competition testing. However, as the performance-enhancing effect is greater than variation of hematologic changes and persistence of rHuEpo in blood, the indirect OFF model, based on the expression of specific genes following rHuEpo administration, should partially overcome this limitation. Fortunately, Epo analogs appear to be more easily detectable, and some athletes were sanctioned for use of NESP at the 2002 Winter Olympics. Most techniques measure the increased immunoactivity of NESP in serum following desialylation with neuraminidase, as measured by conventional immunoassays for Epo. The method requires a
small amount of blood, is simple to perform, is reliable (up to 100% sensitivity), and allows
detection of NESP from 2 to 14 days after the last injection [10353].

A method was described to isolate human erythropoietin (hEPO) from plasma using an EPO-
specific immunoaffinity micro well plate (IAP). The operating conditions of the method
(binding, blocking and elution) were optimised to avoid isoform discrimination and cross-
contamination with other glycoproteins. The overall hEPO recovery was about 56 percent
and significant clean-up for plasmatic hEPO was achieved. Polyvinylpyrrolidone (PVP) was
used as a blocking reagent and elution took place at pH 11.0. Under these conditions all
isoforms from recombinant human EPOs (rhEPOs) and analogues were uniformly recovered
guaranteeing lack of discrimination. The resulting procedure allowed isolating erythropoietin
from plasma in conditions amenable to hEPO analysis by other techniques such as SDS-
PAGE or IEF. Moreover, avoiding contamination with other glycosylated material allowed the
identification in human plasma samples of the non-human N-glycolyl-neuraminic acid
(Neu5Gc) using HPLC-FLD. Neu5Gc is present as 1-2 percent of the sialic acid content in
rhEPO so this approach could be used to unequivocally detect abuse of rhEPOs or
analogues as part of the doping control [10358].

Numerous factors involved in general homeostasis are able to modulate ventilation.
Classically, this comprises several kinds of molecules, including neurotransmitters and
steroids that are necessary for fine tuning ventilation under different conditions such as
sleep, exercise, and acclimatization to high altitude. Recently, however, it has been found
that erythropoietin, the main regulator of red blood cell production, influences both central
(brainstem) and peripheral (carotid bodies) respiratory centers when the organism is
exposed to hypoxic conditions [09158].

Erythropoietin is a naturally occurring hormone produced by the kidney that stimulates red
blood cell production in the bone marrow in response to low circulating oxygen levels. It was
not until 1977 that it was identified and extracted from human urine. This was concurrent with
the development of recombinant DNA technology, and in 1989 Epogen® was released in the
United States and approved for the treatment of anemia. Procrit® was licensed in 1991 for
the treatment of chemotherapy-induced anemia. European formulations include Aranesp®,
Eprex® and NeoRecormon®. Erythropoietin used for medical treatments is administered by
intravenous or subcutaneous injection [08006].

Endurance can be dramatically enhanced by artificially elevating the red blood cell mass, as
seen in the “blood-doping” strategies used by some athletes. By reinfusing previously stored
red blood cells, or by stimulating erythropoiesis with the use of synthetic erythropoietin,
known as EPO, performance can be surreptitiously increased. Detecting such manipulation
is not easy. Erythropoietin products leave the system quickly, and autologous transfusions of
blood cells are difficult to identify. Attempts to identify elevated hematocrit levels in the hours
before competition led to the masking of such practices with intravenous hemodilution
techniques. What has not gone unnoticed is the catastrophic loss of life attributed to
erythropoietin in many sports – particularly cycling, which many have come to regard as a
veritable incubator of doping techniques [08218, 08219].

Erythropoietin abuse in sport was believed to start as soon as the drug was available as a
replacement for the more complex and dangerous doping technique referred to as blood
doping [011]. When a network of blood transfusion for doping purposes was detected in
Spain in 2006, it led to the seizure of samples of whole blood, plasma, and red blood cell
concentrates for autologous blood transfusion, allegedly belonging to elite sportsmen from
different countries. High (supra-physiological) concentrations of erythropoietin were found in
some plasma samples. The finding of rEPO in samples connected to a blood transfusion
doping network shows that to administer recombinant erythropoietin prior to blood withdrawal and storage may be current practice also for doping [08220].

Erythropoietin leads to the production of red blood cells. Since these carry oxygen to active muscles, one would consider enhanced endurance performance because of the additional flux of oxygen. EPO is a circulating glycosylated protein hormone that is the principal regulator of erythropoiesis. It is produced primarily by the kidney inversely related to the concentration of O$_2$ in the blood. Following administration, there is a direct relationship between haemoglobin levels and increased performance following administration of rHuEPO in rats and humans. Methods used in doping include hypoxia and hypoxia-mimetics. One such method is to train at altitude; however, one cannot necessarily train as hard as at lower altitude because of hypoxic-mediated fatigue. Variations on this theme include living at altitude and training at sea level or sleeping in a tent or chamber with diminished oxygen tension (at lower altitude) and training at the same elevation. These methods are not considered doping [10001].

Erythropoietin (EPO), a glycoprotein hormone, stimulates the growth of red blood cells and as a consequence it increases tissue oxygenation. This performance enhancing effect is responsible for the ban of erythropoietin in sports since 1990. Especially its recombinant synthesis led to the abuse of this hormone, predominantly in endurance sports. The analytical differentiation of endogenously produced erythropoietin from its recombinant counterpart by using isoelectric focusing and double blotting is a milestone in the detection of doping with recombinant erythropoietin. However, various analogous of the initial recombinant products, not always easily detectable by the standard IEF-method, necessitate the development of analytical alternatives for the detection of EPO doping [10114].

rHuEPO and its follow-on biological relatives can provide an effective mechanism to stimulate erythropoiesis as noted above; however, the baseline hematocrit increases and may rise even more to dangerous levels, likely due to dehydration, in athletes during and after training and competition. The rheology of blood changes exponentially as the hematocrit rises above 55 percent and accelerates even more rapidly as it rise above 60 percent. Deaths in competitive cyclists have been directly linked to changes in the flow properties of blood, as the hematocrit rises. There are no studies of rHuEPO, or its related proteins in child or adolescent athletes, but theoretically the responses should be no different from older adolescents or young adults. The major issues are those that relate to increased hematocrit- sluggish blood flow in the small vessels of critical organs and pulmonary emboli [10001].

Haemoglobin concentration ([Hb]), reticulocyte percentage (retic%) and OFF(hr score) are well-implemented screening tools to determine potential recombinant human erythropoietin (rHuEpo) abuse in athletes. Recently, the International Cycling Union implemented the OFF(z score) and the Hb(z score) in their anti-doping testing programme. The aim of one study was to evaluate the sensitivity of these indirect screening methods. Twenty-four human subjects divided into three groups with eight subjects each were injected with rHuEpo. Group 1 and group 2 received rHuEpo for a 4-week period with 2 weeks of "boosting" followed by 2 weeks of "maintenance" and a wash-out period of 3 weeks. Group 3 received rHuEpo for a 10-week period (boost in 3 weeks; maintenance in 7 weeks; wash out in 1 week). Three, seven and eight of the 24 volunteers exceeded the cut-off limits for OFF(hr score), [Hb] and retic%, respectively. One subject from group 1, nobody from group 2, and seven subjects from group 3 exceeded the cut-off limit for Hb(z score.) In total, ten subjects exceeded the cut-off limit for the OFF(z score); two subjects from group 1, two subjects from group 2 and six subjects from group 3. In total, indirect screening methods were able to indicate rHuEpo injections in 58 percent of subjects, i.e. 42 percent of our rHuEpo-injected subjects were not
detected. It should be emphasised that the test frequency in real world anti-doping is far less than the present study, and hence the detection rate will be lower [10115].

Stimulation of erythropoiesis by the third-generation erythropoietin drug CERA, a pegylated derivative of epoetin beta, has provided valuable therapeutic benefits to patients suffering from renal anemia, but has also rapidly found application as an illicit performance-enhancing strategy in endurance sports. It was presented a novel method for selective determination of CERA in serum, based on polyethylene glycol precipitation followed by a commercial homogeneous immunoassay. The developed method was highly discriminating between serum samples from CERA-treated patients and control subjects, as the covalently linked polyethylene glycol chain in CERA strongly enhanced the solubility of the protein in a polyethylene glycol-containing medium. Intravenous administration of CERA could be detected for several weeks in the majority of subjects tested. This assay outperforms the currently available CERA detection methods in terms of simplicity, convenience, cost, and throughput, making it ideal as a screening tool for doping control [10116].

The tampering of athlete's urine samples by the addition of proteolytic enzymes during the doping control sampling procedure was reported recently. The aim of one study was the application of a stabilization mixture in urine samples to chemically inactivate proteolytic enzymes and improve the electrophoretic signal of erythropoietin (EPO) in human urine. The stabilization mixture applied was a combination of antibiotics, antimycotic substances and protease inhibitors. A series of incubation experiments were conducted under controlled conditions in the presence and absence of the stabilization mixture in urine aliquots spiked with six proteases. Two different analytical techniques were applied for the qualitative and quantitative EPO measurement: isoelectric focusing (IEF) and chemiluminescent immunoassay respectively. The addition of the chemical stabilization mixture into urine aliquots substantially improved EPO detection in the presence of proteolytic enzymes following incubation at 37 degrees C or storage at -20 degrees C. The results of this study indicated that the stabilization of urine prior to the sample collection procedure with the proposed chemical mixture might prove to be a useful tool for the preservation of anti-doping samples [10117].

A screening method able to differentiate recombinant human erythropoietins (rhEPOs) and analogues like CERA from human urinary erythropoietin (uhEPO) is described. The method is based on the discrimination between isoforms observed when the protein is eluted under acidic followed by basic conditions from immunoaffinity microtiter wells. From a comparison with the complex IEF protocol currently applied in anti-doping analysis, the newly developed assay procedure is amenable to wide screening application and presents good resolving power between rhEPOs and uhEPO [10118].

Erythropoietin (EPO) is an endogenous hormone produced primarily by the kidney which controls the production of erythrocytes. The main stimulus to production is low tissue oxygen (hypoxia) and EPO triggers the formation of red blood cells by binding to a receptor on erythroid progenitor target cells. Alteration in the EPO regulatory system produces a change in circulating EPO in a variety of disease states, such as renal anaemia and polycythaemia. The availability of recombinant EPO in the 1980s transformed the treatment of anaemia, particularly anaemia of end stage renal disease, and led to the development of more sensitive and specific assays for the measurement of EPO. There are more widespread uses for EPO and preliminary studies indicate that EPO may be useful as a neuroprotective agent by reducing inflammation near the site of injury. The use of EPO to boost endurance in athletes has attracted unwanted publicity, although analytical techniques are now available that can differentiate between endogenous and recombinant EPO. Different types of erythropoietic agents have been developed with a longer plasma half-life and the ability to
In recent years the use of erythropoietin has exploded, and the anemia of patients with chronic renal failure has been practically resolved with the administration of rHuEpo (recombinant human, Erythropoietin). However, as a result of an intense commercial campaign, strong therapies with this growth hormone, prescribed to achieve surprising sporting performances, got athletes to run the risk of thrombosis and vascular accidents because of red blood cells increase. Erythropoietin represents a significant subject of research. In fact, besides the ability of stimulating erythrocyte production, it has many pleiotropic effects. Several studies allow the assertion that EPO, in different concentrations, has protective effects mainly on central nervous system and cardiovascular system through various mechanisms, among which a key role seems to be held by the ability to stimulate angiogenesis. The consequent problem is that anaemia therapy with rHuEpo in patients with cancer may accelerate the progression of neoplastic disease by promoting tumour angiogenesis and, thus, metastasization. The study of angiogenic process in tumours led to the synthesis of drugs that, blocking VEGF, exert an anti-angiogenic action, contrasting cancer spread. However, benefits are relatively modest. Is erythropoietin perhaps the further angiogenic hormone to block in tumour pathology? Therefore, Epo plays a role in regenerative medicine since it intervenes in a persistent natural regenerative activity of humans: angiogenesis. The understanding of the regeneration mechanisms of complex structures in the adult salamander has opened original lines of research. Regenerative medicine tries to develop therapeutic pathways through the stimulation of natural regenerative processes in humans [09159].

**Physiology**

In addition to its function as a regulator of hematopoiesis, the cytokine erythropoietin (Epo) initiates adaptive cellular responses to both moderate environmental challenges and tissue damaging insults in various non-hematopoietic mammalian tissues. Epo's neuroprotective and neuroregenerative functions mediated through janus kinases (JAK)/signal transducers and activators of transcription (STAT) transduction pathways and regulation of Epo and Epo receptor expression in the nervous system by hypoxia inducible factor (HIF) have been documented in a variety of in vitro and in vivo studies and homologs of the human Epo gene are present in fish, amphibians and mammals. One study reproduced the hallmarks of Epo-mediated mammalian neuroprotection in the grasshopper nervous system. Recombinant human Epo (rhEpo) increases the survival of dissociated grasshopper brain neurons under normoxic and hypoxic conditions and promotes the regeneration of neurites in vitro. In addition, reestablishment of sound source localization after unilateral tympanic nerve crush injury was accelerated and more complete after application of rhEpo, demonstrating in vivo support of auditory receptor cell axon regeneration. Immunoblots of central nervous tissue extracts from mouse, grasshopper, crayfish and leech labeled protein bands of about 38 kDa, fitting to the molecular weight of Epo reported in earlier studies. These results indicate that a ligand/receptor system that shares structural and functional similarities with mammalian Epo and Epo receptor exerts neuroprotective and neuroregenerative effects in insects. With both upstream (HIF system) and downstream (JAK/STAT pathway) elements of the mammalian Epo system being present in insects and other invertebrates, Epo-like signaling involved in tissue protection appears to be an ancient beneficial function shared by vertebrates and invertebrates [11338].

Erythropoietin (EPO) is a 30 400 molecular weight glycoprotein hormone produced mainly in the kidney, and also in the liver (<10 %) and, in very little quantities, in the brain. The
physiological stimulus for EPO production is tissue hypoxia, which, in the large majority of instances, is directly related to the number of circulating erythrocytes. Thus, EPO and erythropoiesis are part of a negative feedback cycle that keeps tissue oxygen delivery within a narrow range by controlling the number of erythrocytes circulating in the blood. In a normal individual, any loss of erythrocytes, such as by bleeding or haemolysis, decreases delivery of oxygen to the tissues. When this tissue hypoxia is sensed by cells in the kidney and liver capable of producing EPO, they produce and secrete EPO into the plasma. EPO is carried to the bone marrow, where it binds to specific cell surface receptors on its target cells: the CFU-E, pro-erythroblasts, and basophilic erythroblasts. The binding of EPO by these cells increases their ability to survive and reach the reticulocyte stage and thereby contribute to the population of circulating erythrocytes. The increased numbers of circulating erythrocytes in turn deliver more oxygen to the tissues. This increased oxygen delivery is sensed by the EPO producing cells, which then reduce EPO production so that the normal steady state number of erythrocytes is restored [06145].

Effects of hypoxia
The response of the kidneys to hypoxia has been shown to be exponential; that is, in individuals with a normal capacity to produce EPO, a linear decline in haematocrit is accompanied by an exponential increase in plasma EPO levels. This exponential increase is not based on the release of stored, preformed EPO. Rather, the hypoxia is sensed by an intracellular molecule that interacts with an enhancer element of the Epo gene and thereby induces transcription of the gene. The increase in EPO production in the hypoxic kidney is achieved by recruitment of more cells to produce EPO. The EPO producing cells of the kidney are a minor subset of cortical interstitial cells. Under normal conditions, only a few scattered cells produce EPO. When a threshold level of hypoxia is achieved, the cells capable of producing EPO do so at a maximal rate. The greater the areas of renal cortex in which the hypoxia threshold is met, the greater the number of cells that produce EPO [06145].

Mechanism of action of erythropoietin
In the bone marrow, EPO binds to receptors displayed on the cell surface of CFU-E, proerythroblasts, and basophilic erythroblasts. The mature EPO receptor, with a molecular weight of approximately 72,000, is a transmembrane glycoprotein, a member of a much larger family of receptors of cytokines and haematopoietic growth factors. The effect of EPO binding to its receptor, in terms of cellular physiology, has been shown to be the prevention of programmed cell death (apoptosis). In multiple systems of erythropoiesis, EPO has been shown to be a survival factor for the erythroid cells in the later stages of differentiation from the CFU-E through basophilic erythroblasts. Although an effect of EPO on mitosis has been reported for BFU-E and an EPO dependent cell line, EPO is required only for CFU-E and later stages, and apoptosis appears to result when EPO signalling cannot occur [06145].

Effects of hypoxia
The response of the kidneys to hypoxia has been shown to be exponential; that is, in individuals with a normal capacity to produce EPO, a linear decline in haematocrit is accompanied by an exponential increase in plasma EPO levels. This exponential increase is not based on the release of stored, preformed EPO. Rather, the hypoxia is sensed by an intracellular molecule that interacts with an enhancer element of the Epo gene and thereby induces transcription of the gene. The increase in EPO production in the hypoxic kidney is achieved by recruitment of more cells to produce EPO. The EPO producing cells of the kidney are a minor subset of cortical interstitial cells. Under normal conditions, only a few scattered cells produce EPO. When a threshold level of hypoxia is achieved, the cells capable of producing EPO do so at a maximal rate. The greater the areas of renal cortex in
which the hypoxia threshold is met, the greater the number of cells that produce EPO.

*Different ways of action*

In the bone marrow, EPO binds to receptors displayed on the cell surface of CFU-E, proerythroblasts, and basophilic erythroblasts. The mature EPO receptor, with a molecular weight of approximately 72,000, is a transmembrane glycoprotein, a member of a much larger family of receptors of cytokines and haematopoietic growth factors. The effect of EPO binding to its receptor, in terms of cellular physiology, has been shown to be the prevention of programmed cell death (apoptosis). In multiple systems of erythropoiesis, EPO has been shown to be a survival factor for the erythroid cells in the later stages of differentiation from the CFU-E through basophilic erythroblasts. Although an effect of EPO on mitosis has been reported for BFU-E and an EPO dependent cell line, EPO is required only for CFU-E and later stages, and apoptosis appears to result when EPO signalling cannot occur.

Erythropoietin (EPO), the main hemopoietic hormone synthesized by the kidney as well as by the liver in fetal life, is implicated in mammalian erythropoiesis. Production and secretion of EPO and the expression of its receptor (EPO-R) are regulated by tissue oxygenation. EPO and EPO-R, expressed in several tissues, exert pleiotropic activities and have different effects on nonhemopoietic cells. EPO is a cytokine with antiapoptotic activity and plays a potential neuroprotective and cardioprotective role against ischemia. EPO is also involved in angiogenesis, neurogenesis, and the immune response. EPO can prevent metabolic alterations, neuronal and vascular degeneration, and inflammatory cell activation. Consequently, EPO may be of therapeutic use for a variety of disorders. Many tumors express EPO and/or EPO-R, but the action of EPO on tumor cells remains controversial. It has been suggested that EPO promotes the proliferation and survival of cancer cells expressing EPO-R. On the other hand, other reports have concluded that EPO-R plays no role in tumor progression. One review provided a detailed insight into the nonhemopoietic role of EPO and its mechanism(s) of action which may lead to a better understanding of its potential therapeutic value in diverse clinical settings.

*Mechanisms of erythropoietin doping*

The wide-spread assumption that doping with erythropoietin or blood transfusion is only effective by increasing arterial blood \( O_2 \) content because of rising hematocrit is not self-evident. "Natural blood dopers" (horses, dogs) increase both hematocrit and circulating blood volume during exercise by releasing stored erythrocytes from the spleen. Improvement of aerobic performance by augmenting hemoglobin concentration may be expected until the optimal hematocrit is reached; above this value maximal cardiac output declines due to the steep increase of blood viscosity. Therefore an enlarged blood oxygen content might only be useful if the normal hematocrit of man during exercise is suboptimal. However, recent studies suggest that cardiac power rises after erythropoietin allowing an unchanged cardiac output in spite of increased viscosity. Other factors underlying improved performance after blood doping might be: augmented diffusion capacity for oxygen in lungs and tissues, increased percentage of young red cells with good functional properties (after erythropoietin), increased buffer capacity, increase of blood volume, vasoconstriction, reduced damage by radicals, mood improvement by cerebral effects of erythropoietin. Also the importance of placebo is unknown since double-blind studies are rare. It is suggested that blood doping has multifactorial effects not restricted to the increase in arterial oxygen content.

*Receptor biology*

The two erythropoiesis stimulating agents (ESAs), short acting recombinant human erythropoietin (EPO) and long acting continuous erythropoietin receptor activator (CERA),
have been hypothesized to share an in vivo elimination pathway that involves binding to erythropoietin receptor (EPOR) and subsequent internalization. A physiologically based recirculation model and a pharmacokinetic tracer interaction methodology (TIM) were used to compare the in vivo interaction kinetics with EPOR between the two ESAs in adult sheep. Animals treated with EPO experienced a greater EPOR up-regulation than those treated with CERA, as evidenced by an eightfold-higher initial EPOR normalized production rate constant versus a twofold-larger EPOR degradation rate constant. In agreement with in vitro studies, EPO had a lower in vivo equilibrium dissociation constant from EPOR than CERA. The internalization and/or degradation of the EPO-EPOR complex was faster than that of the CERA-EPOR complex. The adopted model enables a mechanism-based explanation for CERA’s slower elimination and greater erythropoietic activity in vivo. As predicted by the model, the slower elimination of CERA is due to less EPOR up-regulation induced by CERA administration; slower binding of CERA to EPOR; and reduced internalization and/or degradation rate of surface-bound CERA. Slower CERA/EPOR complex elimination explains the greater in vivo erythropoiesis reported for CERA, despite its lower affinity to EPOR. A sensitivity analysis showed that the model parameters were reliably estimated using the TIM methodology [11139].

**Erythropoietin and the heart**

Erythropoietin (Epo) has been thought to act exclusively on erythroid progenitor cells. The identification of Epo receptor (EpoR) in non-haematopoietic cells and tissues including neurons, astrocytes, microglia, immune cells, cancer cell lines, endothelial cells, bone marrow stromal cells, as well as cells of myocardium, reproductive system, gastrointestinal tract, kidney, pancreas and skeletal muscle indicates that Epo has pleiotropic actions. Epo shows signals through protein kinases, anti-apoptotic proteins and transcription factors. In light of interest of administering recombinant human erythropoietin (rhEpo) and its analogues for limiting infarct size and left ventricular (LV) remodelling after acute myocardial infarction (AMI) in humans, the foremost studies utilising rhEpo are reviewed. The putative mechanisms involved in Epo-induced cardioprotection are related to the antiapoptotic, anti-inflammatory and angiogenic effects of Epo. Thus, cardioprotective potentials of rhEpo are reviewed in the article by focusing on clinical applicability. An overview of non-haematopoietic Epo analogues, which are a reliable alternative to the classic EpoR agonists and may prevent undesired side effects, is also provided [13312].

**A neuroprotective agent**

The tissue protective functions of the hematopoietic growth factor erythropoietin (EPO) are independent of its action on erythropoiesis. EPO and its receptors (EPOR) are expressed in multiple brain cells during brain development and upregulated in the adult brain after injury. Peripherally administered EPO crosses the blood-brain barrier and activates in the brain anti-apoptotic, anti-oxidant and anti-inflammatory signaling in neurons, glial and cerebrovascular endothelial cells and stimulates angiogenesis and neurogenesis. These mechanisms underlie its potent tissue protective effects in experimental models of stroke, cerebral hemorrhage, traumatic brain injury, neuroinflammatory and neurodegenerative disease. The preclinical data in support of the use of EPO in brain disease have already been translated to first clinical pilot studies with encouraging results with the use of EPO as a neuroprotective agent [09160].

**Neovascularization**
Doping with erythropoietic proteins such as erythropoietin (EPO) is a serious issue in sport. There is little information on the possible ophthalmologic alterations followed by frequent EPO abuse in athletes. EPO is a potent retinal angiogenic factor and is capable of stimulating retinal angiogenesis and neovascularization in the presence of ischemia. Systemic and intravitreal EPO concentrations are highly correlated. A linkage between EPO doping and retinal proliferation is possible and further studies are warranted. Gathering and analyzing data on retinal findings from these athletes, either retrospectively or prospectively might yield preliminary information to support the safety of those athletes. Implications of this hypothesis cover other kinds of neovascularizations and angiogenesis [12246].

**Psychological effects**

One study examined the time course of mean self-esteem and physical self scores in three groups: male endurance athletes treated with recombinant human erythropoietin (rHuEPO group, n=6), a placebo group (n=5) injected with a sodium chloride solution and a control group who did not receive any injection (n=6). Each participant completed the Physical Self Inventory twice a day (between 07.00 and 09.00 h and between 19.00 and 21.00 h). Using a 10 cm visual analog scale, the participants assessed global self-esteem, physical self-worth and the sub-domains of physical condition, sport competence, attractive body and physical strength. This was conducted over three consecutive periods: in the 2 weeks before the course of injections, during the 6 weeks of injections and for 4 weeks after the injections. Aerobic capacity was assessed before and after 4 weeks of treatment. The results showed a significant increase in aerobic physical fitness in the rHuEPO group and a significant increase in perceived physical condition and physical strength scores at the end of treatment. The main psychological result was that endurance athletes were highly sensitive to the effects of rHuEPO on physical fitness. The perception of increased physical condition may lead to a stronger commitment to training. The rHuEPO injections presented a dangerous hedonic effect linked to endurance training. These results confirm the need to tackle rHuEPO abuse at any time during the training season [06158].

**Influence of N-acetylcysteine**

The aim of one study was to follow up whether the modification of pro-antioxidant status by 8-day oral application of N-acetylcysteine (NAC) in healthy men affects the hematological response, whether there is a direct relationship between antioxidant defences and erythropoietin (EPO) secretion and whether NAC intake enhances exercise performance. Fifteen healthy men were randomly assigned to one of two groups: control or NAC (1,200 mg per day for 8 days prior to and 600 mg on the day of exercise trial). To measure the ergogenic effectiveness of NAC, subjects performed incremental cycle exercise until exhaustion. NAC administration significantly influenced the resting and post-exercise level of glutathione (+31 %) as well as the resting activity of glutathione enzymes (glutathione reductase, -22 %; glutathione peroxidase, -18 %). The oxidative damage markers, i.e. protein carbonylation and lipid peroxidation products (thiobarbituric acid reactive substance) were reduced by NAC by more than 30 percent. NAC considerably affected the plasma level of EPO (+26 %), haemoglobin (+9 %), haematocrit (+9 %) and erythrocytes (-6 %) at rest and after exercise. The mean corpuscular volume and the mean corpuscular haemoglobin increased by more than 12 percent. Plasma total thiols increased by 17 percent and directly correlated with EPO level. NAC treatment, contrary to expectations, did not significantly affect exercise performance. The study has shown that 8-day NAC intake at a daily dose of 1,200 mg favours a pro-antioxidant status and affects haematological indices but does not enhance exercise performance [10119].
Kinetics of erythropoietin

The mean half-life of recombinant erythropoietin following repeated 50 IU/kg per day subcutaneous administrations is ~36 h (with a average clearance of 17 mL/h/kg). However, half life is reduced to 4-7 h following intravenous administration and total clearance is nearly three times higher in athletes than in untrained subjects (6.5 mL/h/kg) [08221]. Due to this particular kinetics, intravenous administration of recombinant erythropoietin in athletes would lead to undetectable plasma levels after 2-3 h. Furthermore, due to the long lasting effects of rEPO and derivatives on erythrocyte biology, it is unlikely that athletes will use rEPO or similar compounds close to competitions [08222]. Finally, athletes preparing to dope with autologous transfusions can do without rEPO administration by extracting blood without prior "boosting". Another specific concern on the analytical efficiency of the new method is the use of epoetin delta and CERA (continuous erythropoietin receptor activator). Due to innovative production technology, these new erythropoietin analogues are as yet undetectable by the traditional isoelectric focusing approach, both in urine and in plasma. Therefore, it is consider that in- or near-competition testing for plasma rEPO would primarily waste human and economical resources, whereas the revenues in terms of doping prevention are as yet unpredictable. Even in out-of-competition settings, the specific kinetics of rEPO would make detection rather unlikely, provided that blood is collected in the immediate period following rEPO administration [08045].

Interactions with androgens

Association between androgens and erythropoiesis has been known for more than seven decades. Androgens stimulate hematopoietic system by various mechanisms. These include stimulation of erythropoietin release, increasing bone marrow activity and iron incorporation into the red cells. Before the discovery of recombinant erythropoietin (rhEpo), androgens were used in the treatment of anemia associated with renal disease, bone marrow suppression and hypopituitarism. Anabolism is an additional advantage of androgen therapy. Furthermore, in light of recent reports regarding adverse effects of rhEpo, the role of androgen therapy in various types of anemias should be readdressed. Polycythemia remains a known side effect of androgen therapy. In one review, it was briefly discussed the initial animal and human studies which demonstrated the role of androgens in the treatment of anemia, their mechanism of action, a detailed account of the efficacy of androgens in the treatment of various anemias, the erythropoietic side effects of androgens and finally, the relationship between hematocrit levels and cardiovascular disease [09162].

Effects of exercise on erythropoietin molecules

The anti-doping control of recombinant erythropoietin relies on the detection, in the urine, of its isoelectric pattern, which differs from that of the corresponding natural hormone, the latter being typically more acidic than the former. However, a small number of natural urinary patterns, referred to as "atypical patterns," are less acidic than the dominant form. Based on anecdotal evidence, the occurrence of such patterns seems to be related to particular strenuous exercises. One study aimed to demonstrate this relation using a strenuous exercise protocol. Seven top-level athletes (cyclists) took part in a training protocol including a series of supramaximal short-duration exercises. Erythropoietin (EPO) isoelectric patterns were obtained by submitting blood and urine samples to isoelectric focusing. Additional protein dosages were performed. Supramaximal short-duration exercises induced the transformation of typical urinary natural EPO patterns into atypical ones. None of the obtained atypical patterns fulfilled the 3 criteria mandatory for reporting an adverse analytical finding. Serum EPO patterns were not affected by the exercises that caused the
transformation of urinary patterns. An exercise-induced transient renal dysfunction is proposed as a hypothetic explanation for these observations that rely on parallel investigations of proteinuria in the same samples [09161].

**Effect of endurance training**

Erythropoietin (Epo) administration improves aerobic exercise capacity and insulin sensitivity in renal patients and also increases resting energy expenditure (REE). Similar effects are observed in response to endurance training. The aim was to compare the effects of endurance training with erythropoiesis-stimulating agent (ESA) treatment in healthy humans. Thirty-six healthy untrained men were randomized to 10 weeks of either: 1) placebo (n=9), 2) ESA (n=9), 3) endurance training (n=10), or 4) ESA and endurance training (n=8). In a single-blinded design, ESA/placebo was injected one time weekly. Training consisted of biking for 1 h at 65 percent of Wattmax three times per week. Measurements performed before and after the intervention were as follows: body composition, maximal oxygen uptake, insulin sensitivity, REE, and palmitate turnover. Uncoupling protein 2 (UCP2) mRNA levels were assessed in skeletal muscle. Fat mass decreased significantly after training, whereas ESA induced a small but significant increase in intrahepatic fat. Serum free fatty acid (FFA) levels and palmitate turnover decreased significantly in response to training, whereas the opposite pattern was found after ESA. REE corrected for lean body mass increased in response to ESA and training, and muscle UCP2 mRNA levels increased after ESA. Insulin sensitivity increased only after training. In conclusion: 1) insulin sensitivity is not improved after ESA treatment despite improved exercise capacity, 2) the calorigenic effects of ESA may be related to increased UCP2 gene expression in skeletal muscle, and 3) training and ESA exert opposite effects on lipolysis under basal conditions, increased FFA levels and liver fat fraction was observed after ESA treatment [13313].

Erythropoietin (EPO) and soluble transferrin receptor (sTfR) in serum have been proposed as indirect biomarkers for the detection of recombinant human EPO (rhEPO) misuse in sport. The purpose of one study was to investigate the influence of different levels of physical fitness, sport, different training workload during the sport season, and endurance exercise in the concentrations of these serum biomarkers for their application into mathematical models to indirectly detect rhEPO misuse. Serum EPO and sTfR concentrations were measured in 96 elite athletes of various sports along the sport season, in 21 recreational athletes at baseline (non-exercising) conditions and in 129 other recreational athletes before and after long-distance races (10 and 21 km). In elite athletes, hemoglobin concentrations and percentage of reticulocytes were also measured, and indirect detection models applied. In recreational athletes, for EPO and sTfR, significant differences were only observed after the 21-km race. In baseline conditions, no differences were observed between recreational and elite athletes for EPO and sTfR. In elite athletes, individual EPO and sTfR concentrations slightly changed over the sport season, with coefficients of variation (CV) of 26.1 % and 9.0 %, respectively. Hemoglobin and reticulocytes were influenced by sport, but their individual variation over the sport season was not physiologically relevant (CV of 3.7 % and 21.3 %, respectively). When applying mathematical models for detection of rhEPO administration, only one elite athlete obtained an individual model score above the established thresholds. Physical fitness, sport and different training workload during the sport season had no substantial effect on serum EPO and sTfR concentrations, except in recreational athletes after a 21-km race. Variations observed in mathematical models to detect EPO administration were mainly due to fluctuation in hemoglobin concentrations, commonly observed in elite athletes [06156].

**Effect of marathon**

Erythropoietin (EPO) was studied in 13 female marathon runners before and up to 8 days
after a competition marathon run. The median baseline control value was 13.7 U/l. No change in EPO concentration was found immediately (15 min.) and one day after the run. However, a median increase in EPO concentration (18.1 U/l) was found on day three post-exercise. On day 8 no change was found compared to pre-exercise values. This late increase in EPO concentration would seem to be responsible for the well known increase of red blood cell mass in long distance runners [06157].

Use of erythropoietin in cycling

Imagine a medicine that is expected to have very limited effects based upon knowledge of pharmacology and (patho)physiology, is studied in the wrong population, with low quality studies that use a surrogate endpoint that relates to the clinical endpoint in a partial manner at most. Such a medicine would surely not be recommended. Recombinant human erythropoietin (rHuEPO) use to enhance performance in cycling is very common. A qualitative systematic review of the available literature was performed to look at the evidence for these ergogenic properties of this drug normally used to treat anaemia in chronic renal failure patients. The results of this literature search show there is no scientific basis to conclude rHuEPO has performance enhancing properties in elite cyclists. The reported studies have many shortcomings regarding translation of the results to professional cycling endurance performance. Additionally, the possibly harmful side-effects have not been adequately researched for this population but appear to be worrying at least. It was concluded that rHuEPO use in cycling is rife but scientifically unsupported by evidence and its use in sports is medical malpractice. What its use would have been, if the involved team physicians had been trained in clinical pharmacology and had investigated this properly, remains a matter of speculation. A single well controlled trial in athletes under real life circumstances would give a better indication of the real advantages and risk factors of rHuEPO use, but it would be an oversimplification that this would eradicate its use [12244].

Effect on performance

All kinds of blood manipulations aim to increase the total hemoglobin mass (tHb-mass). To establish tHb-mass as an effective screening parameter for detecting blood doping, the knowledge of its normal variation over time is necessary. The aim of one study, therefore, was to determine the intraindividual variance of tHb-mass in elite athletes during a training year emphasizing off, training, and race seasons at sea level. tHb-mass and hemoglobin concentration were determined in 24 endurance athletes five times during a year and were compared with a control group (n=6). An analysis of covariance was used to test the effects of training phases, age, gender, competition level, body mass, and training volume. Three error models, based on a total percentage error of measurement, the combination of a typical percentage error of analytical origin with an absolute SD of biological origin, and between-subject and within-subject variance components as obtained by an analysis of variance, were tested. In addition to the expected influence of performance status, the main results were that the effects of training volume and training phases on tHb-mass were not significant. It was found that within-subject variations mainly have an analytical origin (typical error approximately 1.4 %) and a very small SD (7.5 g) of biological origin. It was concluded that tHb-mass shows very low individual oscillations during a training year (<6 %), and these oscillations are below the expected changes in tHb-mass due to erythropoetin application or blood infusion (approximately 10 %). The high stability of tHb-mass over a period of 1 year suggests that it should be included in an athlete’s biological passport and analyzed by recently developed probabilistic inference techniques that define subject-based reference ranges [20823].

The performance enhancing (ergogenic) effect of recombinant human Epo (rhEpo) in aerobic sports was investigated shortly after the medicine became available. It soon became clear
that subcutaneous administration of rhEpo at doses of 60 to 350 U/kg body weight and week for 4 to 6 weeks increases \(O_2\text{max}\) and the time to exhaustion substantially. More recent studies in which rhEpo was applied to healthy volunteers in lower dosages demonstrated that \(O_2\text{max}\) is increased by 6-12 percent when the hematocrit (Hct) is increased to approximately 0.50 but also demonstrated that time to exhaustion (in the laboratory) at a given level of \(O_2\text{max}\) is increased by up to 50 percent. A challenge for antidoping work is that when rhEpo administration is discontinued in healthy volunteers, \(O_2\text{max}\) remains elevated for at least 3 weeks. Although Epo is reported to activate several nonhematologic factors (i.e. in addition to stimulating erythropoiesis), which are usually also associated with improvements in aerobic performance, the primary mechanism by which Epo increases exercise performance in humans is through augmented erythropoiesis. Erythropoiesis-stimulating agents are particularly effective in combination with iron supplementation. The administration of iron results in increased ferritin levels in athletes. Ferritin levels more than 1000 g/L have been observed. There are as yet no reports on physical performance in healthy humans with increased circulating Epo and Hb mass because of the administration of compounds stimulating the expression of the endogenous Epo gene or after Epo gene transfer [11116].

Treatment with recombinant human erythropoietin (rhEpo) induces a rise in blood oxygen-carrying capacity (\(\text{CaO}_2\)) that unequivocally enhances maximal oxygen uptake (\(\text{VO}_2\text{max}\)) during exercise in normoxia, but not when exercise is carried out in severe acute hypoxia. This implies that there should be a threshold altitude at which \(\text{VO}_2\text{max}\) is less dependent on \(\text{CaO}_2\). To ascertain which are the mechanisms explaining the interactions between hypoxia, \(\text{CaO}_2\) and \(\text{VO}_2\text{max}\) it was measured systemic and leg \(O_2\) transport and utilization during incremental exercise to exhaustion in normoxia and with different degrees of acute hypoxia in eight rhEpo-treated subjects. Following prolonged rhEpo treatment, the gain in systemic \(\text{VO}_2\text{max}\) observed in normoxia (6-7 %) persisted during mild hypoxia (8 % at inspired \(O_2\) fraction of 0.173) and was even larger during moderate hypoxia (14-17 % at \(O_2\) fraction 0.153-0.134). When hypoxia was further augmented to \(O_2\) fraction 0.115, there was no rhEpo-induced enhancement of systemic \(\text{VO}_2\text{max}\) or peak leg \(\text{VO}_2\). The mechanism highlighted by the data is that besides its strong influence on \(\text{CaO}_2\) rhEpo was found to enhance leg \(\text{VO}_2\text{max}\) in normoxia through a preferential redistribution of cardiac output toward the exercising legs, whereas this advantageous effect disappeared during severe hypoxia, leaving augmented \(\text{CaO}_2\) alone insufficient for improving peak leg \(O_2\) delivery and \(\text{VO}_2\). Finally, that \(\text{VO}_2\text{max}\) was largely dependent on \(\text{CaO}_2\) during moderate hypoxia but became abruptly \(\text{CaO}_2\)-independent by slightly increasing the severity of hypoxia could be an indirect evidence of the appearance of central fatigue [08224].

After 13 weeks of erythropoietin application with an increase in hemoglobin concentration from 142 ± 4 to 156 ± 4 g/l at rest, eight physically active men underwent a graded cycle test to exhaustion. Following erythropoietin application (Post-rHuEpo measurements) maximal work rate and oxygen uptake increased significantly by 9 percent (337 to 368 W) and 8 percent (3,950 to 4,255 ml/min), respectively. Then the extra red cell volume was withdrawn and replaced by a 5 percent albumin solution. After only 2 hours, the cycle test with all measurements was repeated. The performance decreased to 339 W (not significant) and maximal oxygen uptake to 4,060 ml/min. This result is not convincing evidence for a pure effect of Hb concentration. Interestingly the lactate concentrations after hemodilution are the lowest in all tests including the pre-Epo values, whereas arterial norepinephrine concentrations are the highest, hinting at reduced glucose availability or increased strain but lower exhaustion. Also the arrangement of the experiment relative to circadian rhythm has to be considered; in early afternoon the intention to work hard is reduced. Might blood loss for the measurements have influenced maximal work rate? It has also been argued that the enlarged heart work because of rising blood viscosity does not limit maximal cardiac output and thus exercise capacity. A better measure of mechanical work of the heart, however, is
cardiac power estimated as the product of stroke volume times pressure times heart rate. It increases from Pre-rHuEpo (6.66 W) to Post-rHuEpo (7.84 W) but tends also to slightly higher values after hemodilution (6.94 W). In the latter case the stroke volume is clearly higher and the blood pressure lower than Post-rHuEpo (blood pressures at maximal performance are surprisingly low in this investigation). One might speculate that a fully compensating increase of the stroke volume is restricted mechanically during the diastole (e.g. by heart wall stiffness or by too low filling pressure) [08225].

The performance enhancing (ergogenic) effect of recombinant human Epo (rhEpo) in aerobic sports was investigated shortly after the medicine became available. It soon became clear that subcutaneous administration of rhEpo at doses of 60 to 350 U/kg body weight and week for 4 to 6 weeks increases $O_{2max}$ and the time to exhaustion substantially. More recent studies in which rhEpo was applied to healthy volunteers in lower dosages demonstrated that $O_{2max}$ is increased by 6-12 percent when the hematocrit (Hct) is increased to approximately 0.50 but also demonstrated that time to exhaustion (in the laboratory) at a given level of $O_{2max}$ is increased by up to 50 percent. A challenge for antidoping work is that when rhEpo administration is discontinued in healthy volunteers, $O_{2max}$ remains elevated for at least 3 weeks. Although Epo is reported to activate several nonhematologic factors, which are usually also associated with improvements in aerobic performance, the primary mechanism by which Epo increases exercise performance in humans is through augmented erythropoiesis. ESAs are particularly effective in combination with iron supplementation. The administration of iron results in increased ferritin levels in athletes. Ferritin levels more than 1000 microg/L have been observed. There are as yet no reports on physical performance in healthy humans with increased circulating Epo and Hb mass because of the administration of compounds stimulating the expression of the endogenous Epo gene or after Epo gene transfer [11428].

**Effects of repetitive training at low altitude**

Classical altitude training can cause an increase in total hemoglobin mass if a minimum "dose of hypoxia" is reached (altitude ≥2,000 m, ≥3 weeks). It was investigated if repetitive exposure to mild hypoxia during living and training at low altitude (<2,000 m) for several weeks, often performed by elite athletes, might also have significant effects on erythropoiesis. Total hemoglobin mass, erythropoietin (EPO), soluble transferrin receptor (sTfR) and ferritin were determined in 8 elite runners before and after each of 2 training camps at low altitude interspersed by 3 weeks of sea-level training and at the same time points in a control group of 5 well-trained runners. EPO, sTfR and ferritin were also repeatedly measured during the altitude training camps. Repeated measures ANOVA revealed significant increases in EPO- and sTfR-levels during both training camps and a significant decrease in ferritin indicating enhanced erythropoietic stimulation during living and training at low altitude. Furthermore, significant augmentation of total hemoglobin mass by 5.1 percent occurred in the course of the 2 altitude training camps. In conclusion, repetitive living and training at low altitude leads to a hypoxia-induced increase in erythropoietic stimulation in elite 400 m and 800 m runners and, apparently, might also cause a consecutive augmentation of total hemoglobin mass [10120].

**Effect of erythropoietin of scuba diving**

Erythropoiesis is affected during deep saturation dives. The mechanism should be related to a downregulation of serum Erythropoietin (s-EPO) concentration or to a toxic effect of the hyperbaric hyperoxia. It was evaluated s-EPO and other haematological parameters in 6 scuba divers before, during and after a 14-days guinness saturation dive (8-10 m). Athletes were breathing air at 1.8-2 ATA, under the control of a team of physicians. Serum parameters were measured before diving (T0) and: 7 days (T1), 14 days (T2) after the beginning of the dive and 2 h (T3) and 24 h (T4) after resurfacing. Hgb, and many other
haematological parameters did not change whereas Ht, s-EPO, the ratio between s-EPO predicted and that observed and reticulocytes (absolute, percent) declined progressively from T0 to T3. At T4 a significant rise in s-EPO was observed. Hgb did not vary but erythropoiesis seemed to be affected as s-EPO and reticulocyte counts showed. All these changes were statistically significant. The experiment, conducted in realistic conditions of dive length, oxygen concentration and pressure, allows us to formulate some hypotheses about the role of prolonged hyperbarism on erythropoiesis. The s-EPO rise, 24 h after resurfacing, is clearly documented and related to the "Normobaric Oxygen Paradox". This evidence suggests interesting hypotheses for new clinical applications such as modulation of s-EPO production and Hgb content triggered by appropriate O₂ administration in pre-surgical patients or in some anemic disease [13314].

**Effects of erythropoietin on serum hepcidin and serum iron bioavailability**

Hepcidin regulates plasma iron bioavailability and subsequently iron availability for erythropoiesis. rHuEPO has been reported to decrease hepcidin expression in case of repeated subcutaneous injections. Thus, hepcidin level measurement could be a candidate marker for detection of rHuEPO abuse. However, when used for doping, rHuEPO can be injected intravenously and the scheme of injection is unknown. The aim of one study was to evaluate the early effects of a single intravenous rHuEPO injection on serum hepcidin levels. Fourteen male healthy volunteers received one intravenous injection of 50 U/Kg of rHuEPO during a placebo-controlled, randomized, double-blind, cross-over study. Serum hepcidin, quantified by a competitive ELISA method and iron parameters was then evaluated for 24 h. Serum levels of hepcidin were significantly increased 4 h after rHuEPO injection when compared with placebo injection, whereas iron and transferrin saturation dramatically decreased 12 h after rHuEPO injection when compared with placebo injection. In addition, 12 and 24 h after rHuEPO injection serum hepcidin levels were lower compared with placebo injection. Intravenous injection of recombinant EPO induces a precocious and transient increase of serum hepcidin leading to a transient decrease of iron bioavailability. The transitory increase and dynamics of its concentration make difficult the practical use of hepcidin to detect rHuEPO doping [12247].

**New biomarkers**

Erythropoietin (Epo) is produced primarily in the kidneys upon low blood oxygen availability and stimulates erythropoiesis in the bone marrow. Recombinant human Epo (rHuEpo), a drug developed to increase arterial oxygen content in patients, is also illicitly used by athletes to improve their endurance performance. Therefore, a robust and sensitive test to detect its abuse is needed. The aim of one study was to investigate potential human serum biomarkers of Epo abuse employing a proteomic approach. Eight healthy male subjects were injected subcutaneously with rHuEpo (5,000 IU) every second day for a 16-day period. Serum was collected before starting the treatment regime and again at days 8 and 16 during the treatment period. Samples were homogenized and proteins separated by two-dimensional gel electrophoresis (2DE). Spots that changed significantly in response to rHuEpo treatment were identified by mass spectrometry. Both the number of reticulocytes and erythrocytes increased throughout the study, leading to a significant increase in hematocrit and hemoglobin content. In addition, transferrin levels increased but the percentage of iron bound to transferrin and ferritin levels decreased. Out of 97 serum proteins, seven were found to decrease significantly at day 16 compared with pre-Epo administration, and were identified as four isoforms of haptoglobin, two isoforms of transferrin, and a mixture of hemopexin and albumin. In support, total serum haptoglobin levels were found to be significantly decreased at both days 8 and 16. Thus a 2DE proteomic approach for discovery of novel markers of
Epo action appears feasible [11140].

Theoretical aspects of detection blood doping with erythropoietin

Peptidic ESAs

Currently available rhEpo preparations (epoetins) are produced in Epo complementary DNA (cDNA) transfected Chinese hamster ovary (CHO) or baby hamster kidney (BHK) cell cultures. The only therapeutic rhEpo engineered in human cells (epoetin-delta) is off market since the beginning of 2009. Because the patents of the originator epoetins have died, biosimilar products have been approved in many parts of the world. Furthermore, various copied CHO cell-derived rhEpos are available in countries without a regulated market. Endogenous Epo and the epoetins have an invariant sequence of 165 amino acids, but they differ in glycosylation. Compared with the epoetins, endogenous Epo isoforms are more acidic and smaller in size. Epo can be separated by isoelectric focusing (IEF) or electrophoresis of urine samples. After IEF, a double-blotting procedure is performed. The mutein darbepoetin-alfa migrates more in the acidic range than Epo on IEF. The WADA has established criteria to achieve harmonization in the performance of the test for epoetin and darbepoetin in urine. Actually, when urine samples from rhEpo-treated subjects were submitted to two WADA-accredited laboratories, the results were not fully consistent, which, as claimed by the laboratories, was apparently the result of methodologic differences. A recent detection problem has arisen with the addition of proteases by athletes to their urinary samples, which destroys the erythropoietic proteins. The adulteration of urine with proteases is a prohibited method, and techniques have been developed for the detection of their misuse. Another difficulty relates to the fact that once hemoglobin concentrations has been raised in athletes by the administration of recombinant ESAs, only microdoses or less frequent injections of the drugs are needed to maintain [Hb] at the high level. In this situation, the window of detection of rhEpo in urine is only 12-18 hours, compared with about 3 days on regular dosing (50 U/kg body weight 3 times a week). Thus, although the detection of rhEpo in urine is effective if the injection frequency is high, this is certainly not the case when the injection rate is reduced to weekly injections. Because darbepoetin-alfa has a 3- to 4-fold longer half-life (24-26 hours) than the epoetins (6-8 hours), the window of detection of darbepoetin-alfa is prolonged to approximately 7 days. CERA has an even longer half-life of approximately 6 days. IEF of CERA yields bands in the less acidic area compared with native Epo. IEF for investigation of doping with CERA has also been applied to blood samples. In addition, CERA can be detected by ELISA. Epo mimetic peptides (EMPs) are synthetic cyclic peptides of about 20 amino acids. A potent pegylated EMP dimer (INN: peginesatide; Hematide®) proved to stimulate erythropoiesis in experimental animals and in healthy male volunteers. In an alternative approach, EMPs have been constructed onto human IgG1-based scaffolds by recombinant DNA-technology [11428].

Drugs activating the endogenous erythropoietin gene

The Epo enhancer is under the control of HIFs, heterodimeric proteins composed of subunits alpha and beta. HIF-2 is the main factor inducing Epo expression. The C-terminus of HIF-alpha is composed of proline residues that are hydroxylated in the presence of O2. Prolylhydroxylated HIF-alpha binds the von Hippel-Lindau tumor suppressor protein in complex with an E3-ligase and undergoes immediate proteasomal degradation. The transcriptional activity of the HIFs is suppressed by O2-dependent hydroxylation of an asparagine residue. The HIF-alpha hydroxylases contain Fe2+ and are inactivated by Fe2+ removal. However, iron chelators are not suited for stimulation of erythropoiesis in the long-term because iron is required for heme synthesis. HIF-dependent Epo expression is augmented by divalent transition metals, such as cobalt or nickel. It has been known that cobalt increases erythropoiesis in experimental animals. Cobalt is a very potent inducer of Epo transcription. Indeed, the international Epo unit (IU) was originally defined as the dose
eliciting the same erythropoiesis stimulating response in rats as 5 micromol of cobaltous chloride. However, cobalt may be misused by athletes as a proper means to enhance Epo levels and Hb<sub>mass</sub>. Cobalt is very potent, inexpensive, and not comprehended in the WADA’s “Prohibited List” [11428].

**Other erythropoietic hormones**

Several hormones may stimulate the renal and/or hepatic production of Epo, including prostanoids, thyroid hormone, angiotensin II, growth hormone (GH), and testosterone. The latter are of particular interest regards blood doping. The fact that the rise in plasma Epo occurred earlier than the rise in insulin-like growth factor-1 (IGF-1) indicates that GH directly stimulates Epo production. IGF-1 was earlier shown to promote the growth of erythrocytic progenitors. The hormone Epo, which derives from kidneys and liver, stimulates the survival, proliferation, and differentiation of the erythrocytic progenitors in hemopoietic tissues. The enhanced release of reticulocytes leads to an increase in the blood hemoglobin concentration and, thus, the O<sub>2</sub> capacity of the blood and the total Hb mass. Epo gene expression in the kidneys and the liver is controlled at the transcriptional level [11428].

**RBC parameters associated with ESA doping**

There are no major differences in basal hemoglobin concentration RBC count, Hct, and MCHC values in elite athletes compared with healthy nonathletes. An increase in hypochromic red cells has been seen on rhEpo therapy despite the use of parenteral or oral iron. Reticulocyte number was not affected by intravenous iron administration in healthy humans subjected to a bolus injection of rhEpo (300 U/kg intravenously). However, MCHr and Ret [Hb] were increased in the intravenous iron/rhEpo group compared with the group receiving rhEpo alone. Thus, intravenous iron increases the hemopoietic response to rhEpo in normal subjects, and this therapy is probably practiced by cheating athletes. Note that parenteral iron alone did not produce a change in Hb<sub>mass</sub>, hemoglobin concentration, or specific RBC parameters in young female athletes, despite their low baseline hemoglobine (128 g/L) and serum ferritin (35 g/L) levels. There is fair stability of reticulocyte number in top-level athletes, although decreases were observed in some athletes during competition periods. High and middle fluorescence (immature) Ret with a high RNA content (IRF) are relatively frequent in athletes because of continuous bone marrow stimulation linked to hemolysis, which is typical of sports activities. Bolus rhEpo injections (150 U or 300 U/kg body weight) further increase the IRF. The increase in immature Ret starts 36 hours after a single dose of rhEpo, reaching a peak after 3-4 days and normalizing within 7 days. A pharmacodynamic model calculation has revealed that rhEpo transiently increases the life span of circulating Ret from the baseline value of 1.7 days to 3.4 days. Thus, the treatment with rhEpo appears to increase Ret values 2-fold: by increased Ret release from the bone marrow and by prolonged maturation time of circulating Ret. It has also been studied the time course of reticulocyte number after repeated subcutaneous injections of rhEpo (50 U/kg body weight every day) in athletes. Reticulocyte numbers were increased from day 10 to 24 and remained elevated for 7 days after cessation of rhEpo therapy. Reticulocyte numbers were significantly lower than the baseline values 14 and 25 days after the last rhEpo injection. During treatment up to 14 days after the last rhEpo injection, soluble transferring receptor and the sTfr/serum protein ratio were elevated above baseline [11116].

**Micro dosing**

Athletes can illicitly use the effects of microdose recombinant human erythropoietin regimens (rHuEPO) to boost red cell mass and thereby oxygen carrying capacity and endurance performance. There are persistent suggestions that athletes have learnt to use rHuEPO, but test negative, by titrating rHuEPO dosage regimens in order to minimize the appearance of
basic isoforms in urine samples (rHuEPO can be detected via electrophoresis because rHuEPO isoforms are more basic than endogenous erythropoietin isoforms). It is vital for antidoping agencies to determine whether existing deterrent strategies have been circumvented. To establish whether it is possible to confound detection strategies by titrating rHuEPO dosages, a study simulated a so-called ‘microdose’ rHuEPO regimen and measured the level of basic isoforms in urine collected during and after the administration protocol. Two well-trained male subjects (28 years old, 74 kg, 177 cm, regional level triathlete; 31 years old, 62 kg, 170 cm, national level long distance runner) gave informed consent to participate in this study which was reviewed and approved by the Regional Ethics Committee. Initially red cell production was rapidly accelerated in both subjects using high doses of rHuEPO (about 260 IU/kg injections on days 0, 2, 4, 7, 9 and 11) in conjunction with a single intravenous iron treatment (100 mg), with the goal to elevate hemoglobin (Hb) concentration to approximately 170 g/L. Over the next 3 weeks, injections were given every 2-3 days (injections on days 15, 17, 19, 22, 24, 26, 29, 31 and 33) and dosages were adjusted by a pharmacologist guided only by basic hematologic information (blood and reticulocyte counts, no urine profiles were provided as feedback). Microdosages were less than 10 percent of the initial dose (exact dosage undisclosed to prevent replication by athletes). Urine samples were collected three times per day during the microdose phase (7-9h, 11-13h, 19-21h), and analyzed for the presence of rHuEPO at the French national antidoping laboratory. As expected high dose rHuEPO treatment rapidly elevated Hb concentrations within 2 weeks (140 to 166 g/L; 148 to 174 g/L; subjects 1 and 2, respectively). It was found that it was possible to maintain elevated Hb values using microdoses of rHuEPO. After 3 weeks of the microdose regimen Hb concentrations were still 164 g/L and 170 g/L respectively (and 164 g/L and 162 g/L 1 week after all injections ceased). During the microdose phase reticulocyte percentages ranged in value from 0.8-1.2 percent and 0.4-1.1 percent for the two subjects. Urine samples collected more than 24 hours after a microdose injection typically had less than 80 percent basic isoforms, which until recently was the criterion used to declare a sample positive. In some instances samples collected just 12-18 hours after the last injection fell below the 80 percent threshold. It is noteworthy that the pharmacologist was able to quickly devise an effective microdose regimen utilizing limited feedback and with few prior attempts. Interestingly, isoelectric profiles showed the reappearance of endogenous erythropoietin bands during the microdose phase. This is in contrast to the existing paradigm which holds that endogenous erythropoietin production is suppressed when the red cell mass has been increased beyond the homeostatic set point. The implications of this remain unclear, however it can be speculated that were an athlete to receive microdoses of rHuEPO for an extended period (>2-4 weeks), it is conceivable that reappearance of endogenous bands of erythropoietin would be of sufficient magnitude to further reduce the effective window of detection of the test for rHuEPO. The results show that it is conceivable for athletes to maintain illicit rHuEPO doping even during multiday endurance events when competitors may be tested at the end of each day (i.e. at 24 hour intervals). The electrophoretic test has proven legally defensible and remarkably robust. The fact that microdoses of rHuEPO disappear rapidly from the circulation could be exploited by athletes to evade detection. This implies that authorities should supplement the urine test with an approach providing greater reach-back. This research also sharpens awareness that, to be efficient, urine tests should be based on out of competition testing [06154].

**Enzymatic desialylation**

Recombinant erythropoietin (rhEPO) has been misused for over two decades by athletes, mainly but not only in endurance sports. A direct rhEPO detection method in urine by isoelectric focusing (IEF) was introduced in 2000, but the emergence of third-generation erythropoiesis-stimulating agents and so-called biosimilar rhEPOs, together with the sensitivity of human endogenous EPO (huEPO) pattern to enzymatic activities and its
modification following short strenuous exercise, prompted the development of a complementary test based on SDS-PAGE analysis. While Mircera and NESP are easily detected with the existing IEF and SDS-PAGE methods, some samples containing both epoetin-α/β and huEPO present profiles that are still difficult to interpret. As doping practices have moved to micro-dosing, these mixed patterns are more frequently observed. We investigated the impact of enzymatic desialylation on the urinary and serum EPO profiles obtained by SDS-PAGE with the aim of improving the separation of the bands in these mixed EPO populations. It was observed that the removal with neuraminidase of the sialic acid moieties from the different EPOs studied reduced their apparent molecular weight (MW) and increased the migration distance between huEPO and rhEPO centroids, therefore eliminating the size overlaps between them and improving the detection of rhEPO [13310].

Recombinant erythropoietin (rhEPO) has been misused for over two decades by athletes, mainly but not only in endurance sports. A direct rhEPO detection method in urine by isoelectric focusing (IEF) was introduced in 2000, but the emergence of third-generation erythropoiesis-stimulating agents and so-called biosimilar rhEPOs, together with the sensitivity of human endogenous EPO (huEPO) pattern to enzymatic activities and its modification following short strenuous exercise, prompted the development of a complementary test based on SDS-PAGE analysis. It was observed that the removal with neuraminidase of the sialic acid moieties from the different EPOs studied reduced their apparent molecular weight (MW) and increased the migration distance between huEPO and rhEPO centroids, therefore eliminating the size overlaps between them and improving the detection of rhEPO [13311].

Excessive dosing

Mice
To investigate the consequences of inborn excessive erythrocytosis, we made use of our transgenic mouse line (tg6) that constitutively overexpresses erythropoietin (Epo) in a hypoxia-independent manner, thereby reaching hematocrit levels of up to 0.89. It was detected expression of human Epo in the brain and, to a lesser extent, in the lung but not in the heart, kidney, or liver of tg6 mice. Although no acute cardiovascular complications are observed, tg6 animals have a reduced lifespan. Decreased swim performance was observed in 5-months-old tg6 mice. At about 7 months, several tg6 animals developed spastic contractions of the hindlimbs followed by paralysis. Morphological analysis by light and electron microscopy showed degenerative processes in liver and kidney characterized by increased vascular permeability, chronic progressive inflammation, hemosiderin deposition, and general vasodilatation. Moreover, most of the animals showed severe nerve fiber degeneration of the sciatic nerve, decreased number of neuromuscular junctions, and degeneration of skeletal muscle fibers. Most probably, the developing demyelinating neuropathy resulted in muscular degeneration demonstrated in the extensor digitorum longus muscle. Taken together, chronically increased Epo levels inducing excessive erythrocytosis leads to multiple organ degeneration and reduced life expectancy. This model allows investigation of the impact of excessive erythrocytosis in individuals suffering from polycythemia vera, chronic mountain sickness, or in subjects tempted to abuse Epo by means of gene doping [06155].
Laboratory techniques

One study was based on the assumption that changes in an ADMA-DDAH-NOS (ADMA-asymmetrical dimethylarginine; DDAH-dimethyl-arginine dimethylaminohydrolase; NOS-nitric oxide synthase) system could be employed as indirect markers for recombinant human erythropoietin (rHuEPO) administration in doping control. It was assessed a predictive value of four proposed new markers for rHuEPO abuse. Preliminary data showed that concentrations of ADMA, symmetrical dimethylarginine (SDMA), citrulline and arginine in human urine were increased after administration of a single intravenous erythropoietin injection (2000 U/day, Epocrine, St-Petersburg, Russia). The study of variations of ADMA, SDMA, arginine and citrulline levels before and after rHuEPO administration was performed with two healthy male volunteers. Urine samples were collected before rHuEPO administration and urinary concentrations of ADMA and SDMA were determined at 10.0-40 microg/mL and of arginine and citrulline at 0.5-10 microg/mL. A single dose injection of rHuEPO caused an increase in ADMA, SDMA, arginine and citrulline concentrations up to 40-270 microg/mL, 40-240 microg/mL, 10-60 microg/mL and 12-140 microg/mL, respectively. These preliminary results indicated that an indirect approach could be used as a pre-screening of urine samples in order to decrease the number of samples with a low probability of rHuEPO abuse and, thus, save costs and human workload [08226].

Identification of post-translational modifications of proteins in biological samples often requires access to preanalytical purification and concentration methods. In the purification step high or low molecular weight substances can be removed by size exclusion filters, and high abundant proteins can be removed, or low abundant proteins can be enriched, by specific capturing tools. In one paper is described the experience and results obtained with a recently emerged and easy-to-use affinity purification kit for enrichment of the low amounts of EPO found in urine and plasma specimens. The kit can be used as a pre-step in the EPO doping control procedure, as an alternative to the commonly used ultrafiltration, for detecting aberrantly glycosylated isoforms. The commercially available affinity purification kit contains small disposable anti-EPO monolith columns (6 μL volume, Ø7 mm, length 0.15 mm) together with all required buffers. A 24-channel vacuum manifold was used for simultaneous processing of samples. The column concentrated EPO from 20 mL urine down to 55 μL eluate with a concentration factor of 240 times, while roughly 99.7% of non-relevant urine proteins were removed. The recoveries of Neorecormon (epoetin beta), and the EPO analogues Aranesp and Mircera applied to buffer were high, 76 percent, 67 percent and 57 percent, respectively. The recovery of endogenous EPO from human urine was 65 percent. High recoveries were also obtained when purifying human, mouse and equine EPO from serum, and human EPO from cerebrospinal fluid. Evaluation with the accredited EPO doping control method based on isoelectric focusing (IEF) showed that the affinity purification procedure did not change the isoform distribution for rhEPO, Aranesp, Mircera or endogenous EPO. The kit should be particularly useful for applications in which it is essential to avoid carry-over effects, a problem commonly encountered with conventional particle-based affinity columns. The encouraging results with EPO propose that similar affinity monoliths, with the appropriate antibodies, should constitute useful tools for general applications in sample preparation, not only for doping control of EPO and other hormones such as growth hormone and insulin but also for the study of post-translational modifications of other low abundance proteins in biological and clinical research, and for sample preparation prior to in vitro diagnostics [10468].

The sample preparation method preceding the urinary erythropoietin (EPO) doping test is based on several concentration and ultrafiltration steps. In order to improve the quality of isoelectric focusing (IEF) gel results and therefore, the sensitivity of the EPO test, new sample preparation methods relying on affinity purification were recently proposed. One
article focused on the evaluation and validation of disposable immunoaffinity columns targeting both endogenous and recombinant EPO molecules in two World Anti-Doping Agency (WADA) accredited anti-doping laboratories. The use of the columns improved the resolution of the IEF profiles considerably when compared with the classical ultrafiltration method, and the columns’ ability to ensure the isoform integrity of the endogenous and exogenous EPO molecules was confirmed. Immunoaffinity columns constitute therefore a potent and reliable tool for the preparation of urine samples and their use will significantly improve the sensitivity and specificity of the actual urinary EPO test [10469].

An ultra-sensitive quantitative EPO (erythropoietin) lateral flow immunochromatographic test with a detection limit of 1.2 fM (10^{-15} M), 0.035 ng EPO/L, which is 50-100 times more sensitive than a corresponding enzyme based immunoassay, was presented. In comparison with commercial lateral flow tests for other analytes, like cardiac troponins that also require high sensitivity, the detection limit achieved in the presented test is about three orders of magnitude lower. The thin zone for capture and concentration of the analyte, the carbon black nano-strings used as label and the use of a conventional image scanner for the quantitative determination are the key components that enable the high sensitivity obtained. The convective flow in the lateral flow monolith creates short diffusion distances between immobilised antibody, analyte and labelled antibody thus enhancing the binding efficiency. This rapid and sensitive EPO test procedure can be used both to process hundreds of samples in 1 h and be utilized as a 15-minute dipstick test for single determinations. The technique was demonstrated by measuring EPO in urine. EPO, like many of the other urine proteins, is often found in the urine precipitates and the specimens are therefore treated with a urine precipitate dissolution buffer before analysis. It was shown that EPO in urine from normal individuals occurs in low concentration in a wide range between 1.7 and 51 ng/L. The concentration was however subjected to a wide variation during the day due to the EPO production variation and the urine concentration by the kidneys. It was also shown that the presented lateral flow device can be used as a miniaturized affinity column to distinguish an analyte (EPO) from its analogue (darbepoetin), directly by comparing the affinity profiles obtained after interaction with the immobilised antibody. The method for measuring the amount of EPO present in urine, the possibility to rapidly check the amount of EPO after a pre-treatment concentration step, and the potential to identify affinity differences between EPO and its analogues should make the presented method a valuable tool in the fight against EPO doping [08227].

To overcome the limitation of the currently adopted direct method to detect recombinant Human Erythropoietin (rHuEpo) abuse in sport, indirect analysis of blood parameters are increasingly used as part of the anti-doping strategies. The aim of one work was to identify whether immunophenotype modifications on erythroid cells may be indicative of previous rHuEPO administration. The study was conducted on dialyzed patients under treatment with rHuEPO. Dialyzed patients without rHuEPO therapy and volunteer donors were used as controls. The analysis of erythroid cells immunophenotype, performed using a multiparametric flow cytometry technique, showed a peculiar pattern of CD71 expression following rHuEPO treatment. In particular CD71 showed an increased expression in mature and intermediate reticulocytes and a surprisingly decreased expression in immature reticulocytes. In conclusion, the analysis of reticulocyte maturation stages with TO/CD71 double staining may be considered as a valid alternative indirect method for the detection of rHuEPO abuse [08228].

The test used by anti-doping laboratories to detect the misuse of recombinant erythropoietin (rhEPO) is based on its different migration pattern on isoelectric focusing (IEF) gel compared with the endogenous human erythropoietin (hEPO) that can possibly be explained by structural differences. While there is definitely a need to identify those differences by LC-
MS/MS, the extensive characterization that was achieved for the rhEPO was never performed on human endogenous EPO because its standard is not available in sufficient amount. The goal of one study was therefore to develop an analytical method to detect pmol amounts of N-linked and O-linked glycopeptides of the recombinant hormone as a model. Using a nanoflow HPLC-Chip electrospray ionization/ion trap mass spectrometer, the diagnostic ion at m/z 366 of oligosaccharides was monitored in the product ion spectra to identify the four theoretical glycosylation sites, Asn24, Asn38, Asn83 and Ser126, respectively, on glycopeptides 22-37, 38-55, 73-96 and 118-136. With 3 pmol of starting material applied on Chip, only the desialylated N-glycopeptides 22-37 and 38-55/38-43 could be observed, and of all the glycan isoforms, those with the smaller structures were predominantly detected. While the preservation of the sialic acid moieties decreased the detection of all the N-glycopeptides, it allowed a more extensive characterization of the O-linked glycopeptide 118-136. The technique described herein provides a mean to detect glycopeptides from commercially available pharmaceutical preparations of rhEPO with the sensitivity required to analyze pmol amounts of hEPO, which could ultimately lead to the identification of structural differences between the recombinant and the human forms of the hormone 08229.

Recombinant human erythropoietin (rhEPO), generally produced in Chinese hamster ovary (CHO) cells, can be used as not only a therapeutic protein but also a doping agent in sports. Profiling of EPO glycoforms is a critical means for quality control in pharmaceutical industrial and anti-doping analysis of misuse in sports. However, the existing methods for the analysis of EPO are associated with either time consuming or poor resolution. In one work, a rapid and high-resolution glycoform profiling method was presented based on capillary isoelectric focusing (cIEF) with whole column imaging detection (WCID). Experimental conditions that influence the separation were investigated. Under optimized conditions, rhEPO from three different sources were resolved into distinct populations within 5 min with excellent reproducibility. As compared with existing methods, the presented method exhibited the advantages of speed and high resolution. If combined with an effective sample enrichment step and a much more sensitive WCID version, the method can be a potential alternative for the detection of rhEPO misuse in sports 08230.

A screening method able to differentiate recombinant human erythropoietins (rhEPOs) and analogues like CERA, continuous erythropoietin receptor activator, from human urinary erythropoietin (uhEPO) was described. The method is based on the discrimination between isoforms observed when the protein is eluted under acidic followed by basic conditions from immunoaffinity microtiter wells. From a comparison with the complex IEF protocol currently applied in anti-doping analysis, the newly developed assay procedure is amenable to wide screening application and presents good resolving power between rhEPOs and uhEPO 09163.

The measurement of serum erythropoietin (EPO) is important for the detection of recombinant human EPO misuse in sports. It was developed a sensitive and rapid CE immunoassay with enhanced chemiluminescence detection of EPO, in which silica dioxide nanoparticles (SiO₂ NPs) were used as the pseudostationary phase to improve the separation efficiency of analytes. By adopting SiO₂ NPs in the CE immunoassay, the separation can be successfully performed in neutral running buffer solution. However, running buffer of extreme pH was still necessary for the conventional CZE mode. Neutral phosphate buffer (pH 7.4) containing SiO₂ NPs and poly(ethylene oxide) (PEO) was chosen as running buffer. The influences of SiO₂ NPs, PEO and buffer concentration on the separation efficiency and EPO detection were investigated. EPO-horse radish peroxidase (HRP) and immunocomplex were baseline separated in a 10 mM phosphate buffer (pH 7.4) consisting of 0.08 percent PEO and 0.08 percent SiO₂ NPs. The linear range for EPO was
1.8-158.0 ng/mL and the detection limit was 0.9 ng/mL. The assay was successfully applied for the quantification of EPO in human sera and the results correlated well with those obtained using chemiluminescence immunoassay kits, thus demonstrating that the present method was a potential powerful tool for EPO misuse detection and clinical diagnosis [09164].

The tampering of athlete’s urine samples by the addition of proteolytic enzymes during the doping control sampling procedure was reported recently. The aim of one study, funded by the World Anti-Doping Agency (WADA), was the application of a stabilization mixture in urine samples to chemically inactivate proteolytic enzymes and improve the electrophoretic signal of erythropoietin (EPO) in human urine. The stabilization mixture applied was a combination of antibiotics, antimycotic substances and protease inhibitors. A series of incubation experiments were conducted under controlled conditions in the presence and absence of the stabilization mixture in urine aliquots spiked with six proteases. Two different analytical techniques were applied for the qualitative and quantitative EPO measurement: isoelectric focusing (IEF) and chemiluminescent immunoassay respectively. The addition of the chemical stabilization mixture into urine aliquots substantially improved EPO detection in the presence of proteolytic enzymes following incubation at 37 degrees C or storage at -20 degrees C. The results of this study indicated that the stabilization of urine prior to the sample collection procedure with the proposed chemical mixture might prove to be a useful tool for the preservation of anti-doping samples [09165].

Mass spectrometry-based proteomic approaches have been used to develop methodologies capable of detecting the abuse of protein therapeutics such as recombinant human erythropoietin and recombinant human growth hormone. Existing detection methods use antibody-based approaches that, although effective, suffer from long assay development times and specificity issues. The application of liquid chromatography with tandem mass spectrometry and selected reaction-monitoring-based analysis has demonstrated the ability to detect and quantify existing protein therapeutics in plasma. Furthermore, the multiplexing capability of selected reaction-monitoring analysis has also aided in the detection of multiple downstream biomarkers in a single analysis, requiring less sample than existing immunological techniques. The flexibility of mass spectrometric instrumentation has shown that the technique is capable of detecting the abuse of novel and existing protein therapeutics, and has a vital role in the fight to keep sports drug-free [10123].

The sample preparation method preceding the urinary erythropoietin (EPO) doping test is based on several concentration and ultrafiltration steps. In order to improve the quality of isoelectric focusing (IEF) gel results and therefore, the sensitivity of the EPO test, new sample preparation methods relying on affinity purification were recently proposed. One article focused on the evaluation and validation of disposable immunoaffinity columns targeting both endogenous and recombinant EPO molecules in two World Anti-Doping Agency (WADA) accredited anti-doping laboratories. The use of the columns improved the resolution of the IEF profiles considerably when compared with the classical ultrafiltration method, and the columns’ ability to ensure the isoform integrity of the endogenous and exogenous EPO molecules was confirmed. Immunoaffinity columns constitute therefore a potent and reliable tool for the preparation of urine samples and their use will significantly improve the sensitivity and specificity of the actual urinary EPO test [10124].

The tampering of athlete’s urine samples by the addition of proteolytic enzymes during the doping control sampling procedure was reported recently. The aim of one study, funded by the World Anti-Doping Agency (WADA), was the application of a stabilization mixture in urine samples to chemically inactivate proteolytic enzymes and improve the electrophoretic signal of erythropoietin (EPO) in human urine. The stabilization mixture applied was a combination
of antibiotics, antimycotic substances and protease inhibitors. A series of incubation experiments were conducted under controlled conditions in the presence and absence of the stabilization mixture in urine aliquots spiked with six proteases. Two different analytical techniques were applied for the qualitative and quantitative EPO measurement: isoelectric focusing (IEF) and chemiluminescent immunoassay respectively. The addition of the chemical stabilization mixture into urine aliquots substantially improved EPO detection in the presence of proteolytic enzymes following incubation at 37 degrees C or storage at -20 degrees C. The results of this study indicated that the stabilization of urine prior to the sample collection procedure with the proposed chemical mixture might prove to be a useful tool for the preservation of anti-doping samples [10125].

One report summarized the main analytical strategies developed to identify the presence of recombinant erythropoietin (EPO) administered as a doping agent. Indirect evidence is based on the analysis of blood parameters (haemoglobin, haematocrit, reticulocytes, macrocytes, etc.) and serum markers (concentration of EPO and serum transferrin receptors, etc.). The problem of intertechnique comparison for reliable results evaluation is emphasized, especially for serum markers. Charge differences between isoforms of recombinant EPO and native urinary EPO are the grounds for the isoelectric focusing-double blotting-chemiluminescence detection method presently approved for doping control. Works addressing its advantages and limitations are presented and commented on. The chemical bases of the differential detection are highlighted and some future approaches for detection are also presented. The appearance and detectability of EPO analogues and mimetics susceptible for abuse are also addressed [07117].

Erythropoietin (EPO) promotes the production of red blood cells, the key factor in the regulation of the oxygen transport, and has been abused by athletes for performance enhancement in endurance sports. Current methods to detect EPO misuse are based on isoelectric focussing (IEF), double blotting, and chemiluminescence detection. A new approach utilizing SDS-PAGE mobilities of target analytes is presented. Employing two internal standards (novel erythropoiesis stimulating protein and recombinant rat EPO), the assay provides a tool which allows the calculation of relative mobility values for endogenous urinary EPO and recombinant epoetins (e.g. Dynepo) and, thus, the distinction of these analytes in doping control samples. A reference group of 53 healthy volunteers and samples originating from a Dynepo (epoetin delta) excretion study conducted with a single person were analyzed and led to a significant discrimination of endogenous urinary and recombinant EPO. A clear differentiation was accomplished over a period of four days post-administration of a single injection of 50 IU/kg body weight. Hence, the method may be useful as a screening procedure in doping control or as complementary confirmation tool to the established IEF assay [07118].

The detection of recombinant human erythropoietin (rhEPO) is difficult and becomes more challenging when only microdoses are administered intravenously. Twenty-three subjects were divided into two groups: EPO group (n=7) and CONTROL group (n=16). Seven urine and blood samples per subject were collected at least 5 days apart to determine within- and between-subject standard deviations in the percentage of migrating isoforms by the MAIIA test. Six injections of 50 IU/kg bw (boosting dosage) of epoetin beta (Neorecormon) were performed intravenously during a 3-week period, followed by two microinjections of only 10 IU/kg bw. Blood and urine samples were collected 2, 6, 12, and 72 h after the microinjection, as well as 72 h after the last boosting dose. Sensitivities and specificities of the MAIIA test were examined by absolute and passport thresholds. Sensitivity was 100 percent for at least 12 h after the microinjection, with 30 percent of plasma samples still exceeding the 99.9 percent passport threshold 72 h after a microinjection. The specificity was higher for the passport approach compared to the absolute approach, but there were no
differences in sensitivities between approaches or between specimens (urine and plasma). It was concluded that the MAIIA test shows potential for detecting very small doses of rhEPO [13315].

Misuse of recombinant human erythropoietin (rhEPO) is a major concern in competitive sports, and the implementation of tests allowing for higher detection rates than what current tests are capable of is required. In this study, a novel lateral flow EPO isoform test kit, EPO WGA MAIIA, is evaluated on the basis of plasma and urine samples obtained from eight healthy males in connection with a 28-day rhEPO injection period. rhEPO was injected every other day during the first 14 days of the study, and the method proved to be 100% effective in detecting rhEPO in the concomitantly obtained samples. Seven days after the last injection, three positive (>99.99% confidence limit (CL)) subjects were found. When using 99% CL as the cut-off limit, six of the eight subjects (75%) were found to be suspected of doping. Samples obtained 14 and 21 days after the last injection showed no detectable trace of rhEPO. A previous study using indirect methods to determine EPO doping on the same samples indicated only that two of the subjects had suspicious values 7-21 days after the last injection. We propose implementing the easy to-use EPO WGA MAIIA test as an initial screening procedure in anti-doping work to increase the detection rate of potential rhEPO doping athletes and allow for a 10- to 20-fold higher analytical rate than what is possible today [13316].

Among the peptide hormone-derived therapeutics, ESAs and predominantly erythropoietin (EPO) have been subject of extensive studies concerning improved or newly established traceability as well as pure/fundamental research elucidating and later exploiting the small but significant differences between the natural human EPO and its recombinant analogs. In order to probe for the capability of routine doping control methodologies, i.e. isoelectric focusing polyacrylamide gel electrophoresis (IEF-PAGE) and sodium dodecyl sulfate-PAGE (SDS-PAGE), to detect epoetin kappa in human urine, an administration study was conducted. Three male volunteers received 3000 IU intravenously and urine samples were monitored for up to 48 h. Both approaches (IEF- and SDS-PAGE) allowed for the detection of epoetin kappa with SDS-PAGE being superior in terms of the detection window (24 h). While the benefits of SDS-PAGE concerning EPO analyses have been recognized several years ago, its utility for third-generation EPO drugs was established only recently with the introduction of sarcosyl-PAGE (also referred to as SAR-PAGE). Using sarcosyl instead of SDS, enhanced antibody-antigen binding as well as improved band focusing was accomplished, which allowed for a significantly lowered detection limit of the prohibited compound in plasma and urine sports drug testing samples. The different electrophoretic behaviors of recombinant human EPO products and their natural analogs in serum and urine, which are essential to all routinely applied doping control methods, have been attributed to minor but analytically relevant modifications within the glycosidic moiety. Consequently, elucidating the nature of these modifications was of particular interest to research groups. Focusing on recombinant human EPO, glycopeptides derived from enzymatic digests with trypsin and Glu-C were separated by capillary electrophoresis and analyzed by means of ESI-TOF MS. Here, comprehensive glycoform analysis was conducted for both N- and O-glycopeptides, allowing (among others) the identification of a sulfated sialoform of N83 in recombinant human EPO. As dictated by the employed analytical technique, only accurate masses (errors varied up to 30 ppm) of the protonated intact analytes, as well as respective adduct ions, served for characterization purposes. Following a different strategy, namely sequential deglycosylation by exoglycosidase treatment and subsequent SDS-PAGE analysis, human urinary and serum EPO as well as recombinant EPO were investigated concerning their glycosylation pattern. While EPO from all three sources was amenable to degradation by β-N-acetylglucosaminidase, the subsequent incubation with alpha- or beta-
mannosidase did affect only recombinant EPO, demonstrating a distinct difference in the glycosidic moiety potentially offering a new angle for future doping control assays [13012].

Aiming at a fast alternative to conventional EPO doping control tests, the utility of the recently introduced membrane-assisted isoform immunoassay (MAIIA) combined with wheat germ agglutinin (WGA)-based chromatographic separation of recombinant as well as human urinary and serum EPO was evaluated. Nine different recombinant EPO preparations expressed in hamster or human cell lines were differentiated using a “dip-stick test” that allows the completion of a set of samples within 1 h necessitating a minimum of 0.7 pg of EPO (absolute) in the test sample (immunoaffinity-purified extract of 5 ml of urine). In authentic administration study samples, the subcutaneous administration of recombinant EPO was determined up to seven days in urine specimens of patients with renal dysfunction. The same analytical strategy was applied to a set of plasma samples collected from healthy volunteers having received an intravenous “microdose” (10-40 IU/kg BW) 72-96 h post-administration. In contrast to subcutaneously administered recombinant EPO analyzed in urine, only two out of nine plasma samples tested positive under the given administration protocol; however, it was concluded that an intra-individual comparison of Percentage-of-Migrated-Isoform (PMI)-values significantly improves the assay’s sensitivity and thus can enhance its fitness-for-purpose for future doping control [13012].

Employing immuno-magnetic beads-based extraction (IMBE) combined with capillary zone electrophoresis and deep UV laser-induced fluorescence detection, the highly resolved glycoform profiling of EPO was accomplished for pharmaceutical preparations. The approach can support studies concerning isoform composition studies in recombinant EPO products but the sensitivity was not found sufficient for the analysis of urine or serum and the method considered prone to matrix interference; hence, an introduction into sports drug testing programs is not expected [13012].

Development of a mass spectrometric method for the unambiguous detection of doping with recombinant human erythropoietins (rhEPO) has been attempted for many years. Unfortunately, progress in this field was hampered by the unavailability of highly purified human endogenous EPOs (urinary[uhEPO], serum/plasma EPO) – a prerequisite for generating detailed mass spectrometric glycosylation data necessary for revealing significant differences between uhEPO and rhEPOs. The paper presents the worldwide first analytical data on purified human urinary EPO generated with a high resolution high accuracy mass spectrometer (LTQ-Orbitrap). The focus is on the tryptic O-glycopeptide (E117-R131) and its degree of sialic acid O-acetylation. Data are compared with results obtained from 40 rhEPO pharmaceuticals. It could be demonstrated that the O-glycopeptide of uhEPO (ca 100 IU) contains only trace amounts of mono-acetylated mono- and di-sialylated O-glycans but no other O-acetylated structures and in this respect significantly differs from all rhEPOs. Moreover, Dynepo – a rhEPO previously thought to be not O-acetylated - also contains small amounts of O-acetylations within the O-glycan structure. The results might be useful for antidoping purposes as well as the development of EPO pharmaceuticals with closer structural similarity to the endogenous hormone [13317].

The misuse of microdoses of performance enhancing drugs like erythropoietin (EPO) constitutes a major challenge in doping analysis. When injected intravenously, the half-life of recombinant human EPO (rhEPO) like epoetin alfa, beta, and zeta is only a few hours and hence, the window for direct detection of rhEPO in urine is small. In order to investigate the detection window for rhEPO directly in blood and urine with a combined affinity chromatography and lateral flow immunoassay (EPO WGA MAIIA), we recruited nine healthy people who each received six intravenously injected microdoses (7.5 IU/kg) of NeoRecormon (epoetin beta) over a period of three weeks. Blood and urine samples were collected in the
days following the injections and analyzed with EPO WGA MAIIA as well as the current validated methods for rhEPO; isoelectric focusing (IEF) and sarcosyl polyacrylamide gel electrophoresis (SAR-PAGE). For samples collected 18 h after a microdose, the sensitivity of the EPO WGA MAIIA assay was 100 percent in plasma and 87.5% in urine samples at the respective 98% specificity threshold levels. In comparison, the sensitivity in plasma and urine was 75 and 100 percent, respectively, with IEF, and 88 percent in plasma and 100 percent in urine when analyzed with SAR-PAGE. It was concluded that EPO WGA MAIIA is a sensitive assay for the detection of rhEPO, with the potential of being a fast, supplemental screening assay for use in doping analysis [13318].

**Recommended methods for detection of abuse in 2013**

The current technical document published by WADA in 2013 stipulates IEF or SAR both as the initial test and for confirmation purposes. The recommended method used for confirmation depends on the type of substance found in the initial assessment. New developments for ESA screening in urine include the use of liquid chromatography mass spectrometry (LCMS). This technique, commonly used in anti-doping settings, showed promising results but still needs to be validated in the field. Another advance in the field of ESA detection is the MAIIA (membrane-assisted isoform immunoassay) method for the detection of ESAs. It combines immunoassay with chromatography technology and can be used for both urine and blood samples. The first results have been promising, especially for the detection of very low doses of ESA. Another advantage of this new approach is the relatively easy analytical handling of the test and very little time requirements, allowing a high throughput of samples within a short time. On the other hand, the high costs of the MAIIA method may be considered a drawback. As for the LCMS method, validation is still pending [13006].

**Possible origins of undetectable EPO in urine samples**

In order to determine the possible origins of undetectable EPO profiles in athletes’ urine, it was analyzed the data obtained from a large number of official anti-doping urine tests aimed at detecting recombinant erythropoietin. The following variables were considered as potential causes for lack of EPO detection: athlete’s gender, competition effect, urine specific gravity as well as possible usage of proteasic adulterants to evade doping detection. Statistical analyses indicated that undetectable EPO profiles were clearly related to urine properties such as low EPO concentrations or extreme specific gravities. The addition of very small quantities of protease was shown to remove all traces of EPOs in urine. This finding led to the development of a simple, specific and sensitive test that reveals proteasic activity based on albumin digestion. It was concluded that urine characteristics clearly affect the detectability of an EPO profile. At the same time, addition of anti-proteases prevents the adulteration of urine. These two findings have clear practical implications with regards to the timing of urine collection as well as the entire anti-doping control procedure [07119].

**Lateral flow isoform test**

Misuse of recombinant human erythropoietin (rhEPO) is a major concern in competitive sports, and the implementation of tests allowing for higher detection rates than what current tests are capable of is required. In this study, a novel lateral flow EPO isoform test kit, EPO WGA MAIIA, is evaluated on the basis of plasma and urine samples obtained from eight healthy males in connection with a 28-day rhEPO injection period. rhEPO was injected every other day during the first 14 days of the study, and the method proved to be 100 percent effective in detecting rhEPO in the concomitantly obtained samples. Seven days after the last injection, three positive (>99.99% confidence limit (CL)) subjects were found. When using 99 percent CL as the cut-off limit, six of the eight subjects (75%) were found to be suspected of doping. Samples obtained 14 and 21 days after the last injection showed no detectable trace of rhEPO. A previous study using indirect methods to determine EPO doping on the same
samples indicated only that two of the subjects had suspicious values 7-21 days after the last injection. We propose implementing the easy to-use EPO WGA MAIIA test as an initial screening procedure in anti-doping work to (1) increase the detection rate of potential rhEPO doping athletes and (2) allow for a 10- to 20-fold higher analytical rate than what is possible today [13319].

**Erythrocyte aspartate aminotransferase activity**
A reliable and cost-effective screening test for erythropoietin (EPO) doping is still unavailable. Thus a new approach by estimating mean red blood cell (RBC) age by means of erythrocyte aspartate aminotransferase activity (eAST) was developed. We investigated 201 women and 169 men residing at low altitude for peak oxygen uptake, EPO, and eAST. Additionally, it was investigated 63 women and 42 men residing at 2600 m above sea level for EPO and eAST. Furthermore, 22 female and 28 male patients with renal failure receiving recombinant human EPO (rhEPO) were investigated for eAST levels. There was no difference in eAST between trained, moderately trained, and untrained subjects (women and men) at low altitude. Participants receiving rhEPO had a significant dose-dependent increase in eAST. Trained high-altitude residents had higher eAST than untrained high-altitude residents. Since eAST was sensitive to RBC rejuvenation, eAST elevation could indicate EPO use in lowlanders. eAST values above the 95 percent confidence interval (>3.3 U/gHb for men; >4.1 U/gHb for women) are suspected of EPO use [07120].

**Discriminant analysis**
The detection in urine of recombinant human erythropoietin (rHuEPO), a hormone misused by endurance athletes as a doping agent, is based on the differentiation of its isoelectric pattern from that of the corresponding natural hormone. Different empirical criteria have been proposed for discriminating the images of the patterns but none of them have been elaborated from a rational statistical approach. Discriminant analysis was applied to a dataset of profiles defined as positive (116 profiles from 26 subjects) (presence of rHuEPO and possibly residual natural endogenous hormone) and negative (131 profiles from 131 subjects) (presence of natural endogenous hormone only). The different bands were numbered according to a template of 16 possible positions and their relative intensities constituted the 16 variables of the statistical analysis. This method was then tested with data from an administration trial of low doses (6.7-10 IU/kg) following high-dose (265 IU/kg) injections (71 profiles from one subject). The analysis of the dataset clearly separated the negative and positive profiles. A cross-validation procedure confirmed that the analysis was extremely stable: with ten-fold cross-validation, no false positives were observed even with 100,000 simulations. Furthermore, the detection of rHuEPO in the profiles from the low-dose trial was greatly improved in comparison with a previously validated empirical criterion [07121].

**Bayesian inference approach for the detection of abnormal values**
Sports authorities exclude athletes with abnormal levels of blood parameters. Here, the consideration of longitudinal blood profiles together with heterogeneous factors such as ethnicity and age produces a model with enhanced sensitivity to detect blood doping. In sports, rHuEPO, the recombinant form of erythropoietin, is illicitly used to improve physical performance. Some sports federations with a fairly homogeneous population of athletes have discouraged rHuEPO doping by introducing hematocrit (Hct) and hemoglobin (Hb) limits. Athletes tested above these limits are declared unfit for competition: the so-called no-start rule. Unfortunately, since Hct and Hb present elevated between-subject variations and can easily be manipulated, the efficiency of both variables remains limited. Models using multiple hematological variables, such as Abnormal Blood Profile Score (ABPS), were proposed to improve sensitivity/specificity. Along with this, the idea of a hematological passport was also suggested. Sportsmen with significant differences between new test results and an individual
historical baseline could be excluded from competition. Hematological variables depend on various factors such as gender, ethnicity and age. Even though the effects of these factors on hematological parameters have been well described, they have not been taken into consideration in the formulation of a blood model. This leads to an unpredictable number of false-positive findings for heterogeneous populations. Unsurprisingly, sports federations with highly heterogeneous populations refrained from introducing a no-start rule. It was, therefore, propose a blood test that combines a multiparametric approach for increased specificity, a hematological passport for individual longitudinal monitoring, and the formal integration of various factors for heterogeneous populations. The blood test is based on a global Bayesian inference approach for the detection of abnormal values over time. Hb and ABPS3 (with Hct, Hb, RBC count, reticulocytes percentage, mean corpuscular volume, mean corpuscular Hb, mean corpusular Hb concentration variables) markers are used. Effects of gender [male, female], ethnicity [Caucasian, Asian, African, Oceanian], age [<19 years, 19-24 years, >24 years], altitude [<610, 610–1730, >1730], sport [endurance, non-endurance] on the mean of each parameter were taken from published data. Except for gender, the variance of blood parameters is considered independent of the factors and modeled as a log-normal distribution with parameters estimated from data collected on control subjects. Firstly, 135 blood profiles were collected from 22 top-level elite endurance athletes, 11 males and 11 females, participating in a study commissioned by the Swiss Federal Office for Sport to promote drug-free sports. Regular anti-doping tests were conducted on each athlete over a period of 2 years (6 blood and 11 urine samples in average) returning only negative test results. Secondly, 572 blood profiles were collected from 47 male amateur athletes over a period of two months. To summarized, 32 healthy volunteer males participated in this study. The aim was to reproduce rHuEPO doping habits practised in some sports. Eight subjects received subcutaneous injections of 40 IU/kg of EPREX three times a week (group R40), 8 subjects 80 IU/kg doses (group R80), 8 subjects received placebo (group P), and the last 8 subjects (group NT) had no treatment. rHuEPO administration in R40 and R80 groups was nevertheless individualized. A full dosage was administered for Hct below 45 percent, half doses for Hct between 45 and 50 percent, and substitution by isotonic saline when Hct exceeded 50 percent. Five hundred and ten blood samples (178 from doped subjects) were analyzed. In total, 1,039 samples collected in the three studies were used to estimate the specificity. Consideration of a new individual Hb value induces a new distribution of possible values of Hb, and, therefore, new individual reference range. The significant decrease between the first (a population-based threshold) and the last cut-off limit (an individual threshold) can be associated to a larger between-than within-subject variance of the hematological variable. All three aspects of the model (multiparametric approach, longitudinal analysis and consideration of heterogeneous factors) lead to a decrease of the overall variance of hematological data. A heightened sensitivity to discontinuous rHuEPO treatment was observed. A population-based strategy on Hb gives only 3 true positives for a specificity of 0.999, whereas the Bayesian model returned as much as 11 times more true positives. With the ABPS marker, sensitivity was even further improved [07124].
detection models applied. In recreational athletes, for EPO and sTfR, significant differences were only observed after the 21-km race. In baseline conditions, no differences were observed between recreational and elite athletes for EPO and sTfR. In elite athletes, individual EPO and sTfR concentrations slightly changed over the sport season, with coefficients of variation (CV) of 26 percent and 9 percent, respectively. Hemoglobin and reticulocytes were influenced by sport, but their individual variation over the sport season was not physiologically relevant. When applying mathematical models for detection of rhEPO administration, only one elite athlete obtained an individual model score above the established thresholds. Physical fitness, sport and different training workload during the sport season had no substantial effect on serum EPO and sTfR concentrations, except in recreational athletes after a 21-km race. Variations observed in mathematical models to detect EPO administration were mainly due to fluctuation in hemoglobin concentrations, commonly observed in elite athletes [07122].

The effects of recombinant human erythropoietin (rHuEpo) treatment on aerobic power (VO\textsubscript{2max}) are well documented, but little is known about the effects of rHuEpo on submaximal exercise performance. The present study investigated the effect on performance (ergometer cycling, 20-30 min at 80 % of maximal attainable workload), and for this purpose eight subjects received either 5,000 IU rHuEpo or placebo every second day for 14 days, and subsequently a single dose of 5,000 IU/placebo weekly/10 weeks. Exercise performance was evaluated before treatment and after 4 and 11 weeks of treatment. With rHuEpo treatment VO\textsubscript{2max} increased by 13 and 12 percent in week 4 and 11, respectively, and time-to-exhaustion (80 % VO\textsubscript{2max}) was increased by 54 and 54 percent after 4 and 11 weeks of treatment, respectively. However, when normalizing the workload to the same relative intensity (only done at time point week 11), TTE was decreased by 27 percent as compared to pre rHuEpo administration. In conclusion, in healthy non-athlete subjects rHuEpo administration prolongs submaximal exercise performance by about 54 percent independently of the approximately 12 percent increase in VO\textsubscript{2max} [07123].

False-positive detection following strenuous physical exercise
Erythropoietin (Epo) is a glycoprotein hormone that promotes the production of red blood cells. Recombinant human Epo (rhEpo) is illicitly used to improve performance in endurance sports. Doping in sports is discouraged by the screening of athletes for rhEPO in urine. The adopted test is based on a combination of isoelectric focusing and double immunoblotting, and distinguishes between endogenous and recombinant human Epo. It was shown that this widely used test can occasionally lead to the false-positive detection of rhEpo (epoetin-beta) in postexercise, protein-rich urine, probably because the adopted monoclonal anti-Epo antibodies are not monospecific [06161].

Effects of high intensity training on measurement techniques
Exercise induced proteinuria is a common phenomenon in high performance sports. Based on the appearance of so called "effort urines" in routine doping analysis the purpose of this study was to investigate the influence of exercise induced proteinuria on IEF profiles and SDS-PAGE relative mobility values (rMVs) of endogenous human erythropoietin (EPO). Twenty healthy subjects performed cycle-ergometer exercise until exhaustion. VO\textsubscript{2max}, blood lactate, urinary proteins and urinary creatinine were analysed to evaluate the exercise performance and proteinuria. IEF and SDS-PAGE analyses were performed to test for differences in electrophoretic behaviour of the endogenous EPO before and after exercise. All subjects showed increased levels of protein/creatinine ratio after performance (8.8 ± 5.2 to 26.1 ± 14.4). IEF analysis demonstrated an elevation of the relative amount of basic band areas. Using SDS-PAGE analysis it was observed a decrease in rMVs after exercise and no shift in direction of the recombinant human EPO (rhEPO) region. Following identification criteria of the World Anti Doping Agency all samples were negative. The implementation of
the SDS-PAGE method represents a good solution to distinguish between results influenced by so-called effort urines and results of rhEPO abuse. Thus, this method can be used to confirm adverse analytical findings [10126].

New laboratory technique

The constant development of new erythropoiesis-stimulating agents (ESAs), since the first introduction of recombinant erythropoietin (rhEpo) for clinical use, has also necessitated constant development of methods for detecting the abuse of these substances. Doping with ESAs is prohibited according to the World Anti-Doping Code and its prohibited list of substances and methods. Since the first publication of a direct and urine-based detection method in 2000, which uses changes in the Epo isoform profile as detected by isoelectric focusing in polyacrylamide slab gels (IEF-PAGE), the method has been constantly adapted to the appearance of new ESAs (e.g., Dynepo, Mircera). Blood had to be introduced as an additional matrix, because Mircera (a PEGylated Epo) is best confirmed in serum or plasma after immunoaffinity purification. A Mircera ELISA was developed for fast screening of sera. With the appearance of Dynepo and copy epoetins, the additional application of sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE or equivalent) became necessary. The hematological module of the Athlete Biological Passport is the latest development in multivariable indirect testing for ESA doping [11141].

The biochemical actions and side effects of recombinant erythropoietins (rhEPOs), their analogs and mimetics, their misuse as doping agents, and the principal analytical strategies developed to identify them in athletes' biologic fluids are reviewed. Patients who experience a range of pathologies have benefited from the administration of rhEPOs to correct severe anemia. Currently, monitoring the biologic effect of rhEPO in patients under treatment is by measuring the hemoglobin concentration. However, it may be valuable to directly monitor the actual levels of the administered drug and determine a dose-dependent correlation with any clinical adverse effect observed. This may permit the adoption of a patient-specific administration regime. Currently, the method of detecting EPO approved for doping control is an isoelectric-focusing, double-blotting, chemiluminescence assay based on charge differences between isoforms of rhEPOs and endogenous EPO in urine. The advantages and limitations of this method were presented. A new approach using sodium dodecyl sulfate-polyacrylamide gel electrophoresis as a complementary tool to the established method is discussed. The application of matrix-assisted laser desorption/ionization mass spectrometry and liquid chromatography combined with tandem mass spectrometry for the direct detection of the rhEPO molecules may prove to be promising. Indirect evidence of rhEPO abuse by athletes is based on the analysis of blood parameters (hemoglobin, hematocrit, reticulocytes, macrocytes, etc) and serum markers (concentration of EPO and serum transferrin receptors, etc). Enrichment of the screened parameters with gene or biochemical markers revealing altered erythropoiesis and adoption of longitudinal monitoring of athletes' hematologic and biochemical parameters could also be a complementary approach in the fight against doping [11142].

Isoelectric focusing

IEF can be used to differentiate human urinary erythropoietin (uEPO), recombinant human erythropoietin or epoetin (rEPO) and darbepoetin (novel erythropoiesis stimulating protein (NESP)). This is the basis of the method currently used to detect misuse of rEPO and NESP by elite athletes. Recently, an unknown activity has been attributed to some urine samples (denominated “unstable” urine by the World Anti-Doping Agency; WADA). This activity has shown to give rise to artefactual profiles for both rEPO and NESP when incubated with such urine and, thus, raised concerns with respect to doping control. It was evaluated which charges produce the characteristic IEF profiles of uEPO, rEPO and NESP and how these profiles respond to distinct enzymatic reactions. From sialidase digestions it became evident
that only uEPO contains charges different from sialic acid, and a comparison of all substances after complete de-N-glycosylation localized these charges in the carbohydrate moiety. Partial desialylation, or digestion with arylsulfatase from Helix pomatia yielded profiles for recombinants species similar to those observed for unstable urine samples. The contributions from our studies to the anti-doping problem include: protocols that may corroborate the potential misuse of rEPO or NESP based on the particular enzymatic activity of an arylsulfatase preparation, or a broad-specificity sialidase; assurance that the instability observed in some urine samples may only result from false-negatives, but not from false-positive testing; and a simple remedy to prevent an unstable urine from altering the IEF profile by adding selective competitive substrates [06159].

**Band segmentation**

In recent years, the development of methodology and laboratory techniques for doping control of recombinant erythropoietin (rEpo) has become one of the most important topics pursued by doping control laboratories accredited by World Anti-Doping Agency (WADA). The software system GASepo has been developed within the international WADA project as a support for Epo doping control. Although a great number of functions for automatic image processing have been involved in this software, for Epo images with considerably distorted bands additional effort is required from the user to interactively correct the results of improper band segmentation. In this paper a problem of geometrically distorted bands is addressed from the viewpoint of how to transform the lanes in distorted Epo images in order to reach better band segmentation. A method of band straightening via column shift transformation has been proposed that is formulated as an optimization procedure with cost functions. The method involves several novel approaches: two-stage optimization procedure, four cost functions and selection of relevant columns. The developed band straightening algorithm has been tested on real Epo images with distorted bands. Based on the evaluation scheme involving the GASepo software itself a recommendation is made for implementation of the method with the cost function based on correlation matrix. Estimates of computational complexity of the individual steps of BSA are also given [06160].

**DNA testing**

Endogenous and exogenous erythropoietin (EPO) present in urine can be distinguished according to their isoelectric profiles. This methodology requires urine samples to be concentrated about 200 to 1000 times with manipulations that should remove most of the cells occurring in the original sample. In one study, it was tried to obtain DNA profiles from 10 ultrafiltered urines (retentates) in order to evaluate whether a formal genetic identification was technically feasible. No nuclear DNA profiles could be established from retentates, despite 34 PCR-cycles amplifications. Contrastingly, mitochondrial DNA (mtDNA) profiles were obtained for 9 out of the 10 retentates. Apart from some particularities, retentate mtDNA profiles were all distinct and matched mtDNA profiles of corresponding reference samples [08234].

**Differences in laboratory accuracy**

The main action of recombinant human erythropoietin (rHuEpo) is to increase the oxygen carrying capacity of the blood. To prevent a possible misuse of rHuEpo, this is tested in urine samples collected from athletes by World Anti-Doping Agency (WADA)-accredited laboratories. Recently the test has met serious critiques, and the aims of one study were to investigate the detection power of the test as well as the variability in the test power comparing the results of two WADA-accredited laboratories. Eight human subjects were studied for 7 weeks and treated with rHuEpo for 4 weeks with 2 weeks of “boosting” followed by 2 weeks of “maintenance” and a post period of 3 weeks. Urine samples were obtained during all periods. Laboratory A determined rHuEpo misuse in all subjects during the boosting period, whereas laboratory B found no misuse, with one sample to be negative, and
the remaining seven to be suspicious. The detection rates decreased throughout the maintenance and post period when total hemoglobin mass and exercise performance were elevated. During this period, laboratory A found only two of 24 samples to be positive and three to be suspicious, and laboratory B found no positive or suspicious samples. The study demonstrates a poor agreement in test results comparing two WADA-accredited laboratories. Moreover, after the initial rHuEpo boosting period the power to detect rHuEpo misuse during the maintenance and post periods appears minimal [08231].

**Hepcidin as a marker**

Inhibition of hepcidin expression by erythropoietic signals is of great physiological importance; however, the inhibitory pathways remain poorly understood. To investigate the direct effect of erythropoietin (Epo) and the contribution of putative mediators on hepcidin repression, healthy volunteers were injected with a single dose of Epo, either low (63 IU/kg, n=8) or high (400 IU/kg, n=6). Low-dose Epo provoked hepcidin down-modulation within 24 h; the effect was not immediate as hepcidin circadian variations were still present following injection. High-dose Epo induced no additional effect on the hepcidin response, that is hepcidin diurnal fluctuations were not abolished in spite of extremely high Epo levels. It was not found significant changes in putative mediators of hepcidin repression, such as transferrin saturation, soluble transferrin receptor, or growth differentiation factor 15. Furthermore, the potential hepcidin inhibitor, soluble hemojuvelin, was found unaltered by Epo stimulation. This finding was consistent with the absence of signs of iron deficiency observed at the level of skeletal muscle tissue. The data suggest that hepcidin repression by erythropoietic signals in humans may not be controlled directly by Epo, but mediated by a still undefined factor [13307].

The human hepcidin-25 hormone has a key role in iron regulation in blood. The clinical relevance of this hepatic about 2.8 kDa cysteine-rich peptide is rapidly increasing, since altered levels can be associated with inflammatory events and iron dysfunctions, such as hereditary hemochromatosis and iron overload. Moreover, hepcidin has also attracted the anti-doping field for its possible role as indirect marker of erythropoietin blood doping. Methods currently reported are based on immunoassays (ELISA and RIA), or various types of mass spectroscopy (MS)-based protocols, semi-quantitative or quantitative. Despite the great effort in optimizing robust and simple assays measuring hepcidin in real matrices, at present this challenge remains still an open issue. To explore the possibility to face hepcidin detection through the development of affinity-based biosensors, we set up a comparative study by surface plasmon resonance (SPR) technology. An immuno-based, on anti-hepcidin-25 IgG, and a biomimetic-based, on a synthetic peptide corresponding to the hepcidin-binding site on ferroportin (HBD), biosensors were developed. It was reported behaviors and analytical performances of the two systems, discussing limits and potentialities [13308].

Inhibition of hepcidin expression by erythropoietic signals is of great physiological importance; however, the inhibitory pathways remain poorly understood. To investigate the direct effect of erythropoietin (Epo) and the contribution of putative mediators on hepcidin repression, healthy volunteers were injected with a single dose of Epo, either low (63 IU/kg, n=8) or high (400 IU/kg, n=6). Low-dose Epo provoked hepcidin down-modulation within 24 h; the effect was not immediate as hepcidin circadian variations were still present following injection. High-dose Epo induced no additional effect on the hepcidin response, that is hepcidin diurnal fluctuations were not abolished in spite of extremely high Epo levels. We did not find significant changes in putative mediators of hepcidin repression, such as transferrin saturation, soluble transferrin receptor, or growth differentiation factor 15. Furthermore, the potential hepcidin inhibitor, soluble hemojuvelin, was found unaltered by Epo stimulation. This finding was consistent with the absence of signs of iron deficiency
observed at the level of skeletal muscle tissue. Our data suggest that hepcidin repression by erythropoietic signals in humans may not be controlled directly by Epo, but mediated by a still undefined factor [13309].

MicroRNAs

Due to the complexity of detecting and differentiating recombinant EPO from its natural analog in human urine or blood, alternative indirect approaches have been subject of various recent studies. One of these elucidated the impact of EPO administration on circulating and/or renally eliminated microRNAs (miRNA) and their potential as long-term biomarkers for ESA doping. Following the intravenous or subcutaneous administration of Mircera (200 microg), plasma samples were collected for up to 27 days and analyzed for miRNA affected in a statistically significant manner. Among a variety of marker candidates, miR-144 was the most influenced parameter, which was significantly elevated 27 days post-administration of Mircera and thus possibly representing a valuable alternative marker for illicitly administered ESAs. These preliminary findings will require in-depth elucidation and validation but possess the potential for expanded complementary doping control assays. Hepcidin has been considered as another potential marker for EPO administration due to its decreased serum concentration following subcutaneous EPO injections. Whether the effect also prevails upon i.v. applications of 50 IU/kg bodyweight was subject of a study by Laine et al. in 2012. Despite significantly elevated (4 h post administration) and subsequently decreased (24 h post administration) serum hepcidin levels, the dynamics and variability of the marker essentially excluded its utility as indicator for doping control purposes [13012].

MicroRNAs (miRNAs) are small non-coding RNAs that regulate various biological processes. Cell-free miRNAs measured in blood plasma have emerged as specific and sensitive markers of physiological processes and disease. In this study, we investigated whether circulating miRNAs can serve as biomarkers for the detection of autologous blood transfusion, a major doping technique that is still undetectable. Plasma miRNA levels were analyzed using high-throughput quantitative real-time PCR. Plasma samples were obtained before and at several time points after autologous blood transfusion (blood bag storage time 42 days) in 10 healthy subjects and 10 controls without transfusion. Other serum markers of erythropoiesis were determined in the same samples. Our results revealed a distinct change in the pattern of circulating miRNAs. Ten miRNAs were upregulated in transfusion samples compared with control samples. Among these, miR-30b, miR-30c, and miR-26b increased significantly and showed a 3.9-, 4.0-, and 3.0-fold change, respectively. The origin of these miRNAs was related to pulmonary and liver tissues. Erythropoietin (EPO) concentration decreased after blood reinfusion. A combination of miRNAs and EPO measurement in a mathematical model enhanced the efficiency of autologous transfusion detection through miRNA analysis. Therefore, our results lay the foundation for the development of miRNAs as novel blood-based biomarkers to detect autologous transfusion [13320].

Further biomarkers could be derived from circulating miRNAs for the abuse of ESAs. On the basis of microarray results, a significant difference in the levels of miRNAs was measured in plasma after CERA injection, even for a longer period of time as the increase of the specific miR-144 lasted 27 days after CERA administration. Similarly, the same group described that autologous blood transfusion leads to an increase of selected circulating miRNAs in plasma of pulmonary and liver tissue origin compared to a non-transfused control group (personal communication) [13006].

Confounding factors for erythropoietin detection
The detection window for rhEPO is known to be relatively short and depends on the dosage and the method of administration: Whereas subcutaneous administration of rhEPO in clinical dosages (e.g. 50 IU/kg body weight) might be detected over several days, it has been demonstrated that intravenous administration and microdosing (i.e. 500 IU) are virtually undetectable while still producing a measurable erythropoietic effect. In order to blur the IEF picture, athletes nowadays use mixtures of different rhEPO, knowing that these will produce uncharacteristic patterns which will have difficulties in meeting the positivity criteria for positive rhEPO tests set by WADA. To overcome this limitation and other sampling-related problems such as bacterial degradation or exercise-associated proteinuria, which might interfere with IEF results, another method for the detection of EPO misuse, SDS/SAR-PAGE (sodium dodecyl sulfate/sarcosyl polyacrylamide gel electrophoresis) was developed. This method relies on the difference in molecular weight of the different types of EPO and is able to identify different rhEPO variants. With rhEPO being one of the commercially most successful drugs developed over recent decades, many biosimilars were marketed in different countries (epoietin alpha, delta, kappa, omega etc). As these biosimilars are also slightly different in their molecular mass (because they originate from different transfected cells), they are detectable by the same testing principles of SDS-PAGE. Because of low urine excretion Continuous Erythropoietin Receptor Activator (CERA) is harder to detect, however, glomerular permeability is increased with strenuous exercise. In addition CERA can be detected with ELISA. However, even substances with modified molecular structure such as darbepoietin (Aranesp®) or CERA (continuous erythropoietin receptor activator, Mircera®), developed to have a longer half-life in the organism, can be detected, as they usually contain a conventional epoietin backbone paired with another component to slow its excretion and prolong its action in the organism (i.e. methoxy polyethylene glycol for CERA). It has to be acknowledged that not all rhEPO variants will be detectable, as those manufactured by underground laboratories constitute an analytical challenge, these EPO forms being slightly different and changing from batch to batch. Conversely, when applying the WADA positivity criteria, these are often not met. Unfortunately, microdoses of rhEPO, sufficient to give a pharmacological effect can have a detection window as low as 12-18 h. Urine manipulation with protein degrading proteases might decrease this even further [13006].

Available erythropoietins

Peptidic erythropoiesis-stimulating agents
Currently available rhEpo preparations (epoetins) are produced in Epo complementary DNA (cDNA) transfected Chinese hamster ovary (CHO) or baby hamster kidney (BHK) cell cultures. The only therapeutic rhEpo engineered in human cells (epoetin-beta) is off market since the beginning of 2009. Because the patents of the originator epoetins have died, biosimilar products have been approved in many parts of the world. Furthermore, various copied CHO cell-derived rhEpos are available in countries without a regulated market. Endogenous Epo and the epoetins have an invariant sequence of 165 amino acids, but they differ in glycosylation. Compared with the epoetins, endogenous Epo isoforms are more acidic and smaller in size. Epo can be separated by isoelectric focusing (IEF) or electrophoresis of urine samples. After IEF, a double-blotting procedure is performed. The mutein darbepoetin-alfa migrates more in the acidic range than Epo on IEF. The WADA has established criteria to achieve harmonization in the performance of the test for epoetin and darbepoetin in urine. A recent detection problem has arisen with the addition of proteases by athletes to their urinary samples, which destroys the erythropoietic proteins. The adulteration of urine with proteases is a prohibited method, and techniques have been developed for the detection of their misuse. Another difficulty relates to the fact that once hemoglobin concentration has been raised in athletes by the administration of recombinant ESAs, only microdoses or less frequent injections of the drugs are needed to maintain hemoglobin at the
high level. In this situation, the window of detection of rhEpo in urine is only 12-18 hours, compared with about 3 days on regular dosing (50 U/kg body weight 3 times a week). Thus, although the detection of rhEpo in urine is effective if the injection frequency is high, this is certainly not the case when the injection rate is reduced to weekly injections. Because darbepoetin-alfa has a 3- to 4-fold longer half-life (24-26 hours) than the epoetins (6-8 hours), the window of detection of darbepoetin-alfa is prolonged to approximately 7 days. CERA has an even longer half-life of approximately 6 days. IEF of CERA yields bands in the less acidic area compared with native Epo. IEF for investigation of doping with CERA has also been applied to blood samples.47 In addition, CERA can be detected by ELISA. Of particular interest are also recombinant fusion proteins of Epo with the Fc region of human IgG because one of these was shown to stimulate erythropoiesis, when administered as an aerosol in a phase 1 trial. Epo mimetic peptides (EMPs) are synthetic cyclic peptides of about 20 amino acids. A potent pegylated EMP dimer (INN: peginesatide; Hematide) proved to stimulate erythropoiesis in experimental animals and in healthy male volunteers. Peginesatide is currently in phase 3 trials for the treatment of patients with chronic renal failure. Peginesatide can be detected by enzyme-linked immunoassay. In an alternative approach, EMPs have been constructed onto human IgG1-based scaffolds by recombinant DNA technology. The seminal compound, CNTO 528 (Centocor), produced a reticulocytosis and increased hemoglobin concentration on intravenous administration in a phase 1 study in healthy men. The follow-on product CNTO 530, a dimeric EMP fused to a human IgG4 Fc scaffold, has been shown to expand the pool of erythroid progenitors in vitro and in vivo [11116].

**Drugs activating the endogenous Epo gene**
The Epo enhancer is under the control of HIFs, heterodimeric proteins composed of two subunits. HIF-2 is the main factor inducing Epo gene expression. The C-terminus of HIF is composed of proline residues that are hydroxylated in the presence of oxygen. Prolyl hydroxylated HIF binds the von Hippel-Lindau tumor suppressor protein in complex with an E3-ligase and undergoes immediate proteasomal degradation. The transcriptional activity of the HIFs is suppressed by O2-dependent hydroxylation of an asparagine residue. The HIF hydroxylases contain Fe^{2+} and are inactivated by Fe^{2+} removal. However, iron chelators are not suited for stimulation of erythropoiesis in the long-term because iron is required for heme synthesis. HIF-dependent Epo gene expression is augmented by divalent transition metals, such as cobalt or nickel. It has been known that cobalt increases erythropoiesis in experimental animals. Cobalt binds to HIF thereby preventing the docking of von Hippel-Lindau tumor suppressor protein. Cobalt is a very potent inducer of Epo gene transcription. Indeed, the international Epo unit (IU) was originally defined as the dose eliciting the same erythropoiesis stimulating response in rats as 5 micromol of cobaltous chloride. However, the treatment of anemic uremic patients with cobalt (commonly administered as enteric-coated tablets, 30-150 mg daily) is no longer performed because of its toxicity. However, cobalt may be misused by athletes as a proper means to enhance Epo levels and Hb_{mass}. Cobalt is very potent, inexpensive, and not comprehended in the WADA’s “Prohibited List.” Furthermore, the HIF hydroxylases require alpha-ketoglutarate for their catalytic action. alpha-Ketoglutarate competitors (“HIF stabilizers”) are orally active compounds that stimulate Epo production and erythropoiesis. A number of chemically different HIF stabilizers has been identified. However, HIF stabilizers induce the expression of more than 200 genes apart from Epo genes, which may result in serious unwanted effects in athletes. On the other hand, it is probable that some of the HIF-activated genes encode proteins that may increase physical performance (e.g. glycolytic enzymes, glucose transporters, and angiogenic peptides) [11116].

**Other erythropoietic hormones**
Several hormones may stimulate the renal and/or hepatic production of Epo, including
prostanoids, thyroid hormone, angiotensin II, growth hormone (GH), and testosterone. The latter are of particular interest regards blood doping. A study in anemic uremic patients has shown that plasma Epo levels increase 6 hours after the start of GH infusion, with peak values reached after 96 hours. The fact that the rise in plasma Epo occurred earlier than the rise in insulin-like growth factor-1 (IGF-1) indicates that GH directly stimulates Epo production. IGF-1 was earlier shown to promote the growth of erythrocytic progenitors. The concentration of circulating IGF-1 correlates with hematocrit in uremic patients. Synthetic GH secretagogues (ghrelin mimetics), recombinant human GH, and recombinant human IGF-1 are available for therapeutic purposes. Anabolic-androgenic steroids also increase both the production of Epo and the proliferation of erythrocytic progenitors in the bone marrow [11116].

C.E.R.A., a continuous erythropoietin receptor activator

Methoxy polyethylene glycol-epoetin beta is a third-generation molecule of continuous erythropoietin receptor activator (CERA), incorporating a large polymer chain and has an elimination half-life in humans that is up to 6 times longer than darbepoetin alpha and up to 20 times longer than epoetin, making it possible for once in 2 weeks to once a month dosing strategy. The successful conversion of patients on epoetin or darbepoetin to CERA has been successfully demonstrated. The starting dose of CERA would be 125 microg if the patient had previously received <8000 U epoetin weekly or <40 microg darbepoetin weekly, or a dose of 200 microg if the patient had previously received 8000-16,000 units epoetin weekly or 40-80 microg darbepoetin weekly. It is administered either iv or sc. The iv route is recommended for patients receiving hemodialysis because it may be less immunogenic. CERA can be administered once in every 2 weeks or once monthly to patients whose hemoglobin has been stabilized by treatment with an EPO [12242].

Since the 90's, human erythropoietin is produced recombinantly and used clinically. There are various products from different suppliers, which differ primarily in their production but not in their half-life or effectiveness. 2001 genetically modified darbepoetin alpha was launched, which is characterized by an approximately three times longer half-life. A further extension of the half-life to 130 hours is achieved with the current continuous erythropoietin receptor activator (CERA), which therefore must be applied only once or twice a month. The indication for epoetin therapy is primarily for the symptomatic renal anemia and chemotherapy-associated anemia. Corrections of low hemoglobin levels in asymptomatic patients are not allowed. The generally recommended hemoglobin target range is 10-12 g/dL. Hb values > 13 g/dL should be avoided because they are associated with significant adverse effects and do not improve patient survival [11465].
erythropoiesis-stimulating agent (ESA) that has recently been linked with abuse in endurance sports. In order to combat this new form of doping, we examined an enzyme-linked immunosorbent assay (ELISA) designed to detect the presence of C.E.R.A. in serum samples. The performance of the assay was evaluated using a pilot excretion study that involved six subjects receiving C.E.R.A. Validation data demonstrated an excellent reproducibility and ensured the applicability of the assay for anti-doping purposes. To maximize the chances of detecting the drug in serum samples, we propose the use of this specific ELISA test as a high-throughput screening method, combined with a classic isoelectric focusing test as a confirmatory assay. This strategy should make C.E.R.A. abuse relatively easy to detect, thereby preventing the future use of this drug as a doping agent [09171].

Erythropoietin (EPO) has been misused in sports for many years due to its performance-enhancing effect. In the last decade, detection of abuse has been possible with isoelectric focusing (IEF) based on the different isoform profiles of endogenous and recombinant EPO. The release of new EPOs on the market, such as the recombinant erythropoietin epoetin delta (Dynepo™) and the chemically modified EPO, CERA (Mircera™) potentially represents analytical challenges to the fight against doping. One study set out to investigate the possibility of and the time window for detecting the administration of a single dose of Dynepo™ and CERA. Our results are in agreement with earlier findings that detection of Dynepo™ is best achieved by combining IEF with SDS-PAGE. Hematological parameters were monitored for possible effects due to the long half-life (130 hours) of CERA in blood. Interestingly, although several haematological parameters were significantly changed after the injection of CERA, the endogenous EPO signal was still present in all collected samples. Due to the long half-life and the large size of the CERA molecule (about 60 kDa), it was uncertain whether CERA would be excreted into urine in detectable amounts unless urine collection was preceded by strenuous physical exercise. It was found that CERA can be detected in urine without prior exercise in several, but not all, subjects. CERA is nevertheless best detected in serum with regard to both probability and length of detection, in addition to stability in matrix over time [11143].

Darpoietin/NESP

Erythropoietin (EPO) is a hormone that regulates red blood cell production. Recombinant human EPO (rHuEPO) and NESP (novel erythropoiesis stimulating protein) have been produced for therapeutic purposes and also to improve sports performance. The primary sequences of rHuEPO and NESP differ by just five amino acids. Due to the high homology, no antibodies that are able to discriminate between both molecules have been obtained until now. The aim of one work was to design synthetic peptides corresponding to the sequence that differs between EPO and NESP (87-90aa), that can then be used as immunogens to develop specific rabbit polyclonal antibodies for selectively detecting EPO and NESP. Three peptides were synthesized: EPO (81-95), NESP (81-95), and NESP (86-104), and these were coupled to KLH and OVA for immunization and screening purposes, respectively. The sera obtained were tested by ELISA on synthetic peptide-OVA conjugates and purified by immunoaffinity chromatography against the corresponding synthetic peptide. The specific purified antibodies were characterized by ELISA, SDS-PAGE, and isoelectric focusing, followed by western blot. Antisera raised against EPO (81-95) recognized rHuEPO but not NESP. In contrast, anti-NESP (84-106) sera gave a specific anti-NESP response only after immunoaffinity purification on a NESP (86-91) column. An efficient strategy for generating specific antibodies against EPO and NESP can be achieved by selecting suitable synthetic peptides. The antibodies obtained are able to differentiate between rHuEPO and NESP, and may be particularly useful for screening purposes in both therapeutic and antidoping contexts.
Darbepoetin alfa (DPO) or Novel Erythropoiesis Stimulating Protein (NESP), an analog of recombinant human erythropoietin (rhEPO), is abused as a blood doping agent along with the latter in human sports. One paper described a new method for unequivocal identification of DPO in human plasma. The analyte was extracted from plasma by immunoaffinity separation with anti-rhEPO antibodies, digested by trypsin followed by PNGase F, and analyzed by liquid chromatography coupled to tandem mass spectrometry. The deglycosylated tryptic peptide was employed in DPO identification using liquid chromatographic retention time and major product ions of the peptide. The limit of detection of this method for DPO was 0.1 ng/mL in plasma, and that of identification was 0.2 ng/mL. This method is definitive and devoid of false positive results, providing "mass fingerprints" for identification of DPO in human plasma samples. Although this method is not applicable to identification of rhEPO in human plasma because it cannot differentiate rhEPO from endogenous EPO, it is the first successful attempt towards establishing a reliable and selective method for definitive identification of exogenously administered EPOs in doping control analyses.

Darbepoetin alfa is a modified erythropoietin (EPO) molecule with a longer serum half-life than recombinant human erythropoietin (rhEPO). Because the detection period of rhEPO in urine is only 2-3 d after the last injection, blood algorithms have been developed in order to expand the detection window of rhEPO misuse. The main objectives were to establish the period of detection of darbepoetin alfa by isoelectric focusing (IEF) and examine the applicability of blood algorithms and individual variations in blood variables in an antidoping context. Six recreationally active males and six recreationally active females had 0.78 microg/kg per week of darbepoetin alfa administered for 3 weeks. Blood and urine samples were collected continuously during and after administration. Urine samples were analyzed by IEF and immunoblotting for darbepoetin alfa, and blood samples were analyzed for erythropoietic sensitive blood variables on a hematological analyzer. Darbepoetin alfa was detected in 8 of 12 samples at 10 d after the last injection. Ten subjects showed variations in hemoglobin concentration > 10 percent, whereas only three males and one female exceeded suggested upper hemoglobin concentration limits of 17.0 and 16.0 g/dL, respectively. Four subjects exceeded the 1:1000 ON- as well as the OFF-model cutoff limit. It was concluded that the large number of samples containing detectable amounts of darbepoetin alfa at 10 days into the washout period stipulate the possibility of a 7-days window of detection after administration, wherein a sample would be regarded as an adverse analytical finding. The marked variations in all examined blood parameters could be used for the targeting of urine samples. These preliminary findings open up for larger scale studies with more frequent urine sampling in the washout period on elite athletes.

Darbepoetin alpha (a hyperglycosylated rhEPO): It has five N-glycosylation sites as compared to three in the rhEPO. This is created by a process called "site mutagenesis" and confers higher negative charge and threefold longer half-life. This is based on the principle that increase in number of glycosylation sites may enhance its activity. This helps in giving once a week dosing strategy. The approved dosage in anemia of CKD is 0.45 mcg/kg iv or sc. Weekly monitoring of hemoglobin is suggested upon initiation of therapy and then to maintain hemoglobin levels <12 g/dL and to avoid increases of hemoglobin >1 g/dL over a 2-week period.

The current official direct recombinant erythropoietin (rHuEPO) detection anti-doping test based on 1D isoelectric focusing (IEF) of urinary proteins was performed to determine the detection window of darbepoetin-alpha when applying the positivity criteria established by the World Anti-Doping Agency (WADA). Following WADA's positivity criteria, the IEF based
The misuse of recombinant human erythropoietin (rhEPO) increases the proliferation/production of erythrocytes, which enhance oxygen transport capacities, and has grave consequences with respect to human health and fairness in sports. For sports drug testing, the current analytical methods for rhEPOs are mainly gel electrophoretic methods, such as isoelectric focusing-polyacrylamide gel electrophoresis. Mass spectrometry is fundamentally necessary for the reliable identification of rhEPOs in doping control. In this study, a high-sensitivity and high-throughput mass spectrometric qualitative detection method for darbepoetin alfa in human urine was established by a bottom-up approach. The novel method involves the immunopurification of human urine (10 mL), protease digestion with endoproteinase Glu-C (V8-protease) in an ammonium bicarbonate buffer (pH 7.8) and ultra-performance liquid chromatography using a charged surface hybrid C(18) column coupled with electrospray-ionisation high-sensitivity tandem mass spectrometry for improved selectivity of the target molecules. The specific fragment digested from darbepoetin alfa was (90)TLQLHVDKAVSGLRSLTTLLRALGAQKE(117) (V(11)). The lower limit of detection of urinary darbepoetin alfa was 1.2 pg/mL. The limit of detection for the confirmation analysis was estimated to be 5 pg/mL. The developed method allows high-throughput confirmation analysis, namely 6 h for sample preparation and an analytical run time of only 10 min per sample; this high-throughput method dramatically decreases the workload in the laboratory. Darbepoetin alfa could be identified in human urine collected after the intravenous administration of 15 microg darbepoetin alfa (n=3). This mass spectrometric method is an innovative and powerful tool for detecting darbepoetin alfa in human urine for doping control testing [13322].

Epoetin delta (Dynepo®)

A novel recombinant human erythropoietin (epoetin delta, Dynepo®) has been marketed in the European Union for the treatment of chronic kidney disease, cancer patients receiving chemotherapy, and so forth. Epoetin delta is engineered in cultures of the human fibrosarcoma cell line HT-1080 by homologous recombination and “gene activation." Unlike recombinant erythropoietins produced in other mammalian cells, epoetin delta is supposed to have a human-type glycosylation profile. However, the isoelectric focusing profile of epoetin delta differs from that of endogenous erythropoietin (both urinary and plasmatic). In one work, structural and quantitative analysis of the O- and N-glycans of epoetin delta was performed and compared with glycosylation from recombinant erythropoietin produced in Chinese hamster ovary cells. From the comparison, significant differences in the sialylation of O-glycans were found. Furthermore, the N-glycan analysis indicated a lower heterogeneity from epoetin delta when compared with its ovary cell homologue, being predominantly tetraantennary without N-acetyllactosamine repeats in the former. The sialic acid
characterization revealed the absence of N-glycolylneuraminic acid. The overall sugar profiles of both glycoproteins appeared to be significantly different and could be useful for maintaining pharmaceutical quality control, detecting the misuse of erythropoietin in sports, and establishing new avenues to link glycosylation with biological activity of glycoproteins [08232].

Aiming for the determination of detection windows concerning the administration of Dynepo or Mircera, haematological parameters as well as SDS-PAGE and IEF-PAGE were conducted on urine and serum samples of participants of an excretion study. Following a single subcutaneous injection of 75 microg (men) or 50 microg (women) of Mircera or 4000 IU of Dynepo, urine, EDTA blood, and serum were collected up to 21 days. Dynepo was identified in urine up to 4 days while Mircera was observed in urine in several cases for more than 6 days and in serum in most volunteers up to 14 days [12016].

Hematide®

Erythropoietin (EPO) and other erythropoiesis-stimulating agents possess a high misuse potential in elite sport due to their ability to increase the oxygen transport capacity, which plays a vital role in enhancing endurance performance. Currently, a new generation of EPO-mimetic peptides is under development from which peginesatide (also referred to as Hematide®), a pegylated homodimeric peptide of approximately 45 kDa with no structural relationship to erythropoietin, is the most advanced drug candidate undergoing phase-III clinical trials. Since preventive doping research aims at the development of detection methods before a drug receives clinical approval, a selective and sensitive assay has to be established knowing that conventional doping control assays for EPO will not succeed in detecting peginesatide. Thus, a pegylated EPO-mimetic peptide simulating the structure and properties of the lead drug candidate peginesatide was synthesised as a model compound for this new class of emerging drugs and characterised by means of gel electrophoresis, matrix-assisted laser desorption/ionisation (MALDI) mass spectrometry, as well as liquid chromatography/electrospray ionisation tandem mass spectrometry (LC/ESI-MS/MS) after proteolytic digestion. Based on these results, a mass spectrometric detection method of the product in plasma was developed targeting a pentapeptide fragment after protein precipitation and subtilisin digestion. Its fitness for purpose was evaluated by the determination of selected method characteristics focusing particularly on specificity, recovery (about 60 %), and limit of detection (1 ng/mL) [13339].

Erythropoiesis-stimulating agents (ESAs) have frequently been confessed to be illicitly used in elite sports due to their endurance enhancing effects. Recently, peginesatide, the first representative of a new generation of ESAs, referred to as Erythropoietin (EPO)-mimetic peptides, obtained approval in the USA under the trade name Omontys(®) for the treatment of anaemic patients. Lacking sequence homology with EPO, it consists of a pegylated homodimeric peptide of approximately 45 kDa, and thus, specific approaches for the determination of peginesatide in blood were developed as conventional detection assays for EPO do not allow for the analysis of the EPO-mimetic peptides. However, as urine specimens are the most frequently provided doping control samples and pharmacokinetic studies conducted in rats and monkeys revealed the excretion of the pegylated peptide into urine, a detection method for peginesatide in urine would be desirable. A mass spectrometric assay in human urine was developed consisting of protein precipitation with acetonitrile followed by proteolytic digestion after the removal of the acetonitrile fraction under reduced pressure. Purification and concentration of the resulting proteotypic target peptide was accomplished by means of solid-phase extraction on strong cation-exchange resin prior to liquid chromatographic-tandem mass spectrometric analysis. Method validation was
performed for qualitative purposes and demonstrated specificity, precision, linearity as well as sufficient sensitivity (limit of detection: 0.5 ng/ml) while proof-of-concept for the applicability of the assay for the determination of peginesatide in authentic urine samples was obtained by analyzing animal in vivo specimens collected after a single i.v. administration of peginesatide over a period of 4 days [12259].

As recently reported, dried blood spot (DBS) analysis is an advantageous technique for doping control purposes due to the minimal invasive sample collection, the simple and economic manner, as well as the low susceptibility to manipulation. Its general applicability to the sports drug testing arena has been shown for analytes of various substance classes, all of which comprise exclusively low molecular mass compounds. The aim of one study was to investigate whether the technique of DBS analysis is applicable also to (pegylated) peptides with relevance for doping controls. As target analyte, peginesatide (Omontys, Hemitide), a recently approved pegylated erythropoietin-mimetic peptide of approximately 45 kDa, tested for the treatment of anaemia in patients with renal failure, was chosen, which has been prohibited in elite sports due to its assumed endurance enhancing effects. Therefore, a detection method for peginesatide employing DBS was developed based on extraction, proteolytic digestion and cation-exchange purification followed by liquid chromatography-tandem mass spectrometry analysis. Eventually, the assay was validated for qualitative purposes and proved to be specific, sensitive (limit of detection, 10 ng/mL) and precise (relative standard deviations below 18 %), demonstrating the general suitability of DBS analysis in sports drug testing also for (pegylated) peptides [12260].

Non-EPO-related erythropoiesis stimulating agents

With the market for anti-anemia drugs in 2012 estimated to be close to USD 10 billion in the USA alone, it is clear that there is a strong research incentive for pharmaceutical companies which has led to the development of new ESAs, unrelated to the conventional EPO. Several approaches have been proposed:

Most of the substances are still in clinical trials, but the past has shown that black market laboratories are quick in copying drugs before even official approval has been granted to the developing pharmaceutical companies. One drug which had US Food and Drug Administration (FDA) approval in the USA until recently is peginesatide (marketed as Omontys®), a peptide structurally unrelated to EPO but with erythropoietic abilities. After
hypersensitivity reactions in first-time users had resulted in three deaths, the drug was withdrawn from the market in February 2013. Fusion proteins are peptides resulting from the fusion of genes that initially coded for different proteins. The resulting peptides very often have properties from both of the genes they originated from. Fusion proteins are found in cancer cells, where they occur naturally as a result of cancer-associated mutation. In EPO research, fusion proteins showing erythropoietic capacity have been created and advanced to clinical trials. Some have been attached to immunoglobulin, which facilitates their administration (e.g. as an aerosol through a nasal spray). CNTO 530, an IgG4 fused peptide, increased erythropoietic activity after a single administration in mice. Unfortunately EPO gene manipulation has for many years been recognized as a potential undetectable doping method. There are several scientific reports on the successful transfer of the EPO gene via a viral vector into muscle or dermal cells. The technique demonstrated reliable increase in all erythropoietic markers. Hypoxia inducible factor (HIF) 1alpha is the upstream regulator of the EPO signal in the organism. Under conditions of normoxia, this protein is usually immediately degraded by prolyl hydroxylases after its synthesis. Hypoxia, however, inhibits prolyl hydroxylases and thereby stabilizes the HIF-1alpha protein which can then fulfill its action and induce the transcription of EPO. EPO will subsequently stimulate the erythropoietic cascade. Therapeutic anti-anemia strategies aim to inhibit the prolyl hydroxylases that induce the breakdown of HIF-1alpha. A multitude of substances have been developed in this context and are currently at various stages of clinical experimentation [13006].

Other than through prolyl hydroxylases and HIF-1alpha, EPO gene expression is also regulated through transcription factors that will negatively affect the transcription: So-called GATA proteins bind to a certain sequence on the EPO promoter gene and inhibit its transcription, thus negatively affecting the EPO cascade. The activity of these GATA binding proteins can be altered by GATA inhibitors, which have been shown to measurably affect erythropoiesis. As most of the substances mentioned above are not naturally occurring in the body, their detection with conventional methods is, in theory, not problematic. Furthermore, many of the drugs are aimed at long-term action to overcome the frequent injections necessary with conventional EPO, which would improve the quality of treatment for the patient, but also the detection window for anti-doping tests. Interestingly, the EPO gene transfer seems also to be detectable: Lasne et al. demonstrated in primates that the EPO originating from the transferred gene is different from the endogenous one, possibly because of the mild difference in cell organelles between the different types of cells. Whereas natural, endogenous EPO originates from kidney fibroblasts, the EPO genes are often transferred into muscle cells by using their cell organelles and thus creating a slight difference in glycosylation and molecular mass [13006].

**Synthetic peptide-based EPO receptor agonist**

The development of erythropoiesis-stimulating agents (ESA) for the treatment of anemia has been a highly active field over the past 2 decades, wherein 6 different rEPOs have been licensed worldwide and more than 90 biosimilar rEPOs or copies have become available in countries with low regulatory controls of pharmaceutical products. This frenzied rhythm is expected to continue because new generations of ESAs are expected in the near future, such as the synthetic peptide-based EPO receptor agonist Hematide®; the conjugated EPO-mimetic peptide Sestide®; hypoxia-inducible transcription factor stabilizers, such as FG-2216®; and modified cells that carry the human EPO gene or the EPO protein, such as EpoDure®. In parallel with increasing numbers of prescribed ESAs, some designer rEPOs have been created by black market laboratories to get around existing drug tests. All ESAs aim to improve oxygen transport by the metalloprotein hemoglobin. Consequently, measurement of hemoglobin concentration (HGB), one of the most common medical tests in a full blood count profile, has been used as a biomarker of blood doping. In the mid-1990s,
some sports federations introduced upper limits on HGB and hematocrit (HCT) levels, and athletes with values above these limits were temporarily suspended from competition in an attempt to limit the abuse of rEPO. Interestingly, such doping biomarkers are independent from the marketing of novel doping substances, and although the pharmaceutical industry continues to market new drugs every year, the biology of the human body is relatively stable for general physiological functions. The evolution of the human body takes at least several generations, and owing to this biological stability, a biomarker of doping such as hemoglobin measurement will remain sensitive to any past, present, or future ESA abuse. As a result, there is an ongoing paradigm shift in testing, from the direct identification of banned substances in the biological fluids of athletes to the detection of abnormalities in biomarkers that potentially indicate that doping has occurred. Although it is difficult to predict which of the new ESAs will be available during the 2016 Olympic Games in Rio de Janeiro and beyond, the biological characteristics of the athletes participating in these games will not differ from the biological characteristics of athletes that are competing today. Consequently, all of the doping biomarkers that have already been developed will remain applicable in the upcoming Olympic Games and for several decades into the future, whereas a toxicology test must be established for almost every newly marketed drug. For example, today’s biomarkers of blood doping are already sensitive to gene doping with the human EPO gene [11426].

EPO-Fc fusion protein

The neonatal Fc receptor (FcRn) has been under investigation for several years as a pharmaceutical drug target. Clinical studies have shown that fusion proteins consisting of human recombinant erythropoietin (rhEPO) and the Fc-part of IgG can be transported after pulmonary administration via FcRn across the airway epithelium to the blood stream. So far, no clinically approved pharmaceutical formulation of EPO-Fc is available. Since various forms of recombinant erythropoietins have been frequently misused by athletes as performance-enhancing agents, EPO-Fc might play a similar role in sports in the future. In order to investigate the detectability of EPO-Fc in human blood, different strategies were tested and developed. Only two of them fulfilled the necessary requirements regarding sensitivity and specificity. A rapid protocol useful for screening purposes first enriches EPO-Fc from human serum via high capacity protein A beads and subsequently detects EPO-Fc in the eluate with a commercial EPO ELISA kit. The limit of detection (LOD) of the method is about 5 pg (45 micromol) EPO-Fc and is independent of the serum volume used. For screening and/or confirmation purposes a second protocol was evaluated, which consists of a fast EPO immunopurification step followed by sodium dodecyl sulfate or sarcosyl polyacrylamide gel electrophoresis (SDS-PAGE, SAR-PAGE) and Western double-blotting with chemiluminescence detection – a method already established in routine EPO antidoping control. The latter strategy allows the detection of EPO-Fc in serum together with all other recombinant erythropoietins and with an identical LOD (5 pg/45 micromol) as for the rapid screening protocol [12245].

A long-acting erythropoietin

The Fc fusion technology has been introduced to generate long-acting antagonistic drugs such as Enbrel, Oencia and Amevive. Here, Genexine created a novel noncytolytic hybrid Fc (hyFc) as a carrier of agonistic protein drugs using naturally existing IgD and IgG4 Fcs without any mutation in the hyFc region. The erythropoietin (EPO) fused with hyFc exhibited little binding activity to FcyR and C1q molecules that are main mediators for death of target cells. The EPO-hyFc showed higher in vitro and in vivo bioactivities than EPOIgG1 Fc and highly glycosylated EPO (Aranesp). Phase I clinical trial with EPO-hyFc is currently undergoing in Korea [12261].
New erythropoietin-like drug principles

Among the class of ESAs banned in sports, erythropoietin (EPO) and respective mimetics such as Hematide (Peginesatide) represent the major challenges for doping control laboratories. As a medicinal success story developed over 140 plus years, EPO and its derivatives have been misused to increase performance which resulted in numerous cases of adverse analytical findings and doubt as to the honesty and validity of athletes and their sport victories. The traceability of EPO abuse has been a complex issue and the methodologies available to sports drug testing laboratories enabling the differentiation of recombinant human EPO from its naturally produced analogue are laborious and time-consuming. Moreover, findings of EPO in particular, have frequently been challenged by athletes. Consequently, much effort and research resources were invested in improving the analytical approaches by focusing on sample preparation alternatives as well as identifying and eliminating technical issues. A technical problem concerning lane streaking during isoelectric focusing polyacrylamide gel electrophoresis (IEF-PAGE) was identified to result from detergents present in commonly used application pieces. Already a brief contact of nitrile glove-protected fingertips with the electrolyte strips considerably affected the analytical result making an evaluation impossible. Thus, the use of latex-based gloves or (metal) forceps was recommended to circumvent the issue. Another reason for insufficient EPO analytical data (especially due to extensive smearing) was found to be the presence of therapeutic amounts of heparin in urine. Due to its polyanionic nature, heparin interacts with carrier ampholytes commonly employed in IEF-PAGE and thus interferes significantly with the focusing of EPO isoforms as demonstrated with urine samples collected after co-administration of Dynepo and heparin. Following immunoaffinity purification (which is routinely employed in several doping control analytical procedures), the interference of heparin was eliminated. Further, SDS-PAGE (sodium dodecyl sulphate-polyacrylamide gel electrophoresis) analysis of EPO was not affected by heparin and would provide supporting information in case of inconclusive test results [12016].

Increasing the blood's capacity for oxygen transport by erythropoiesis-stimulating agents (ESAs) constitutes a prohibited procedure of performance enhancement according to the World Anti-Doping Agency (WADA). The advent of orally bio-available small-molecule ESAs such as hypoxia-inducible factor (HIF) stabilizers in the development of novel anti-anaemia therapies expands the list of potential ESA doping techniques. Here, the erythropoiesis-stimulating properties and doping relevance of experimental HIF-stabilizers, such as cobaltous chloride, 3,4-dihydroxybenzoic acid or GSK360A, amongst others, are discussed. The stage of clinical trials is reviewed for the anti-anaemia drug candidates FG-2216, FG-4592, GSK1278863, AKB-6548, and BAY85-3934. Currently available methods and strategies for the determination of selected HIF stabilizers in sports drug testing are based on liquid chromatography-electrospray ionization-tandem mass spectrometry (LC-ESI-MS/MS). For the support of further analytical assay development, patents claiming distinct compounds for the use in HIF-mediated therapies are evaluated and exemplary molecular structures of HIF stabilizers presented. Moreover, data concerning the erythropoiesis-enhancing effects of the GATA inhibitors K7174 and K11706 as well as the lipidic small-molecule ESA PBI-1402 are elucidated the context of doping analysis [12258].

Darbepoetin, an analogue of rhEPO with a half-life of 18-24 h, as well as epoietin delta and continuous erythropoiesis receptor activator (CERA) with a half-life of about 6 days, are novel protein-based, stimulating erythropoiesis agents employed in blood doping. Both erythropoietin and darbepoetin bind to the EPO receptor inducing intracellular signalling via the same intracellular molecules as native EPO [12011].

Erythropoietin promotes the production of red blood cells. Recombinant human erythropoietin
is illicitly used to improve performance in endurance sports. Expression of the erythropoietin gene is negatively controlled by the transcription factor GATA-binding protein (GATA). Specific GATA inhibitors have recently been developed as novel drugs for the management of anemia. These drugs could, therefore, be illicitly used like recombinant human erythropoietin to improve performance in sports. To examine alterations in levels of plasma protein after administration of GATA inhibitors, proteomic analyses were conducted on mouse plasma samples treated with the potent GATA inhibitor K-11706. The analysis based on gel electrophoresis identified 41 protein spots differentially expressed when compared with normal plasma. Each spot was identified with liquid chromatography coupled to tandem mass spectrometry and 2 of them, fetuin-B and prothrombin, were verified by Western blotting. The results showed that the expression of fetuin-B in mice plasma was increased by K-11706, but not by recombinant human erythropoietin or hypoxia. These results suggest the potential of proteomic-based approaches as tools to identify biomarkers for the illegal use of novel drugs (e.g. GATA inhibitors). Also, fetuin-B could be a sensitive marker for the detection of abuse of GATA inhibitors [11433].

Recombinant human erythropoietin (rHuEPO) engineered in Chinese hamster ovary (CHO) cell cultures (Epoetin alfa and Epoetin beta) and its hyperglycosylated analogue Darbepoetin alfa are known to be misused by athletes. The drugs can be detected by isoelectric focusing (IEF) and immunoblotting of urine samples, because "EPO" is in reality a mixture of isoforms and the N-glycans of the recombinant products differ from those of the endogenous hormone. However, there is a plethora of novel erythropoiesis stimulating agents (ESAs). Since the originator Epoetins alfa and beta are no longer protected by patent in the European Union, rHuEPO biosimilars have entered the market. In addition, several companies in Asia, Africa and Latin America produce copied rHuEPOs for clinical purposes. While the amino acid sequence of all Epoetins is identical, the structure of their glycans differs depending on the mode of production. Some products contain more acidic and others more basic EPO isoforms. Epoetin delta is special, as it was engineered by homologous recombination in human fibrosarcoma cells (HT-1080), thus lacking N-glycolyneuraminic acid like native human EPO. ESAs under development include EPO fusion proteins, synthetic erythropoiesis stimulating protein (SEP) and peptidic (Hematide®, CNTO 528) as well as non-peptidic EPO mimetics. Furthermore, preclinical respectively clinical trials have been performed with small orally active drugs that stimulate endogenous EPO production by activating the EPO promoter ("GATA-inhibitors": diazepane derivatives) or enhancer ("HIF-stabilizers": 2-oxoglutarate analogues). The prohibited direct EPO gene transfer may become a problem in sports only in the future [10121].

Erythropoietin (EPO) is a glycoprotein that is mainly produced in the adult kidney, and it was initially highlighted for its action on the hematopoietic system. Moreover, EPO is also expressed in several non-hematopoietic tissues, where it plays a role in the protection from apoptosis and inflammation due to hypoxia, toxicity or injury. These protective effects are mainly known and studied in cardioprotection and neuroprotection but are also reported in retina degeneration, auditory injury and pancreatic-related diseases. The tissue protective effect of EPO is mainly mediated through the interaction with the heterodimeric receptor EPOR/betacR. Human recombinant EPO (HuREPO), which has been developed to treat anemia, is not adequate for tissue protection. The low affinity of the alternative receptor for EPO involves the injection of excessive concentration of erythropoiesis-stimulating agents (ESAs), implicating side effects due to the cross-talk with hematopoietic activity. For these reasons, EPO derivatives with less affinity for the EPO homodimeric receptor are under development. In this review, it was provided an overview of the erythroid and non-erythroid functions of EPO by detailing the molecular mechanisms activated by the binding of EPO to its receptors in different tissues [11466].
Adverse effects of erythropoietin

Adverse effects of recombinant human erythropoietin [12242]:
- flu-like symptoms: commonest side effect but subsides within 24 hours
- allergic and anaphylactic reactions
- seizures and hyperkalemia: rare
- hyperviscosity
- thrombosis: a meta-analysis involving nearly 10,000 cancer patients indicates that treatment with rhEPO increases the risk of thrombosis
- hypertension
- possibility of cancer progression: there is somewhat less convincing evidence that rhEPO enhances tumor progression
- pure red cell aplasia (mainly reported in patients with CKD): autoantibodies in the serum can neutralize both rhEPO and endogenous EPO. This was mainly observed in CKD patients, especially after sc injection. Its incidence after 2000 has reduced, especially with the iv formulations

Novel erythropoietin doping strategies

There are several theoretical ways of doping with erythropoietin as basis [12242]:

a. Synthetic erythropoiesis protein (SEP): SEP consists of a polypeptide chain similar to that of EPO and two covalently attached, branched polymer moieties that bear a total of eight negative charges. These polymers enhance the molecule’s stability by protecting it from proteolytic cleavage. It is also less immunogenic as it is synthesized chemically and has less contaminating antigens.

b. PO mimetics: They are small molecules capable of activating EPO-R in a way similar to EPO. On binding to the EPO-R, they cause the receptor to dimerize and activate multiple cellular signaling pathways. Subsequently, multiple genes are transcriptionally induced and mediate proliferative, antiapoptotic, and erythropoietic effects of EPO (e.g. Hematide).

c. Inhibition of hematopoietic cell phosphatase (HCP): An indigenous negative regulator of the EPO–EPO-R signaling cascade. Combination of EPO mimetics with HCP inhibitors could provide an oral substitute of endogenous EPO with equivalent potency.

d. EPO delivery by cell encapsulation: In this method, the modified cells are enclosed inside semi-permeable membrane polymers that isolate the encapsulated cells and thus prevent antigen recognition and immune rejection. Cell encapsulation as a form of immunoprotection has been shown to enhance erythropoiesis.

e. EPO gene doping: Gene doping is defined as the transfer of genetic material to improve athletic performance. In 2003, the IOC and the World Anti-Doping Authority incorporated gene doping into their list of prohibited practices. Two approaches are used here:
   i. In vivo gene transfer through intramuscular injection of a virus containing gene encoding EPO. Other gene delivery methods include plasmid DNA, liposomes, and protein-DNA conjugates, or direct injection of EPO gene into muscles.
   ii. Ex vivo gene transfer into cells that are subsequently transplanted into the recipient organism.

Detection rate
Hemoglobin concentration ([Hb]), reticulocyte percentage (retic%) and OFF(hr score) are well-implemented screening tools to determine potential recombinant human erythropoietin (rHuEpo) abuse in athletes. Recently, the International Cycling Union implemented the OFF(z score) and the Hb(z score) in their anti-doping testing programme. The aim of this study is to evaluate the sensitivity of these indirect screening methods. Twenty-four human subjects divided into three groups with eight subjects each (G1; G2 and G3) were injected with rHuEpo. G1 and G2 received rHuEpo for a 4-week period with 2 weeks of "boosting" followed by 2 weeks of "maintenance" and a wash-out period of 3 weeks. G3 received rHuEpo for a 10-week period (boost = 3 weeks; maintenance = 7 weeks; wash out = 1 week). Three, seven and eight of the 24 volunteers exceeded the cut-off limits for OFF(hr score), [Hb] and retic%, respectively. One subject from G1, nobody from G2, and seven subjects from G3 exceeded the cut-off limit for Hb(z score.) In total, ten subjects exceeded the cut-off limit for the OFF(z score); two subjects from G1, two subjects from G2 and six subjects from G3. In total, indirect screening methods were able to indicate rHuEpo injections in 58 percent of subjects. However, 42 percent of these rHuEpo-injected subjects were not detected. It should be emphasised that the test frequency in real world anti-doping is far less than the present study, and hence the detection rate will be lower [10122].

**MicroRNAs**

MicroRNAs (miRNAs) are small, non-protein coding transcripts involved in many cellular and physiological mechanisms. Recently, a new class of miRNA called 'circulating miRNAs' was found in cell-free body fluids such as plasma and urine. Circulating miRNAs have been shown to be very stable, specific, and sensitive biomarkers. In one paper, it was investigated whether circulating miRNAs can serve as biomarkers for erythropoiesis-stimulating agent abuse. To this end, we analyzed miRNA levels in plasma by miRNA microarrays and quantitative real-time polymerase chain reaction (PCR). Plasma samples are derived from a clinical study with healthy subjects injected with erythropoiesis-stimulating agent (C.E.R.A.). Based on microarray results, we observed a significant difference in the levels of miRNAs in plasma after C.E.R.A. injection. It was demonstrated that a specific miRNA, miR-144, exhibit a high increase that lasts 27 days after C.E.R.A. stimulation. Considering the fact that miR-144 is an essential erythropoiesis agent in different organi-3sm, these findings suggest the possibility of using miR-144 as a sensitive and informative biomarker to detect CERA. abuse [11464].

**Detection of misuse of erythropoietin in competitive sports and laboratory testing**

Two different analytical techniques, isoelectric focusing (IEF) and chemiluminescent immunoassay, were applied for quantification of EPO. Urine samples were treated with a stabilization mixture to chemically inactivate proteolytic enzymes and improve the electrophoretic signal of EPO, a method that might improve measurement of EPO. Novel indirect methods based on haematological and/or molecular derivatives profiling also theoretically show promise as screening tools, followed by analytical testing of those athletes who are suspected of doping. However, an indirect technique that utilizes multiple markers of enhanced erythropoiesis, combined with a confirmatory test (isoelectric patterning), is likely to be the most feasible protocol for detection of rhEPO. This protocol was approved by the IOC Medical Commission as the "ON model" and has been applied since the 2000 Sydney Summer Olympics. An already established method in routine EPO antidoping control is the sequential deglycosylation by exoglycosidase treatment (Reagent Array Analysis Method, RAAM) and subsequent sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE), which has disclosed a structural difference between human endogenous and recombinant EPOs. A rapid protocol was introduced for screening purposes by enriching EPO-neonatal fetal receptor (Fc) from human serum and subsequently achieving detection of
EPO-Fc in the eluate with a commercial EPO ELISA kit. rhEPO and the Fc part of IgG can be transported after pulmonary administration via the Fc receptor and airway epithelium to the blood circulation. It was recently shown that a fast EPO immunopurification step combined with SDS-PAGE and Western double-blotting with chemiluminescence detection is capable of disclosing EPO-neonatal Fc receptor in serum together with all other recombinant EPOs. Transcriptomics, proteomics and metabolomics have been introduced in the last decade for the discovery of biomarkers as an indirect method for doping detection. However, the results, especially with regard to rhEPO, have not as yet led to a routine application in doping control, this mainly due to the complexity and inter-individual variability of human transcriptomes, proteomes and metabolomes [12011].

Administration of rhEPO was prohibited in 1990 by the International Olympic Committee (IOC). The detection of EPO abuse has been challenging for several reasons [12050]:

- availability of specialized dedicated laboratories with immense infrastructure
- screening in large numbers may be difficult as it requires highly trained technicians and standardization between laboratories
- it is difficult to discriminate between the endogenous EPO and recombinant exogenous hormone
- EPO has a relatively short half-life in serum (the half-life of rhEPO-a is 8.5 ± 2.4 hours when administered iv and 19.4 ± 10.7 hours when administered sc)
- EPO is undetectable in urine after 3-4 days of injection.

Direct method of erythropoietin detection relies on the physicochemical properties of the hormone. It is based on different carbohydrate components of recombinant and endogenous hormones, conferring different net electrical charges and thus distinguishable isoelectric points. This is the underlying principle of the only direct method of rhEPO detection that has been approved by the court of arbitration for sport. It uses electrophoretic techniques to separate the isoform profiles of recombinant and endogenous EPO in the urine according to their isoelectric points. Indirect methods of detecting misuse of erythropoietin are [12242]:

- the hematocrit
- the reticulocyte hematocrit (fractional volume of the reticulocyte pool in the bloodstream, which equals the product of the number of reticulocytes and their mean corpuscular volume: Ret × MCV Ret)
- macrocyte percentage
- serum soluble transferrin receptor (sTfR)

To use these indirect methods, two statistical models were used: “ON” model and “OFF” model. ON model detects current users and is indicative of accelerated erythropoiesis that occurs during rhEPO use (HE model uses hemoglobin and serum EPO and HES model uses hemoglobin, serum EPO concentration, and sTfR). OFF model is designed to differentiate between recent rhEPO users and non-users. This is consistent with down-regulation of erythropoiesis, which occurs following discontinuation of rhEPO (HR model uses hemoglobin and reticulocyte count and HRE model uses hemoglobin, reticulocytes, and serum EPO concentration). Many common hematological conditions and inter-individual genetic variations associated with extreme hematological profiles can also obscure the specificity of these indirect detection methods [12242].

A rapid and easy-to-use test kit, EPO WGA MAIIA, which can be used for distinguishing various endogenous human erythropoietins (hEPOs) and several recombinant hEPO and EPO analogues, has been evaluated. The test is based on chromatographic separation of the glycosylated isoforms of EPO using wheat germ agglutinin (WGA) and a sensitive immunoassay using anti-EPO carbon black nanostrings and image scanning for
quantification. All of the reactions take place along the porous layer of a lateral flow microcolumn containing WGA and anti-EPO zones. The presence of molecules resembling hEPOs, such as Mircera, was detected by the aberrant affinity interaction with the antibody zone on the strip. It was possible to distinguish nine recombinant hEPOs expressed in hamster and human cell lines, as well as Aranesp and Mircera, from endogenous urine hEPO. The required amount of EPO in the samples, a few picograms, is very low compared with other methods for EPO isoform identification. This EPO isoform determination method opens the possibility to monitor recombinant EPO therapy for clinical research and seems to be a valuable candidate to the arsenal of EPO doping control tests [12248].

Capillary electrophoresis electrospray-mass spectrometry was used to detect and characterize the great variety of O- and N-glycopeptide glycoforms of recombinant human erythropoietin (rhEPO) using an orthogonal accelerating time-of-flight mass spectrometer to obtain their exact molecular masses (CE-TOF-MS). rhEPO was digested with trypsin and Glu-C and analyzed by CE-TOF-MS to detect O(126), N(83), N(24)-N(38) and N(24) and N(38) glycopeptide glycoforms, respectively. Neuraminidase was first used to enhance the detection of the glycopeptides and detect all possible glycoforms contained in each glycosylation site. O(126) and N(83) glycopeptides were extensively characterized. Twelve sialoforms corresponding to 5 different glycoforms were detected in N(83), and for the first time, a sulfated sialoform of this glycopeptide was also detected. In the case of O(126), different sialoforms with different types of sialic acids (Neu5Gc and Neu5Ac) were detected and an estimation of the relative percentage of Neu5Gc versus Neu5Ac was also carried out for this glycopeptide. N(24) and N(38) glycosylation sites were also characterized by CE-TOF-MS after Glu-C digestion and these results permitted to rule out some glycan combinations for N(24)-N(38) glycopeptide glycoforms. The study provided a reliable glycopeptide map of rhEPO and may be regarded as an excellent starting point to analyze rhEPO glycopeptides in biological fluids and detect the use of this hormone in sports [12249].

Recombinant human erythropoietin (rHuEPO) is a 30-34 kDa glycoprotein banned by the racing authorities. For some years this molecule has been detected in race horses in USA and in Europe, and even in racing camels. Although direct methods to differentiate horse endogenous EPO and rhEPO have been developed either by LC-MS/MS or by isoelectric focusing (IEF) with double-blotting, the short confirmation time of such prohibited hormone in plasma remains a problem for horseracing doping control laboratories. In order to improve the rHuEPOs confirmation process in horse plasma or urine in terms of reliability and delay, a small anti-EPO monolith membrane contained in a disposable column (anti-EPO monolith column) has been successfully used and validated (n=10). This new sample preparation, combined with LC-FAIMS-MS/MS, has been performed on plasma and urine samples collected from one horse which received an Eprex® treatment during six consecutive days and a second one with a single injection of Aranesp®. This inventive technology allowed the possibility to confirm the presence of rHuEPO within one day with a limit of detection validated for both urine and plasma at 250 pg/mL by means of a disposable, ready to use immunoaffinity column. The lower limit of detection (LLOD) obtained for each matrix was 100 pg/mL. These results provide an important improvement for rHuEPO doping control in horseracing especially the possibility to confirm these banned molecules in both matrices, urine and plasma, with a confidence of two specific target peptides [12250].

Erythropoietin (EPO) is an important glycoprotein hormone. Recombinant human EPO (rhEPO) is an important therapeutic drug and can be also used as doping reagent in sports. The analysis of EPO glycoforms in pharmaceutical and sports areas greatly challenges analytical scientists from several aspects, among which sensitive detection and effective and facile sample preparation are two essential issues. Herein, we investigated new possibilities for these two aspects. Deep UV laser-induced fluorescence detection (deep UV-LIF) was
established to detect the intrinsic fluorescence of EPO while an immuno-magnetic beads-based extraction (IMBE) was developed to specifically extract EPO glycoforms. Combined with capillary zone electrophoresis (CZE), CZE-deep UV-LIF allows high resolution glycoform profiling with improved sensitivity. The detection sensitivity was improved by one order of magnitude as compared with UV absorbance detection. An additional advantage is that the original glycoform distribution can be completely preserved because no fluorescent labeling is needed. By combining IMBE with CZE-deep UV-LIF, the overall detection sensitivity was $1.5 \times 10^{-8}$ mol/L, which was enhanced by two orders of magnitude relative to conventional CZE with UV absorbance detection. It is applicable to the analysis of pharmaceutical preparations of EPO, but the sensitivity is insufficient for the anti-doping analysis of EPO in blood and urine. IMBE can be straightforward and effective for sample preparation. However, antibodies with high specificity were the key for application to urine samples because some urinary proteins can severely interfere the immuno-extraction [12251].

Human erythropoietin (hEPO), a hormone involved in the formation of red blood cells, is a 30 kDa glycoprotein with a high carbohydrate content. The production of recombinant hEPO has made possible its widespread therapeutic use and its banned use in competition sports. Methods to analyze EPO and other erythropoiesis stimulating agents (ESAs) are necessary for the characterization and quality control of these biopharmaceuticals and also for doping control. In this paper, high resolution separation methods, namely high performance liquid chromatography (HPLC) and capillary electrophoresis (CE), with special attention to CE-coupled mass spectrometry, are reviewed. The usefulness of these techniques when applied in different modes to separate the glycoprotein isoforms, aggregates or excipients are detailed. In addition, sample preparation methods that have been applied to ESA samples for subsequent determination by HPLC or CE, as well as the potential compatibility of other preparation methods, are discussed. Applications of the HPLC and CE methods regarding regulatory considerations for biopharmaceuticals analysis, with emphasis on biosimilars, and doping control are also included [12252].

Direct detection of doping with recombinant erythropoietins (rhEPO) is accomplished by isoelectric focusing (IEF) or sodium dodecylsulfate (SDS) polyacrylamide gel electrophoresis (PAGE). In a recent publication, Lasne et al [Electrophoresis 2011; 32: 1444] showed that improper use of nitrile examination gloves during sample collection, sample preparation, and IEF-PAGE may lead to distorted or absent EPO IEF-profiles. In order to clarify which substances are responsible for this observation, a mass spectrometric study on water extractable compounds found in nitrile gloves was performed. Several substance classes were shown to be present, among them polyethylene glycols (PEG), anionic and nonionic surfactants, as well as alcohol ethoxylates and plasticizers. It could be demonstrated that alkylbenzenesulfonates, the main category of detectable anionic detergents, and among them sodium dodecylbenzenesulfonate (SDBS) and its homologs, are the prime reason for the interference of nitrile gloves with EPO IEF-PAGE [12253].

Erythropoietin (EPO) is a peptide hormone responsible for hypoxia-induced promotion of erythrocyte production. The possibility of enhancing oxygen transport through an increase of erythrocytes has led to EPO abuse in sports. Detection of exogenous EPO is most commonly done via isoelectric focusing (IEF) which is a method provided by the Technical Document TD2009EPO of the World Anti-Doping Agency (WADA). Before analysis, collected urine samples need to be concentrated 500- to 1000-fold, leading to high protein abundance in the retentates. Reduction of protein concentration through an immunoaffinity purification using ELISA wells has been successfully used prior to SDS-PAGE. This ELISA kit was used to purify samples using an IEF-compatible elution. The purification showed recovery ratios between 50 and 90 percent depending on substance and application volume. Application of immunopurified samples to IEF was shown to improve the quality of the gels by reducing
streaks and curvatures within the lanes and bands of the gel. The result was an increase of
quality for IEF gels [12254].

Isoelectric focusing
Erythropoietin (EPO) is a peptide hormone responsible for hypoxia-induced promotion of
erthrocyte production. The possibility of enhancing oxygen transport through an increase of
erthrocytes has led to EPO abuse in sports. Detection of exogenous EPO is most
commonly done via isoelectric focusing (IEF) which is a method provided by the Technical

Dipstick test
Recently a novel technology, referred to as the 'EPO WGA MAIIA' test, has been developed
by Swedish researchers to discriminate between endogenous and recombinant human
erthropoietin. In contrast to existing electrophoretic methods that are used by antidoping
laboratories, this dipstick-based technique is simple and fast. Moreover it can be applied to
either blood or urine specimens. These characteristics could prove advantageous if the test
were adopted by antidoping authorities to determine blood doping in sport. It was evaluated
the sensitivity of EPO WGA MAIIA to detect the presence of recombinant human
erthropoietin (rhEPO) in some archived plasma specimens which had been collected from
healthy, active subjects either 72 h or 96 h after a 'microdose' intravenous injection of rhEPO.
Under these conditions the test had modest sensitivity to discriminate rhEPO, with only two
of nine subjects exceeding an arbitrary cut-off 3.09 standard deviations beyond the expected
population mean. Sensitivity was improved to five out of six subjects if positivity was
assessed according to the subject's own previous values rather than a population-based
threshold. It was conclude that, with further refinement, the dipstick test may supplement
existing antidoping tests [12256].

Transgene detection
The practice of doping threatens fair competition in sports. With the very recent reports on
successful gene therapies for several diseases, the likelihood for abuse of gene transfer
techniques in elite sports is rapidly increasing. It is therefore very important to develop valid
detection techniques for transgenic DNA (tDNA) with ultimate sensitivity and specificity. To
date, three slightly different procedures have been reported to reliably detect tDNA with
sufficiently high sensitivity. Two utilize a real-time PCR-based approach and one uses a
primer-internal, intron-spanning PCR approach (spiPCR). The specificity and sensitivity of
these techniques, however, is still a matter of debate. Based on spiPCR, here we present a
novel one-tube nested PCR approach that minimizes the chances for cross-contamination
and shows increased sensitivity compared to non-nested PCR techniques. To further reduce
the occurrence of false-positives based on cross-contamination, a multi-functional 19bp
extended erythropoietin standard (EPO) was cloned which can be easily differentiated from
transgenic EPO DNA (tEPO) and can be used as an internal or external positive control in
PCR-based applications. It was found that one-tube nested PCR is superior in terms of
sensitivity and specificity compared to conventional PCR, and shows similar sensitivity
compared to real-time based PCR assays. Although it did not reach sensitivity of spiPCR, the
one-tube nested PCR technique described here is less laborious, less expensive and much faster than spIPCR. This technique might therefore be useful as a pre-screening tool for gene doping in the future [12257].

**Effects outside the bone marrow**

Systemic administration of erythropoietin protects the myocardium from an ischemic insult and promotes beneficial remodeling. It was hypothesized that intracardiac injection of erythropoietin may exhibit cardioprotective potential with reduced systemic toxicity. In conclusion, one study demonstrated that intramyocardial erythropoietin injection, following myocardial infarction, reduced inflammation, enhanced angiogenesis and proliferation, improved myocardial functions, and did not lead to intramural thrombus formation [08233].

**Economy**

The European Commission have granted marketing authorizations to three companies for generic versions, or “biosimilar”*, of the hormone erythropoietin. Amgen, the world's largest biotechnology company by sales, started selling Epogen®, its recombinant version of this naturally occurring hormone, in 1989, producing it from cells into which the relevant gene had been engineered. The drug's ability to boost red blood-cell production has led to its widespread use to treat the anemia associated with some diseases. Epogen and its newer incarnation, Aranesp, earned nearly USD 7 billion for Amgen in 2006, and more than USD 3 billion for Johnson & Johnson, which has licensed the drug from Amgen and markets it in the United States, Europe and elsewhere. Now that the commission has allowed other companies to market their own version, revenues from Johnson & Johnson's estimated 250,000 European customers look set to erode. Sandoz, the generic-drugs branch of Novartis, had its version of the drug on the market in the United Kingdom and Germany, and it cost 25-30 percent less than Johnson & Johnson is charging [07128].

**Experimental**

Recent publications reflect the anti-doping authorities' concern about the use of altitude simulator systems as violating the spirit of sport criterion [Levine 2006; Loland and Murray 2007; Spriggs 2005]. The aim of one study was to determine whether intermittent hypoxic treatments could modify the hemoglobin, hematocrit, reticulocytes, and erythropoietic stimulation index (OFF-Hr Score) values after administration of rHuEPO-alpha. Although these hematological parameters are of secondary nature some international sport federations currently exclude athletes who show aberrant values of these parameters from competition. Ten young male Wistar rats were treated, three times a week for 2 weeks, with 500 IU of rHuEPO-alpha. After the treatment, the animals were randomly divided into two groups: normoxic and hypoxic. The normoxic group was maintained at 21 percent O$_2$ 24 h a day for 23 days. The hypoxic group was maintained 12 h at 21 percent O$_2$ and 12 h at 12 percent O$_2$ (~4,000 m) the same time period. After the rHuEPO-alpha treatment, the hypoxic group of animals had a faster recovery rate in the reticulocyte count, elevated concentrations of hemoglobin and hematocrit and a significant increase in the endogenous EPO levels when compared with the normoxic group of animals. These changes led to significant modifications in the OFF-Hr Score between the hypoxic and normoxic animals. Intermittent hypoxic treatments after rHuEPO administration can significantly modify the main hematological parameters tested by the anti-doping authorities. The results in an animal model suggest checking the described phenomena in humans in order to reach major conclusions [09166].

Athletes who abuse recombinant human erythropoietin (rhEPO) consider only the benefit to
performance and usually ignore the potential short and long-term liabilities. Elevated haematocrit and dehydration associated with intense exercise may reveal undetected cardiovascular risk, but the mechanisms underlying it remain to be fully explained. One study aimed to evaluate the cardiovascular effects of rhEPO in rats under chronic aerobic exercise. A ten week protocol was performed in four male Wistar rat groups. rhEPO in trained rats promoted erythrocyte count increase, hypertension, heart hypertrophy, sympathetic and serotonergic overactivation. The suddenly died rat's tissues presented brain with vascular congestion; left ventricular hypertrophy, together with a "cardiac-liver", suggesting the hypothesis of heart failure as cause of sudden death. In conclusion, rhEPO doping in rats under chronic exercise promotes not only the expected RBC count increment, suggesting hyperviscosity, but also other serious deleterious cardiovascular and thromboembolic modifications, including mortality risk, which might be known and assumed by all sports authorities, including athletes and their physicians [09167].

The aim of one study was to determine whether intermittent hypoxic treatments could modify the hemoglobin, hematocrit, reticulocytes, and erythropoietic stimulation index (OFF-Hr Score) values after administration of rHuEPO-alpha. Although these hematological parameters are of secondary nature some international sport federations currently exclude athletes who show aberrant values of these parameters from competition. Ten young male Wistar rats were treated, three times a week for 2 weeks, with 500 IU of rHuEPO-alpha. After the treatment, the animals were randomly divided into two groups: normoxic and hypoxic. The normoxic group was maintained at 21 percent O\textsubscript{2} 24 h a day for 23 days. The hypoxic group was maintained 12 h at 21 percent O\textsubscript{2} and 12 h at 12 percent O\textsubscript{2} the same time period. After the rHuEPO-alpha treatment, the hypoxic group of animals had a faster recovery rate in the reticulocyte count, elevated concentrations of hemoglobin and hematocrit and a significant increase in the endogenous EPO levels when compared with the normoxic group of animals. These changes led to significant modifications in the OFF-Hr Score between the hypoxic and normoxic animals. Intermittent hypoxic treatments after rHuEPO administration can significantly modify the main hematological parameters tested by the anti-doping authorities. The results in an animal model suggest checking the described phenomena in humans in order to reach major conclusions [09168].

Recombinant human erythropoietin (rHuEPO) engineered in Chinese hamster ovary (CHO) cell cultures (Epoetin alfa and Epoetin beta) and its hyperglycosylated analogue Darbepoetin alfa are known to be misused by athletes. The drugs can be detected by isoelectric focusing (IEF) and immunoblotting of urine samples, because "EPO" is in reality a mixture of isoforms and the N-glycans of the recombinant products differ from those of the endogenous hormone. However, there are a plethora of novel erythropoiesis stimulating agents (ESAs). Since the originator Epoetins alfa and beta are no longer protected by patent in the European Union, rHuEPO biosimilars have entered the market. In addition, several companies in Asia, Africa and Latin America produce copied rHuEPOs for clinical purposes. While the amino acid sequence of all Epoetins is identical, the structure of their glycans differs depending on the mode of production. Some products contain more acidic and others more basic EPO isoforms. Epoetin delta is special, as it was engineered by homologous recombination in human fibrosarcoma cells (HT-1080), thus lacking N-glycolyneuraminic acid like native human EPO. ESAs under development include EPO fusion proteins, synthetic erythropoiesis stimulating protein (SEP) and peptidic (Hematide, CNTO 528) as well as non-peptidic EPO mimetics. Furthermore, preclinical respectively clinical trials have been performed with small orally active drugs that stimulate endogenous EPO production by activating the EPO promoter ("GATA-inhibitors": diazepane derivatives) or enhancer ("HIF-stabilizers": 2-oxoglutarate analogues) [09169].
Blood substitutes, in general

Historically, blood loss from critical surgery or trauma has been treated with either volume-replacing fluids or transfusions. Progress in chemical and biotechnological research has allowed the development of a novel approach to this issue, in the form of temporary oxygen carriers, widely known as “blood substitutes.” The blood substitutes currently available are chiefly polymerized hemoglobin solutions or hemoglobin-based oxygen carriers (HBOCs) and perfluorocarbons (PFCs). Alternatives include artificial RBCs, in which hemoglobin and supporting enzyme systems are encapsulated into liposomes. Major clinical advantages of these substitutes include sterilization of viral and bacterial contaminants, room temperature storage, longer shelf life, and absence of RBC antigens [10353].

Perfluorocarbon emulsions

PFCs are inert, water-insoluble, synthetic aromatic or aliphatic compounds, consisting primarily of carbon and of fluorine substitutions for most hydrogen atoms. PFCs are substantially clear and colorless liquid emulsions that are heterogeneous in molecular weight, surface area, electronic charge, and viscosity; their high content of electron-dense fluorine atoms results in little intramolecular interaction and low surface tension, making such substances excellent solvents for gases, especially oxygen and carbon dioxide. Some of these molecules can dissolve 100 times more oxygen than plasma. PFCs are naturally hydrophobic and need to be emulsified to be injected intravenously. Recently, sophisticated technology has allowed the generation of stable emulsions that contain tiny particles with a median diameter < 0.2 μm and that display a very low molecular weight (about 500 Da). Considerable effort has focused on ensuring the long-term stability of ready-to-use, concentrated PFCs. Since PFCs dissolve rather than bind oxygen, their capacity to serve as a blood substitute is determined principally by the pO₂ gradients in the lung and at the target tissue. Therefore, their oxygen transport properties differ substantially from those of whole blood and, especially, from those of RBCs. Erythrocytes exhibit a sigmoidal oxygen dissociation curve, whereas PFCs are characterized by a linear relationship between pO₂ and oxygen content. At a conventional ambient pO₂ of 135 mm Hg, the oxygen content of 900 ml/L perfluorocarbon is less than 50 ml/L, whereas an optimal oxygen content of 160 ml/L, which is still lower than that of whole blood in normal conditions, can be achieved only by a pO₂ greater than 500 mm Hg. In practice, at a conventional alveolar pO₂ of 135 mm Hg, PFCs will not be able to provide sufficient oxygenation to peripheral tissues. Owing to this limitation, optimization of the oxygen transport capacity can be achieved only through a substantially raised arterial pO₂ (i.e. ventilation with 100 % oxygen), which appears unsuitable and most unlikely outside a controlled hospital setting. Moreover, prolonged oxygenation may lead to oxidative stress and tissue damage and may trigger potentially adverse genetic effects. Owing to their small size, PFCs efficiently perfuse the microcirculation where erythrocytes may not flow. In tiny capillaries, PFCs produce the greatest benefit, as they increase local oxygen delivery much more efficiently than would be expected from the increase in oxygen content in larger arteries. In addition, as gases are in the dissolved state within PFCs, the pO₂ in the microcirculation may be considerably increased, thereby promoting an extremely efficient oxygen delivery to peripheral tissues. PFCs undergo a rapid and atypical metabolism. After initial uptake by the mononuclear phagocytic system, the emulsion particles are rapidly degraded, and the PFCs re-enter the blood stream mainly bound to blood lipids; they are finally excreted by the lungs via exhalation. The half-life of PFCs depends on the chemical composition and appears strongly dose dependent, ranging from 2 to 6 h. The first demonstration of the clinical efficacy of PFCs was provided in mice in 1966. Since the mid-1980s, improvements in both oxygen
capacity and emulsion properties of PFCs have led to the development of second-generation PFC-based oxygen carriers; two PFC products are being tested in phase III clinical trials. A delayed and transitory “flu-like” syndrome was occasionally described; symptoms consisted mainly of back pain, malaise, flushing, and a transient fever lasting several hours. As PFCs are cleared by cells of the reticulo-endothelial system, and the febrile response was blocked by ibuprofen or dexamethasone, it is conceivable that this syndrome was elicited by the release of inflammatory cytokines, namely, interleukin 6. An additional threat is the effect of PFCs on platelet function. Aggregation by collagen, ADP, or arachidonic acid appears substantially inhibited in a dose-dependent fashion in ex vivo porcine platelets following infusion of perflubron emulsion at a dose of 3 ml/kg. Given some elite athletes’ innate inclination to experiment with novel doping strategies, it is speculated that some have used artificial oxygen carriers, but no clearly positive cases have been detected so far. There are several issues regarding efficacy and clinical safety of blood substitute administration in athletes. Scientific data concerning the performance benefits are inconclusive. Although the use of PFCs may theoretically produce an athletic advantage, the biochemical characteristics (linear relationship between dissolved oxygen and pO₂), the form of administration (intravenous), the need for high oxygenation, the short half-life (up to 6 h) and the side effects still hinder the diffusion of this rather atypical form of blood doping. Despite these clear limitations, international sporting federations have been commendably proactive in adding this category of compounds to their banned substance lists [10353].

Efaproxiral

Efaproxiral is an analog of the cholesterol drug bezafibrate developed for the treatment of depression, traumatic brain injury, ischemia, stroke, myocardial infarction, diabetes, hypoxia, sickle cell disease, hypercholesterolemia and as a radio sensitizer. The chemical is a propanoic acid in the class of amphipathic carboxylic acids. Most propanoic acid produced is consumed as a preservative for both animal feed and food for human consumption. One use for efaproxiral is to increase the efficacy of certain chemotherapy drugs which have reduced efficacy against hypoxic tumours, and can thus be made more effective by increased offloading of oxygen into the tumour tissues. No benefit was seen for efaproxiral in phase III clinical trials. The increased oxygenation of tissues could theoretically also produce enhanced exercise capacity in feline, rat and canine models for approximately 100 min. immediately after a high dosage 45 min. intravenous infusion. This has led World Anti-Doping Agency to categorize efaproxiral under a prohibited method to artificially enhance the uptake, transport or delivery of oxygen. There is no existing evidence that efaproxiral can effectively enhance performance in humans. Efaproxiral can be absorbed via transdermal, rectal, inhalation and gastrointestinal routes, though not at plasma concentrations great enough to alter the oxygen-haemoglobin dissociation curve. Efaproxiral is explicitly excluded from the 2012 World Anti-Doping Agency list of Prohibited Substances and is explicitly included in the Prohibited Methods section M1 as a forbidden procedure to alter the oxygen-haemoglobin dissociation curve in order to allosterically modify hemoglobin. Efaproxiral (2-[4-[[3,5-dimethylanilino]carbonyl][methyl]phenoxyl]-2-methylpropionic acid, formerly referred to as RSR13) is thus prohibited in sports according to the World Anti-Doping Agency (WADA). The drug as well as structurally related compounds and a stable isotope-labeled derivative have been synthesized to elucidate the fragmentation pathway of efaproxiral, using electrospray ionization (ESI) and tandem mass spectrometry by employing a novel linear ion trap–orbitrap hybrid mass spectrometer – in positive and negative ionization modes. The elimination of 2-methyl acrylic acid (-86 u) has been identified as a major fragmentation process in both charge states. Negative ionization and collision-induced dissociation (CID) caused an additional release of carbon dioxide (-44 u), and positive
ionization the loss of formic acid (\(-46 \text{ u}\)). Efaproxiral was incorporated into an existing screening procedure for doping controls using solid-phase extraction (SPE) followed by liquid chromatography-tandem mass spectrometry, enabling a limit of detection of 2.5 ng/mL and interday precisions ranging from 7.9 to 13.0 percent [06162].

**Ex vivo erythrocyte generation**

The generation of RBC from haematopoietic cells or human induced pluripotent stem cells can now be considered as realistic and can be accomplished on an industrial basis. Understandably this is a most favourable achievement for healthcare systems and patients in order to face the increasing demand for a wider availability of blood, but is also a serious threat for sport medicine, since it reasonably offers the possibility of effective blood doping. The techniques that have been described so far can be used to obtain very large quantities of RBC, yielding as much as a 130-fold increase over the original quantity of progenitor cells and, thereby, producing nearly 560 units of RBC per umbilical cord donation (assuming 5x10⁶ CD34+ cells per donation). Umbilical cord blood is an optimal source for medical and ethical reasons, although it is also viable for blood doping, since the RBC that can be obtained are safe and highly controlled after selection of proper antigenic determinants. The procedure can even be implemented using bone marrow-derived hematopoietic cells or fibroblasts from the recipient. However, more realistically, the use of these biotechnological approaches in the doping context could become plausible only after the development of methods based on the use of hematopoietic stem cells derived from peripheral blood [12234].

The manufacture of RBC could overcome several problems of the procedures currently used in the doping context for blood collection and storage. Long storage is not required and the production can be tailored according to the athlete's needs. Moreover, the RBC are fresh and thereby more functional with regards to gas exchange than those maintained in blood bags, even when properly stored. The amount of RBC administered intravenously can be regulated by appropriate dilution to avoid anomalous laboratory test results even with proteomic studies and the biological characteristics and behaviour of these "new" RBC do not differ from those of their "natural" counterparts. To the best of our knowledge, the only indices that could be used in the anti-doping context are shape and dimensions, which seem to be slightly greater for manufactured RBC. In conclusion, the scientific as well as the sport medicine communities should be aware of the risk that these novel approaches to the generation of RBC could have with regards to blood doping and should cooperate closely to increase knowledge about RBC manufacturing and to develop appropriate tests to identify their unfair use in sports [12234].

**Biological engineering from progenitor cells**

The production of biomaterial particles with similar (or even identical) chemical and physical properties as those of mature, functional RBC has been reported, so we have already alerted the scientific community as well as anti-doping authorities on the possible, surreptitious use of these bioengineering techniques for unfair and illicit purposes in sports. The generation of RBC from haematopoietic cells or human induced pluripotent stem cells can now be considered as realistic and can be accomplished on an industrial basis. Understandably this is a most favourable achievement for healthcare systems and patients in order to face the increasing demand for a wider availability of blood, but is also a serious threat for sport medicine, since it reasonably offers the possibility of effective blood doping. The techniques that have been described so far can be used to obtain very large quantities of RBC, yielding as much as a 130-fold increase over the original quantity of progenitor cells and, thereby,
producing nearly 560 units of RBC per umbilical cord donation (assuming $5 \times 10^6$ CD34+ cells per donation). Umbilical cord blood is an optimal source for medical and ethical reasons, although it is also viable for blood doping, since the RBC that can be obtained are safe and highly controlled after selection of proper antigenic determinants. The procedure can even be implemented using bone marrow-derived hematopoietic cells or fibroblasts from the recipient. However, more realistically, the use of these biotechnological approaches in the doping context could become plausible only after the development of methods based on the use of hematopoietic stem cells derived from peripheral blood [13290].

The manufacture of RBC could overcome several problems of the procedures currently used in the doping context for blood collection and storage. Long storage is not required and the production can be tailored according to the athlete’s needs. Moreover, the RBC are fresh and thereby more functional with regards to gas exchange than those maintained in blood bags, even when properly stored. The amount of RBC administered intravenously can be regulated by appropriate dilution to avoid anomalous laboratory test results even with proteomic studies and the biological characteristics and behaviour of these “new” RBC do not differ from those of their “natural” counterparts. To the best of our knowledge, the only indices that could be used in the anti-doping context are shape and dimensions, which seem to be slightly greater for manufactured RBC. In conclusion, the scientific as well as the sport medicine communities should be aware of the risk that these novel approaches to the generation of RBC could have with regards to blood doping and should cooperate closely to increase knowledge about RBC manufacturing and to develop appropriate tests to identify their unfair use in sports [13290].

**Irradiation of red blood cells**

Gamma irradiation of red blood cell (RBC) concentrates is routinely used to prevent transfusion-associated graft-versus-host disease. So far, the effects of ionizing radiation on RBC structure and function and especially the proteome are not fully understood. RBC concentrates were irradiated with 30 Gy and stored for 1 or 15 days at 4 ± 2°C. Following cell lysis and hemoglobin depletion, 2D-DIGE was used to examine the changes of the cytosolic RBC proteome. Significantly altered spots were analyzed using bottom-up proteomic approaches and selected marker proteins validated by western blotting. Gamma irradiation was found to enhance conventional RBC storage lesions. Following 15 days of postirradiation storage, the abundances of a total of 27 spots were significantly altered and 3 out of 13 identified proteins were selected and validated as potential marker proteins for the assessment of irradiation-induced cytosolic RBC lesions. Gamma irradiation and subsequent ex vivo storage according to the Council of Europe guidelines were found to affect RBC protein structures. The validated marker proteins can serve as a basis for the development of a screening assay to monitor the quality of irradiated RBC concentrates during ex vivo storage [13305].

**Enhancement of oxygen transfer**

2,3 DPG

Rapid growth during adolescence caused by metabolic changes and their metabolic response to anaerobic and aerobic exercise differs considerably from that in adults and this is especially true in the responses to stresses, such as altitude exposure. However, there is little information on the suitability of exercise training at altitude for young athletes. Six male
Korean adolescent alpine skiers (13-17 years), with a skiing career of 3-5 years, participated in the study. All subjects were exposed to an altitude of 2700 m (8858 ft) for 5 weeks and altitude exposure consisted of 6 d/week of training (4-5 h/d), with living quarters at 2100 m. The 5 week of ski training at altitude were maintained at the same level (the same number of slalom and giant slalom skiing trials) as at sea level. There was a significant increase in oxygen transport capacity, despite decreased erythropoietin (EPO) production (-31 %) after altitude training. Red blood cell (RBC), hemoglobin (Hb), hematocrit (Hct), and 2,3 DPG concentrations increased significantly during altitude exposure and after return to sea level. The results indicate that applying altitude training in adolescent skiers may improve their endurance performance. However, EPO production during altitude training needs to be evaluated in larger future studies [12263].

Hypoxia-inducible factor

Another alternative to stimulate erythropoiesis is represented by low molecular mass compounds acting as prolylhydroxylase inhibitors. Among these, some so-called hypoxia-inducible factor (HIF) stabilizers have advanced to phase-II clinical trials and demonstrated their capability to increase EPO serum levels and, consequently, elevated hematocrit values. With the disclosure of some lead drug candidates, model substances have been used to establish LC-MS/MS-based detection methods to allow the implementation of this class of prohibited compounds into routine doping controls. Supported by distinct dissociation pathways (e.g. nominal loss of 10 Da), both targeted and nontargeted detection strategies were developed and detection limits between 0.6-10 ng/mL and 300-1000 ng/mL, respectively, were accomplished [12017].

Hemoglobin-based oxygen carriers (HBOCs)

Hemoglobin-based oxygen carriers (HBOCs) are blood substitutes, synthesized by polymerizing hemoglobin, which are being developed and investigated as alternatives to blood for medical purposes. However, due to their ability to increase the oxygen carrying capacity when taken by healthy individuals, HBOCs have been used as a doping agent among endurance athletes and are included in the World Anti-Doping Agency’s Prohibited List. To maintain the fairness of competitions and continue the battle against doping, it is essential to be able to detect HBOCs if present in an athlete's blood. To achieve this goal, it is necessary to differentiate HBOCs from the native hemoglobin and to do so in a cost and time effective manner. It was developed a rapid capillary zone electrophoresis (CZE), UV absorbance, method capable of detecting HBOCs, in whole blood samples, at levels below those considered necessary to provide a performance enhancement. The approach to the analysis for HBOCs utilizes the whole blood sample, not just the plasma, and does not require the use of immunoprecipitants to ensure accurate analysis. By lysing the red blood cells and using centrifugal filtration, followed by our CZE separation, we are able to effectively distinguish between native hemoglobin and HBOCs. Through this method, we have been able to reliably detect concentrations of HBOCs at the equivalent of 5.5 g/L, the equivalent to a 3.5 percent increase in blood hemoglobin concentration for an athlete [12265].

Artificial oxygen carriers (AOCs) can be abused by the athletes to improve their aerobic capacity. The AOCs produce a performance enhancing effect, especially in endurance sports. This article presents a method for the rapid screening of hemoglobin-based oxygen carriers (HBOCs) in blood samples. Common screening tests to reveal HBOC misuse by
athletes are based on colorimetric detection since HBOC use causes discoloration of the plasma. In this communication we are presenting a different approach for HBOC detection using an hematological analyzer capable of measuring hemoglobin by two methods: a standard cyanmethemoglobin colorimetric method to calculate the amount of total hemoglobin (HGBtot) and a flow cytometric optical method to calculate the amount of hemoglobin within the red blood cells (HGBcell). Thanks to this dual contemporary hemoglobin measurement, the HGB delta value (corresponding to free HGB) is automatically calculated by subtraction of HGBcell from HGBtot and can be used as a fast screening index of HBOC abuse. It was tested the effectiveness of this approach using 68 normal blood samples with different basal HGB values fortified with three different HBOCs at varying concentrations. It was evaluated the performance of the method by calculating the correlation between HGBcell and HGBtot values in normal samples. Finally we used a simple statistical approach to calculate a reliable HGB delta cut-off value (0.35 g/dL) as a limit of decision to discriminate between a clear negative sample and a suspect sample to submit to a confirmation analysis [09173].

Blood doping involves the use of products that enhance the uptake, transport, or delivery of oxygen to the blood. One approach uses artificial oxygen carriers, known as hemoglobin-based oxygen carriers (HBOCs). This study describes an analytical strategy based on CE for detecting intact HBOCs in plasma samples collected for doping control. On-capillary detection was performed by UV/Vis at 415 nm, which offered detection selectivity for hemoproteins (such as hemoglobin and HBOCs). On-line ESI-MS detection with a TOF analyzer was further used to provide accurate masses on CE peaks and to confirm the presence of HBOCs. An immunodepletion sample preparation step was mandatory prior to analysis, in order to remove most abundant proteins that interfered with CE separation and altered the ESI process. This analytical method was successfully applied to plasma samples enriched with Oxyglobin, a commercially available HBOC used for veterinary purposes. Detection limits of 0.20 and 0.45 g/dL were achieved in plasma for CE-UV/Vis at 415 nm and CE-ESI-TOF/MS, respectively [10127].

Artificial oxygen carriers (AOCs) can be abused by the athletes to improve their aerobic capacity. The AOCs produce a performance enhancing effect, especially in endurance sports. This article presents a method for the rapid screening of hemoglobin-based oxygen carriers (HBOCs) in blood samples. Common screening tests to reveal HBOC misuse by athletes are based on colorimetric detection since HBOC use causes discoloration of the plasma. Finally we used a simple statistical approach to calculate a reliable HGB delta cut-off value (0.35 g/dL) as a limit of decision to discriminate between a clear negative sample and a suspect sample to submit to a confirmation analysis [10128].

Hemoglobin is naturally suited to bind, carry, and deliver oxygen when encased by the RBC membrane; once removed, it becomes dysfunctional and rapidly dissociates. The administration of free hemoglobin to humans is unsuitable; dimers of about 32 kDa produced
by dissociation are cleared by the kidney where they may accumulate, generate renal obstruction and oxidant injury or necrosis, and trigger renal failure. Therefore, hemoglobin must be stabilized before it can be safely infused. HBOCs are intra- and/or inter-molecularly "engineered" human or animal hemoglobins, optimized for oxygen delivery and longer intravascular circulation. Several approaches have been attempted to stabilize and modify the hemoglobin molecule: polymerization of human (PolyHeme®) or bovine (HBOC-201) hemoglobin with glutaraldehyde or raffinose (Hemolink®), pyridoxylation, conjugation with polyethylene or maleimide-polyethylene glycol (MP4), and the cross-linking of the subunits by diaspirein (HemAssist) and oxidized mono/di/tri/poly saccharides. Most of the synthetic compounds exhibit low oxygen affinity, high cooperativity, an enhanced Bohr effect, and a slower rate of autoxidation of the heme iron, which finally results in more efficient oxygen delivery. The presence of 2,3-diphosphoglycerate within erythrocytes maintains the normal affinity of hemoglobin for oxygen. As erythrocyte-free hemoglobin loses this interaction, unmodified human HBOC solutions have a very high oxygen affinity which compromises their function. Chemical methods developed to overcome this problem have resulted in carriers that effectively release oxygen at the physiological pO₂ of peripheral tissues. A common feature of all HBOCs is their resistance to disaggregation when dissolved in infusion media, which contrasts to the native hemoglobin property of natural dissociation under non-physiologic conditions. First-generation HBOCs were developed principally to serve as oxygen carriers and as a substitute for erythrocytes in situations of acute and clinically threatening blood depletion, such as peri-operative use. Depending on the type of modification used to stabilize the protein, second-generation HBOCs were considered to be useful in other clinical settings, such as enhancement of radiation therapy and nitric oxide scavenging. Third-generation HBOCs, based on microencapsulation of hemoglobin and RBC enzymes either in liposomes or in biodegradable nanocapsules, appear so far to be the most promising products and are currently under evaluation in phase II and III clinical trials. The plasma half-life ranges from 12 to 48 h for cross-linked and surface-linked hemoglobin, respectively. There are several concerns about the therapeutic and unfair use of HBOCs. Phase II clinical trials and biological studies suggest that resuscitation with HBOCs, in lieu of stored RBCs, attenuates the systemic inflammatory response invoked in the pathogenesis of multi-organ failure. Specifically, HBOCs obviate stored RBC-provoked neutrophil priming, endothelial activation, and systemic release of interleukins 6, 8, and 10. Some HBOCs are in clinical phase III trials, but no product has yet achieved market as free hemoglobin and many forms of modified hemoglobins display strong vasoconstrictor reactivity due to the scavenging of endogenous nitric oxide, a powerful vasoactive agent released from endothelial cells. Therefore, administration of HBOCs may generate microvascular permeability and failure, causing systemic and pulmonary hypertension. Additional threatening side effects include gastrointestinal dysfunction characterized by increased tone of the intestinal sphincters, marked flatulence and meteorism, renal toxicity, and alteration of some biochemical and hematologic parameters, including increase in liver enzymes and alteration of platelet function. If one of the HBOCs becomes available, red (hemoglobin-colored) plasma or urine would make it readily detectable. However, HBOCs recently have been included within the International Olympic Committee and the World Anti-Doping Agency lists of substances and methods prohibited in sports [10353].

The development of artificial oxygen carriers has attracted considerable recent interest because of the increasing cost of collecting and processing blood, public concerns about the safety of blood products, complications from blood transfusions, military requirements for increased volumes of blood during military conflicts, and a decrease in the number of new donors. To overcome these problems, perfluorocarbon-based oxygen carriers as well as acellular- and cellular-type, hemoglobin-based oxygen carriers have been developed for use as artificial oxygen carriers. Despite their extensive evaluation, including formulation and pharmacology, they have not been extensively used in clinical settings. One of the reasons
for this is that their pharmacokinetics have not been well characterized. Artificial oxygen carriers require not only an acceptable level of physicochemical activity, but also clinical efficacy, as reflected by their retention in the circulation, and the absence of measurable accumulation in the body, if unexpected adverse effects are to be avoided. In one review, the pharmacokinetic properties of artificial oxygen carriers are discussed, with a focus on recent developments of the research related to the pharmacokinetic properties a cellular type of hemoglobin-based oxygen carrier [11145].

Modified stromal-free hemoglobins have been investigated as oxygen carriers since 1940. Cell-free Hb maintains its ability to transport oxygen. However, Hb tetramers rapidly breakdown into dimers and monomers, which diffuse freely into the renal tubules and are cleared by the kidney. To overcome these limitations, modification methods were developed in the last few decades, such as purification, conjugation, crosslinkage and polymerization. Crosslinked and polymerized stromal-free Hb are capable of carrying oxygen to tissues and organs, as well as achieving blood plasma expansion. Hemopure (glutaraldehyde polymerized bovine Hb in Ringer lactate) is an example. Polyhemoglobin consists of stromal-free Hb crosslinked with a bifunctional or polyfunctional crosslinking agent, yielding a water-soluble Hb product. It has a very high oxygen affinity and can transport and supply oxygen to vital tissues and organs, maintaining intravascular oncotic pressure. Nanobiotechnology has been used for the preparation of polyhemoglobin by assembling Hb molecules into soluble nanodimension complexes. Liposome-encapsulated Hbs are artificial red cells, in which Hb and supporting enzyme systems are encapsulated into liposomes. They present several advantages, such as decreasing the toxicity of free Hb, increasing its circulation time and permitting co-encapsulation of Hb protectants and other compounds. It must be stressed that HBOCs may be misused in endurance sports in order to improve the maximal oxygen capacity (one of the limiting factors of endurance performance), and not owing to their plasma expander properties. Since 2003, HBOCs are banned in sport, as enhancement of oxygen transfer was prohibited by the IOC. Analysis of HBOCs can be performed by two screening procedures (direct visual screening of plasma discoloration and electrophoretic technique). Two complementary methods may confirm the presence of exogenous Hb in plasma: a SEC-HPLC with photodiode array detection, which in tandem with the electrophoretic screening technique, provides evidence of the presence of HBOCs; and an HPLC analysis of enzymatic digests (peptide segments arising from the tryptic digestion of bovine HBOC), with detection by ESI ion trap MS. Concerning Hemopure, besides the SEC-HLPC, a method was described for its detection in athletes’ blood samples; after a visual screening of plasma samples (red coloration), cell-free human Hb is analyzed with the Advia 120 hematology system, followed by an HPLC separation, in order to distinguish between human Hb and Hemopure. Regarding the presence of HBOCs in urine, some authors advocate that urinary concentrations are too low and variable to be considered of any value in developing an effective test for HBOC [11146].

Whereas many tissues and organs of the human body such as joints or cardiac valves can be replaced by artificial substitutes, medical science is still on the quest for a suitable blood replacement that features all qualities of the simple red blood cell to carry oxygen. So far, the greatest advances have been made in the development of HBOCs which, in contrast to other approaches such as perfluorocarbons, rely on hemoglobin molecules of animal origin or from genetic engineering. A HBOC (Oxyglobin®) was approved for veterinary use in certain countries 15 years ago. Such substances are understood to have entered the world of sports already with the aim of improving oxygen delivery to tissues and have allegedly been used by athletes in an attempt to boost performance. However, the definite proof of the efficiency of these substances to improve performance is still lacking and the few studies showing a positive effect have been criticized. It has been speculated that the oxygen transport effects are impaired by a significant vasoactive action of the HBOCs related to NO scavenging.
properties of free hemoglobin, which interferes with oxygen delivery. With the advancement of medical science it can nevertheless be anticipated that sooner or later a viable HBOC that is able to improve oxygen delivery and thereby performance in humans will be available. The detection of HBOC is straightforward and relies on electrophoresis as a screening procedure and size exclusion–high-performance liquid chromatography (SEC-HPLC) [13006].

Hemoglobin-based oxygen carriers (HBOCs) are thought to have an adverse risk:benefit profile when compared to that of transfusing stored red blood cells (RBCs). However, there are clinical circumstances when RBC transfusion is not an option (e.g. patient refusal, unavailability owing to issues of compatibility or remote location). For these circumstances assessment of the risks of an HBOC should be compared to the risks of untransfused acute anemia. In this article we compare the risk of allowing a patient with severe anemia to have a further small decrease in hemoglobin (Hb) concentration to the risk of infusing an HBOC. It was conclude that at Hb concentrations less than 6 g/dL, the risk of a further decrease in Hb concentration greatly exceeds the risk of HBOC infusion. Thus, it was suggested that there may be a place for use of HBOCs when RBC transfusion is not an option [13349].

The development of oxygen (O₂)-carrying blood substitutes has evolved from the goal of replicating blood O₂ transport properties to that of preserving microvascular and organ function, reducing the inherent or potential toxicity of the material used to carry O₂, and treating pathologies initiated by anemia and hypoxia. Furthermore, the emphasis has shifted from blood replacement fluid to "O₂ therapeutics" that restore tissue oxygenation to specific tissues regions. One review covered the different alternatives, potential and limitations of hemoglobin-based O₂ carriers (HBOCs) and perfluorocarbon-based O₂ carriers (PFCOCs), with emphasis on the physiologic conditions disturbed in the situation that they will be used. It describes how concepts learned from plasma expanders without O₂-carrying capacity can be applied to maintain O₂ delivery and summarizes the microvascular responses due to HBOCs and PFCOCs. The review also presented alternative applications of HBOCs and PFCOCs namely: How HBOC O₂ affinity can be engineered to target O₂ delivery to hypoxic tissues; and how the high gas solubility of PFCOCs provides new opportunities for carrying, dissolving, and delivering gases with biological activity. It is concluded that the development of current blood substitutes has amplified their applications horizon by devising therapeutic functions for O₂ carriers requiring limited O₂ delivery capacity restoration. Conversely, full, blood-like O₂-carrying capacity reestablishment awaits the control of O₂-carrier toxicity [13350].

The worldwide blood shortage has generated a significant demand for alternatives to whole blood and packed red blood cells for use in transfusion therapy. One such alternative involves the use of acellular recombinant hemoglobin (Hb) as an oxygen carrier. Large amounts of recombinant human Hb can be expressed and purified from transgenic Escherichia coli. The physiological suitability of this material can be enhanced using protein-engineering strategies to address specific efficacy and toxicity issues. Mutagenesis of Hb can
- adjust dioxigen affinity over a 100-fold range
- reduce nitric oxide (NO) scavenging over 30-fold without compromising dioxigen binding
- slow the rate of autooxidation
- slow the rate of hemin loss
- impede subunit dissociation
- diminish irreversible subunit denaturation

Recombinant Hb production is potentially unlimited and readily subjected to current good manufacturing practices, but may be restricted by cost. Acellular Hb-based O₂ carriers have
superior shelf-life compared to red blood cells, are universally compatible, and provide an alternative for patients for whom no other alternative blood products are available or acceptable. Remaining objectives include increasing Hb stability, mitigating iron-catalyzed and iron-centered oxidative reactivity, lowering the rate of hemin loss, and lowering the costs of expression and purification. Although many mutations and chemical modifications have been proposed to address these issues, the precise ensemble of mutations has not yet been identified. Future studies are aimed at selecting various combinations of mutations that can reduce NO scavenging, autooxidation, oxidative degradation, and denaturation without compromising O₂ delivery, and then investigating their suitability and safety in vivo [13351].

Hemoglobin-based oxygen carriers (HBOCs) are thought to have an adverse risk:benefit profile when compared to that of transfusing stored red blood cells (RBCs). However, there are clinical circumstances when RBC transfusion is not an option (e.g., patient refusal, unavailability owing to issues of compatibility or remote location). For these circumstances assessment of the risks of an HBOC should be compared to the risks of untransfused acute anemia. In this article we compare the risk of allowing a patient with severe anemia to have a further small decrease in hemoglobin (Hb) concentration to the risk of infusing an HBOC. We conclude that at Hb concentrations less than 6 g/dL, the risk of a further decrease in Hb concentration greatly exceeds the risk of HBOC infusion. Thus, it was suggested that there may be a place for use of HBOCs when RBC transfusion is not an option [13352].

**Allosteric modulators of hemoglobin**

Allosteric ("different shape," from allos = other and steric = solid or space) activators or inhibitors of proteins are substrates designed to alter the affinity of a protein for a ligand or an enzyme for its substrate. Allosteric modulators usually bind non-covalently to the enzyme at regulatory sites that are distant from the catalytic or active sites. The improvement of oxygen delivery to hypoxic tissues by a decrease in the oxygen affinity of hemoglobin has been a major aim in recent years, because this may reduce the consequences of anemia and/or improve tissue oxygenation in cases of decreased blood perfusion. The spectrum of clinical applications of allosteric modulators is rather broad. Since these synthetic compounds increase tumor pO₂ and reduce the tumor hypoxic fraction, they have been developed to maximize the effectiveness of radiation therapy. They also may be useful in acute ischemic disorders, such as acute coronary syndrome and brain ischemia, as they improve myocardial oxidative metabolism and contractile function in models of myocardial ischemia and increase brain pO₂, thus reducing neuronal cell death following cerebral ischemia. Although these modulators has not been tested in humans for sport performance enhancement, its biological effects make it a potentially effective performance-enhancing agent for endurance athletes. Nearly one-third of patients undergoing therapy experience significant side effects, including headache, nausea, mucosal irritation, hypoxemia, allergic reaction, and transient renal dysfunction characterized by increased levels of serum creatinine [10353].

**New products**

Nearly 14 million units of packed red blood cells are transfused in the United States each year. According to the U.S. Department of Health and Human Services, in 1999, 6 percent of hospitals reported a shortage of blood, resulting in the cancellation or postponement of surgical procedures. The many limitations and risks of transfusions of packed red blood cells in critically ill patients have facilitated interest in developing alternative agents for oxygen delivery. Over the past few decades, safe and effective substitutes have been in development. However, no currently approved agent provides both oxygen transport and volume in place of packed red blood cells. Oxygen therapeutic products have several
advantages compared with packed red blood cells, including a prolonged shelf-life, lack of a cross-matching requirement, and minimal infectious risks or concerns about immunogenicity. Hemoglobin-based oxygen carriers and perfluorocarbons are being developed. Two products are undergoing clinical trials. Polyheme is undergoing a phase III study in trauma patients, and Hemopure is being evaluated in a phase II study in patients undergoing cardiopulmonary bypass surgery. A third product (Hemolink) was being evaluated in a phase III study in patients undergoing coronary artery bypass grafting surgery; however, the trial was suspended. In addition, several other hemoglobin-based oxygen carriers are in the preclinical stages. Oxygen therapeutics have several potential clinical applications in the management of perioperative blood loss, trauma, acute normovolemic hemodilution, traumatic brain injury, and blood requirements in patients who refuse or have contraindications to transfusions of red blood cells [06163].

Laboratory techniques

Hemoglobin-based oxygen carriers (HBOCs) are blood substitutes based on hemoglobin of either bovine or human origin and they can potentially be misused in elite sports to improve endurance performance. Recently, three methods have been proposed in doping control analysis to allow HBOCs screening and identification by application of electrophoresis, size-exclusion chromatography coupled with HPLC and LC coupled with tandem mass spectrometry (LC/MSMS). In view of the Athens 2004 Olympic Games, modifications were introduced in order to increase the specificity of these methods. The sample preparation protocols of the electrophoretic and SEC-HPLC methods were modified with the introduction of sequential ultra filtration steps to remove all heme containing material below 100 kDa, thus leaving only HBOCs material for analysis. Furthermore, a modification of the LC/MSMS methodology was introduced to allow full scan MS-MS spectra of peptide segments arising from the tryptic digestion of bovine HBOCs. These relatively simple methodological modifications have major impact, as far as time and cost effectiveness is concerned in doping control procedures, because they provide a useful tool in order to identify which suspect samples from the initial visual screening are due to hemolysis and exclude them from further analysis [06164].

HBOCs such as Hemopure and Oxyglobin (approximate average mol weight=250 kDa) consist of inter- and intramolecularly covalently crosslinked bovine hemoglobin, and they have been prohibited from use in sports due to the potential increase in blood oxygen transport capacity that they afford. Owing to their xenobiotic nature, several different LC-MS/MS approaches have been established to determine their presence in human serum. Chemical stabilization of the hemoglobin subunits using crosslinking agents resulted in an N-terminal derivatization of methionines of beta chains, which have been identified as potential targets in analytical approaches employing proteasomal degradation of serum with endoproteinase Glu-C. Alternative procedures have exploited the differences in the primary structures of bovine and human hemoglobins, as well as the presence of crosslinks in hemoglobin molecules. Due to a sequence homology of only 85 percent, several proteotypical peptides uniquely derived from bovine hemoglobin upon trypsin digestion are detectable using LC-MS/MS approaches and provide evidence for the presence of HBOCs at concentration levels of 2 mg/mL. Additionally, crosslinks introduced at lysines of hemoglobins impede the activity of trypsin at the respective residues and considerably change the ratios of tryptic peptides obtained from bovine hemoglobin and Hemopure. The latter information in particular will be useful for differentiating between human hemoglobin and its crosslinked analogs (e.g. PolyHeme) if these are launched by pharmaceutical companies [07050].

These relatively simple methodological modifications have major impact, as far as time and cost effectiveness is concerned in doping control procedures, because they provide a useful tool in order to identify which suspect samples from the initial visual screening are due to hemolysis and exclude them from further analysis [07129].

**Hemopure®**

Hemoglobin-based oxygen carriers (HBOCs) such as are touted as a tenable substitute for red blood cells and therefore potential doping agents, although the mechanisms of oxygen transport of HBOCs are incompletely understood. It was investigated whether infusion of Hemopure increased maximal oxygen uptake (VO_{2max}) and endurance performance in healthy subjects. Twelve male subjects performed two 4-minute submaximal exercise bouts equivalent to 60 percent and 75 percent of VO_{2max} on a cycle ergometer, followed by a ramped incremental protocol to elicit VO_{2max}. A crossover design tested the effect of infusing either 30 g (6 subjects) or 45 g (6 subjects) of Hemopure versus a placebo. Under our study conditions, Hemopure did not increase VO_{2} (2max) nor endurance performance. However, the infusion of Hemopure caused a decrease in heart rate of approximately 10 bpm and an average increase in mean (approximately 7 mmHg) and diastolic blood pressure (approximately 8 mmHg) at submaximal and maximal exercise intensities. Infusion of Hemopure did not bestow the same physiological advantages generally associated with infusion of red blood cells. It is conceivable that under exercise conditions, the hypertensive effects of Hemopure counter the performance-enhancing effect of improved blood oxygen carrying capacity [07130].

**Laboratory technique**

A specific, sensitive and rapid analytical procedure based on capillary electrophoresis with UV/Vis detection at 405 and 415 nm was developed and validated to detect human haemoglobin and haemoglobin-based oxygen carriers (Hemopure®, Oxyglobin® and Polyheme®) in blood samples collected for doping control. The electrophoretic separation, based on capillary dynamic coating, was achieved in less than 10 min. The effects of capillary temperature, injection conditions and initial ramping were investigated. The optimum separation voltage was 25 kV with a capillary temperature of 20 °C, initial ramping of 1 kV/s and an injection pressure of 0.5 psi for 10 s. The removal of haptoglobin using anti-human haptoglobin antibody prior to the analysis was mandatory to increase the specificity of the analysis. Sufficient resolution between endogenous haemoglobin variants and the three haemoglobin-based oxygen carriers here investigated was obtained, thus allowing discrimination between a normal haemolysed sample and a sample in which Oxyglobin®, Hemopure® or Polyheme® is present. Good repeatability of migration times (CV % less than 1), peak resolution and adequate sensitivity (limit of detection: 2.5 mg/mL) was obtained [11463].
**Hematide/Peginesatide**

In addition to recombinant EPO and its derivatives, EPO-mimetic agents have been under development for several years with Hematide/Peginesatide being the first representative that received FDA approval (March 2012). Due to its ability to stimulate erythropoiesis it has been considered a banned substance by WADA for several years; however, its dissimilar structure compared to EPO does not allow its detection in blood or urine employing conventional EPO tests. Consequently, complementary methods were required and established on three different platforms: ELISA, SDS-PAGE, and LC-MS/MS. The ELISA utilized the sandwich-approach with a capture antibody directed against the PEG moiety and an antibody recognizing the homodimeric peptide residue allowing for colorimetric qualitative and quantitative determination with an LOD of 0.5 ng/ml in serum and plasma.\[80\] Since purely immunological detection assays require a second, independent confirmatory assay, the option of SDS-PAGE followed by western blotting was exploited, demonstrating comparable sensitivity as the ELISA-based assay. Authentic administration study plasma samples were obtained from a clinical study where healthy individuals received Peginesatide at 50 microg/kg bodyweight intravenously. Sample collection was conducted up to 28 days and both assays enabled the detection of the injected EPO-mimetic drug up to 10 days. Using LC-MS/MS, the detection of peginesatide was accomplished in serum and plasma following a simple protein precipitation and subsequent enzymatic hydrolysis of the peptidic moiety. Due to the presence of various non-natural amino acids, subtilizing yielded the desired diagnostic (proteotypical) target peptide, which was detected down to 1 ng/ml in spiked plasma and serum specimens. Considering pharmacokinetic data on peginesatide, plasma concentrations up to 500 ng/ml are expected when therapeutic dosages (e.g. 50 microg/kg bodyweight) are administered. Hence, the utility of alternative minimal-invasive sample collection strategies such as DBS sampling was evaluated and found to provide a conceivable matrix allowing for detection limits of 10 ng/ml by means of LC-MS/MS [13012].

**Hypoxia-inducible factor (HIF) stabilizers**

Another alternative to stimulate erythropoiesis is represented by low molecular mass compounds acting as prolylhydroxylase inhibitors. Among these, some so-called hypoxia-inducible factor (HIF) stabilizers have advanced to phase-II clinical trials and demonstrated their capability to increase EPO serum levels and, consequently, elevated hematocrit values. With the disclosure of some lead drug candidates, model substances were used to establish LC-MS/MS-based detection methods to allow the implementation of this class of prohibited compounds into routine doping controls. Supported by distinct dissociation pathways (e.g. nominal loss of 10 Da), both targeted and non-targeted detection strategies were developed and detection limits between 0.6-10 ng/ml and 300-1000 ng/mL, respectively, were accomplished [13012].

**Cobalt salt as erythropoietic agent**

Unfair athletes seek ways to stimulate erythropoiesis, because the mass of haemoglobin is a critical factor in aerobic sports. Here, the potential misuse of cobalt deserves special attention. Cobalt ions (Co²⁺) stabilize the hypoxia-inducible transcription factors (HIFs) that increase the expression of the erythropoietin (Epo) gene. Co²⁺ is orally active, easy to obtain, and inexpensive. However, its intake can bear risks to health. To elaborate this issue, a review of the pertinent literature was retrieved by a search with the keywords “anaemia”, “cobalt”, “cobalt chloride”, “erythropoiesis”, “erythropoietin”, “Epo”, “side-effects” and “treatment”, amongst others. In earlier years, cobalt chloride was administered at daily doses of 25 to 300 mg for use as an anti-anaemic agent. Co²⁺ therapy proved effective in
stimulating erythropoiesis in both non-renal and renal anaemia, yet there were also serious medical adverse effects. The intake of inorganic cobalt can cause severe organ damage, concerning primarily the gastrointestinal tract, the thyroid, the heart and the sensory systems. These insights should keep athletes off taking Co²⁺ to stimulate erythropoiesis [13321].

**Phthalates**

One idea was to identify markers that indirectly allude to the autologous transfusion. After withdrawal, freshly donated blood requires an initial processing and storage for a certain amount of time, which mostly occurs in plastic bags. The softening substances of these plastic blood bags or so-called plasticizers are phthalates (di-(2-ethylhexyl)phthalate (DEHP)) and their derivates. A considerable amount of the phthalates will diffuse from the plastic bag into the stored blood during long-term storage and will be transfused with the blood. Monfort et al. demonstrated that phthalates are metabolized in the human body to distinct molecules (mono-(2-ethylhexyl)phthalate (MEHP), mono-(2-ethyl-5-hydroxyhexyl)phthalate (MEHHP), and mono-(2-ethyl-5-oxohexyl)phthalate (MEOHP)) and can be detected in urine for a short time after transfusion using LCMS methods. The measurement of phthalates is the first approach using urine as a matrix, which is collected commonly at anti-doping controls. This may also include using phthalate analyses for homologous blood transfusion for which the direct test requires the collection of blood samples. Blood samples are now collected in a much higher percentage than in the past but not in all subjects. On the other hand, as phthalates are ubiquitous and present in many products of daily use, testing for phthalates will very likely not be a suitable stand-alone detection method for blood transfusion. Therefore, several validation studies have been conducted in order to identify threshold values for the different metabolites in athletes, taking into account the normal daily exposure to plasticizers. Recently, two further metabolites were described as possible markers (mono-(2-ethyl-5-carboxypentyl)phthalate (5cx-MEPP) and mono-(2-carboxymethylhexyl)phthalate (2cx-MMHP)) for blood transfusions measured by ultraperformance liquid chromatography tandem mass spectrometry together with the molecules MEHP, MEHHP, and MEOHP. The use of urine for the detection of blood transfusions with phthalates seems promising as all urine samples submitted to doping analysis in any accredited laboratory could provide corroborating evidence in subjects potentially using blood transfusion, e.g., based on ABP data. Phthalate data could also be applied together with other indirect markers in a multifactor approach [13006].

Elevated concentrations of phthalates and respective metabolites in urine have further been suggested as indicators for illicit blood transfusions in sport. In a follow-up study, it was reported on an LC-MS/MS methodology allowing the quantification of the main five metabolites of one of the most common plasticizers di-(2-ethylhexyl)phthalate (DEHP). Using enzymatic hydrolysis followed by LLE, target analytes were separated on a C-18 analytical column (2.1 x 100 mm, particle size 1.7 microm) and determined in positive and negative ESI with MRM detection. The accuracy of the analysis was supported by three isotopically labelled internal standards, and quantification limits between 1.2 and 2.6 ng/mL were accomplished. Applying the method to reference groups consisting of 30 control individuals and 464 athletes from the doping control pool, threshold concentrations were suggested for each analyte (ca. 160–340 ng/mL), above which suspicion of blood transfusion was mentioned to be indicated [13009].

**Granulocyte colony-stimulating factor (G-CSF)**
The use of growth factors in sports is restricted under the terms of the World Anti-Doping Code (WADC). While the beneficial effects of erythropoietin (EPO) on erythropoiesis and therefore its performance-enhancing properties have been well documented and established for decades, the aim of one study was to elucidate the relevance of the cytokine G-CSF in a doping control context, particularly concerning its influence on selected blood parameters representing central aspects of the Athlete Biological Passport. For that purpose, the effect of repeated subcutaneous granulocyte colony-stimulating factor (G-CSF) injections in therapeutic dosages (10 µg/kg/d) on white blood cells, erythrocytes, hemoglobin, hematocrit and percent reticulocytes was analyzed by using commonly employed fluorescence flow cytometry-based approaches. A total of 20 people were tested (14 male, 6 female) and both white blood cell count and reticulocyte percentages were found to significantly increase following a 5-day treatment with G-CSF. Simultaneously, all other volume-dependent parameters (red blood cell count, hemoglobin, hematocrit) slightly but significantly decreased. Due to the relevance of these measurands for the validity of blood tests for doping controls and the anecdotal evidence of G-CSF being potentially misused by elite athletes, G-CSF analyses might be indicated in case of unusually altered blood profiles [12239].

Other blood products

Actovegin

In recent years, the use of Actovegin® (calf blood hemodialysate) in sports medicine has caused a lot of controversy in many sports disciplines. Although it is unlikely for this deproteinised substance to have oxygen-enhancing capacity, there is an anecdotal belief that Actovegin® can increase an athlete’s performance. Actovegin® is produced by Nycomed Austria GmbH and has been used by doctors across Europe, China and Russia for about 60 years. Nevertheless, very little is known regarding the effects of Actovegin on muscle injuries. One article reviewed the current evidence on Actovegin®, its legal status with sports governing bodies and its potential role in sport injuries. It was also reported experience with this drug in treating muscle injuries. In a pilot study, players in the Actovegin treatment group were able to return to play 8 days earlier (95% confidence interval -1.2 to -14.8) compared to physiotherapy alone, which was a significant difference. No adverse reactions were recorded in any of the participants [11299].

Calf-derived deproteinised haemodialysate, Actovegin (Nycomed Austria), is a component in calves’ blood that gained attention when its use by the Australian rugby teams was reported to improve endurance and recovery from injuries. Although the medical research suggests some evidence (i.e. ‘potential’) of efficacy in the treatment of soft tissue injuries, the Australian Sports Anti-Doping Authority (ASADA) said that Actovegin was not then on the WADA's list of prohibited substances. Thus its use as a substance when restricted to intramuscular injections is therefore not prohibited. However, it is illegal as a method when injected into a vein. Actovegin was initially listed on the banned list by the International Olympic Committee (IOC) in December 2000 because of the concerns about its abuse in cycling. It was, however, removed from the IOC banned list in February 2001 pending further research. Actovegin is not a prohibited substance in WADA’s most current lists in 2012 although these lists do have an inclusion statement not present in previous versions: the prohibition of any growth factor(s) affecting muscle, tendon or ligament protein synthesis/degradation, vascularisation, energy utilisation, regenerative capacity or fibre type switching. This inclusion statement has, however, created more uncertainty over other therapeutic substances, besides Actovegin, used in sports medicine settings. So far, the
lawful challenge of using Actovegin as a tendon healing substance has not been made, although this legal issue is evolving at the time of writing. According to the latest 2012 WADA prohibited list, Actovegin is not prohibited in any sports. However, to complicate matters, WADA has issued specific guidance on Actovegin on its website that, according to section M2 of the WADA code, the volume of intravenous injection of any non-prohibited substance must not exceed 50 mL with a simple syringe, and further serial injections must be at least six hours apart. This means that under the latest (2012) interpretation of the Code, Actovegin cannot be administered by intravenous infusion or single intravenous injection with a volume exceeding 50 mL. Detection of doping of Actovegin would depend on catching athletes in the act of performing the banned method (not adhering to the rule of an intravenous injection of less than 50 mL or an intramuscular injection of Actovegin) and not simply detecting Actovegin in the athlete’s body [12015].

There is much speculation that Actovegin® is ergogenic, but no scientific work has been published in this field. Eight participants (mean age, height and mass of 24 years, 176 cm and 80.1 kg, respectively) completed 3 exhaustive arm crank ergometry tests. Following Baseline testing 2 further tests were performed 2 h following the injection of either 40 mL of Actovegin® or a saline placebo. Peak power (Wpeak), peak physiological responses, concentrations of blood glucose and lactate, exercise efficiency (%), VO₂ gain (mL/W), and the respiratory compensation point (RCP) were determined. Values of mean bias were calculated to further explore quantitative differences between trials. Strong trends for variations in Wpeak and RCP were evident; likely meaningful effects existed between the Baseline and both injection trials, but only a trivial effect was noted between placebo and Actovegin®. Concentrations of blood lactate and glucose changed across time, but did not differ between the 3 trials. The data suggests the Actovegin® is not ergogenic and did not influence functional capacity in the context of the exhaustive, upper-body test employed [12271].

**Intravenous fluid use in athletes**

Time allowing, euhydration can be achieved in the vast majority of individuals by drinking and eating normal beverages and meals. Traditionally, the use of intravenous (IV) administration of fluids has thus been reserved for the treatment of clinical dehydration and in the setting of presumed heat illness in the collapsed athlete. Treatment of exercise-associated hyponatremia with hypertonic IV infusion to correct plasma sodium levels is also a standard and accepted use of IV fluid infusions. In clinical practice, the use of IV fluids is more widespread, in both the prevention and treatment of exercise-related conditions. The use of IV fluid for prehydration is difficult to quantify. Anecdotally, IV hydration is common among some teams. A recent survey of the National Football League teams revealed that 24 of 32 of the teams utilized IV infusion of fluids for prehydration in at least some otherwise healthy individuals. The most common reason cited was the prevention of muscle cramps (23 of 24 teams). Of teams that administered IV fluids prior to competing, there was an average of 5 to 7 athletes per team receiving IV infusions. Timing of IV and the type of fluids utilized prior to competition had not been studied regarding exercise performance. In the National Football League, an average of 1.5 L of normal saline was administered approximately 2.5 hours prior to competition. With modern sports’ premium on winning, it only follows that individuals and teams look for performance advantages. This mind-set has led to an expanded role for IV hydration outside the context of medical emergencies to include prevention and rapid treatment of dehydration and exercise-associated muscle cramps (EAMC). Important to the competitive athlete is prevention of dehydration as it is linked to a decline in athletic performance. Among elite triathletes, muscle cramping is one of the most common reasons cited for not finishing. Intravenous (IV) prehydration and rehydration has been proposed as
an ergogenic aid to achieve euhydration more effectively and efficiently. PubMed database
was searched in November 2011 for all English-language articles related to IV utilization in
sport using the keywords intravenous, fluid requirements, rehydration, hydration, athlete,
sport, exercise, volume expansion, and performance. Limited evidence exists for
prehydration with IV fluids. Although anecdotal evidence does exist, at this time there are no
high-level studies confirming that IV prehydration prevents dehydration or the onset of
exercise-associated muscle cramps. Currently, there are no published studies describing IV
fluid use during the course of an event, at intermission, or after the event as an ergogenic
aid. It was concluded that convincing research to support IV fluid administration prior to
competition for performance enhancement, dehydration prevention, or muscle cramp
prevention does not exist. Current studies do not support the use of IV fluids for rehydration
when an athlete can tolerate oral fluids. IV fluids and plasma binders are not allowed in
World Anti-Doping Agency-governed competitions. Routine IV therapy cannot be
recommended as best practice for the majority of athletes [12272].

Discussion on dangerous dehydration in sports

Pre- and postexercise body weight measurements are the most common means to estimate
overall water loss but are condition specific. More elaborate indices of dehydration can be
measured using blood and urine samples, but these tests are often impractical or unavailable
to most athletes. Sweat composition is another parameter that is difficult to directly measure.
Furthermore, sweat composition is highly variable, as body weight, genetics, heat
acclimatization, and metabolic efficiency all influence the sweat rate and composition.
Studies utilizing labeled deuterium oxide (D$_2$O) fluid show that during exercise D$_2$O appears
in sweat 10 minutes after oral ingestion. A follow-up study compared ingestion of labeled oral
fluid versus a combination of oral and IV labeled D$_2$O. After dehydration, subjects were
rehydrated and exercised until D$_2$O was measured in sweat. There were no differences in the
groups despite an apparent increase in plasma volume afforded by IV rehydration. It appears
that 1 to 2 percent body weight loss is well tolerated by the exercising athlete. Dehydration,
defined as greater than 2 percent loss of body weight, can negatively affect performance. In
highly trained endurance athletes, plasma volume and sodium serum concentration were
preserved despite a 5 percent body weight loss. In Ironman triathletes, dehydration to 5
percent body weight loss did not correlate with occurrence of medical complications. As
degree of dehydration increases, more physiological detrimental effects may occur. This
finding is more pronounced in the endurance athlete performing in hot and humid conditions.
Progressive dehydration can lead to diminished cognitive function and may, in severe cases
(>12 %), cause death [12272].

Oral versus intravenous fluids

Safety of the athlete is always a primary concern of the treating physician, and avoiding harm
is imperative. Comparing IV versus oral hydration methodologies reveals several differences.
First, IV hydration has increased risks relative to oral hydration. Even though severe
complications are relatively low, one must consider infection, bleeding, soft tissue infiltration,
and air embolism as potential complications that are nonexistent with oral hydration. Second,
physiologically, IV hydration bypasses the oropharyngeal reflex and the associated cascade
digestive enzymes and hormones. The potential consequences of these differences are
poorly understood in the context of athletic performance. In addition to the safety of IV
rehydration, the practitioner must consider legal and ethical questions. According to World
Anti-Doping Agency regulations, the routine practice of administering IV fluids (>50 mL per 6
hours) to healthy individuals is prohibited. The code states the following in section M2,
numeral : “Intravenous infusions and/or injections of more than 50 mL per 6 hour period are
prohibited except for those legitimately received in the course of hospital admissions or clinical investigations” [12272].

Exertional muscle cramp prevention

Exercise-associated muscle cramps (EAMC) are a major problem during competition for many athletes, including team, individual, and endurance athletes. Some controversy exists regarding the etiology of EAMC; the cause is likely multifactorial. Recent evidence suggests the etiology of EAMC is related to muscle fatigue and neuronal excitability. Several studies have shown no correlation between hydration status or electrolyte concentrations with EAMC. However, there may be a subset of muscle cramping that is associated with a loss of both body fluid and sodium. These individuals are the so-called heavy sweaters. Although only anecdotal evidence does exist, at this time there are no high-level studies confirming IV prehydration prevents EAMC. Further studies need to be performed assessing the efficacy of IV fluids in the prevention of muscle cramping. There are no published studies on the treatment of EAMC with IV fluids during competition. However, current best practice recommendations are to replace fluid and salt losses, eliminating potential muscle cramping. For a large majority of individuals, this can be accomplished by oral intake of fluid and electrolytes. There are beneficial anecdotal reports of EAMC treatment in elite and professional-level athletes with IV hydration during the course of an event [12272].

Preexercise fluid requirements

Prior to exercise, it is highly recommended to address an athlete’s fluid status. There are multiple published guidelines regarding prehydration. The American College of Sports Medicine has published a position statement including specific recommendations for preexercise hydration. Its recommendations include the following:

- hydration should begin hours prior to exercise, especially if known deficits are present
- fluids should be consumed at a slow, steady rate, with 5 to 7 mL/kg taken 4 hours prior to exercise
- if urine output is insufficient, the color is dark, or the specific gravity is greater than 1.020, it is recommended to consume an additional 3 to 5 mL/kg 2 hours prior to exercise.

Per oral fluid absorption rate is influenced by the osmolality of the fluid. In one study the concentration of sodium (0, 20, 50 mEq) was varied to determine if absorption was based on the sodium ion. Sodium concentration did not produce significant changes in the rate of absorption but was primarily dependent on carbohydrate concentration. Subjects ingested 1100 mL per hour of drink, with an average absorption rate of 550 mL per hour. This represented 50 percent of the ingested fluids per hour. The sweat rate was also measured during this time and was 634 mL per hour. Therefore, absorbed fluid represented 86 percent of fluid loss through sweat. Again, there were no differences among varying sodium concentrations [12272].

IV volume expanders

Hyperhydration through the use of plasma volume expanders may be accomplished via oral or IV routes. Glycerol is the primary agent for oral hyperhydration. Glycerol hyperhydration and rehydration may benefit endurance athletes performing in hot and humid environmental conditions. Glycerol hyperhydration allows an excess of 1.5 L of hydration prior to an event. Current recommendations for endurance athletes intending to hyperhydrate with glycerol are
1.2 g/kg in 26 mL/kg of fluid over a period of 60 minutes, ending 30 minutes prior to exercise. Side effects from glycerol include nausea, gastrointestinal discomfort, and light-headedness, which sometimes preclude its utilization. There are IV formulations with comparable solutes for plasma volume expansion. The infusion of 6 percent dextran solution (403 ± 21 mL) on stroke volume during submaximal exercise resulted in an 11 percent increase in stroke volume in the untrained men but no increase in endurance-trained men. Infusion of dextran above 400 mL did not result in a further increase in stroke volume. In a follow-up study, maximal oxygen uptake and exercise time to fatigue were measured after untrained men were infused with either 200 to 300 mL or 500 to 600 mL of 6 percent dextran. The elevation of plasma volume by 200 to 300 mL via dextran infusion resulted in 15 percent increase in stroke volume, 4 percent increase in VO₂max, and an increase in the exercise time to fatigue. In contrast, further expansion of plasma volume to 500 to 600 mL resulted in excessive hemodilution and return to baseline VO₂max and exercise time to exhaustion. IV infusion of 6% dextran was also studied in elite endurance-trained cyclists chosen to reflect high baseline blood volumes via training adaptations. Infusion of 6 percent dextran increased blood volume (547 ± 61 mL). No change in maximal oxygen intake or endurance performance (time to exhaustion at 95% VO₂max) was found. Highly trained athletes may already be at the optimum blood volume, which is at or near the limits of their diastolic reserve capacity. Hypervolemia can be induced through either training adaptations or acute volume expansion with 6 percent dextran in euvoletic subjects. Both hypervolemic states showed improved cycling time trial performance, but no difference was seen between the hyperhydrated states. Albumin has been investigated for the purpose of volume expansion. Albumin infusion increased plasma volume 13 percent over the saline infusion. There were lower heart rates in the albumin infusion group at 25 minutes and 40 minutes. No differences were found in performance time, final heart rate, or rectal temperature between the 2 group [12272].

Rehydration

If rapid recovery from dehydration is desired, one should ingest 1.5 L of fluid for each kilogram of body weight lost. Replacing 150 percent of body weight loss over 60 minutes has been tolerated without complications. Even though the majority of cases of dehydration can be treated via oral consumption, IV treatment of severe dehydration (>7 % body weight loss), exertional heat illness, nausea, emesis, or diarrhea, and in those who cannot ingest oral fluids for other reasons, is clinically indicated. Otherwise, as the American College of Sports Medicine consensus guidelines state, “IV fluids do not provide an advantage over drinking oral fluids and electrolytes.” Limited evidence exists for prehydration with IV fluids. At the time of this publication, only 1 clinical trial has been published comparing the exercise performance of a group prehydrated with rapidly infused IV (normal saline) and euhydrated (oral) subjects. Ten moderately fit first responders wearing chemical protective clothing exercised on a treadmill. Hyperhydration occurred prior to exercise on the treadmill. No significant differences between the 2 groups were found for maximum heart rate, maximum core temperature, and exercise duration [12272].

The effect of an IV infusion during exercise has been studied. Although impractical in the competing athlete, the effect of an IV saline infusion versus no infusion during cycling has been compared. Nine males exercised to exhaustion at 84 ± 3 percent of maximum O₂ consumption on a cycle ergometer while receiving no fluids or an infusion of 0.9 percent normal saline (mean volume, 1280 ± 107 mL). Measured variables included core and skin temperatures, time to exhaustion, blood samples, and expired gases (breath by breath). Recorded measurements included hydrogen ion concentration, blood lactate level, peak O₂ uptake, carbon dioxide production, and end-tidal partial pressure of carbon dioxide. A decreased core temperature (38.5 ± 0.2 versus 39.0 ± 0.2) and heart rate (186.0 ± 5.1
versus 194.1 ± 3.9) was found for the IV group, but this did not translate to improved performance as measured by endurance time. No other significant differences were found between groups. The effects of a saline infusion during exercise on a cycle ergometer at 60 percent of maximum aerobic power for 50 minutes in warm and cool environments have been investigated. The control group received no infusion, and measured outcomes included forearm blood flow, heart rate, and esophageal temperature. Restoration of plasma volume via IV infusion decreased heart rate by 6 beats per minute at the 50-minute mark in the warm environment. No difference was found in the cold environment. Importantly, no performance data was reported. Similarly, markers of cardiovascular drift that included stroke volume, heart rate, and rectal temperature have been studied in 10 endurance-trained athletes who cycled in a 22°C room for 2 hours. The study group received an IV infusion, and a control group received no fluid replacement. There was no oral fluid replacement group in the study. No difference between the groups was demonstrated at 1 hour of exercise. However, after 2 hours of exercise, the rectal temperature was 0.6°C higher in the group not receiving IV infusion. Also, stroke volume and cardiac output were 11 to 16 percent lower in the control group versus the IV infusion group [12272].

Fluid hydration during an event is critical for preventing the unwanted effects of dehydration. Currently, there are no published studies describing IV fluid use during the course of an event, at intermission, or after the event as an ergogenic aid. In these settings, there is a perceived benefit for the convenience and speed of fluid replacement. The speed of replacing plasma volume by IV infusion is primarily a consequence of bypassing gastric emptying, which is volume dependent. Large volumes of IV fluid can be given over a short period. An 18G peripheral IV can provide 50 to 60 mL per minute of IV fluid by gravity. No high-level studies have determined the ideal rate for IV fluids hydration in healthy subjects [12272].

Athletes frequently need to rapidly replace fluid volumes between training sessions or events when there is limited time (2-a-day practices or stacked training sessions). Some athletes have turned to IV hydration for its speed of fluid administration. Studies evaluating the benefits of IV hydration for repeated performances include a dehydration phase via exercise, a rehydration time, and a second exercise phase. The hydration routes in acclimated and nonacclimated highly trained cyclists were studied by dehydrating to 4 percent body weight loss. Rehydration occurred to 2 percent body weight loss with 0.45 percent oral or IV fluid. A control group received no fluids. Subjects then cycled at 70 percent VO2peak to exhaustion in 37°C. No difference was found in exercise time to exhaustion. Plasma volume was better restored during rehydration with IV fluids at preexercise and 5 minutes of exercise. At 15 minutes, there was no difference between IV and oral rehydration. The same study design evaluated perceptual responses to exhaustion after IV or oral rehydration. Perceived exertion, thirst, and thermal sensations were measured. Central perceived exertion was lower in the oral rehydration group at 5 and 15 minutes. Overall perceived exertion was lower in the oral rehydration group at 15 minutes. Thermal sensation was higher in IV group at 15 minutes. Thirst ratings were lower at 0, 5, and 15 minutes with oral rehydration. Thus, all measures were more favorable in the oral rehydration group. In a similar study, 8 males were dehydrated via a 75-minute phase to 1.7 to 1.8 L of fluid loss. The negative fluid balance was replaced in 20 minutes by either IV of 0.45% normal saline or oral rehydration. The participants then completed a heat tolerance (treadmill speed of 2.4 m per second and an incline grade of 2.3 %) at 37°C and 45 percent relative humidity. More rapid restoration of plasma volume was accomplished in the IV treatment group with no advantages over oral rehydration in physiological strain, heat tolerance, ratings of perceived effort, or thermal sensations. Sensation of thirst was lower in the oral rehydration group. Performance (heat tolerance time) was not significantly improved in the IV group. The effect of IV hydration on recovery following marathon running has also been studied. IV fluids were administered
immediately postmarathon to assess time to recovery in 66 participants. The experimental group received 2.5 L of 2.5 percent glucose/0.45 percent sodium chloride solution, whereas the placebo group received 100 mL of 0.9% sodium chloride solution. No significant differences between the groups were found for time to recovery, number of days with pain, number of days with stiffness, sleep disturbance, fatigue, rectal temperature, and loss of appetite. The current data thus suggest that IV rehydration is faster than oral. There may be physiological benefits of decreased heart rate and norepinephrine in athletes rehydrated via IV route, but the clinical significance is not known. Oral rehydration does decrease thirst better than IV rehydration and may decrease perceived exertion [12272].

Plasma volume expanders

The use of plasma volume expanders (PVE), such as dextran (DEX) and hydroxyethyl starch (HES), is prohibited in sports. DEX is a naturally occurring glucose polymer, whereas HES is synthetically produced from amylopectin starch by substitution with hydroxyethyl groups. In doping control, the commonly applied enzymatic and colorimetric screening methods are lacking adequate specificity for DEX and HES. Also, gas chromatographic-mass spectrometric (GC-MS) screening methods have specificity issues with DEX. In addition, due to the nature of the target compounds, time-consuming derivatisation steps are required in GC-MS. Based on the high molecular weight of carbohydrate polymers excreted in urine after administration of DEX and HES, a screening method was developed involving size exclusion chromatography (SEC) combined with time-of-flight mass spectrometry (TOFMS). By using solely a SEC guard column as an analytical column allowed sufficient chromatographic resolution in a minimal amount of time and with reasonable repeatability (average RSD of 10 %). Detector response was linear throughout the measurement range for both analytes. Limits of detection were 100 and 250 microg/mL for DEX and HES, respectively. Ion suppression was found to be 52 percent at maximum. In-source collision-induced dissociation (ISCID) was used to produce characteristic fragments at a mass accuracy better than 2 mDa. The specificity of the SEC-ISCID-TOFMS method was demonstrated with 120 PVE negative doping control samples analyzed in parallel with a routine GC-MS screening method. In addition, seven urine samples from diabetic athletes, causing interpretation problems in routine GC-MS, showed here a definitely negative profile [13340].

Plasma volume expanders comprise a heterogeneous group of substances used in medicine that are intravenously administered in cases of great blood loss owing to surgery or medical emergency. These substances, however, can also be used to artificially enhance performance of healthy athletes in sport activities, and to mask the presence of others substances. These practices are considered doping, and are therefore prohibited by the International Olympic Committee and the World Antidoping Agency. Consequently, drug testing procedures are essential. One article provided an overview of plasma volume expanders, assembling pertinent data such as chemical characteristics, physiological aspects, adverse effects, doping and analytical detection methods, which are currently dispersed in the literature [11147].

The use of plasma volume expanders (PVE), such as dextran (DEX) and hydroxyethyl starch (HES), is prohibited in sports. DEX is a naturally occurring glucose polymer, whereas HES is synthetically produced from amylopectin starch by substitution with hydroxyethyl groups. In doping control, the commonly applied enzymatic and colorimetric screening methods are lacking adequate specificity for DEX and HES. Also, gas chromatographic-mass spectrometric (GC-MS) screening methods have specificity issues with DEX. In addition, due
to the nature of the target compounds, time-consuming derivatisation steps are required in GC-MS. Based on the high molecular weight of carbohydrate polymers excreted in urine after administration of DEX and HES, a screening method was developed involving size exclusion chromatography (SEC) combined with time-of-flight mass spectrometry (TOFMS). By using solely a SEC guard column as an analytical column allowed sufficient chromatographic resolution in a minimal amount of time and with reasonable repeatability (average RSD of 10%). Detector response was linear throughout the measurement range with $R^2 > 0.99$ for both analytes. Limits of detection were 100 and 250 $\mu$g/mL for DEX and HES, respectively. Ion suppression was found to be 52 percent at maximum. In-source collision-induced dissociation (ISCID) was used to produce characteristic fragments at a mass accuracy better than 2 mDa. The specificity of the SEC-ISCID-TOFMS method was demonstrated with 120 PVE negative doping control samples analyzed in parallel with a routine GC-MS screening method. In addition, seven urine samples from diabetic athletes, causing interpretation problems in routine GC-MS, showed here a definitely negative profile [11148].

Hypovolemia from a range of etiologies can lead to severe morbidity and mortality unless blood volume and tissue perfusion are restored. The treatment of hypovolemia has included the improvement and restoration of blood volume loss by the intravenous infusion of plasma expanding therapeutic agents. These have included crystalloid and/or colloid solutions, and a brisk controversy as to which modality is better has engaged therapeutics for the past 30 years. In addition, those favoring either modality have debated which crystalloid, and which colloid, is better. This area was given a dramatic turn a decade ago when a Cochrane meta-analysis concluded that albumin, a historically important plasma expander, resulted in increased mortality when administered to critically ill patients. Although subsequently modified by other studies, the Cochrane meta-analysis has served to generate an ongoing interest in the safety of plasma expanders. One review assessed the safety of these therapies from the viewpoint of the heterogeneous range of clinical indications for which they are used [11149].

Plasma volume expanders comprise a heterogeneous group of substances used in medicine that are intravenously administered in cases of great blood loss owing to surgery or medical emergency. These substances, however, can also be used to artificially enhance performance of healthy athletes in sport activities, and to mask the presence of others substances. These practices are considered doping, and are therefore prohibited by the International Olympic Committee and the World Antidoping Agency. Consequently, drug testing procedures are essential. The present work provides an overview of plasma volume expanders, assembling pertinent data such as chemical characteristics, physiological aspects, adverse effects, doping and analytical detection methods, which are currently dispersed in the literature. Crystalloid solutions are primarily extravascular space expanders, since 1 h after infusion, approximately three-quarters have already moved out from capillary blood into the interstitial space. However, they are the least expensive and most readily available of the plasma volume expanders. The second important group is represented by colloid solutions. These homogeneous noncrystalline solutions contain high-molecular weight (MW) substances, such as proteins, large glucose polymers or blood derivatives, which do not settle out under the influence of gravity. Colloid solutions are intravascular space expanders, since colloid molecules cannot pass easily through the endothelium; hence, they exert an oncotnic pressure, which attracts extravascular fluid into the circulation. The resulting expansion is at least equivalent to the infused volume. In both groups, fluid administration initially results in expansion of the intravascular compartment. The basic difference is the extent and persistence of effects, which depend on whether or not there is a free transfer of molecules across the vascular endothelium. Hemoglobin-based oxygen carriers (HBOCs) are described in the colloid group, since they consist of high-MW substances that pull
interstitial fluid into the intravascular space due to their relevant oncotic pressure. These HBOCs combine oxygen transport with volume-expanding properties. Other oxygen carriers, such as perfluocarbons, are not been included in this group, since they are not considered plasma expanders. The third group of PVEs includes osmotic diuretics, which are low-MW substances that are freely filtered at the glomerulus, being only slightly reabsorbed at the renal tubules. The additional osmotically active particles in the glomerular filtrate prevent water reabsorption and promote diuresis. Increased osmotic pressure in plasma draws water from tissues into the vascular space, expanding plasma volume. Osmotic diuretics are mainly used to reduce cerebral edema and intra-ocular pressure and to preserve kidney [11146].

Dextran and hydroxyethyl starch

Dextrans are branched polysaccharides, made up of glucose units, mainly in alpha-1,6 linkage, in predominantly linear macromolecules. Preparation consists of Leuconostoc bacteria acting on sucrose, acid hydrolysis and subsequent ethanol fractionation, leading to the final dextran products. Currently, there are two commercially available types: Dextran 40 and Dextran 70; they do not transmit hepatitis virus and are inexpensive. Renal elimination depends on molecular weight. Dextran molecules of less than 50-55 kDa are freely filtered at the renal glomerulus, while elimination of molecules of greater than 55 kDa may take several days. Dextrans prevent hypovolemia, exert thromboprophylactic activity and improve microcirculation. However, severe adverse effects may occur, such as anaphylactic or anaphylactoid reactions, renal impairment in patients with risk factors, as well as biochemical alterations. Blood volume expansion in athletes by dextran was studied in 1994 (Utah research), evidencing enhancing effects. Therefore, since January 2000, the use of dextran by athletes has been prohibited by the IOC and WADA. An initial screening for dextran by Benedict’s reaction and TLC is performed by the same procedure as described for HES. A characteristic pattern of bands, different from the HES profile, may indicate the presence of dextran in urine. Confirmation must be made by chromatographic/MS techniques. A commonly used identification method for urinary dextran consists of qualitative analysis of the partially methylated alditol acetates obtained by degradation and subsequent derivatization. However, this method is unable to perform the required quantitation by partially methylated alditol acetates derivatization procedures. The dextran polymer is enzymatically hydrolyzed by alpha-1,6-glucosidase (dextranase), generating isomaltose subunits. Subsequent acetylation allows the chromatographic separation of different disaccharides, such as lactose, saccharose and isomaltose, as well as the identification and quantification of the analyte in human urine [11146].

A rapid screening procedure based on liquid chromatography-electrospray ionization-tandem mass spectrometry with in-source collision-induced dissociation was developed for detection of the polysaccharide-based plasma volume expanders dextran and hydroxyethyl starch (HES) in human urine. The in-source fragmentation strategy of the approach represented a valuable tool in the analysis of the polysaccharide-based compounds, allowing the use of tandem mass spectrometry. After direct injection of urine specimens, analytes were chromatographically separated on a monolithic reverse-phase column and detected via multiple reaction monitoring of diagnostic ions at detection limits of 10 microg/mL for HES and 30 microg/mL for dextran. Validation was performed regarding the parameters specificity, linearity, precision (8-18 %) and accuracy (77-105 %) and the method was applied to the investigation of approximately 400 doping control samples and seven dextran and two hydroxyethyl starch post-administration samples. The approach demonstrated its capability as a rapid screening tool for the detection of dextran and hydroxyethyl starch and represents an alternative to existing screening procedures since time consuming hydrolysis or derivatization steps were omitted [08235].
Hydroxyethyl starch (HES)

The polysaccharide hydroxyethyl starch (HES) consists of d-glucose units joined by alpha-1,4 linkage, in a branching structure, in which the number of a-1,6 branch points can vary. Hydroxyethyl groups are attached to carbons 2, 3 or 6 of the glucose units. HES solutions are artificial colloids derived from corn starch amylopectin. They are used for treatment and prevention of hypovolemia, being among the most frequently used PVEs in the medical field. HES prevents dehydration and enhances microcirculation. However, it has been associated with unwanted side effects, such as pyrexia, anaphylactoid reactions and effects on coagulation. HES is removed from the circulation predominantly by renal excretion. The first phase occurs almost immediately upon administration, because polymers with a MW less than 59 kDa are rapidly eliminated by glomerular filtration. The second phase is more prolonged, due to the enzymatic degradation of higher molecular weight HES molecules. The hydroxyethyl groups remain intact and attached to the glucose units. Volume expansion is seen for approximately 24 h, with 29 to 38 percent of the colloid still available intravascularly after this period. The most common form of HES is hetastarch HES 450/0.7, which means it has an average MW in kDa/average molar substitution that represents the average number of hydroxyethyl residues per glucose unit. Hydroxyethyl starch has been exploited by the athletic community, owing to blood volume increase, preventing dehydration and enhancing microcirculation, control of hematocrit value and, mainly, masking blood doping by rEPO. Therefore, HES has been prohibited since 2000 by the IOC, and more recently by the WADA. An initial screening has been described, based on acid hydrolysis of HES in urine and detection of the resulting glucose and glucose derivatives by Benedict’s reaction. Following, hydrolysates from suspect urine samples are submitted to TLC and a characteristic pattern of bands may suggest the presence of HES. Such samples are sent to chromatographic/MS techniques for confirmation. Other polysaccharides may also present suspect results by Benedict’s reaction. The TLC procedure may suggest possible polysaccharides. Several procedures based on LC-(ESI)-MS/MS with in-source collision-induced dissociation and direct injection of urine (for HES and dextran). Voluven is a third-generation HES. It must be mentioned that there has been renewed interest in the clinical applicability of HES. High doses of first- and second-generation HES were demonstrated to be associated with several adverse effects, mainly on renal function and coagulation. Major developments have been achieved over recent years concerning safety, and the newest generation presents significantly improved properties in comparison with earlier products. The third-generation of HES, the tetrastarches, enhance degradation and minimize retention in the circulation and tissues. Moreover, extensive clinical studies in major surgery showed that very high doses of Voluven produced no adverse effects on coagulation [11146].

The artificial colloid hydroxyethyl starch (HES) is among the most frequently used plasma volume expanders in the medical field. However, in 1998, its misuse by the athletic community was officially reported and since 2000, HES is prohibited by the International Olympic Committee (IOC). Therefore, several methods enabling the detection of HES in urine were developed, most based on gas chromatography-mass spectrometry (GC-MS). In one work, a simple and low-cost screening method, intended to reduce the number of samples to be analysed by GC-MS, was developed. The method is based on the acid hydrolysis of HES and detection of the resulting glucose and hydroxyethyl glucose derivatives by Benedict’s reaction (reduction of copper sulfate to brick-red cuprous oxide by glucose and/or derivatives). Samples considered suspect were submitted to GC-MS analysis for identification of HES. The method was successfully applied for screening of HES in 2627 urine samples from 1346 Brazilian soccer players and 1281 athletes from the Pan-American Games (Rio de Janeiro, 2007); 71 (2.7 %) samples, considered suspect, were submitted to GC-MS, but no positive results were found. Moreover, a thin layer chromatography (TLC) method was adapted for visualisation of the characteristic band pattern of HES hydrolysis.
In one contribution it was tested the possibility to use microwave irradiation for the screening and confirmation pre-treatment steps of hydroxyethylstarch, with the aim to speed up gas chromatography-mass spectrometric procedures. Acid hydrolysis and derivatization processes were conducted in a temperature-controlled single beam microwave oven for organic synthesis. The kinetics of hydroxyethylstarch chemical hydrolysis and derivatization were investigated at different microwave power, incubation temperature and incubation time. The best hydrolysis conditions were found at a microwave power value of 1200 W (T 100°C) with an incubation time of 2 min; whereas the best derivatization conditions were found at a microwave power value of 1020 W (T 100°C) with an incubation time of 5 min. The effectiveness of this approach was evaluated by gas chromatography-mass spectrometry analyzing more than 20 different pools of blank urine samples spiked with hydroxyethylstarch at a concentration of 1 mg/mL. The results showed that the effect of microwave irradiation on the chemical hydrolysis process was very remarkable: the total sample preparation time can be shortened by 58 min compared to the reference method (2 min instead of 60 min). In addition to this, the time necessary for the derivatization process can also be drastically shortened with respect to the reference procedure (5 min instead of 30 min). The repeatability of the hydrolysis and derivatization recoveries, the limit of detection and the matrix interferences were comparable to the reference method accredited under the ISO 17025 guidelines and presently followed by the accredited sports anti-doping laboratory of Rome [10494].

The morphological and structural properties of basic types of starch used as excipients in solid drug form technology with reference to its bioadhesive properties with fully polymer biodegradation. The production technology and application of: carboxymethyl starch (CMS), pregelled starch, hydroxyethyl starch (HES), hydroxypropyl starch (HPS) and the share of modified starch in technology of selected food products is provided. It was focused on hydroxyethyl starch, which is used not only as blood and plasma substitution but also as drug camouflage agent in sports competition. In papers were presented based on literature data actually used types of starch and their chemical modifications products in drug forms and food technology [09174].

Hydroxyethyl starch (HES) is a widely used plasma substitute for correcting perioperative hypovolemia. HES preparations are defined by concentration, molar substitution, mean molecular weight, the C(2)/C(6) ratio of substitution, the solvent, and the origin. The possible unwanted side effects of HES are anaphylactic reactions, alterations of hemostasis resulting in increased bleeding, kidney dysfunction, accumulation, and pruritus. In view of the potential side effects, it is crucial to distinguish among the different HES preparations; all HES preparations are not the same. The first generation of HES preparation showing a high mean molecular weight (>450 kD) and a high molar substitution (>0.7) was associated with negative effects with regard to coagulation, organ function, and accumulation. One review focused on whether modern (third generation), more rapidly degradable HES preparations with a lower mean molecular weight (130 kD) and a lower molar substitution (<0.5) are safer and have fewer side effects. Several studies demonstrated that such modern HES preparations appear to be safe with regard to hemostasis, kidney function, itching, and accumulation. Modern HES preparations are dissolved in balanced, plasma-adapted solutions that no longer contain unphysiological amounts of sodium and chloride and are thus suitable for correcting hypovolemia [09175].

High doses of first- and second-generation HES were associated with adverse effects on renal function, coagulation, and tissue storage, thereby limiting their clinical applicability. Newer HES products have lower molar substitution and in vivo molecular weight, resulting in
more rapid metabolism and clearance. In this review article, the differences between HES generations are highlighted, with particular emphasis on the improved safety profile of the third generation products. These improvements have been achieved with no loss of efficacy, and they contradict the assumption that efficacy of HES solutions is directly linked to plasma concentration. The impact of source material on structure and pharmacokinetics is highlighted, and the role of the carrier solution is critically assessed [09176].

The artificial colloid hydroxyethyl starch (HES) is among the most frequently used plasma volume expanders in the medical field. However, in 1998, its misuse by the athletic community was officially reported and since 2000, HES is prohibited by the International Olympic Committee (IOC). Therefore, several methods enabling the detection of HES in urine were developed, most based on gas chromatography-mass spectrometry (GC-MS). In the present work, a simple and low-cost screening method, intended to reduce the number of samples to be analysed by GC-MS, was developed. The method is based on the acid hydrolysis of HES and detection of the resulting glucose and hydroxyethyl glucose derivatives by Benedict’s reaction (reduction of copper sulfate to brick-red cuprous oxide by glucose and/or derivatives). Samples considered suspect were submitted to GC-MS analysis for identification of HES. The method was successfully applied for screening of HES in 2627 urine samples from 1346 Brazilian soccer players and 1281 athletes from the Pan-American Games (Rio de Janeiro, 2007); 71 (3 %) samples, considered suspect, were submitted to GC-MS, but no positive results were found. Moreover, a thin layer chromatography (TLC) method was adapted for visualisation of the characteristic band pattern of HES hydrolysis products [10129].

Glucose solution

Glucose solutions, given by intravenous infusion, exert volume effects that are governed by the amount of fluid administered and also by the metabolism of glucose. They can be used with or without saline. Glucose solutions are frequently used to hydrate patients with acute disease or after surgery. Hypertonic glucose solutions are given to provide glucose as a metabolic substrate. Although glucose is not considered an illegal substance, the WADA decided that glucose infusions are illegal, unless they are used as a legitimate medical treatment in case of dangerous hypoglycemia during competition. An interesting reagent-free method using mid-infrared attenuated total reflection (ATR) for analysis of glucose (and also albumin, ALB), owing to the significant mid-infrared absorption bands has been reported. The calibration model of glucose in urine has been established, using ATR mid-infrared spectroscopy combined with partial least-squares regression analysis [11146].

Saline solution

A 0.9 percent sodium chloride isotonic solution remains in the circulation only briefly. Approximately 20-30 min after the infusion, only 20-25 percent remains in the intravascular compartment. Therefore, large volumes need to be infused to result in effective plasma volume expansion; in such cases, however, hyperchloremic metabolic acidosis may result. A balanced electrolyte solution with glucose is likely to maintain close-to-normal plasma osmolarity and energy metabolism [11146].

Ringer lactate (or acetate) solution

This solution has become widely accepted for fluid replacement because it contains electrolytes in plasma concentrations. It consists of a balanced electrolyte composition, containing potassium, sodium, calcium, chloride and lactate (acetate). Besides, coagulation
problems do not occur and solutions are low-cost. However, large quantities involve risks and complications, such as reduction of the osmotic pressure, superhydration, edema, hyponatremia and pulmonary dysfunction from water [11146].

**Hypertonic crystalloid solution**

The high osmolarity of these solutions rapidly mobilizes extravascular fluid into the circulation. However, irritation to veins and hypertension may result. Hypertonic saline solutions are solutions with high levels of sodium (e.g. 7.5 %). Plasma expansion peak occurs in 5 min, but the effect duration is brief. The main advantages are the small volume required and low cost [11146].

**Albumin**

Albumin is the major protein of human plasma, with a molecular weight of approximately 69 kDa. It makes up 60 percent of total plasma protein, being responsible for approximately 80 percent of its osmotic pressure. ALB is highly soluble in water, and bears a strong negative charge. Preparations of human ALB (pooled from human donors' plasma) have been used in medical and surgical emergencies. In general, infusion of 100 mL of 25 percent albumin expands the plasma volume by 450 mL. Controversy regarding risks and benefits compared with crystalloids has continued to date. Adverse effects associated with administration of ALB have been closely scrutinized and debated, and a recent study showed no difference in mortality between intensive care unit patients receiving ALB and those receiving saline as resuscitation fluid. Abnormal elevation of urinary albumin is a sign of kidney damage, but it may also be a long-term consequence of performance-enhancing substances intake. It is well known that exercise induced albuminuria is a common consequence of physical activity, being transient. Therefore, when urinary ALB levels exceed the established range of albuminuria due to exercise, this may be a sign of misuse. Detection of ALB in physiological fluids has been performed by various methods, including electrophoresis (serum protein fractionation) or dye binding with spectrophotometric detection. In urine, it is commonly determined by various quantitative immunochemical methods, such as immunonephelometry, immunoturbidimetry and radioimmunoassay or by semi-quantitative dipsticks. Recent studies have revealed that the ALB molecule is not a clearly defined entity in urine. Modified ALB forms, such as degraded and fragmented species of ALB, truncated forms and ALB bound to ligands present in urine have been identified [11146].

**Plasma protein fraction**

Plasma protein fraction is produced by partially fractionating a large plasma pool. It contains ALB plus several globulins fractions, closely resembling plasma in its constitution. Plasma protein fractions are effective PVEs that can be handled as pharmaceutical products. They are hepatitis-virus free but, being human-derived colloids, present disadvantages such as risks of infections and elevated cost [11146].

**Plasma**

Fresh frozen plasma has been considered most useful, since it contains nearly all the clotting factors in normal concentration, excepting platelets. However, risk of viral hepatitis is the same as for whole blood. Plasma as a PVE must be stored in a deep-freeze unit and requires special handling before administration [11146].

**Gelatins**
Gelatins are heterogeneous mixtures of polypeptides, containing large amounts of proline and hydroxyproline residues. They are usually prepared by hydrolysis of bovine collagen. Further modifications produce different types of gelatins: succinylated gelatin (Gelofusine®); urea-linked gelatin (Haemacel® and polygeline) and oxypolygelatin. The expansion capacity of gelatins is limited (1 mL corresponds to an expansion of 0.8 mL) owing to their short intravascular life. They may, however, affect coagulation or provoke anaphylactoid reactions. Since gelatins are rapidly removed by glomerular filtration, 70-90 percent are found in the urine within a few hours. In certain circumstances, however, gelatin preparations can be adequately used in patients with impaired kidney function. Gelatin-derived preparations are prohibited as intravenous infusions. Apparently, such infusions are not a preferred means of doping. No reports on gelatin misuse have been found. Owing to the large amounts of hydroxyproline in gelatin and its absence in normal plasma and urine, the determination of this amino acid enables measurement of the content of modified gelatin in these physiological fluids by any standard amino acid analyzer method. A specific quantitative gas-liquid chromatographic (GLC) assay of hydroxyproline was also developed. Moreover, gelatin-derived polypeptides can be detected by the biuret method. In case of hydroxyproline-free gelatin, determination can be made by reversed phase-LC and detection at 220 nm [11146].

**alpha-Keratose**

An interesting compound, alpha-keratose, is a protein derived from keratins, which are complex proteins found in skin, hair, nail, feathers and similar tissues. The preferred source for keratose preparations is human hair, which is abundant, renewable, nontoxic, non-antigenic and inexpensive. However, it presents disadvantages such as aggregation of red blood cells, among others. New approaches to developing keratin-based high viscosity plasma expanders have been studied, leading to improved compositions. A homogeneous liquid plasma expander composition, consisting of alpha-keratose and an electrolyte solution, has been described by [11146].

**Combined solutions (hypertonic crystalloid/colloid)**

Owing to the brief plasma expansion of hypertonic crystalloids, the colloids HES or dextran can be added to increase expansion duration. Hypertonic saline dextran requires only small volumes to rapidly elevate blood pressure and is capable of prolonged maintenance of volemic expansion. It was introduced in 1985, but its take-up has been slow, mainly due to concerns about complications and lack of human trials. However, it became apparent that hypertonic saline dextran may be an efficient means of correcting hypotension and a trend towards increased survival has also been suggested [11146].

**Pullulan**

Pullulan is a fungal non-ionic exopolysaccharide produced from starch by Aureobasidium pullulans. It consists of alpha-1,6 linked maltotriose residues and its molecular weight ranges from thousands to millions daltons. A. Pullulan is easily soluble in hot and cold water, producing clean and viscous solutions. It is blood compatible, biodegradable, nontoxic, non-immunogenic, nonmutagenic and noncarcinogenic, and is therefore being explored for medical application, including use as a potential plasma-blood substitute [11146].

**Levan**
Levan, a branched polymer of d-fructose, has great potential as a functional biopolymer in the pharmaceutical and chemical industries, depending on the molecular weight. To date, microbial levans are produced from a sucrose-based substrate by enzymatic reaction using a variety of microorganisms, including the recently investigated Bacillus subtilis. Levans with small molecular weights are nontoxic and non-antigenic, being slowly eliminated from the body when injected into the bloodstream. Therefore, levan with a MW below 100 kDa has potential as a PVE [11146].

**Acetyl starch**

An interesting alternative to the PVEs used to date is the synthetic colloid acetyl starch (ACS). Efficient preparation yields polysaccharide based products suitable for pharmaceutical and biomedical applications, especially as PVEs. ACS avoids accumulation of persisting macromolecules and presents an excellent physiological compatibility. It is as effective as HES, with identical plasma concentrations during the first 6 h after infusion. In contrast to the biphasic elimination of an HES solution, an equivalent ACS solution is eliminated monophasically. Although the initial phase of glomerular filtration is similar for both (immediate elimination of molecules <50,000 Da), HES undergoes a further prolonged phase of enzymatic degradation, while ACS is rapidly degraded to acetic acid and glucose, which are excreted renally. Significant amounts of HES are still detectable after 24 h, but ACS is nearly completely metabolized. Apparently, ACS is not a preferred PVE for doping purposes. No reports on ACS misuse were found. Acetyl starch can be determined using the method based on MALDI-TOF-MS. Moreover, a rapid LC method for quantitation in blood samples has been outlined, using a size-exclusion chromatography (SEC) system, with a refractive index detector [11146].

**Polyvinylpyrrolidone**

This compound was developed in Germany during World War II. However, it is no longer acceptable as a PVE since it remains indefinitely in organs and tissues, resulting in storage diseases [11146].

**Mannitol**

Mannitol, a six-carbon sugar alcohol, is used as an osmotic diuretic; it is applied by intravenous infusion to preserve renal function and to reduce raised intracranial and intraocular pressure, as well as to promote the excretion of poisons and toxic wastes. Adverse reactions may occur, such as pulmonary congestion, heart failure, electrolyte imbalance, headache, convulsions and others. The potential misuse of mannitol in sports is due to its urine-diluting effect, which lowers the concentration of banned substances in urine, and a possible bodyweight decrease. To detect a doping offence, urinary mannitol concentrations after a prohibited intravenous administration must be differentiated from mannitol resulting from a permitted oral intake. A GC-MS analytical method is described based on the peracetyl derivatives of the analytes. All possible urinary hexitols, including mannitol, can be rapidly separated and identified. The method was applied to an excretion study to investigate urinary mannitol concentrations following oral intake. Preliminary results, with regard to a threshold level for mannitol that could be utilized in doping control, were promising [11146].

**Glycerol**

Glycerol is prohibited as an ergogenic aid by the World Anti-Doping Agency (WADA) due to the potential for its plasma expansion properties to have masking effects. However, the
scientific basis of the inclusion of glycerol as a "masking agent" remains inconclusive. The purpose of this study was to determine the effects of a hyperhydrating supplement containing glycerol on doping-relevant blood parameters. Nine trained males ingested a hyperhydrating mixture twice per day for 7 days containing 1.0 g/kg body mass (BM) of glycerol, 10 g of creatine and 75 g of glucose. Blood samples were collected and total hemoglobin (Hb) mass determined using the optimized carbon monoxide (CO) rebreathing method pre- and post-supplementation. BM and total body water (TBW) increased significantly following supplementation by 1.1 ± 1.2 and 1.0 ± 1.2 L, respectively. This hyperhydration did not significantly alter plasma volume or any of the doping-relevant blood parameters (e.g. hematocrit, Hb, reticulocytes and total Hb-mass) even when glycerol was clearly detectable in urine samples. In conclusion, this study shows that supplementation with hyperhydrating solution containing glycerol for 7 days does not significantly alter doping-relevant blood parameters [12338].

Glycerol ingestion creates an osmotic drive that enhances fluid retention. The major practical applications for athletes are to either hyperhydrate before exercise so that they have more fluid to be lost as sweat during subsequent performance, thereby delaying the progression of dehydration from becoming physiologically significant, or improve both the rate of rehydration and total fluid retention following exercise. Recently we showed that rehydration may be improved further by combining glycerol with intravenous fluids. Improvements in endurance time, time trial performance and total power and work output have been seen during exercise following glycerol-induced hyperhydration or rehydration. Another recent trial showed that the increased body weight associated with the extra fluid does not inadvertently affect running economy. Concerns that the haemodilution associated with the fluid retention in the vascular space may be sufficient to mask illegal doping practices by athletes led the World Anti-Doping Agency (WADA) to add glycerol to its list of prohibited substances in 2010. Recent evidence suggests that doses of > 0.032 ± 0.010 g/kg lean body mass (much lower than those required for rehydration) will result in urinary excretion that may be detectable, so athletes under the WADA jurisdiction should be cautious to limit their inadvertent glycerol intake [12273].

Glycerol is a 3-carbon sugar alcohol that provides the backbone of triglycerides and is naturally found in foods as a component of dietary fats. However, its various physical and chemical properties are valuable in food technology: glycerol is added to manufactured foods and drinks as an emulsifier, humectant, sweetener, filler and thickener. Its viscosity also makes it useful as a component of lotions and creams, explaining its common availability for purchase in purified form under the name of glycerine. Although it has been suggested as a gluconeogenic precursor that could provide a substrate for exercise, the ingestion of glycerol by athletes is best known for its role as an osmolyte. When ingested or released following lipolysis, glycerol contributes to the osmotic pressure of body fluids until it is slowly metabolised. When consumed simultaneously with a substantial volume of fluid, there is a temporary retention of this fluid and expansion of body fluid compartments. Effective protocols for glycerol hyperhydration are 1-1.5 g/kg glycerol with an intake of 25-35 ml/kg of fluid. Such a protocol typically achieves a fluid expansion or retention of approximately 600-1000 ml above a fluid bolus alone by a reduction in urinary volume. Several challenging situations commonly arise in sport in which athletes have made use of these strategies to promote better hydration status. These include hyperhydration before exercise in hot environments where a large fluid deficit will otherwise accumulate, and reduction of diuresis associated with aggressive rehydration (eg, following weight-making practices in sport or after dehydrating exercise). General guidelines for fluid intake in exercise typically discount the value of hyperhydration or fluid overloading strategies. Indeed, there are occasional side-effects of glycerol use including nausea, gut discomfort and headaches from increased intracranial pressure. However, more focused reviews of glycerol hyperhydration in specific
situations in sport, including a meta-analysis of glycerol hyperhydration before exercise in hot environments, have reported evidence of enhanced fluid balance and endurance performance compared with the intake of large volumes of water alone or no hyperhydration. There has been less focus, but some support, for the addition of glycerol to rehydration beverages to promote the rapid reversal of dehydration and assist the performance of subsequent exercise. Indeed, there anecdotal reports that some athletes add glycerol to rehydration beverages for practical reasons; for example, to reduce overnight diuresis and its interruption to sleep patterns when completing dehydrating exercise sessions late in the day. The apparent contradictions in the literature may be due to the specificity of the situations in which glycerol hyper/re-hydration is beneficial. The major problem related to the use of glycerol by athletes, however, arises because of recent changes to antidoping codes. The 2011 World Anti-Doping Agency (WADA) list of substances prohibited at all times includes the category of Diuretics and other Masking agents (section 5). Plasma expanders further qualified in this section are: "e.g. glycerol, intravenous administration of albumin, dextran, hydroxethyl starch and mannitol." How the normal dietary intake of glycerol is distinguished from specific intake to aid fluid balance is unclear [11150].

The three-carbon sugar alcohol glycerol is used for hyperhydration and due to its ability to be easily and cleanly metabolized, for providing energy. Higher doses may cause headache, blurred vision and possible additional stress on the cardiovascular system. Administration of glycerol to endurance athletes promotes increased fluid retention and improved performance, principally under hot and humid conditions. Glycerol is considered relevant for sports drug testing, owing to the properties described above. Ingestion of large quantities causes glycerol to appear in urine, since it is rapidly reabsorbed by the proximal and distal tubules, causing minimal diuresis. Glycerol was formerly considered to be a diuretic by the US Olympic Committee, being banned because of a detrimental effect of dehydration and dilution of prohibited substances in urine. In 1997, the US Olympic Committee removed the ban on glycerol (owing to the minimal diuresis) and approved the use of glycerol ingestion. However, in the WADA 2010 Prohibited List, it appears again as a banned substance. A quantitative analytical method is described for glycerol, using a GC-isotope-dilution MS-based approach. Due to the natural occurrence of glycerol trace amounts in human urine, a range of normal levels in elite athletes’ urine, was initially determined. The analytical methods described above for the different groups of PVEs are, in their majority, based on chromatographic/MS techniques. They are accurate, specific and sensitive, being the most used methods for the identification of misused substances. The other detection procedures, including simple screening methods, may be used for clinical purposes, and also in order to precociously detect the presence of urine samples that are potentially positive for PVEs [11146].

The administration of glycerol to endurance athletes results in an increased fluid retention and improved performance, particularly under hot and humid conditions. Consequently, glycerol is considered relevant for sports drug testing and methods for its detection in urine specimens are required. A major issue in this regard is the natural occurrence of trace amounts of glycerol in human urine, which necessitates a quantitative analysis and the determination of normal urinary glycerol levels under various sporting conditions. A quantitative method was established using a gas chromatography/isotope-dilution mass spectrometry-based approach that was validated with regard to lower limit of detection (0.3 microg/mL), lower limit of quantification (0.9 microg/mL), specificity, linearity (1.0-98.0 microg/mL), intraday and interday precision (<20 % at 2.4, 24.1 and 48.2 microg/mL) as well as accuracy (92-110 %). Sample aliquots of 20 microL were enriched with five-fold deuterated glycerol, dried and derivatised using N-methyl-trimethylsilyl trifluoroacetamide before analysis. The established method was applied to a total of 1039 doping control samples covering various sport disciplines (349 endurance samples, 286 strength sport samples, 325 game sport samples and 79 other samples) in- and out-of-competition, which
provided quantitative information about the glycerol content commonly observed in elite athletes' urine samples. About 85 percent of all specimens yielded glycerol concentrations < 20.0 microg/mL and few reached values up to 132.6 microg/mL. One further sample, however, was found to contain 2690 microg/mL, which might indicate the misuse of glycerol, but no threshold for urinary glycerol concentrations has been established yet due to the lack of substantial data. Based on the results obtained from the studied reference population, a threshold for glycerol levels in urine set at 200 microg/mL is suggested, which provides a tool to doping control laboratories to test for the misuse of this agent in elite and amateur sport [08236].

Studies have shown that beverages containing glycerol can enhance and maintain hydration status and may improve endurance exercise performance by attenuating adverse physiological changes associated with dehydration. Improvements to performance include increased endurance time to exhaustion by up to 24 percent, or a 5 percent increase in power or work. However, some studies have found no performance benefits during either prolonged exercise or specific skill and agility tests. In studies that have shown benefits, the improvements have been associated with thermoregulatory and cardiovascular changes. These include increased plasma volume and sweat rates, as well as reduced core temperature and ratings of perceived exertion. In a very small number of subjects, glycerol consumption has been associated with side-effects including nausea, gastrointestinal discomfort, dizziness, and headaches. In summary, while glycerol and fluid ingestion results in hyperhydration, the documented benefits to exercise performance remain inconsistent [09177].

The authors determined, through a meta-analytic approach, whether glycerol-induced hyperhydration (GIH) enhances fluid retention and increases endurance performance (EP) significantly more than water-induced hyperhydration (WIH). Collectively, studies administered 24 mL of fluid/kg body weight (BW) with 1.1 g glycerol/kg BW, and hyperhydration was measured 136 min after its onset. Compared with WIH, GIH increased fluid retention by 7.7 mL/kg BW (pooled effect size, PES: 1.64, n=14). The use of GIH was associated with an improvement in EP of 2.6 percent (n=4). Unarguably, GIH significantly enhances fluid retention better than WIH. Because of the dearth of data, the effect of GIH on EP must be further investigated before more definitive conclusions can be drawn as to its ergogenic property [07131].

Due to its considerable polarity but modest proton affinity, glycerol analysis is difficult to be combined with most other routine doping control detection assays; however, since it was categorized as S5 substance in 2010, several studies particularly concerning its variability were conducted. In 2011, it was investigated the urinary excretion of ingested glycerol at rest and the influence of 1 g/kg of body weight on blood parameters such as hemoglobin and hematocrit. The urinary glycerol levels increased from baseline values (11 ± 16 microg/mL) to over 50 000 microg/mL accompanied by a modest though statistically significant plasma expansion. In another study, the correlation of glycerol ingestion and thus increased plasma glycerol with significantly increased renal elimination of glycerol was demonstrated. It was shown that glycerol administration higher than 0.1 g/kg of bodyweight resulted in urinary excretion exceeding the commonly observed urinary amounts of glycerol, hence, allowing a differentiation of legitimate hyperhydration with glycerol from its illicit use as a masking agent [13012].

Glycerol is prohibited as a masking agent by the World Anti-Doping Agency and a urinary threshold has recently been recommended. However, little is known about urinary glycerol excretion after exercise, when exogenous glycerol is metabolized increasingly and endogenous glycerol levels are elevated. The purpose of the placebo-controlled cross-over
study was to determine the effects of pre-exercise glycerol administration on glycerol metabolism, urinary excretion, and selected blood parameters. After administration of glycerol (1.0 g/kg body weight (BW) + 25 mL fluid/kg BW) or placebo (25 mL fluid/kg), 14 cyclists exercised 90 min at 60 percent VO_{2\max}. Samples were taken at 0 h (before administration), 2.5 h (before exercise), 4 h (after exercise) and 6.5 h and additional urine samples were collected until 24 h. Exercise increased endogenous plasma glycerol (0.51 ± 0.21 mmol/L) but peak concentrations were much higher in glycerol (2.5 h: 15.6 ± 7.8 mmol/L). Urinary glycerol increased rapidly (58 ± 71 microg/ml after 2.5 h) and was significantly higher than in placebo until 13.6 ± 0.9 h. In comparison with placebo administration, glycerol caused significantly greater changes in plasma volume and haemoglobin concentrations after 2.5 h. BW and urine production were significantly different between placebo and glycerol after 2.5 h and post-exercise. Despite exercise-induced increases in endogenous glycerol in the control group, urinary excretion remained well below the previously recommended threshold. In addition, exercise-related glycerol degradation did not appear to negatively affect the detection of exogenously administered glycerol [13353].

The use of glycerol in combination with excess fluid can be used to increase total body water. Because glycerol hyperhydration may also be misused to mask the effects of blood doping on doping-relevant parameters, namely haemoglobin and haematocrit, glycerol has been prohibited by the World Anti-Doping Agency since 2010. In order to test this rationale, the purpose of this meta-analysis was to quantify the effects of glycerol hyperhydration on plasma volume, haemoglobin, and haematocrit in comparison to administration of fluid only. Following a literature search, a total of seven studies was included and meta-analyses were performed separately for the effects on plasma volume (5 studies, total n=54) and on haemoglobin (6 studies, n=52) and haematocrit (6 studies, n=52). The meta-analysis revealed that the increase in plasma volume was 3 percent larger after glycerol administration when compared to fluid only. Reductions in haemoglobin were 0.2 g/dL larger and there was no difference in the changes in haematocrit between glycerol and fluid administration. In comparison with other plasma-volume expanding agents, glycerol hyperhydration has a very limited potential in increasing plasma volume and altering doping-relevant blood parameters [13354].

Glycerol is an endogenous substance that is on the World Anti-Doping Agency's list of prohibited threshold substances due to its potential use as a plasma volume expansion agent. The WADA has set the threshold for urine glycerol, including measurement uncertainty, at 1.3 mg/mL. Glycerol in circulation largely comes from metabolism of triglycerides in order to meet energy requirements and when the renal threshold is eclipsed, glycerol is excreted into urine. In part due to ethnic differences in postprandial triglyceride concentrations, we investigated urine glycerol concentrations in a population of elite athletes competing in North America and compared the results to those of athletes competing in Europe. 959 urine samples from elite athletes competing in North America collected for anti-doping purposes were analyzed for urine glycerol concentrations by a gas chromatography mass-spectrometry method. Samples were divided into groups according to: Timing (in- or out-of-competition), Class (strength, game, or endurance sports) and Gender. 333 (35 %) samples had undetectable amounts of glycerol (<1 microg/mL). 861 (90 %) of the samples had glycerol concentrations ≤20 microg/mL. The highest glycerol concentration observed was 652 microg/mL. Analysis of the data finds the effects of each category to be statistically significant. The largest estimate of the 99.9th percentile, from the in-competition, female, strength athlete samples, was 1813 microg/mL with a 95 % confidence range from 774 to 4251 μg/mL. This suggests a conservative threshold of 4.3 mg/mL, which would result in a reasonable detection window for urine samples collected in-competition for all genders and sport classes [13355].
Polyethylene glycol

Previous studies have found that increasing plasma viscosity as whole blood viscosity decrease has beneficial effects in microvascular hemodynamics. As the heart couples with systemic vascular network, changes in plasma and blood viscosity during hemodilution determine vascular pressure drop and flow rate, which influence cardiac function. One study aimed to investigate how changes in plasma viscosity affect on cardiac function during acute isovolemic hemodilution. Plasma viscosity was modulated by hemodilution of 40 percent of blood volume with three different plasma expanders (PEs). Dextran 2000 kDa (Dx2M, 6.3 cP) and dextran 70 kDa (Dx70, 3.0 cP) were used as high and moderate viscogenic PEs, respectively. Polyethylene glycol conjugated with human serum albumin (PEG-HSA, 2.2 cP) was used as low viscogenic PE. The cardiac function was assessed using a miniaturized pressure-volume conductance catheter. After hemodilution, pressure dropped to 84 percent, 79 percent, and 78 percent of baseline for Dx2M, Dx70 and PEG-HSA, respectively. Cardiac output markedly increased for Dx2M and PEG-HSA. Dx2M significantly produced higher stroke work relative to baseline and compared to Dx70. It was concluded that acute hemodilution with PEG-HSA without increasing plasma viscosity provided beneficial effects on cardiac function compared to Dx70, and similar to those measured with Dx2M. Potentially negative effects of increasing peripheral vascular resistance due to the increase in plasma viscosity were prevented [10359].

Newer plasma expanders

A variety of PVEs are constantly being modified or improved, aiming to obtain more efficient compounds and to avoid adverse effects evidenced in the past. For example, Voluven, a third-generation HES, has been improved owing to severe problems presented by the older generations. Research activities for development or improvement of new generation drugs will continue. Many interesting modified or new compounds have been developed, but several are still being submitted to animal or human trials. In the future they will probably undergo advanced clinical trials and soon after will be approved for clinical use. Among these compounds are: some polymerized Hb preparations; Hb vesicles; PEGconjugated albumin (a new-generation PVE that provides, according to preclinical studies, excellent microvascular and systemic recovery from hemorrhagic shock and extreme hemodilution); another albumin-based oxygen-carrying plasma expander, PEG-conjugated recombinant human serum ALB (HSA) incorporating the synthetic iron-porphyrin; many plant derived carbohydrates, such as alginates, inulin, carboxymethyl starch, pullulan and carboxymethylated Konjac glucomannan, a carboxymethylated polymer of mannose and glucose; and several other conjugated products. All of these are considered advisable as potential plasma expanders. Furthermore, using nanotechnology, nanoparticles (artificial red blood cells) are also being prepared for biomedical use, as oxygen carriers. In addition to the most used PVEs described, a few novel plasma expanders must be mentioned. Two new starches, carboxymethyl starch and carboxymethylated HES have been reported as presenting advantages over HES, with regard to their volume expansion effect and pharmacokinetic characteristics: although being considered as promising colloids, no precise statements were found about their potential use as PVEs. Another new-generation PVE, polyethylene glycol (PEG)-conjugated albumin, may provide, according to preclinical studies, the most extended and complete microvascular and systemic recovery from hemorrhagic shock, extreme hemodilution and endotoxemia. Moreover, it postpones the need of reestablishing intrinsic blood oxygen-carrying capacity to Hb concentrations lower than those associated with accepted transfusion triggers. Two other polysaccharides, alginate and inulin, have also been evaluated, being considered potential plasma expanders. Alginites are, a family of polysaccharides (mixture of manuronic and guluronic acid compounds) extracted from algae, are used extensively in biotechnology (e.g. agar). Produced by brown seaweed, they result in a high viscosity solution at a comparatively low concentration, with an extremely low oncotic
pressure. By mixing with a conventional plasma expander, such as Dextran 70, a specific viscosity may be obtained. Inulin, extracted from plant sources, may be crosslinked with different substances, resulting in compounds with high colloid osmotic pressure, strong expansion efficacy and no organ dysfunction, being therefore considered advisable as a potential plasma expander [11146].

**Intravenous rehydration**

Fluid is typically administered via intravenous (IV) infusion to athletes who develop clinical symptoms of heat illness, based on the perception that dehydration is a primary factor contributing to the condition. However, other athletes also voluntarily rehydrate with IV fluid as opposed to, or in conjunction with, oral rehydration. The voluntary use of IV fluids to accelerate rehydration in dehydrated, though otherwise healthy athletes, has recently been banned by the World Anti-Doping Agency. However, the technique remains appealing to many athletes. Given that it now violates the Anti-Doping Code, it is important to determine whether potential benefits of using this technique outweigh the risks involved. Several studies have shown that rehydration is more rapid with IV fluid. However, the benefits are generally transient and only small differences to markers of hydration status are seen when comparing IV and oral rehydration. Furthermore, several studies have shown improvements in cardiovascular function and thermoregulation with IV fluid, while others have indicated that oral fluid is superior. Subsequent exercise performance has not been improved to a greater extent with one technique over the other. The paucity of definitive findings is probably related to the small number of studies investigating these variables and the vast differences in the designs of studies that have been conducted. The major limitation of IV rehydration is that it bypasses oropharyngeal stimulation, which has an influence on factors such as thirst sensation, antidiuretic hormone (arginine vasopressin) release, cutaneous vasodilation and mean arterial pressure [10130].

**Hyponatremia**

The case histories were presented of four athletes taking part in a 95-mile ultra-endurance foot race in Scotland who were hospitalised after developing exercise-associated hyponatraemia and rhabdomyolysis. Exercise-associated hyponatraemia is relatively uncommon in temperate climates. Risk factors disposing to this disorder are discussed. Exercise-associated hyponatraemia is thought to be due to overconsumption of hypotonic fluid with other associated pathophysiology including an inability to suppress fully antidiuretic hormone during exercise or to mobilise adequate sodium from osmotically inactive internal stores. Non-specific symptoms make this disorder difficult to diagnose on site without the assistance of serum sodium measurement, but any delay in treatment of patients with encephalopathy can prove fatal. Mainstays of treatment include fluid restriction, hypertonic saline, loop diuretics and mannitol [09178].
CREATED HYPOXIA

The intermittent hypobaric hypoxia induced by specific facilities such as tents and rooms to simulate altitudes of up to 5500 m is an effective artificial technique to boost erythropoiesis, and is even more effective than natural exposure to the hypoxic environment of high altitudes (2800 m). This technique increases erythropoietin serum concentrations in trained athletes, although the main hematological parameters do not significantly differ from those of similarly trained athletes exposed to natural hypobaric hypoxia [06005].

In 1973, Sir Roger Bannister said that no clear proof of benefit of altitude training had emerged during a panel discussion on this topic, published in Br J Sports med. To date, most altitude training research is oriented towards individual endurance athletes, while the potential benefits for team sports remain largely unexplored. Hence, the safety and equality aspects of competitive football matches held above 2500 m have been passionately debated for over two decades. In 1993 this debate was invigorated when Brazil lost its first qualification game for a World championship in the stadium of La Paz (Bolivia), located at an altitude of 3600 m. Undoubtedly, the altered environment at altitude had a significant impact on players physical performances, and some athletes were better able to cope with the change in altitude than others, especially those who were better acclimated. Recently, the fact that Argentina suffered their worst loss in 60 years, a sound defeat of 6-1 against host Bolivia in a South Africa World Cup qualifier, clearly demonstrates that playing international games at altitude is a major challenge. Despite the apparent lack of strong scientific evidence, it is striking to observe that altitude-training centres have been established around the globe, and are now offering team sport players the opportunity to train under sport-specific hypoxic conditions. Forty years after the publication of the initial altitude training issue major advances have been made from a performance and mechanistic perspective. The three main points are [13324]:

- the current level of evidence for the efficacy of hypoxic methods to improve exercise performance at moderate or high altitude (acclimatisation) is well established. However, the benefits of using a “living high-training low”, “living high-training high” and “living low-training high” altitude training intervention or a combination of those methods to improve team sport-related physical performance on return to sea level are not as definitive
- training camps as short as 2 weeks can increase haemoglobin mass substantially in a range of professional team sport players, while limited data currently exists regarding the time course of non-haematological adaptations
- it is undeniable that no single recommendation is likely suitable for all players in a team, or across all team sports, requiring the development of optimised interventions at the individual player level.

Different ways of altitude training

In 2007, it was presented the main altitude/hypoxic training methods used by elite athletes: “live high – train high” (LHTH) and “live high – train low” (LHTL); sleeping at altitude to gain the haematological adaptations (increased erythrocyte volume) but training at sea level to maximise performance (maintenance of sea-level training intensity and oxygen flux). The LHTL method can be accomplished through a number of methods and devices:
natural/terrestrial altitude, nitrogen dilution, oxygen filtration and supplemental oxygen.

Another method is the “live low – train high” (LLTH) method including intermittent hypoxic exposure at rest (IHE) or during intermittent hypoxic training sessions (IHT). Noteworthy, all supporting references were conducted with endurance elite athletes (i.e., cyclists, triathletes, cross-country skiers, runners, swimmers, kayakers and rowers) and there is an extensive literature relative to LHTH as well as LHTL. However, there is a lack of evidence for the applicability of these methods in team-sport athletes. In recent times, media reports have provided us with coverage of some high-profile clubs or national squads in various team-sport disciplines undertaking fitness programmes at altitude during the early preseason or in preparation of a major competition. Despite the evident observation that athletes from different team sports and from all around the world are using altitude training more than ever before, it is stunning to note that to date there are only two hypoxic training studies that have been conducted with team-sport players. Therefore, there is an urgent need for mechanistic as well as applied studies investigating team-sport performance changes following hypoxic training in a sport-specific population before solid evidence-based recommendations can be definitely formulated. In parallel, over the last few years, an increasing interest for the practical application of altitude training in team sports – mainly in football but also in the rugby union or the Australian football league – was noted due to several reasons. First, there were controversies regarding the possibility of playing international football matches above 2500 m in the mountainous regions of South America, while guaranteeing players health and safety. Second, the FIFA 2010 Senior (South Africa) and 2011 U-20 (Columbia) World Cups held at altitude have highlighted the need for the squads to achieve optimal acclimatisation. Third, the development of new hypoxic devices (e.g., mobile inflatable hypoxic marquees) and methods (repeated sprints in hypoxia). This increased interest was translated by the organisation of international symposia on the topic by the leading sports organisation; for example, FIFA, symposium on playing football at altitude; International Olympic Committee, consensus statement on thermoregulatory and altitude challenges for all high-level athletes [13325].

Nomenclature

The intrinsic differences between factors underlying endurance (e.g., maximal aerobic speed, economy) and team-sport performance (e.g., repeated-sprint ability) as well as the constraints in the respective competition calendars explain why the aims and contents of the hypoxic methods and their periodisation in the yearly programme are largely different between individual and team sports. As such, we believe that the current nomenclature is probably not appropriate anymore for exploring the new boundaries of contemporary hypoxic methods offered to team-sport athletes. In 2010, we proposed to slightly modify the nomenclature by introducing the possibility of combining different hypoxic methods. New approaches include “IHE during interval-training” (IHT = IHT + IHE) and “live high-train low and high” (LHTLH = LHTL + IHT). Since more information became available on enhanced glycolysis and buffering capacity with IHT, it is discussed also the potential benefits of these hypoxic methods for anaerobic performance. Unfortunately, there is to date no expert consensus on how we should name the different hypoxic methods. IHT that should refer to interval training in hypoxia is also used for continuous low-intensity (<70 % VO2max) long duration (>30 min) exercise in hypoxia. Recently, it was also proposed a new hypoxic method (RSH, repeated sprint training in hypoxia) presumably based on different mechanisms than IHT. The time has come to update the current nomenclature since each method is likely based predominantly on different mechanisms; for example, increased oxidative capacity (CHT), buffering capacity (IHT) or compensatory fiber-selective vasodilatation (RSH). It is therefore suggested to divide the LLTH method in four subsets; that is, IHE, CHT (continuous >30 min low intensity training in hypoxia), IHT (interval-training in...
hypoxia) and RSH. Another point that deserves attention is the nature of altitude stress. With mounting evidence suggesting that hypobaric hypoxia induces different physiological adaptations than normobaric hypoxia, it is therefore believed that it is paramount to systematically report the method lowering ambient oxygen partial pressure [13325].

**Physiological mechanisms**

Altitude training has been used regularly for the past five decades by elite endurance athletes, with the goal of improving performance at sea level. The dominant paradigm is that the improved performance at sea level is due primarily to an accelerated erythropoietic response due to the reduced oxygen available at altitude, leading to an increase in red cell mass, maximal oxygen uptake, and competitive performance. Blood doping and exogenous use of erythropoietin demonstrate the unequivocal performance benefits of more red blood cells to an athlete, but it is perhaps revealing that long-term residence at high altitude does not increase hemoglobin concentration in Tibetans and Ethiopians compared with the polycythemia commonly observed in Andeans. This review also explores evidence of factors other than accelerated erythropoiesis that can contribute to improved athletic performance at sea level after living and/or training in natural or artificial hypoxia. It was described a range of studies that have demonstrated performance improvements after various forms of altitude exposures despite no increase in red cell mass. In addition, the multifactor cascade of responses induced by hypoxia includes angiogenesis, glucose transport, glycolysis, and pH regulation, each of which may partially explain improved endurance performance independent of a larger number of red blood cells. Specific beneficial non-hematological factors include improved muscle efficiency probably at a mitochondrial level, greater muscle buffering, and the ability to tolerate lactic acid production. Future research should examine both hematological and non-hematological mechanisms of adaptation to hypoxia that might enhance the performance of elite athletes at sea level [07137].

The purpose of hypoxic environments or other ergogenic aids that produce similar results is to increase aerobic exercise performance as demonstrated by improved performance in events such as distance running and cycling (e.g, le Tour de France). The mechanism by which hypoxic environments exert their effect is via changes in the partial pressure of oxygen, which leads to an increase in the body's hematocrit level. The decreased partial pressure of oxygen in the pulmonary capillaries results in a decrease in the percent oxyhemoglobin saturation. These changes increase the drive to breathe, thus increasing ventilation. The body senses these changes in partial pressure and increases the production of red blood cells (RBCs) as a result of the stimulus from the hormone, erythropoietin, which is secreted by the kidneys. The RBCs are rich in the oxygen-carrying protein, hemoglobin, which binds oxygen during transportation in the cardiorespiratory system. Thus, an increase in red blood cell mass (RBCM), increasing how much space in the blood is occupied by RBC, is the most important adaptation to occur through the use of a hypoxic environment. The greater the RBCM, the greater the oxygen-carrying capacity of the blood and, therefore, the aerobic potential of the system. RBCM may increase by about 9 percent during altitude training, which can translate into improvements in run performance of about 13.4 ± 10.0 s over 5000 m [07133].

**Cellular mechanisms**

The effects of concurrent hypoxic/endurance training on mitochondrial respiration in permeabilized fibers in trained athletes were investigated. Eighteen endurance athletes were divided into two training groups: normoxic (Nor, n=8) and hypoxic (H, n=10). Three weeks
(W1-W3) of endurance training (5 sessions of 1 h to 1 h and 30 min per week) were completed. All training sessions were performed under normoxic or hypoxic conditions (approximately 3,000 m) for Nor and H group, respectively, at the same relative intensity. Before and after the training period, an incremental test to exhaustion in normoxia was performed, muscle biopsy samples were taken from the vastus lateralis, and mitochondrial respiration in permeabilized fibers was measured. Peak power output (PPO) increased by 7.2 and 6.6 percent for Nor and H, respectively, whereas maximal \( \text{O}_2 \) uptake (\( \text{VO}_2\text{max} \)) remained unchanged for Nor and H, respectively, between pretraining (W0) and posttraining (W4). Maximal ADP-stimulated mitochondrial respiration significantly increased for glutamate + malate and significantly decreased for palmitate + malate in the H group. In contrast, no significant differences were found for the Nor group. The findings demonstrate that a 3-week training period increased the PPO at sea level without any changes in \( \text{VO}_2\text{max} \) and that a 3-week hypoxic exercise training seems to alter the intrinsic properties of mitochondrial function, i.e. substrate preference [07138].

Training at high altitude

High altitude training has become a mainstay in endurance sports, with live high-train low as the current protocol of choice. Athletes either live or sleep in artificial or natural hypoxic conditions with the aim to increase serum erythropoietin concentrations, which are thought to improve maximum oxygen uptake and thus exercise performance. Changes, however, are not very striking and only apparent in so-called responders, who are not a well-defined group and may be as little as 50 percent of the trained study population. Whereas some studies show minor improvement, others report no change or even worsening. Furthermore, the mechanisms behind the proposed beneficial changes remain obscure and are far from being proven. There is an evident lack of sufficiently powered randomized, double-blinded studies, with training protocols that are identical for all groups and groups that are indeed comparable. Several studies discriminate between responders and non-responders, without clearly assessing the characteristics of the so-called responders. Until this has been done, it remains unclear if such a group really exists and how these subjects are characterized. This, however, would be of immense value, so protocols could be tailored to athletes' needs. Taken together, the current literature on natural or artificial hypoxia somewhat documents improved performance at high but not low altitude [12266].

Altitude training is a well-established “natural” and legal technique to improve endurance performance at sea level. At higher altitudes, the relative oxygen content of the air is diminished; after a sufficient period of time, the body responds with a complex series of biological and metabolic changes. An understanding of the metabolic adjustment to altitude requires a review of human acclimatization and adaptation. The term acclimatization is suited to relatively short exposures to altitude, such as short periods in training camps, while adaptation refers to changes occurring over generations under constant exposure. Some, but not all, of the main features of acclimatization and adaptation are similar. Acclimatization is basically heterogeneous, depending upon the type of environmental stress to which the athlete is exposed. Passive stresses, such as altitude and climate, are persistent and substantially uniform over time, whereas active ones like training regimen and diet are more variable and possibly mutable. Finally, compliance to excessive stress is highly sensitive to individual characteristics. The duration of exposure to passive stress modifies the nature and resiliency of changes following stress removal. After exposure to moderate altitude, some initial changes occur in response to the changed conditions; as the exposure duration increases, the repertoire of changes expands and stabilizes. Therefore, the longer the body is in a fully acclimatized condition, the more habitual the changes become. Upon exposure to a passive stress, the body undergoes a hierarchy of responsive changes and eventually
becomes fully acclimatized to the point that the changes become constant as well as permanent while residing in the environment. Full acclimatization is compromised by shorter periods of exposure; generally, the shorter the time spent at altitude, the less dramatic is the acclimatization and the changes that do occur are quite transient [10363].

To determine the time course of hemoglobin mass (Hb$_{mass}$) to natural altitude training, Hb$_{mass}$, erythropoietin (EPO), reticulocytes, ferritin and soluble transferrin receptor (sTfR) were measured in 13 elite cyclists during, and 10 days after, 3 weeks of sea level (n=5) or altitude (n=8, 2760 m) training. Mean Hb$_{mass}$, with a typical error of approximately 2 percent, increased during the first 11 days at altitude (2.9 ± 2.0 %) and was 3.5 ± 2.5 percent higher than baseline after 19 days. The concentration of EPO increased 64 ± 19 percent after 2 nights at altitude but was not different from baseline after 12 nights. Hb$_{mass}$ and [EPO] did not increase in sea level. Reticulocytes (%) were slightly elevated in altitude at days 5 and 12, sTfR was elevated at day 12, but both returned to baseline by day 20. Hb$_{mass}$ and [EPO] decreased on descent to sea level while ferritin increased. The mean increase in Hb$_{mass}$ observed after 11 days (approximately 300 h) of altitude training was beyond the measurement error and consistent with the mean increase after 300 h of simulated live high:train low altitude. The results suggest that in elite cyclists, hemoglobin mass increases progressively with 3 weeks of natural altitude exposure, with greater increases expected as exposure persists [10108].

Several physiologic changes occur following acclimatization at high altitude. They can be divided into immediate (taking place over a few days) and long-term changes, which require weeks to a few months. Immediate changes include decrease in maximum cardiac output, decreased maximum heart rate, increased erythropoiesis, increased excretion of base via the kidneys to restore acid-base balance, and an increase in the number of mitochondria and oxidative enzymes in RBCs that allow a more efficient unloading of oxygen to peripheral tissues. The combination of altitude and time necessary to achieve significant athletic benefits, lasting 2 to 3 weeks after return from altitude, has been conventionally established at 2200 m for 4 weeks. This convention is supported by the practical evidence that a significant (77 to 92 %) and stable (over 24 h) increase in Epo production occurs rapidly (within 6 h), once a threshold altitude of 2100 to 2500 m is reached. Below these altitudes, Epo increases are modest (24 to 30 %) and unsteady, reaching a peak at 6 h after exposure. Accordingly, 4 weeks of training at an altitude of 1740 m produce no changes in hemoglobin and a negligible increase in maximum oxygen consumption in highly trained athletes. The mechanism of the greater hematologic response to high altitude includes improved oxyhemoglobin desaturation that usually occurs as the oxygen partial pressure (pO$_2$) falls to the steep portion of the oxyhemoglobin dissociation curve. Hypothetically, the higher the altitude, the greater the ergogenic benefits achieved. However, an upper limit of altitude should be set to limit the side effects of altitude exposure, such as chronic mountain sickness with depression, headache, loss of appetite, sickness, and sleeplessness. The concentration of Epo in blood starts to increase from the first day of living at an altitude of 2500 m; by 2 weeks it stabilizes and after 4 weeks returns to the baseline. Therefore, a period lasting not less than 3 to 4 weeks appears most appropriate. Like astronauts who enter microgravity, people acclimatized to high altitude who descend to sea level undergo a rapid adaptive mechanism that modifies the excessive blood volume and RBC mass for the new environment. This physiologic process, called neocytolysis, results in selective hemolysis of young circulating erythrocytes. While both RBC production and survival remain normal, the RBC mass decreases up to 15 percent over a few days. Serum Epo levels are also profoundly suppressed on descent. Therefore, Epo dynamically suppresses erythropoiesis by initiating neocytolysis when serum levels are reduced below a nadir threshold [10353].

A review of the current literature supports the benefits of altitude training, though there is a
large variation in outcomes, possibly due to the heterogeneity of settings and periods of living at altitude or to the effects of active stresses and confounding variables (athletic discipline, training regimen, diet). Since RBCs carry oxygen through the bloodstream, a substantial increase in the packed cells following altitude exposure allows more efficient oxygen delivery to the muscles at sea level, reducing fatigue and giving the athlete an edge. With acclimatization, there is convincing evidence of decreased production or increased clearance of lactate in muscles, moderate evidence of enhanced muscle buffering capacity and tenuous evidence of improved mechanical efficiency of cycling. Acclimatization to high altitude induces further central and peripheral adaptations that improve oxygen delivery and utilization. Moreover, hypoxic exercise may increase the training stimulus, thus magnifying the effects of endurance training. Several strategies have been proposed to optimize the acclimatization changes: live high and train high, live high and train low, and intermittent exposure. The current literature indicates that continuous living and training at moderate altitude does not improve sea-level performance of high-level athletes. Although oxygen delivery and utilization may be slightly improved, a lack of adequate training adaptation and/or decreased exercise intensity due to hypoxia can lead to a relative detraining effect that may overwhelm any advantage gained through altitude-induced acclimatization.

Therefore, acclimatization to a moderately high altitude, accompanied by training at low altitude (the so-called “living high-training low” theory), is likely the most effective variant of altitude training to improve sea-level endurance performance. Such improvement is due to a wide series of physiological and biochemical adaptations, including a consistent improvement in maximal oxygen uptake, a rise of circulating Epo, the levels of which can be nearly double those of the initial sea-level baseline, and an increase of up to 10 g/l of hemoglobin concentration in blood. Despite promising results, some later investigations described wide interindividual variability in adaptive response and athletic performance after a traditional altitude training camp. Although the concentration of Epo in plasma rises significantly, the aggregate variation is definitely broad, ranging from 41 to 400 percent, and responders had a significantly larger and more persistent increase in absolute terms and when expressed as a percentage of sea-level baseline. Taken together, current evidence suggests that short-term intermittent exposure to moderate hypoxia and hypobaric chambers may not be sufficient to improve aerobic capacity and to induce altitude acclimatization, whereas longer periods, up to 4 weeks, may be effective in eliciting hematologic modifications and improvement in endurance performance [10353].

In general, the efficacy of simulated altitude is achieved by an increased erythropoietic response and improved performance in athletes of endurance sport disciplines. Although earlier evidence in untrained subjects was promising, it is as yet questionable whether elite athletes, who may be closer to the maximal structural and functional adaptive capacity of the respiratory system, may achieve real gains from simulated altitude devices. Most clinical discrepancies are due to the marked heterogeneity in exercise, environmental conditions, nutritional therapies, duration, repetition rate, and intensity of the artificial hypoxic stimulus. If a distinct advantage is needed in endurance events, the use of high-altitude simulators would appear less risky than other forms of blood doping. However, there are some ethical and clinical concerns among coaches, athletes, and the scientific community that the use of these expedients may be unsafe and unethical for use in sports. Just as training preparation that gives an athlete a technological or athletic advantage that is too expensive or innovative for most other competitors to use is considered unfair, simulated altitude may currently be considered unethical. Although this position has been questioned, as the biological changes induced by altitude simulation are almost indistinguishable from those of real exposure and training at altitude, simulated altitude, called “holistic blood doping,” ultimately reproduces most of the physiological and pathological effects of rHuEpo and is now considered an illegal means of performance improvement. Finally, it is recognized that some athletes experience considerable reduction in the ability to train at the appropriate intensity...
A factor of importance to the outcome of an altitude-training programme is the training undertaken during the intervention period. The severity of altitude, time spent training at altitude, history of altitude training and timing of training leading into competition represent important factors to consider when designing a training programme at altitude. A considerable interindividual variability in the reduction of aerobic power at altitude exists, and this should be considered. Consequently, individual adjustments of training intensity and periodisation of training at altitude are required to avoid over-reaching and/or detraining. The proposed actions to individualise the ‘altitude dose’ and training content should include daily assessment of sleep quality, mood state and frequent monitoring of the changes in HR-derived measures. Training load during the altitude sojourn should also be carefully monitored. Ideally, this can be achieved by quantifying the duration and the intensity (CR-10 Borg scale) for each training session. Although monitoring perceived training load and wellness using psychometric and the Lake Louise acute mountain sickness questionnaires are also useful to help prevent the risk of negative adaptations. Careful daily monitoring of indirect measures of cardiac autonomic activity such as heart rate variability or heart rate responses, together with ratings of perceived exertion (RPE) responses to a submaximal run (e.g. 4-8 min at 10-12 km/h over 20-40 m shuttles) can help predict/prevent sickness and maintain the training process. In addition to the higher physiological stress, some critical aspects of sport-specific decision-making processes together with skill execution (short-passing ability) and perceived well-being are likely to be negatively affected by acute moderate altitude exposure as a result of exacerbated fatigue levels. When 28 international male football players belonging to the English national squad were tested in preparation of the 2010 FIFA World Cup, exposure to a simulated altitude of 1800 m compromised their ability to sustain work output during 10 min of constant-load cycling at 85 percent of maximum heart rate, and was also associated with higher RPE values. Cognitive function (as measured during the last 5 min of the 10 min constant-load test) was also impaired by acute altitude exposure with a 9 percent reduction in simple reaction time. As such, careful monitoring of decision-making responses (i.e., ideally assessed daily in the initial stages during a hypoxic intervention) undoubtedly has merit [13327].

Team sports are increasingly popular, with millions of participants worldwide. Athletes engaged in these sports are required to repeatedly produce skilful actions and maximal or near-maximal efforts (e.g., accelerations, changes in pace and direction, sprints, jumps and kicks), interspersed with brief recovery intervals (consisting of rest or low-intensity to moderate-intensity activity), over an extended period of time (1–2 h). While performance in most team sports is dominated by technical and tactical proficiencies, successful team-sport athletes must also have highly-developed, specific, physical capacities. Much effort goes into designing training programmes to improve these physical capacities, with expected benefits for team-sport performance. Recently, some team sports have introduced altitude training in the belief that it can further enhance team-sport physical performance. Until now, however, there is little published evidence showing improved team-sport performance following altitude training, despite the often considerable expense involved. In the absence of such studies, this review will identify important determinants of team-sport physical performance that may be improved by altitude training, with potential benefits for team-sport performance. These determinants can be broadly described as factors that enhance either sprint performance or the ability to recover from maximal or near-maximal efforts. There is some evidence that some of these physical capacities may be enhanced by altitude training, but further research is required to verify that these adaptations occur, that they are greater than what could be achieved by appropriate sea-level training and that they translate to improved team-sport performance [13331].
The internationalism of field-based team sports (TS) such as football and rugby requires teams to compete in tournaments held at low to moderate altitude (1200–2500 m). In TS, acceleration, speed and aerobic endurance are physical characteristics associated with ball possession and, ultimately, scoring. While these qualities are affected by the development of neuromuscular fatigue at sea level, arterial hypoxaemia induced by exposure to altitude may further hinder the capacity to perform consecutive accelerations (CAC) or sprint endurance and thereby change the outcome of a match. The higher the altitude, the more severe the hypoxaemia, and thus, the larger the expected decline in aerobic endurance, CAC and match running performance. Therefore, it is critical for athletes and coaches to understand how arterial hypoxaemia affects aerobic endurance and CAC and the magnitude of decline they may face at altitude for optimal preparation and increased chances of success. One mini review summarises the effects of acute altitude/hypoxia exposure on aerobic endurance, CAC and activity profiles of TS athletes performing in the laboratory and during matches at natural altitude, and analyses the latest findings about the consequences of arterial hypoxaemia on the relationship between peripheral perturbations, neural adjustments and performance during repeated sprints or CAC. Finally, it was briefly discussed how altitude training can potentially help athletes prepare for competition at altitude [13332].

Over the past two decades, intermittent hypoxic training (IHT), that is, a method where athletes live at or near sea level but train under hypoxic conditions, has gained unprecedented popularity. By adding the stress of hypoxia during “aerobic” or “anaerobic” interval training, it is believed that IHT would potentiate greater performance improvements compared to similar training at sea level. A thorough analysis of studies including IHT, however, leads to strikingly poor benefits for sea-level performance improvement, compared to the same training method performed in normoxia. Despite the positive molecular adaptations observed after various IHT modalities, the characteristics of optimal training stimulus in hypoxia are still unclear and their functional translation in terms of whole-body performance enhancement is minimal. To overcome some of the inherent limitations of IHT (lower training stimulus due to hypoxia), recent studies have successfully investigated a new training method based on the repetition of short (<30 s) “all-out” sprints with incomplete recoveries in hypoxia, the so-called repeated sprint training in hypoxia (RSH). The aims of one review are therefore threefold: first, to summarise the main mechanisms for interval training and repeated sprint training in normoxia. Second, to critically analyse the results of the studies involving high-intensity exercises performed in hypoxia for sea-level performance enhancement by differentiating IHT and RSH. Third, to discuss the potential mechanisms underpinning the effectiveness of those methods, and their inherent limitations, along with the new research avenues surrounding this topic [13333].

To examine with a parallel group study design the performance and physiological responses to a 14-day off-season ‘live high-train low in the heat’ training camp in elite football players 17 professional Australian Rules Football players participated in outdoor football-specific skills (32 ± 1°C, 11.5 h) and indoor strength (23 ± 1°C, 9.3 h) sessions and slept (12 nights) and cycled indoors (4.3 h) in either normal air (NORM, n=8) or normobaric hypoxia (14 ± 1 h/day, FiO\textsubscript{2} 15.2–14.3 %, corresponding to a simulated altitude of 2500–3000 m, hypoxic (HYP), n=9). They completed the Yo-Yo Intermittent Recovery level 2 (Yo-YoIR2) in temperate conditions (23 ± 1°C, normal air) precamp (Pre) and postcamp (Post). Plasma volume (PV) and haemoglobin mass (Hb\textsubscript{mass}) were measured at similar times and 4 weeks postcamp (4WPost). Sweat sodium concentration [\textsuperscript{+}Na\textsubscript{sweat}] was measured Pre and Post during a heat-response test (44°C). Both groups showed very large improvements in Yo-YoIR2 at Post (+44 %), with no between-group differences in the changes. Postcamp, large changes in PV (+5.6 %) and [\textsuperscript{+}Na\textsubscript{sweat}] (+29 %) were observed in both groups, while Hb\textsubscript{mass} only moderately increased in HYP (+2.6 %). At 4WPost, there was a likely slightly greater increase in Hb\textsubscript{mass} (+4.6 %) and PV (+6 %) in HYP than in NORM. It was concluded that the combination of
heat and hypoxic exposure during sleep/training might offer a promising 'conditioning cocktail' in team sports [13334].

Water polo requires high aerobic power to meet the demands of match play. Live high:train low (LHTL) may enhance aerobic capacity at sea level. Before the Olympics, the Australian women's water polo team utilised LHTL in an attempt to enhance aerobic fitness. Over 6 months, 11 players completed three normobaric LHTL exposures (block 1:11 days at 3000 m; block 2+3:9 days at 2500 m, 11 days normoxia, 10 days at 2800 m). Haemoglobin mass (Hbmass) was measured through carbon monoxide-rebreathing. Before each block, the relationship between Hbmass and water polo-specific aerobic fitness was investigated using the Multistage Shuttle Swim Test (MSST). Effect size statistics were adopted with likely, highly likely and almost certainly results being >75, >95, >99 percent, respectively. A Pearson product moment correlation was used to characterise the association between pooled data of Hbmass and MSST. Hbmass (pre 721 ± 66 g) likely increased after block 1 and almost certainly after block 2+3 (% change: block 1: 3.7 %; block 2+3: 4.5 %) and the net effect was almost certainly higher after block 2+3 than before block 1 (pre) by 8.5 percent. There was a very large correlation between Hbmass (g/kg) and MSST score. It was concluded that LHTL exposures of <2 weeks induced approximately 4% increase in Hbmass of water polo players. Extra Hbmass may increase aerobic power, but since match performance is nuanced by many factors it is impossible to ascertain whether the increased Hbmass contributed to Australia's Bronze medal [13335].

Repeated sprint ability (RSA) is a critical success factor for intermittent sport performance. Repeated sprint training has been shown to improve RSA, it was hypothesised that hypoxia would augment these training adaptations. Thirty male well-trained academy rugby union and rugby league players participated in this single-blind repeated sprint training study. Participants completed 12 sessions of repeated sprint training (10×6 s, 30 s recovery) over 4 weeks in either hypoxia (13 % F\textsubscript{O}\textsubscript{2}) or normoxia (21 % F\textsubscript{O}\textsubscript{2}). Pretraining and post-training, participants completed sports specific endurance and sprint field tests and a 10×6 s RSA test on a non-motorised treadmill while measuring speed, heart rate, capillary blood lactate, muscle and cerebral deoxygenation and respiratory measures. Yo-Yo Intermittent Recovery Level 1 test performance improved after RS training in both groups, but gains were significantly greater in the hypoxic (33 ± 12 %) than the normoxic group (14 ± 10 %). During the 10×6 s RS test there was a tendency for greater increases in oxygen consumption in the hypoxic group (hypoxic 7 ± 9 %, normoxic (~0.3 ± 8.8 %) and reductions in cerebral deoxygenation after hypoxic than normoxic training. Twelve RS training sessions in hypoxia resulted in twofold greater improvements in capacity to perform repeated aerobic high intensity workout than an equivalent normoxic training. Performance gains are evident in the short term (4 weeks), a period similar to a preseason training block [13336].

It was described the 3-year process underpinning a multinational collaboration to investigate soccer played at high altitude – La Paz, Bolivia (3600 m). There were two main aims: first, to quantify the extent to which running performance would be altered at 3600 m compared with near sea level; and second, to characterise the time course of acclimatisation of running performance and underlying physiology to training and playing at 3600 m. In addition, this project was able to measure the physiological changes and the effect on running performance of altitude-adapted soccer players from 3600 m playing at low altitude. A U20 Bolivian team (n=19) played a series of five games against a U17 team from sea level in Australia Town=n=20). 2 games were played near sea level (Santa Cruz 430 m) over 5 days and then three games were played in La Paz over the next 12 days. Measures were (1) game and training running performance – including global positioning system (GPS) data on distance travelled and velocity of movement; (2) blood – including haemoglobin mass, blood
volume, blood gases and acid–base status; (3) acclimatisation – including resting heart rate variability, perceived altitude sickness, as well as heart rate and perceived exertion responses to a submaximal running test; and (4) sleep patterns. It was concluded that pivotal to the success of the project were the strong professional networks of the collaborators, with most exceeding 10 years, the links of several of the researchers to soccer federations, as well as the interest and support of the two head coaches [13337].

Altitude training is used by elite athletes to improve sports performance, but it may also disrupt sleep. The aim of one study was to examine the effects of 2 weeks at high altitude on the sleep of young elite athletes. Participants (n=10) were members of the Australian under-17 soccer team on an 18-day (19-night) training camp in Bolivia, with six nights at near sea level in Santa Cruz (430 m) and 13 nights at high altitude in La Paz (3600 m). Sleep was monitored using polysomnography during a baseline night at 430 m and three nights at 3600 m (immediately after ascent, 1 week after ascent and 2 weeks after ascent). Data were analysed using effect size statistics. All results are reported as comparisons with baseline. Rapid eye movement (REM) sleep was likely lower immediately upon ascent to altitude, possibly lower after 1 week and similar after 2 weeks. On all three nights at altitude, hypopneas and desaturations were almost certainly higher; oxygen saturation was almost certainly lower; and central apnoeas, respiratory arousals and periodic breathing were very likely higher. The effects on REM sleep were common to all but one participant, but the effects on breathing were specific to only half the participants. It was concluded that the immediate effects of terrestrial altitude of 3600 m are to reduce the amount of REM sleep obtained by young elite athletes, and to cause 50 percent of them to have impaired breathing during sleep. REM sleep returns to normal after 2 weeks at altitude, but impaired breathing does not improve [13338].

Recovery

During an altitude sojourn the whole squad should be carefully monitored to try to avoid over-reaching, dehydration or upper respiratory tract infection, taking into account that hypoxia may impact on sleep quality/quantity and therefore player recovery. Avoiding illness is not always possible; however, by allowing adequate rest (first 1-2 days) and easing into training at altitude (following 2–3 days) before taking up regular training a player's immune system is not placed under excessive stress from both hypoxia and hard training. Higher heart rates and lower SpO2 values reflect the inadequate ability of a player to adjust to the hypoxic environment. Practically, we encourage monitoring a range of haematological and immune function parameters including iron status, vitamins, oxidative stress, as well as self-reported wellness and session RPE, before leaving for altitude, particularly during the early phase of chronic altitude training (within the first 2 days of ascent/exposure) and if possible every week thereafter. As training sessions in hypoxia increase the use of carbohydrates during exercise, appropriate nutrition is important. Reportedly, a high-CHO meal consumed prior to moderate exercise in hypoxic conditions reduced oxygen desaturation compared with a high-protein meal. Further, football players competing in the 2008 European Championships (Switzerland-Austria with venues elevation <600 m) experienced a decrease in extracellular and body mass (indicating fluid loss), which may be caused by a loss of appetite, dehydration or a change in energy balance (energy expenditure or food availability). In team-sport players, a diet high in carbohydrate could therefore improve tolerance to intense and stressful hypoxic training sessions, which is important when looking at increasing sport-specific fitness. At altitude, respiratory alkalosis during the first few days of exposure initiates a chronic loss of bicarbonate, which may be restored in order to help effectively buffer acidosis during high-intensity exercise and thereby maximise the potential for interval-training quality. Dehydration is common at altitude (diuresis) and may also be caused by sweating and fluid loss through the upper airways (low humidity) due to increased ventilation to defend
the immediate fall in SpO2 due to the reduction in the partial pressure of oxygen at altitude. Because the combination of hypoxia and a strenuous training programme could lead to the development of a chronic state of hypohydration, checking hydration status and electrolyte balance before, during and after training or the game is recommended. Practically, quantifying urine osmolality (>700 mOsm/kg), urine specific gravity (>1.020 g/mL) and/or body mass change (>2% body mass loss from water deficit) can be used as index of dehydration. Because sweat rates and sweat electrolyte content vary greatly among individuals, the development of individualised fluid and electrolyte replacement strategies is required for the preservation of performance and protection of player health. Global sleep quality (number of arousals and awakenings) can ideally be monitored using polysomnography, but alternatives including actigraphy, sleep questionnaires and other sleep monitoring devices are available in situations where this tool is not practicable [13339].

To examine the time course of wellness, fatigue and performance during an altitude training camp (La Paz, 3600 m) in two groups of either sea-level (Australian) or altitude (Bolivian) native young soccer players. Wellness and fatigue were assessed using questionnaires and resting heart rate (HR) and HR variability. Physical performance was assessed using HR responses to a submaximal run, a Yo-Yo Intermittent recovery test level 1 (Yo-YoIR1) and a 20 m sprint. Most measures were performed daily, with the exception of Yo-YoIR1 and 20 m sprints, which were performed near sea level and on days 3 and 10 at altitude. Compared with near sea level, Australians had moderate-to-large impairments in wellness and Yo-YoIR1 relative to the Bolivians on arrival at altitude. The acclimatisation of most measures to altitude was substantially slower in Australians than Bolivians, with only Bolivians reaching near sea-level baseline high-intensity running by the end of the camp. Both teams had moderately impaired 20 m sprinting at the end of the camp. Exercise HR had large associations with changes in Yo-YoIR1 in both groups. Thus, despite partial physiological and perceptual acclimatisation, 2 weeks is insufficient for restoration of physical performance in young sea-level native soccer players. Because of the possible decrement in 20 m sprint time, a greater emphasis on speed training may be required during and after altitude training. The specific time course of restoration for each variable suggests that they measure different aspects of acclimatisation to 3600 m; they should therefore be used in combination to assess adaptation to altitude [13339].

Performance in athletic activities that include a significant aerobic component at mild or moderate altitudes shows a large individual variation. Physiologically, a large portion of the negative effect of altitude on exercise performance can be traced to limitations of oxygen diffusion, either at the level of the alveoli or the muscle microvasculature. In the lung, the ability to maintain arterial oxyhaemoglobin saturation (SaO2) appears to be a primary factor, ultimately influencing oxygen delivery to the periphery. SaO2 in hypoxia can be defended by increasing ventilatory drive; however, during heavy exercise, many athletes demonstrate limitations to expiratory flow and are unable to increase ventilation in hypoxia. Additionally, increasing ventilatory work in hypoxia may actually be negative for performance, if dyspnoea increases or muscle blood flow is reduced secondary to an increased sympathetic outflow (e.g. the muscle metaboreflex response). Taken together, some athletes are clearly more negatively affected during exercise in hypoxia than other athletes. With careful screening, it may be possible to develop a protocol for determining which athletes may be the most negatively affected during competition and/or training at altitude [13340].

What recommendations to overcome some of the limitations of the current studies? It was commonly agreed that the current level of evidence for the efficacy of hypoxic methods to improve acclimatisation at moderate or high altitude is well established, but rather low when it comes to improved sea level exercise performance. Part of this inconsistency is linked to the fact that various hypoxic methods (hypobaric vs normobaric
hypoxia), training modalities or training states of the players have been employed within as well as between studies with discrepancies between measuring methods frequently seen (e.g. Hbmass). In addition, performance changes resulting from altitude training are not that reproducible even when the mean improvements in underlying physiology are more consistent. Furthermore, the ability to detect a relatively small signal is swamped by the noise of the range of factors that can impinge on individual performance, let alone that of a team. Important methodological limitations of some of the current literature also include uncontrolled trials, non-randomised study protocols and neither single-blinded nor double-blinded designs. Lack of blinding in interventions, leading to expectation (placebo and nocebo) effects, should be avoided wherever possible (ie, double-blinding natural LHTH studies is impossible), especially in a population of team-sport players where team connection has a widespread effect on performance. Future studies should avoid methodological shortcomings such as absence of lead-in period, undefined training cycle or players' recent training history. Such trial specifications are standard in many other exercise physiology fields and need to be adhered to in the area of altitude-training research in order to move this growing field forward. In addition, it would be worth recording through questionnaire the players' belief in the efficacy of altitude training before they go to the camp to further clarify if expectation is any way associated with benefit. When possible it is also encouraged to use double baseline measures, and carefully documenting training content/load before, during and after the altitude-training intervention will allow a more systematic comparison of various hypoxic methods. Performance changes should not only be monitored shortly (ie, few days) after the intervention but also for few weeks after the last day of exposure to distinguish the short from middle/long-term (or delayed) effects. Ideally, players would need to be accustomed to performing similar (if not identical) performance tests as part of their usual battery of team fitness testing in order to facilitate this process. It is also important to report eventual dropouts, which indirectly reflect how players coped with the altitude intervention. Further, the level of adherence of the players to the intervention must be measured: “How do the players think the intervention worked for them?” Finally, there is a need for consensus between practitioners and researchers to define what difference in magnitude, in terms of peak sprint or maximal aerobic velocities for instance, after any altitude-training intervention can realistically be considered a meaningful ‘improvement’ (ie, greater than the ‘smallest worthwhile change’ or the typical error of measurement) relevant for competitive team-sport performance. In this context, developing a long history of standardised performance tests is important to obtain an indication of each player’s sensitivity to a given altitude-training intervention. Only then meaningful recommendations for team-sport players could be derived. Some of the key research gaps in the field of altitude-training methods relevant for team sports can be addressed [13327]:

- determining whether performance and physiological changes induced by altitude-training protocols are actually transferred to competitive match outcomes: how to accurately measure these effects?
- verifying the usefulness of new hypoxic training methods (e.g. live high and train low and high interspersed, repeated sprints in hypoxia, live high – train low under heat stress or altitude training combined with blood occlusion) in a range of professional team sports, to determine whether the capacities meant to be improved actually are.
- evaluating the combination of altitude-training methods and the effect that they have on the magnitude and time course of several aspects of match-related performance and adaptive responses during isolated or periods of intensified competition
- validating the efficacy of LLTH methods when attempting to improve sea-level performance, preacclimation, prevention of detraining during off-season/injury periods or to prolong the beneficial effects of an extended altitude-training block
- determining whether the breathing abnormalities that occur during sleep at high altitude by many players, and the accompanying sleep fragmentation, affect the efficacy of altitude training
- clarifying how increased oxygen delivery/utilisation conferred by hypoxic interventions improves match-related performance, prevents premature and excessive neuromuscular fatigue and improves recovery processes in team-sport-related activities
- determining under which circumstances altitude exposure can be used either as a substitute to reduce the inevitable detraining effect seen in long-term injured players or to further stimulate the cardiovascular and metabolic systems, while keeping training load lower than at sea level
- clarifying some of the jet lag-related methodological (circadian rhythms) issues, and establish whether teams should train or be tested at the new destination or at the origin time, also taking into account the delay before competition and the details of the altitude stress
- understanding whether the cellular and molecular basis of hypoxic adaptations (downstream targets of HIF-1alpha) differ between the various altitude-training interventions, and the impact of titrated “hypoxic doses”
- hedging more light on putative adaptive mechanisms (eg, running economy, lactate metabolism and muscle/blood buffer capacity along with compensatory vasodilation associated to reduced oxygen content and potential on fibres behaviour and fatigability) and signalling pathways (e.g. mitochondrial efficiency and biogenesis, capillarisation and sodium/potassium handling) of non-haematological adaptations important for team-sport physical performance
- identifying physiological (with a particular emphasise on genetic and ventilatory responses) and psychosociological factors of primary influences affecting individual player responses to hypoxic training
- quantifying the extent of biomechanical/skill-based adaptations associated with hypobaric hypoxia, and the optimal dosing and timing of those aerodynamics and neuromuscular control adjustments in regards to physiological ones
- measuring the magnitude and rate of changes and the underpinning physiological (Hbmass, oxygen cost of breathing) and biomechanical (neural activation strategies, kinetic/kinematic adjustments) adaptations when altitude-resident players descend from altitude and when sea-level players live high and train low
- investigating if hypobaric and normobaric hypoxia hold the same potential for improvement in match-specific fitness and share similar underlying physiological mechanisms, and therefore determining whether they can be used interchangeably.

**Effects on sleep**

Sleeping at moderate altitude does not cause major disruption to players’ sleep in general, but it does cause minor to moderate disruption to rapid eye movement sleep, which is important for mental recovery. These symptoms, present in about 25 percent of the players in a team when sleeping at moderate altitude, should improve over 2–3 nights. Depending on the altitude and the individual, sleep disturbance can be caused by periodic breathing resulting from the interplay between hypercapnia and hypoxia leading to central sleep apnoea. Nearly 40-50 percent of the members of a team may experience moderate/severe disordered breathing at high altitude (3600 m). This disruption is unavoidable in terrestrial altitude, but it could be avoided in simulated altitude with the use of a ‘rest high, sleep low, train low’ paradigm for affected individuals. If this new paradigm is used, the potential benefit associated with avoiding disordered breathing during sleep should be considered against the potential cost of spending less time at altitude. Finally, when considering the effects of altitude training on sleep, it is also important to consider any potential effects of travel fatigue.
Altitude exposure causes acute sleep disruption in non-athletes, but little is known about its effects in elite athletes. The aim of one study was to examine the effects of altitude on two groups of elite athletes, that is, sea-level natives and high-altitude natives. Sea-level natives were members of the Australian under-17 soccer team (n=14). High-altitude natives were members of a Bolivian under-20 club team (n=12). Teams participated in an 18-day (19 nights) training camp in Bolivia, with 6 nights at near sea level in Santa Cruz (430 m) and 13 nights at high altitude in La Paz (3600 m). Sleep was assessed on every day/night using activity monitors. The Australians’ sleep was shorter, and of poorer quality, on the first night at altitude compared with sea level. Sleep quality returned to normal by the end of the first week at altitude, but sleep quantity had still not stabilised at its normal level after 2 weeks. The quantity and quality of sleep obtained by the Bolivians was similar, or greater, on all nights at altitude compared with sea level. The Australians tended to obtain more sleep than the Bolivians at sea level and altitude, but the quality of the Bolivians’ sleep tended to be better than that of the Australians at altitude. It was concluded that exposure to high altitude causes acute and chronic disruption to the sleep of elite athletes who are sea-level natives, but it does not affect the sleep of elite athletes who are high-altitude natives.

Hypoxic tents

Hypoxic tents (chambers) function in the same fashion as that of altitude in the live high – train low approach. The athlete sleeps in the hypoxic tent to simulate sleeping at altitude and then trains during the day at or near sea level in normoxia, which allows the maintenance of training intensity. A study using the live high – train low strategy, but incorporating an enriched nitrogen tent to simulate altitude, showed that hypoxic exposure increases muscle buffering capacity and reduces VO₂ for a given submaximal workload during sea-level exercise, suggesting improved exercise efficiency. These improvements are similar to the live high – train low altitude studies. However, two of the benefits of using a hypoxic tent (artificial altitude) are reduced daily travel time to and from altitude and reduced cost of travel to an altitude-training camp if not already in proximity. Much of the debate on the potential banning of hypoxic environments has focused primarily on the use of artificially-produced hypoxic environments and the passive mode of operation, such as hypoxic tents (nitrogen enriched) and not altitude training per se. However, there are many progressive arguments for the use of hypoxic tents. To summarize, the empirical evidence strongly suggests that hypoxic tents can enhance performance and are safe if used as directed.

There is actual debate on a position of the World Anti-Doping Agency (WADA), which has cautiously refrained from banning hypoxic tents (written in 2007) and intends to monitor their health risk. Regardless of teleological and deontological concepts, it was highlight that the health risks inherent to the widespread use of these artificial performance-enhancing devices would make them as unsafe as other forms of blood doping.

As altitude training has some logistical and biological disadvantages, scientists have investigated alternative techniques of simulating altitude exposure which may offer the same physiological benefits while minimizing the drawbacks. Since the introduction of the hypoxic training theory in 1930, several techniques have been developed, including regular high-altitude flights, training in altitude chambers, and training by inhalation of low-oxygen-gas mixtures. These techniques were used primarily for altitude pre-acclimatization and for the treatment of chronic disorders including lung disease, bronchial asthma, hypertension, diabetes mellitus, Parkinson’s disease, emotional disorders, radiation toxicity,
and prophylaxis of certain occupational diseases. The basic mechanisms of the beneficial effects of hypoxic training involve regulation of respiration, free-radical production, and mitochondrial respiration. In general, hypoxic exposure can be divided into hypoxia at rest, with the primary goal of stimulating altitude acclimatization, and hypoxia during exercise, to enhance the training stimulus. Moreover, the hypoxic stimulus may be continuous or intermittent. A sleep chamber that enables endurance athletes to “train while they sleep” has been developed. The chamber simulates the reduced air pressure of altitude environments equivalent to approximately 2000 to 3000 m. Athletes who use a hypoxic apartment typically “live and sleep high” in the hypoxic apartment but train at or near sea-level conditions, thus enabling them to achieve a similar advantage to those living at high altitude. The appropriate use of the chamber (6 to 8 h a day for 2 to 3 weeks) produces substantial increases in serum Epo, reticulocyte count, and RBC mass (up to 23 %), which, in turn, may lead to improvement in post-altitude endurance performance. Altitude simulation technology has continued to evolve. The hypoxic tent system is one of the first alternatives to the sleep chamber. The hypoxic tent system creates a hypoxic environment via a patented air separation unit that continually pumps low-oxygen content air. Inside the tent, the total pressure is unchanged, but the pO2 is reduced, allowing athletes to obtain the advantages of altitude training at any location. Unlike the constant hypoxia at higher altitudes, the intermittent hypoxia generated by the hypoxic tent system promotes gradual biological adaptation to yield better performance not only in a low-oxygen environment but also in normoxic conditions, such as at sea level. Earlier studies on simulated altitude by normobaric or hypobaric hypoxia convincingly demonstrated increases in Epo of a magnitude similar to those observed in response to a real altitude exposure of about 2.500 m. Hypoxic sleeping devices (hypobaric chamber) may simulate altitudes of up to approximately 4575 m and 4270 m. An alternative technique to simulate altitude is breathing hypoxic, normobaric gas mixtures. In these conditions, athletes breathe air with progressive decreases of the fraction of inspired oxygen (from 12.2 % to 10.0 %). This method is a modification of the “high-low” strategy, since athletes live in a natural terrestrial altitude environment while they train at sea level breathing supplemental oxygen. Limited data regarding the efficacy of hyperoxic training suggests that high-intensity workouts at moderate altitude and endurance performance at sea level may be enhanced when supplemental oxygen training is employed at altitude over several weeks [10353].

Living high, training low

Altitude training first became popular with athletes as part of their physical preparation for competition nearly fifty years ago, and over the intervening period many different altitude training protocols have evolved. In the past 15 years, numerous investigations have been conducted to examine the effects of Live high:train low (LHTL) altitude training, where athletes live at moderate altitude (2000-3000 m) but train near sea-level, on subsequent sports performance. Several researchers have concluded that, provided athletes are exposed to an adequate ‘dose’ of altitude (a combination of the duration and severity of hypoxic exposure), LHTL can lead to worthwhile performance improvements of 1-2 percent. An hypoxic dose of > 12 hours per day for at least 3 weeks at an elevation of 2100 m to 2500 m has been suggested as sufficient for athletes to benefit from the exposure. Despite other researchers finding no performance benefit from LHTL, including one recent placebo-controlled double-blind study this form of altitude training remains popular amongst elite athletes. The specific facilities required for LHTL altitude protocols can be logistically and financially inaccessible to many athletes. Either a location with rapid travel options between a low altitude training venue and a moderate altitude residential facility, or a special purpose ‘altitude house’ is required where the hypoxic environment can be simulated by reducing the oxygen content of the ambient air. One alternative, acute (60-90 min daily) intermittent
hypoxic exposure (IHE), was highlighted by a recent meta-analysis as one of the most beneficial forms of altitude training in sub-elite athletes. However, the authors of two recent reviews of the literature held an opposing view: that more studies suggest unchanged or impaired performance resulting from IHE than improved performance. Although the effectiveness of IHE is highly debated, this method offers major practical advantages over LHTL in terms of cost-effectiveness, time-efficiency, accessibility and portability. The combination of these practical advantages and the 1-5 percent performance improvements that have been reported by some researchers ensure that IHE remains a method of interest to elite athletes and coaches. However, there have been no previous studies that have directly compared these two methods in the same population and very few studies have used elite athletes. In light of the debate surrounding the purported effects of LHTL and IHE on sports performance, insight might be gained by examining the underlying physiological effects of these protocols. The erythropoietic effect of prolonged hypoxic exposure has been studied in detail due to the positive relationship between haemoglobin mass (Hbmass) and maximal oxygen consumption (VO2max). Haemoglobin mass increases of 1-4 percent following an adequate dose of LHTL have been demonstrated by several researchers, although it has been suggested recently that athletes with already high Hbmass may benefit less. The effect of IHE on Hbmass has not been examined, although, evidence of increased haemoglobin concentration ([Hb]) and increased serum erythropoietin concentration following IHE are suggestive of a positive haematological adaptation. However, due to the confounding influence of plasma volume fluctuations on [Hb], measurement of Hbmass is a more relevant method for the true effect of IHE on athletes' blood to be determined. Considerations of non-haematological adaptations to hypoxia reveal a potentially common mechanism of physiological adaptation following IHE and LHTL; there is evidence of similar improvements in sub-maximal exercise efficiency in runners from two separate studies, following IHE. The aim of one study was to compare directly the effects of LHTL and IHE on the running and blood characteristics of elite triathletes. Changes in total haemoglobin mass (Hbmass), maximal oxygen consumption (VO2max), velocity at VO2max (vVO2max), time to exhaustion (TTE), running economy, maximal blood lactate concentration ([La]) and 3 mM [La] running speed were compared following 17 days of LHTL (240 h of hypoxia), IHE (10.2 h of hypoxia) or placebo treatment in 24 Australian National Team triathletes (7 female, 17 male). There was a clear 3.2 ± 4.8 percent (mean ± 90% confidence limits) increase in Hbmass following LHTL compared with placebo, whereas the corresponding change of -1.4 ± 4.5 percent in IHE was unclear. Following LHTL, running economy was 2.8 ± 4.4% improved compared to IHE and 3mM [La] running speed was 4.4 ± 4.5% improved compared to Placebo. After IHE, there were no beneficial changes in running economy or 3mM [La] running speed compared to Placebo. There were no clear changes in VO2max, vVO2max and TTE following either method of hypoxia. The clear difference in Hbmass response between LHTL and IHE indicated that the dose of hypoxia in IHE was insufficient to induce accelerated erythropoiesis. Improved running economy and 3mM [La] running speed following LHTL suggested that this method of hypoxic exposure may enhance performance at submaximal running speeds. Overall, there was no evidence to support the use of IHE in elite triathletes. Despite a clear 3.2 percent increase in haemoglobin mass following 17 days of Live high: train low altitude training, no change in maximal aerobic capacity was observed. There were positive changes in running economy and the lactate-speed relationship at submaximal running speeds following Live high: train low altitude training. There was no evidence to support the use of daily 60-90 minute intermittent hypoxic exposure in elite triathletes [13326].

At the Olympic level, differences in performance are typically less than 0.5 percent. This helps explain why many contemporary elite endurance athletes in summer and winter sport incorporate some form of altitude/hypoxic training within their year-round training plan, believing that it will provide the "competitive edge" to succeed at the Olympic level. The
The purpose of one paper was to describe the practical application of altitude/hypoxic training as used by elite athletes. Within the general framework of the paper, both anecdotal and scientific evidence will be presented relative to the efficacy of several contemporary altitude/hypoxic training models and devices currently used by Olympic-level athletes for the purpose of legally enhancing performance. These include the three primary altitude/hypoxic training models:

- live high+train high (LH+TH)
- live high+train low (LH+TL)
- live low+train high (LL+TH)

The LH+TL model has been examined in detail including its various modifications: natural/terrestrial altitude, simulated altitude via nitrogen dilution or oxygen filtration, and hypobaric normoxia via supplemental oxygen. A somewhat opposite approach to LH+TL is the altitude/hypoxic training strategy of LL+TH, and data regarding its efficacy will be presented. Recently, several of these altitude/hypoxic training strategies and devices underwent critical review by the World Anti-Doping Agency (WADA) for the purpose of potentially banning them as illegal performance-enhancing substances/methods. The paper concluded with an update on the most recent statement from WADA regarding the use of simulated altitude devices [07135].

Live high-train low (LH+TL) altitude training was developed in the early 1990s in response to potential training limitations imposed on endurance athletes by traditional live high-train high (LH+TH) altitude training. The essence of LH+TL is that it allows athletes to "live high" for the purpose of facilitating altitude acclimatization, as manifest by a profound and sustained increase in endogenous erythropoietin (EPO) and ultimately an augmented erythrocyte volume, while simultaneously allowing athletes to "train low" for the purpose of replicating sea-level training intensity and oxygen flux, thereby inducing beneficial metabolic and neuromuscular adaptations. In addition to "natural/terrestrial" LH+TL, several simulated LH+TL devices have been developed to conveniently bring the mountain to the athlete, including nitrogen apartments, hypoxic tents, and hypoxicator devices. One of the key questions regarding the practical application of LH+TL is, what is the optimal hypoxic dose needed to facilitate altitude acclimatization and produce the expected beneficial physiological responses and sea-level performance effects? The purpose of one paper was to objectively answer that question, on the basis of an extensive body of research by a group in LH+TL altitude training. On the basis of consistent findings from the research group, it was recommended that for athletes to derive the physiological benefits of LH+TL, they need to live at a natural elevation of 2000-2500 m for >4 weeks for >22 h/day [07136].

To determine and compare the erythropoietic response and exercise performance of adolescent cross-country skiers, as a result of "living high-training high" (HH) and "living high-training low" (HL). Nine female and six male adolescent cross-country skiers volunteered to participate in separate trials. In the first trial (HH), the skiers lived and trained for 21 days at 1550-2050 m, while in the second trial (HL) they trained near sea level (450-500 m) but resided at 1550 m. All participants underwent maximal cycle ergometer tests for the determination of VO₂max and cardiorespiratory parameters via an open circuit system at sea level before ascent to altitude, and 1-2 days after descent from altitude. Blood samples were drawn prior to and immediately after maximal cycle exercise testing, at sea level prior to ascent, on days 1 (D1) and 21 (D21) at altitude (1740 m), and 1-2 days post-altitude, for the determination of serum erythropoietin (EPO) concentration, haemoglobin (Hb), hematocrit (Ht), and red blood cell (RBC) volume. The results showed that both boys and girls cross-country skiers, significantly improved their sea level VO₂max after 21 days of living at moderate altitude and training near sea level. The study demonstrates that living at moderate
altitude, 1550-2050 m and training low, near sea level (450-500 m) significantly increases VO$_{2\text{max}}$ and RBC mass for both boys and girls. Results indicate that applying the training concept "living high – training low" in adolescent athletes may improve their endurance performance [11144].

Methods such as the intake of erythropoietin (EPO, a natural hormone) and blood doping are banned by sport governing bodies owing to the invasive nature of the injections, potentially harmful outcomes, and the fact that they are a biomedical short cut allowing the body to exceed its genetic potential for adaptation. For example, EPO, which is injected subcutaneously, is now mass-produced and readily available as recombinant EPO. Its mechanism of action is the same as the endogenous EPO secreted by the kidneys, stimulating the production of RBCs to ultimately increase the RBCM. Research indicates that injection of recombinant EPO can significantly increase the level of hemoglobin (152 ± 4.2 g/L to 169 ± 9.3 g/L) after 6 weeks of injections, with analogous changes demonstrated in hematocrit (44.5 % ± 1.5 % to 49.7 % ± 1.9 %). Similarly, blood doping, the reinfusion of whole blood or packed RBCs, serves to increase total hemoglobin level, bypassing the need to produce EPO to stimulate the production of RBCs. Thus, blood doping's result is effectively the same as injecting recombinant EPO. These techniques have known dangers; for example, the injection of recombinant EPO can have side effects such as hypertension, seizures, and the development of thrombi. In contrast, the use of altitude training and (or) hypoxic devises (i.e. hypoxic tents) is not banned, but much debate has focused on the use of these methods to improve aerobic performance. Scientific research supported by universities and sport governing bodies has focused on the use of altitude training and hypoxic tents now more than ever before. Depending on the training system used, athletes can either sleep and train at altitude, or sleep at altitude and train at sea level. The latter strategy of "live high–train low" is arguably the preferred method. The benefits of increased RBCM occur as a result of sleeping in the hypoxic environment (e.g. the tent) and the benefits of physical training are realized by training at or near sea level (maintaining training intensity). If the live high–train low strategy is used, it makes the use of hypoxic sleeping tents a valuable part of the training regimen. No longer is it necessary to travel to altitude to sleep and then travel back down to train at or near sea level, and anecdotal guidelines for hypoxic training regimens are outlined by a body of accumulating research literature [07133].

Research suggests that a minimum of 8-10 h/day exposure to hypoxic environments is needed to elicit an adaptive response in the RBCM. Based on this timeline for daily exposure, the physiological benefits of the hypoxic environment may be evident in approximately 4 weeks. However, the rapidity and amplitude of the physiological response to the hypoxic environment is dependent on each individual’s specific response. The guidelines for altitude or simulated altitude show some variability, but it is suggested that a range of approximately 2200-4000 m above sea level is sufficient to stimulate an increase in RBC production and thus aerobic athletic performance. Hypoxic tents can achieve an altitude equivalence of 4285 m, which is capable of inducing performance-enhancing changes in RBCM. The development of protocols with the inclusion of hypoxic environments has evolved through scientific research, and two of the pre-eminent scientists are B. Levine and J. Stray-Gundersen. These investigators came to be recognized with their initial study, entitled "Live High – Train Low", using moderately to highly trained club- and collegiate-level runners. The concept of sleeping in hypoxia (moderate altitude), but training at or near sea level was in contrast to the more traditional live high – train high approach. The benefit of living high and training low was to spend 8-12 h/day in hypoxia, which stimulated an increase in RBCM, but allowed for the maintenance of training intensity and fitness level by training at or near sea level in normoxia. The study's performance-based outcome measure was a 5000 m time trial, while the laboratory-based outcome measures were maximal O$_2$ uptake (i.e. VO$_{2\text{max}}$), anaerobic capacity (i.e. accumulated O$_2$ deficit), maximal steady state at
ventilatory threshold, running economy, velocity at VO\textsubscript{2,max}, and blood compartment volumes. Four weeks of hypoxic acclimatization with the maintenance of sea-level training intensity (living high, training low) improved sea-level running performance and increased RBCM and VO\textsubscript{2,max}. A follow-up study was then completed using elite distance runners. The purpose was to determine if elite athletes who may be near their maximal structural and functional adaptive capacity of the respiratory system might achieve similar performance gains as the moderately to highly trained distance runners. The findings indicated that 3000 m time trial performance at sea level could be improved by 1.1 percent and VO\textsubscript{2,max} could be increased by 3 percent, with one third of the runners achieving personal best times for their competitive running distance after the altitude training camp. Twenty hours after ascent, the circulating erythropoietin levels were nearly double the initial sea-level values (8.5 ± 0.5 to 16.2 ± 1.0 IU/mL). The hemoglobin concentration measured at sea level increased by 1 g/dL (13.3 ± 0.2 to 14.3 ± 0.2 g/dL) over the duration of the training camp. The results indicated that the natural stimulation of the kidneys to produce endogenous EPO could improve sea-level endurance performance even in elite distance runners. In general, hematocrit studies suggest that training at or near sea level in coordination with sleeping in a hypoxic environment can increase RBC production, improving both laboratory and performance outcome measures [07133].

The concept of living at “high” altitude and training at “low” altitude (“live high-train low,” LHTL) has been increasingly used in recent years by endurance athletes with the expectation that sea-level performance may as a consequence be improved. The LHTL strategy combines living at moderate altitude, to increase hemoglobin mass (Hb\textsubscript{mass}) and red cell volume (RCV), with training at low altitude to maintain a high absolute training intensity. This concept has been shown to be superior to normal sea-level training or classical live high-train high (LHTH) altitude training for improving sea-level performance in elite endurance athletes. However, studies of whether exposure to moderate altitude increases Hb\textsubscript{mass} and RCV in elite endurance athletes have given controversial results. Results from the only published LHTL study that reported increase in RCV have been discussed, because RCV was measured indirectly with the Evans blue dye method, for which the adequacy for estimating RCV after hypoxic exposure has been questioned. LHTL studies that directly measured Hb\textsubscript{mass} with the carbon monoxide (CO)-rebreathing method did not report increased Hb\textsubscript{mass} and RCV. However, two LHTH studies, in which subjects generally spend more time at altitude, have recently reported increased Hb\textsubscript{mass} after exposure to moderate altitude. Thus it has been hypothesized that the hypoxic dose (living altitude combined with the duration of the altitude exposure) is the key factor. No controlled LHTL study has been published that has used a presumably adequate hypoxic dose at real altitude similar to the study by Levine and Stray-Gundersen and measured Hb\textsubscript{mass} directly with the CO-rebreathing technique [06165].

The effect of live high-train low on hemoglobin mass (Hb\textsubscript{mass}) and red cell volume (RCV) in elite endurance athletes is still controversial. It was expected that Hb\textsubscript{mass} and RCV would increase, when using a presumably adequate hypoxic dose. An altitude group (AG) of 10 Swiss national team orienteers (5 men and 5 women) lived at 2,500 m (18 h per day) and trained at 1,800 and 1,000 m above sea level for 24 days. Before and after altitude, Hb\textsubscript{mass}, RCV (carbon monoxide rebreathing method), blood, iron, and performance parameters were determined. Seven Swiss national team cross-country skiers (3 men and 4 women) served as "sea level" (500-1,600 m) control group (CG) for the changes in Hb\textsubscript{mass} and RCV. The AG increased Hb\textsubscript{mass} and RCV whereas there was no change for the CG. Serum erythropoietin, reticulocytes, transferring, soluble transferrin receptor, and hematocrit increased, whereas ferritin decreased in the AG. These changes were associated with an increased maximal oxygen uptake and improved 5,000-m running times from pre- to postaltitude. Living at 2,500 m and training at lower altitudes for 24 days increases Hb\textsubscript{mass} and RCV. These changes
may contribute to enhance performance of elite endurance athletes [06165].

The "living high-training low" model (Hi-Lo) may improve aerobic performance in athletes, and the main mechanism of this improvement is thought to be augmented erythropoiesis. A positive effect of Hi-Lo has been demonstrated previously by using altitudes of 2,000-3,000 m. Since the rate of erythropoiesis is altitude-dependent, it was tested whether a higher altitude (3,500 m) during Hi-Lo increases erythropoiesis and maximal aerobic performance. Nordic skiers trained for 18 days at 1,200 m, while sleeping at 1,200 m in ambient air (control group, n=5) or in hypoxic rooms (Hi-Lo, n=6; 3 x 6 days at simulated altitudes of 2,500, 3,000 and finally 3,500 m, 11 h/day). Measurements were done before, during (blood samples only) and 2 weeks after the intervention (POST). Maximal aerobic performance was examined from \( \text{VO}_{2\text{max}} \) and time to exhaustion (T\text{exh}) at \( v\text{VO}_{2\text{max}} \) (minimum speed associated with \( \text{VO}_{2\text{max}} \)), respectively. Erythropoietin and soluble transferrin receptor responses were higher during Hi-Lo, whereas reticulocytes did not change. In POST (vs before): hematological parameters were similar to basal levels, as well as red blood cell volume, being 2.68 + 0.83 L (v. 2.64 + 0.54 L) in Hi-Lo and 2.62 + 0.57 L (vs 2.87 + 0.59 L) in controls. At that time, neither \( \text{VO}_{2\text{max}} \) nor T\text{exh} were improved by Hi-Lo, \( \text{VO}_{2\text{max}} \) being non-significantly decreased by 2.0 percent (controls) and 3.7 percent (Hi-Lo). The present results suggest that increasing the altitude up to 3,500 m during Hi-Lo stimulates erythropoiesis but does not confer any advantage for maximal \( \text{O}_2 \) transport [06166].

**Short-term normobaric hypoxia**

One study aimed to determine the impact of short-term normobaric hypoxia on physiology and performance in highly trained athletes. Twelve (7 male and 5 female) athletes were randomly assigned into two groups and spent 8 h per night for two consecutive nights a week over 3 weeks under either short-term normobaric hypoxia (simulating 3636 m altitude, inspired \( \text{O}_2=13 \% \)) or in normobaric normoxia in a single-blind study. Following a 3 week washout period, athletes were then exposed to the other condition. Athletes were tested for maximal oxygen consumption and time to exhaustion on an electromagnetically braked cycle ergometer before and after each treatment in addition to being tested for anaerobic performance (Wingate test) on a modified Monark cycle ergometer. Blood samples were taken throughout the experiment and vastus lateralis muscle biopsies were taken before and after each treatment. Increases in red blood cell count, haematocrit, haemoglobin, platelet number and erythropoietin concentration were observed following short-term normobaric hypoxia. Except for a modest decrease in phosphofructokinase activity following short-term normobaric hypoxia, no changes were observed in muscle enzyme activities, buffer capacity, capillary density or morphology. No performance measures were changed following short-term normobaric hypoxia or normobaric normoxia. Although short-term normobaric hypoxia exposure increased levels of a number of haematological parameters, this was not associated with improved aerobic or anaerobic performance in highly trained athletes [06167].

**Effect of intermittent hypoxic training on cycling performance**

One study aimed to investigate the effects of a short-term period of intermittent hypoxic training (IHT) on cycling performance in athletes. Nineteen participants were randomly assigned to two groups: normoxic (NT, n=9) and intermittent hypoxic training group (IHT, n=10). A 3-week training program (5 x 1 h-1 h 30 min per week) was completed. Training sessions were performed in normoxia (approximately 30 m) or hypoxia (simulated altitude of 3,000 m) for NT and IHT group, respectively. Each subject performed before (W0) and after
(W4) the training program, three cycling tests including an incremental test to exhaustion in normoxia and hypoxia for determination of maximal aerobic power \((\text{VO}_{2\text{max}})\) and peak power output (PPO) as well as a 10-min cycle time trial in normoxia (TT) to measure the average power output \((P(\text{aver}))\). No significant difference in \(\text{VO}_{2\text{max}}\) was observed between the two training groups before or after the training period. When measured in normoxia, the PPO significantly increased by 7 and 7 percent in NT and IHT groups, respectively. However, only the IHT group significantly improved (11 %) PPO when measured in hypoxia. The NT group improved in TT by 8 percent, whereas IHT group did not show any significant difference. Intermittent training performed in hypoxia was less efficient for improving endurance performance at sea level than similar training performed in normoxia. However, IHT has the potential to assist athletes in preparation for competition at altitude [07139].

**Effects on laboratory parameters of intermittent hypoxic training**

The aim of one study was to assess the effect of intermittent hypoxia exposure on direct and indirect methods used to evaluate recombinant human erythropoietin (rhEPO) misuse. Sixteen male triathletes were randomly assigned to either the intermittent hypoxia exposure group (experimental group) or the control normoxic group (control group). The members of the experimental group were exposed to simulated altitude (from 4000 to 5500 m) in a hypobaric chamber for 3 h per day, 5 days a week, for 4 weeks. Blood and urine samples were collected before and after the first and the final exposures, and again 2 weeks after the final exposure. While serum EPO significantly increased after the first and final exposures, hemoglobin, percentage of reticulocytes, and soluble transferrin receptor were not elevated. Second-generation ON/OFF models (indirect rhEPO misuse detection) were insensitive to intermittent hypoxia exposure. The distribution of the urinary EPO isoelectric profiles (direct rhEPO misuse detection) was altered after intermittent hypoxia exposure with a slight shift towards more basic isoforms. However, those shifts never resulted in misinterpretation of results. The intermittent hypoxia exposure protocol studied did not produce any false-positive result for indirect or direct detection of rhEPO misuse in spite of the changes in EPO serum concentrations and urinary EPO isoelectric profiles, respectively [07140].

Aim of one study was to determine the influence of classic altitude training on hemoglobin mass (Hb-mass) in elite swimmers under the following aspects: normal oscillation of Hb-mass at sea level; time course of adaptation and de-adaptation; gender influences; influences of illness and injury; and interaction of Hb-mass and competition performance. Hb-mass of 45 top swimmers (male 24; female 21) was repeatedly measured (about 6 times) over the course of 2 years using the optimized CO-rebreathing method. Twenty-five athletes trained between one and three times for 3-4 weeks at altitude training camps at 2,320 m and 1,360 m. Performance was determined by analyzing 726 competitions according to the German point system. The variation of Hb-mass without hypoxic influence was 3.0 percent (males) and 2.7 percent (females). At altitude, Hb-mass increased by 7.2 ± 3.3 percent (2,320 m) and by 3.8 ± 3.4 percent (1,360 m). The response at 2,320 m was not gender-related, and no increase was found in ill and injured athletes \((n=8)\). Hb-mass was found increased on day 13 and was still elevated 24 days after return \((4.0 \pm 2.7 \%)\). Hb-mass had only a small positive effect on swimming performance; an increase in performance was only observed 25-35 days after return from altitude. In conclusion, the altitude \((2,320 \text{ m})\) effect on Hb-mass is still present 3 weeks after return, it decisively depends on the health status, but is not influenced by sex. In healthy subjects it exceeds by far the oscillation occurring at sea level. After return from altitude performance increases after a delay of 3 weeks [13291].
Position statement on hypoxic training

Team sports are activities that enjoy worldwide participation with large numbers of players training and competing at all levels. As skill proficiency increases, it is clear that overall technical and tactical effectiveness – rather than (competitive) physical performance per se – have a greater impact on winning. Over the last two decades, however, it is indisputable that team sports have experienced a tremendous increase in the tempo of play and energy demands imposed on players during matches. In this context, coaches and their staff are continuously looking for innovative ways to improve match outcomes, and moderate altitude training (2000–3000 m) has emerged as a popular ergogenic aid. Precompetition acclimatisation while residing at altitude (e.g. training for 1-2 weeks at the competition venue elevation) versus using altitude training to improve players’ “trainability” and competition performance in the days and weeks following return to sea level (e.g. 2-3 weeks of living high and training low during the preseason) are two distinct forms of altitude interventions that were debated by the expert panel. Despite altitude training being an area of interest for many sporting organisations — for example, Fédération Internationale de Football Association (FIFA), symposium on playing football at altitude and the International Olympic Committee (IOC), consensus statement on thermoregulatory and altitude challenges for all high-level athletes — research on the impact of altitude training for team sports is still in its infancy. An Altitude Training and Team Sports conference was held in Doha, Qatar on 24–25 March 2013. The original aims of the conference were to present cutting-edge research on the basic and applied aspects of altitude training and its impact on the physical performance of team-sport players. To this end, a panel of international experts was invited to address specific issues (detailed in the different review papers of this supplement) related to this topic. This position statement provides an overview of research and practical issues that may be of importance to consider when intending to use altitude training with team-sport players [13327].

To quantify the year-to-year variability of altitude-induced changes in haemoglobin mass (Hb_mass) in elite team-sport athletes 12 Australian-Footballers completed a 19-day (ALT1) and 18-day (ALT2) moderate altitude (2100 m), training camp separated by 12 months. An additional 20 participants completed only one of the two training camps (ALT1 additional n=9, ALT2 additional n=11). Total Hb_mass was assessed using carbon monoxide rebreathing before (PRE), after (POST1) and 4 weeks after each camp. The typical error of Hb_mass for the pooled data of all 32 participants was 2.6 percent. A contemporary statistics analysis was used with the smallest worthwhile change set to 2 percent for Hb_mass. POST1 Hb_mass was very likely increased in ALT1 (3.6 ± 1.6 %, n=19) as well as ALT2 (4.4 ± 1.3 %, n=23) with an individual responsiveness of 1.3 and 2.2 percent, respectively. There was a small correlation between ALT1 and ALT2 for a change in Hb_mass, but a moderately inverse relationship between the change in Hb_mass and initial relative Hb_mass (g/kg). It was concluded that two preseason moderate altitude camps 1 year apart yielded a similar (4 %) mean increase in Hb_mass of elite footballers, with an individual responsiveness of approximately half the group mean effect, indicating that most players gained benefit. Nevertheless, the same individuals generally did not change their Hb_mass consistently from year to year. Thus, a “responder” or “non-responder” to altitude for Hb_mass does not appear to be a fixed trait [13328].

Aviability of Hb_mass in altitude training

To quantify the year-to-year variability of altitude-induced changes in haemoglobin mass (Hb_mass) in elite team-sport athletes 12 Australian-Footballers completed a 19-day (ALT1) and 18-day (ALT2) moderate altitude (2100 m), training camp separated by 12 months. An additional 20 participants completed only one of the two training camps (ALT1 additional n=9, ALT2 additional n=11). Total Hb_mass was assessed using carbon monoxide rebreathing
before (PRE), after (POST₁) and 4 weeks after each camp. The typical error of Hb\text{mass} for the pooled data of all 32 participants was 2.6 percent. A contemporary statistics analysis was used with the smallest worthwhile change set to 2 percent for Hb\text{mass}. POST₁ Hb\text{mass} was very likely increased in ALT₁ (3.6 ± 1.6 %, n=19) as well as ALT₂ (4.4 ± 1.3 %, n=23) with an individual responsiveness of 1.3 and 2.2 percent, respectively. There was a small correlation between ALT₁ and ALT₂ for a change in Hb\text{mass}, but a moderately inverse relationship between the change in Hb\text{mass} and initial relative Hb\text{mass} (g/kg). It was concluded that two preseason moderate altitude camps 1 year apart yielded a similar (4 %) mean increase in Hb\text{mass} of elite footballers, with an individual responsiveness of approximately half the group mean effect, indicating that most players gained benefit. Nevertheless, the same individuals generally did not change their Hb\text{mass} consistently from year to year. Thus, a “responder” or “non-responder” to altitude for Hb\text{mass} does not appear to be a fixed trait [13327].

**For players of which team sports might altitude training be relevant?**

The physical (total distance covered, high-speed running or sprinting) and physiological (cardiovascular load, blood lactate concentration) demands of major team (football, rugby or Australian football) and racket sports (tennis and squash) during training and competition have been described by using miniaturised smart sensor devices (e.g. Global Positioning System technology, video tracking, portable gas analysers). In many team sports, the running distance during matches has considerably increased in recent years due to new tactical approaches having been adopted by many teams, thereby increasing the importance of endurance capacity. Team sports share the common feature of high-intensity, intermittent exercise patterns with continuously changing pace and also experience marked variability of game characteristics between sports, between playing positions and playing styles within the same sport and even from one match to the next. This creates a diversity of physiological challenges and performance needs across team-sport players. While elite team-sport players do not exhibit the specific physical/physiological capacities of elite endurance and sprint athletes, they generally possess an efficient combination of ‘aerobic’ and ‘anaerobic’ potential, though the relative contribution of oxidative versus glycolytic component varies widely across players and sports. Although aerobic metabolism dominates the energy delivery during most team sports, decisive actions (eg, sprints, jumps and tackles) are covered by means of anaerobic metabolism. As a result, the demands of team sports lend themselves towards a potential gain from adaptations to hypoxia from aerobically (maximal oxygen uptake (VO\text{2max}), economy and PCr resynthesis) and anaerobically (muscle buffer capacity) derived mechanisms. However, because the extent to which a player may benefit from different altitude-training methods may differ according to both their general and specific training focus (more aerobic vs anaerobic type of adaptations), no uniform recommendations can be made across all team sports. Nonetheless, it is anticipated that those activities displaying shorter exercise-to-rest ratios and/or requiring prolonged time spent at a high relative exercise intensity are more likely to benefit from altitude training. It was agreed that the effectiveness of any altitude-training programme might be worthwhile for some, but certainly not all, team members. For instance, it is intuitive that altitude training may have greater benefits for players covering large distances (>100 m/min) with high-intensity repeated efforts (ie, ‘invasion’ sports), as Australian football players do, compared with volleyball players, who run relatively less (distance covered generally <50 m/min) during a match. It is worth noting that since the impact of fitness on match running performance is likely player-dependent, playing style-dependent and position-dependent, the possible performance benefits of altitude training for team sports might not be as straightforward as for individual sports, where physical capacities strongly determine final performance. Considering soccer for instance, while it is appealing that altitude training may positively affect midfielders’ or attackers’ activity patterns, less evident is its possible impact for central defenders and goalkeepers. However, these assumptions await scientific evidence. Although
it is difficult to derive sound conclusions based on the limited literature available, it is proposed that incorporating information in accordance with time-dependent metabolic and match profiling (exercise-to-rest ratios), along with supplemented data from position-specific and player profile-related requirements could enable more informed judgements of the relevance of altitude training for a given player. It has been acknowledged that in elite endurance as well as team-sport athletes the effect of altitude training on red cell mass may depend on the initial haemoglobin mass (Hbmass). The proposed rationale is that an initial high Hbmass will not allow Hbmass to increase substantially following altitude training, whereas an initial low value will likely lead to meaningful enhancements in Hbmass. Noteworthy, however, is the observation that meaningful increases in Hbmass also occur in highly trained endurance athletes – that is, with some of the highest reported preintervention Hbmass values – from different sports and after various forms of altitude training. In team sports, where a high Hbmass is not necessarily a pre-requisite in all positions, players are generally characterised by a low to moderate Hbmass (or VO2max values usually ranging from 55 to 65 mL/min/kg) in comparison with endurance athletes, whose performance is largely related to aerobic capacity. There remains considerable controversy about the extent to which Hbmass increases in response to altitude training and two recent meta-analyses also offer somewhat conflicting viewpoints [13327].

In elite junior soccer players, the potential for altitude training to increase Hbmass was 3 percent after 12 days at 3600 m, and it is likely also present at the lower altitudes usually used for altitude-training camps by team-sport players. The rationale for attempting to increase Hbmass in team-sport players would be to increase their VO2max and enhance blood buffer capacity, and thereby decrease relative exercise intensity during games and increase tolerance for repeated-sprint exercises, respectively. While it is noted that, in some players, those values might already be near the upper limit of aerobic power, the expert panel agreed that any improvement in blood oxygen carrying capacity needs to be balanced so as not to limit explosive-type performance gains. What type of altitude-training interventions should be recommended for team-sport players? Contemporary altitude-training practices among athletes include: living high and training high (LHTH), living high and training low (LHTL) as well as living low and training high (LLTH). These paradigms can be achieved with natural altitude, simulated altitude or a combination, but it is important to note that the physiological responses to natural and simulated altitude may be quite different and controversy still exists as to what is the most efficient hypoxic exposure. In a 2009 meta-analysis of sea-level performance after hypoxic exposure, it was found that in elite endurance athletes, an enhancement of maximal aerobic power output was only possible with natural LHTL (4.0 %) and unclear with LHTH (1.6 %) and LLTH (0.6 %). While it is arguably easier to accumulate hours of hypoxia with LHTH, a recent meta-analysis concluded that Hbmass increases at approximately 1.1 percent per 100 h of altitude exposure regardless of the type of exposure (i.e. LHTH (>2100 m) or LHTL (3000 m)). Owing to possible inter-individual variability (e.g. individual responsiveness is approximately half the group mean effect in professional football players completing an LHTH training camp), when it comes to improving player’s fitness, one may question whether having all the team members residing and training at the same natural altitude is a sound approach if no individual adjustments in training content are made. Another recognised concern of hypoxic exposure is the large and individual decrease in maximal aerobic power (VO2max, 7 % per 1000 m altitude ascent), which may slow down the process of phosphocreatine resynthesis when recovering from high-intensity efforts. Compared to sea-level, VO2max was reduced by 20 percent in a cohort of non-acclimatised soccer players at a natural altitude of 3600 m, while at the same simulated altitude a single 5 s treadmill sprint performance was preserved. However, after repetitive efforts of short duration a larger fatigability is commonly observed in hypoxia, this effect may also be dependent on other factors such as training background, work-to-rest ratio and hypoxia severity [13327].
In order to maintain high-intensity training effectiveness (i.e. prevent premature fatigue), which represents a significant portion of competitive teams' training content, regular training practices of LHTH altitude camps may need to be modified. These modifications could be avoided by descending the whole squad to lower training venues but the logistical constraints and extended travel times may actually result in additional fatigue. Alternatively, work : rest ratios could be altered during sessions also taking into account the altitude of the training venue and players’ background. Practically, this requires adjusting distance or time of efforts and/or recovery times in order to modify the intensity or duration of practice bouts at altitude. Only with these adjustments can dramatic reductions in training quality along with accompanying negative alterations in mechanical and neuromuscular stimuli be avoided. Another solution could be to live in a natural, hypobaric hypoxic environment, but train at or near ‘simulated’ sea level with the aid of supplemental oxygen. While scientific evidence is still lacking, training with oxygen cylinders requires a stationary training situation, which is clearly unpractical for training sport-specific, technically complex activities commonly associated with team sports. Conversely, artificial altitude models (LHTL) may be more convenient for the team-sport players with the possibility of remaining in one training venue, while individualising the ‘altitude dose’ and training contents in line with their characteristics and field positioning. Exercise capacity during high-intensity intermittent exercise not only depends on the blood oxygen-carrying capacity, but also on molecular adaptations in the skeletal muscle and the efficiency of the neuromuscular system. Although not a consensus, LLTH altitude training regimes including near or maximal-intensity efforts (repeated sprint training in hypoxia) have proved superior to training at sea level in enhancing peripheral adaptations (i.e. oxidative capacity, capillary density and muscle glycolytic potential as well as increased expression of hypoxia inducible factor 1alpha (HIF-1alpha) and downstream genes to oxygen and transport) and, thereby, high-intensity intermittent performance. Likewise, resistance training combined with systemic hypoxia has been reported to further increase muscle strength, although other studies have shown no additional effect of hypoxia on strength gains. With only two known studies recruiting team-sport players, it was recognised that there needs to be more research to determine which form of LLTH altitude-training intervention may be more effective for maximising strength gains and multiple-sprint performance, while taking into account the specific characteristics of the different team sports and of the player for a given activity [13327].

What are the most relevant performance tests to provide ecologically valid data of the benefits of altitude training in a population of team-sport players? Assessment of the physiological determinants of physical performance is an integral part of sport science support for elite teams. At present, however, virtually all performance tests commonly used to judge the efficacy of any altitude-training intervention have been based on indicators of endurance-like performance (e.g. time trials). As such, the extent to which altitude training affects anaerobic performance is largely unaccounted for in the available literature. While altitude training is thought to improve some aspects of performance by only a small amount, high reliability (i.e. typical errors of 1-2 % with the tested-dependent variable having an error of measurement smaller than the smallest important effect) is a fundamental criterium guiding the selection of a particular field-based or laboratory-based test in the plethora of tests available today. It would be worthwhile to centre the test battery on the key elements of aerobic-type and anaerobic-type performance meant to be improved by the altitude-training intervention in question. As a single performance test cannot address the full complexity of team-sport performance, a broad suite of tests is expected. It was agreed that, in a population of team-sport players, relevant tests would at least include an evaluation of acceleration/peak sprinting and maximal aerobic velocities, while jump, repeated-sprints (with or without agility sequences) and running economy (e.g. 10-12 km/h for 5 min) tests can elegantly complete the test battery. In the absence of a gold-standard for repeated-sprint
testing for instance, coaching teams should adjust sprint distances, frequency, recovery time/type according to their players and sport requirements, ensuring that the tests are valid and reliable. Sport scientists have been tempted to directly measure the acute effects of an altitude exposure or the efficacy of a period of altitude acclimatisation on the occurrence of repeated high-intensity actions (frequency of maximal accelerations) and match running performance, as recently garnered from total distance covered or distances completed across different preselected time intervals. However, given the numerous confounding factors such as temporal changes in a team, opposition’s tactics and playing system and/or the contributions of substitutions, it must be questioned whether time motion analysis data can realistically be used in isolation to identify the benefits of any altitude-training intervention on athletic performance. In other words, one should proceed cautiously when inferring physical performance of team-sport players from their activity profiles since distances covered only reflect the “external physical output” of players. Important, high-intensity activity in professional soccer is not always related to team success, while those players performing more high-intensity work are also often covering lower total distances. Practically, it was therefore recognised that it is important to simultaneously measure the external (e.g., distance covered within different velocity zones) and internal loads (e.g., heart rate, perceptual responses) — irrespective of whether total distance covered has increased or not in response to altitude training — in order to objectively determine if a player is working easier physiologically to produce the same external physical output. Controlled experimental simulations of match-play activity performed on the field such as the Yo-Yo Intermittent Recovery test (level 2) and the 30-15 Intermittent Fitness Test or simulating team-sport running performance on a non-motorised treadmill in the laboratory environment are recommended to evaluate altitude training usefulness. Standardised drills in the form of small-sided games that replicate to a certain extent the physical intensity, movement (running performance) patterns and the technical requirements (skill component) of competitive match play for instance, with a simultaneous evaluation of total distance covered and distance ran at high speed, are also likely suitable [13327].

What is the optimal altitude dose to be used?

In individual athletes, the success of altitude training requires living high enough (>2000 m), for enough hours/day (>14–16 h/day), for a sufficient period of time (>19–20 days) in order to sustain an erythropoietic effect of hypoxia; that is, the so-called altitude dose (300–400 h). The time course of the erythropoietic response to altitude training is highly individual ranging from no response until 15 percent after 3–4 weeks. Training camps as short as 2 weeks have also been shown to increase Hbmass substantially in elite youth soccer (i.e. LHTH), elite water polo (i.e. LHTL) and Australian football players (i.e. LHTL and LHTH). Limited data currently exists regarding the time course of non-haematological adaptations, which may also be potentially beneficial for team-sport performance, during and after an altitude-training camp, thereby limiting the possibility to offer scientifically based recommendations about these adaptations. Most altitude-training venues around the world, which are equipped with the necessary facilities to suit team-sports (i.e. comfortable rooms and playing fields), are in the 1800–2500 m range. In the majority of research studies moderate altitudes (2000–3000 m) have been used arguably because at those heights robust and reliable erythropoietin (EPO)-induced expansion of red cell mass is usually observed, with athletes suffering from only minor side effects. Limited data are available on how these entities should be balanced and how far the boundaries of hypoxic exposure can be extended. At present, the optimal altitude for a team to reside at is unknown, but there is a widespread belief that elevations higher than 3000 m should be used with caution because of the excessive loss of training intensity and the characteristics of ball flight will change substantially due to the thinness of the air. On the one hand, the degree of hypoxia determines the magnitude of the induced physiological changes in a dose–response relationship, with higher altitudes triggering
larger/faster increases in red cell mass. On the other hand, exposure to chronic (several days to several weeks) hypoxia using elevations >3000–3500 m can be unproductive for some individual players as the stress on their body and the resultant side effects – for example, loss of appetite, inhibition of protein synthesis, muscle wasting, prevalence and severity of acute mountain sickness, excessive ventilatory work and/or metabolic compensation – from such high altitude could outweigh any erythropoietic benefits and thereby impair performance gains. Reportedly, however, sleep quality is rapidly increased with acclimatisation and may not even be adversely affected by acute (1–2 days) or chronic (1–2 weeks) exposures to high altitudes (>3500 m). This reinforces the potential value of individualising altitude-training “prescription” with artificial exposures as a prerequisite in order to maximise the performance of each player, and thereby reduce some of the individual responses seen today [13327].

Players who have had previous hypoxic exposure may adapt sooner to hypoxic conditions due to an increase in the magnitude of hyperventilation in the first few days of re-exposures. Although absolute mean changes in physiological capacities (i.e., Hbmass) appear to be repeatable after both LHTL and LHTH, individual athletes do not exhibit consistency in altitude-induced Hbmass changes from year-to-year, that is, the magnitude of the correlations between Hbmass changes are only small to moderate with differences in the individual responses to each intervention as large as 8 to 10 percent. More importantly, subsequent physical performance benefits may be even more variable from an intervention to another one. However, even though altitude training (at least in elite endurance athletes) results in an increase in VO_{2max} of more than half the magnitude of the increase in Hbmass, the weak (but significant) correlation found between these factors suggests that other non-haematological factors are also likely to be important. Although irrefutable scientific support is lacking, the effects of altitude training on some of the determinants of physical performance in team players may depend on the training phase of the competitive season. Importantly, altitude training needs to fit within the busy competition schedule of a team, without compromising the quality of the technical and tactical training. With the advent of hypoxic facilities (hypoxic chambers and/or altitude dormitories) in a growing number of high-level professional clubs and sport institutes, the prospect of implementing altitude interventions in a congested calendar is no longer as daunting. Larger physiological changes are generally expected for altitude training conducted preseason compared to in-season, likely due to lower initial fitness levels. Preseason generally provides a window of about a month or two to embark on a 2-week to 4-week sojourn at a natural or simulated altitude aiming to primarily enhance convective oxygen transport. The increased oxygen transport capacity of blood in response to altitude training may allow training at higher intensities during subsequent training in normoxia (improved lactate metabolism), thereby optimising the training stimuli by enhancing some neuromuscular and cardiovascular determinants of team-sport performance [13327].

Today, the busy competition schedules of major team sports often makes prolonged (>2 weeks) stays at altitude (at least for natural altitude exposure) unrealistic for anything other than preseason camps and the most important international tournaments. During the competition period, a 2-week camp implemented during the mid-season break for instance – be it LHTL or LLTH – may boost physical performance; nevertheless, longer exposures are certainly required to maximise the magnitude of these responses. Coaching teams involved in sports (e.g. water-polo and rugby) with a competition calendar targeting major international tournaments (i.e., Olympics and World Cup) in addition to regular league matches could accommodate an LHTL intervention during the competition preparation phase to maximise physiological adaptations of their squads. With minimal travel, modest expense and relatively minor disruption of training and daily life, a few blocks of LLTH altitude intervention (simulated altitude of 2500-3500 m; 2-3 sessions/week for 2-4 weeks; supra-maximal...
intensity workouts) could also be included in their yearly programme in order to add variety to training and help maintain in-season sprint speed and maximise explosive power/maximal strength capacity. Upon removal of the hypoxic stimulus, a reversal of some altitude-specific adaptations can occur relatively quickly (within few weeks; ie, neocytolysis, red blood cell destruction). Nevertheless, with a typical exposure of 300-400 h, the increase above prealtitude Hbmass values persists for 2-3 weeks, which does not support the proposal of short-term neocytolysis after altitude descent. Accordingly, the ability of the players to train at a high level for several weeks on return to sea level, due to the positive acclimatisation responses to altitude, may allow them to achieve a higher level of fitness (i.e. one that may last longer than the acclimatisation effects themselves) and more importantly performance. While the entire physiological acclimatisation is mostly undetectable 4 weeks of postdescent, performance gains seem to be more resilient and may last up to 4 weeks after the altitude camp. However, coaches should not expect any altitude-induced physiological changes to be maintained throughout the entire duration of a team-sport season if no additional hypoxic stimulus is added thereafter to the training programme. Although this awaits stronger scientific evidence, it was recognised that some of the side effects (decrease in Na\(^+/\)K\(^+\) ATPase activity and decreased plasma volumes) of each of the individual altitude-training interventions could potentially be attenuated when using combined (or mixed) methods. For players and coaches looking to elicit ‘aerobic’ and ‘anaerobic’ benefits to improve sea-level performance, living high and training low and high is an attractive altitude intervention for team sports. Proposed LHTL modifications which involve interspersing ‘blocks’ of nightly exposure to hypoxia, with several nights of normoxia (“intermittent” LHTL), to lessen any adverse psychological and physiological (eg, minimising the detrimental effects of chronic hypoxic exposure on muscle Na\(^+/\)K\(^+\) ATPase activity, especially in athletes undertaking heavy training) impacts of prolonged (>20 h/day) room confinement. Reportedly, a combined approach of LHTL plus additional hypoxic training sessions resulted in greater enhancement in the physiological capacities (VO\(_{2}\text{max}\) and Hbmass) that underpin endurance performance (3 km time trial) compared with LHTL or LLTH. Currently, however, the optimal characteristics of exercise in hypoxia or the combination of the various methods are unclear. Although altitude-training interventions combined with other challenging environmental conditions (eg, heat exposure to increase plasma volume) could potentially be useful to improve selected aspects of team-sport performance, at this stage, there is insufficient evidence to recommend such innovative mixed methods [13327].

Does the reduced air resistance with terrestrial altitude (hypobaric hypoxia) significantly modify match-related performance and the aerodynamics of the ball compared to exposure to simulated altitude (normobaric hypoxia)? What is the impact on training or competition? LHTH altitude has been, and will remain, widely used by teams to acclimatise before matches at altitude. This approach is supported by the lack of direct transfer of the benefits induced by a normobaric acclimation to the hypobaric situation and, in comparison, larger ventilatory acclimatisation, minimised acute mountain sickness prevalence and improved performance using terrestrial altitude or hypobaric chambers. As a general recommendation, suitable strategies to maximise physiological acclimatisation (oxygen transport and acid–base balance) should last 3-7 days for low altitude (500–2000 m), 1-2 weeks for moderate altitude (2000–3000 m) and at least 2 weeks if possible for high altitude (>3000 m). When designing acclimatisation strategies it is of utmost importance to consider the altitude of residence of the team and the ultimate competition altitude. The expert panel agreed that for squads who must compete at a moderate altitude within 2 weeks of ascent, living at the competition altitude (whenever possible at the competition venue) and not higher is advisable. Practically, shorter recovery periods before players can repeat high-intensity efforts and improved willingness to possess the ball can be viewed as signs of positive physiological acclimatisation. Because it does not simulate the reductions in air density, which affect motor ball trajectory and consequently motor skill proficiency, using normobaric
hypoxia is not optimal for preparation for competition at a natural altitude. The major
determinants of air density are barometric pressure, temperature and, to a lesser extent,
humidity. Upon ascent to natural altitude, changes in these variables will have a
proportionate effect on air density (air density reduces by about 10 percent for every 1000 m
increase in altitude) and, consequently, physical performance and player behaviour. This is a
serious concern in team sports where performance relies directly on repeated high-intensity
activities such as sprinting and involves a large technical skill component essential for
training and competition. At natural altitude, any potential advantage associated with reduced
air resistance (increased single sprint performance) is offset by the increased metabolic
challenge in hypoxic conditions (impaired repeated sprint ability). Regarding the effects of
moderate altitude exposure on activity profiles during actual soccer match play, not only is
total distance covered reduced above 1200 m, but also, a larger reduction in match running
performance is seen at 1600 m for higher intensity tasks such as high velocity running or
maximal acceleration. Thirteen days of acclimatisation nor life-long residence at high-altitude
(3600 m) protected against detrimental effects of altitude on match activity profile.
Additionally, for sea-level players a significant number of repetitions are arguably necessary
to make the appropriate motor skill adjustments required for competitive success in a
reduced air density environment [13327].

The decreasing air density associated with increasing altitude also results in changes in the
drag and lift forces acting on the flying object (ball, missile), thereby altering its flight
characteristics. This is typically manifested as a reduction in the lateral deflection or curve of
the projectile and an increased flight, as the projectile will travel more easily through the
thinner air. As a result, a soccer player's technical skills may be impacted when shooting,
controlling long passes and clearing the ball using punted and long kicks out of defence.
Undoubtedly, the goalkeeper could also be deceived by shots at goal, owing to the faster
flight of the ball and its altered trajectory. However, those effects have yet to be quantified,
and whether a technical acclimatisation to altitude takes place, beyond physiological
acclimatisation, needs to be researched, with a careful monitoring of the extent and the time
course of these adaptations for a range of heights. Despite the absence of scientific
evidence, it is reasonable to suggest that extra time and practice is probably required to
allow adequate adjustments in motor skills and movement timing as the terrestrial altitude
where teams reside, train and compete increases. Because physiological and aerodynamic
(also likely to be highly individual) adaptations may not necessarily share the same time
course, it is advised that teams experience these responses in a training camp setting well
ahead of the competitive event. Arguably, when a team prepares for competition at one
altitude but has to contest games at various altitudes during the tournament (eg, 1986 and
2010 FIFA World Cups), without a suitable time period to readjust to the biomechanical
constraints, the coach may need to make tactical changes. Likewise, teams will also have to
readjust upon return to sea level and whether LHTH should not be recommended when
competing at sea level in a short window (<7-10 days) requires research [13327].

One meta-analysis uses raw data from 17 studies that used carbon monoxide rebreathing to
determine Hbmass prealtitude, during altitude and postaltitude. Seven studies were classic
altitude training, eight were live high train low (LHTL) and two mixed classic and LHTL.
Separate linear-mixed models were fitted to the data from the 17 studies and the resultant
estimates of the effects of altitude used in a random effects meta-analysis to obtain an
overall estimate of the effect of altitude, with separate analyses during altitude and
postaltitude. In addition, within-subject differences from the prealtitude phase for altitude
participant and all the data on control participants were used to estimate the analytical SD.
The 'true' between-subject response to altitude was estimated from the within-subject
differences on altitude participants, between the prealtitude and during-altitude phases,
together with the estimated analytical SD. During-altitude Hbmass was estimated to increase
by 1.1 percent/100 h for LHTL and classic altitude. Postaltitude Hbmass was estimated to be
3.3 percent higher than prealtitude values for up to 20 days. The within-subject SD was
constant at 2 percent for up to 7 days between observations, indicative of analytical error. A
95 percent prediction interval for the “true” response of an athlete exposed to 300 h of
altitude was estimated to be 1.1–6.0 percent. It was concluded that camps as short as 2
weeks of classic and LHTL altitude will quite likely increase Hbmass and most athletes can
expect benefit [13329].

Correlation between Hbmass and altitude training result

Endurance athletes have been using altitude training for decades to improve near sea-level
performance. The predominant mechanism is thought to be accelerated erythropoiesis
increasing hemoglobin mass [Hbmass] resulting in a greater maximal oxygen uptake (O2max).
Not all studies have shown a proportionate increase in O2max as a result of increased Hbmass.
The aim of one study was to determine the relationship between the two parameters in a
large group of endurance athletes after altitude training. 145 elite endurance athletes (94
male and 51 female) who participated in various altitude studies as altitude or control
participants were used for the analysis. Participants performed Hbmass and O2max testing
before and after intervention. For the pooled data, the correlation between per cent change
in Hbmass and per cent change in O2max was significant with a slope of 0.48 intercept free to
vary and 0.62 when constrained through the origin. When separated, the correlations were
significant for the altitude and control groups, with the correlation being stronger for the
altitude group (slope of 0.57 to 0.72). It was concluded that, with high statistical power,
altitude training of endurance athletes will result in an increase in O2max of more than half the
magnitude of the increase in Hbmass, which supports the use of altitude training by athletes.
But race performance is not perfectly related to relative O2max, and other non-haematological
factors altered from altitude training, such as running economy and lactate threshold, may
also be beneficial to performance [13330].

Physiological markers worthwhile monitoring to identify altitude responders?

At present, there is no gold-standard test battery to facilitate the detection of team members
who are unlikely to cope well with the stress of altitude or who will respond positively. As a
general rule, however, preascent evaluations should ensure that players are free of illness,
injury and fatigue. A comprehensive initial assessment would also include other measures
such as “normal” iron and nutritional-hydration status, body mass and psychological
attributes. Only players who fulfil these criteria should add the stress of hypoxia to their
training. A conservative approach might be prudent for at-risk players – those who are
currently unfit and not coping well with altitude stress – to ensure that they are not worked
too hard at hypoxia until fully recovered. Arterial oxyhaemoglobin saturation (SpO2) in
hypoxia is largely controlled by the hypoxic ventilatory response. An enhanced resting
ventilatory response to hypoxia, which is mediated primarily by the peripheral
chemoreceptors in the carotid bodies, is arguably beneficial as the body responds to the
hypoxic stimulus more quickly. Reportedly, the ability to maintain SpO2 during heavy exercise
at sea level has a strong influence on the ability to maintain VO2max and exercise
performance with acute altitude exposure. As such, although their mode of evaluation (rest
vs exercise; hypoxic dosage) is still debated, determining chemosensitivity parameters (ie,
desaturation and ventilatory response to hypoxia) may help detect at-risk players before a
sojourn to altitude. Although irrefutable scientific support is lacking, coaches and support
staff can also be proactive by implementing short-term, intermittent normobaric hypoxia
exposures (30-60 min at altitude ranging 3000-4500 m) before travel for those with a blunted
hypoxic ventilatory response in order to reduce the prevalence and severity of acute
mountain sickness [13327].
Another explanation proposed to account for the lack of adaptation to altitude training is depleted iron stores prior to and as a result of altitude exposure. In iron deficient athletes (serum ferritin <35 ng/mL for females and <50 ng/mL for males) the likelihood of an altitude-induced increase in Hbmass is minimal, suggesting that normalisation with oral (ferrous sulfate) supplements and monitoring iron status of each team member is an absolute necessity before exposure to hypoxia. Iron-deficiency per se could result in decreased training potential or physical performance in team-sport players, not only because of blunted erythropoiesis but also due to its negative impact on other iron-dependent physiological processes at the mitochondrial level and in myoglobin content. We recommend that iron deficient players receive iron supplementation, in order to normalise serum ferritin stores before departing for altitude, and maintenance of iron supplementation for all players while at altitude in order to prevent bias arising from iron deficiency. As with any other training stimulus, there is considerable variation in the response to altitude training. This is evidenced by decreased sympathetic activity and strong erythropoietic responses to altitude in some participants, while others see little or no changes in such variables with chronic exposure. Likewise, most players experience significant impairment of training velocities and oxygen uptake at a moderate altitude, while few would be able to maintain training and oxygen flux near what they would be able to at sea level. The concept of “responders” and “non-responders” was created without offering plausible mechanisms. While factors influencing the magnitude of individual response to hypoxia may be genetically inherited traits (i.e. HIF-1alpha functions as a master regulator of many genes, notably of erythropoiesis, pH regulation and glycolysis), it remains possible that certain psychosociological concerns, not physiological ones, may also determine how specific team members will respond. For some players leaving their family (spouse and parents) and regular training environment for the duration of a camp can be problematic. This may partly explain the within and between years variability observed in the response of an individual athlete. As such, it may not be appropriate to divide team members into “responders” and “non-responders” but rather to question whether the intervention had a measurable impact on player performance. A proposition would be to identify those who will respond with a fast/high, moderate/medium and slow/low response compared to the group mean response. Importantly, in the same individuals, changes in physiological and performance measures (i.e. the former to a higher extent than the latter) after two virtually identical altitude-training camps are not necessarily consistent. This reinforces that altitude training-related gains may not only be dependent on positive physiological adaptations but also on a complex interaction of other factors including fitness, training status and fatigue. Substantially increased feelings of fatigue (players’ perception of how hard they are training along with their fatigue, stress and muscle soreness levels), submaximal heart rates, poorer training quality and disrupted sleep structure, as measured from validated tools also give the coach invaluable insight to help delineate those players who are coping well with the stress of hypoxia from those who are not. The majority of training benefits at sea level are accrued with adequate attention given to consistent training, suitable recovery/nutrition and skill development. How are these factors taken into account when training at altitude? It was recognised that disrupted training and recovery are expected at altitude, especially for novice players, and therefore require careful management [13327].

The ethics of hypoxic training

Unlike many forms of doping, the use of hypoxic chambers within sports does not involve synthetic substances that can easily be characterized as artificial or unnatural. Moreover, it cannot easily be aligned with the antisocial connotations of drug abuse, which are so
effective at garnering political sport. At most, the arguments surrounding its use involve its
effect as a form of cheating or as a health risk. Yet, for some time now it has not been
possible to describe the use of such chambers as a form of cheating since they have been
legal. Moreover, a number of high profile athletes have used them extensively without any
moral outrage reported. The science of hypoxia involves changes in the partial pressure of
oxygen within an environment, which increases the body’s hematocrit level. These changes
reduce the partial pressure of oxygen in the pulmonary capillaries, which leads to an
increased need to breathe. In turn, the body senses the changes and increases the
production of red blood cells, which are rich in oxygen carrying protein (hemoglobin). This
enhanced production leads to a greater aerobic potential for the individual. The pop singer
Michael Jackson was photographed within such a chamber. Such a context easily frames
this technology as something alien to “normal” human practices. Indeed, the characteristics
of the technology tend to have required obstructive practices for athletes who will need to
spend extensive time in these isolated booths. Such spaces conjure up images of athletes as
rats in laboratories simply growing stronger almost by magic. Such images forces one to
question whether the WADA Code seeks to protect an athletically moral practice. Hypoxic training has also been particularly interesting because it seems to have divided the scientific community and its support for WADA’s work [06168].

Yet, the more intriguing characteristics of this issue relate to the ethical debate that has
ensued. During 2006, the ethical status of hypoxic chambers was put to the recently formed Ethical Issues Review Panel in WADA. The Panel’s report raises a number of specific arguments as critical to the ethical status of hypoxic training, beginning its discussion paper by asking what it is about sport that people find honorable, admirable, and beautiful. Their position concludes that hypoxic training is a violation of the “spirit of sport” (WADACode) insofar as it does not require the “virtuous perfection of natural talents” matters to sport. In short, their view was that the use of such chambers was “passive” requiring no skill, knowledge, or effort on the part of the athlete. They state: “my responsibility for my performance is diminished by technologies that operate upon me, independent of any effort on my part.” As was mentioned earlier, the “spirit of sport” concerns constitute only one element of the process by which a technology might be deemed a doping technology. The final outcome of this inquiry made in September 2006 was that the hypoxic chambers should remain legal [06168].

It seems remarkable that, for so many years, athletes have used hypoxic training without it
giving rise to moral outrage. The idea of spending time locked in a room doing nothing
cannot easily be associated with the practice ethos of sports. Yet, this view of what hypoxic
training entails is also ambiguous or, at least, contingent. For instance, there already exist
rooms, which resemble regular rooms within a home. Moreover, one could envision its
construction as a space of reflection on an athletic life or for learning essential information
about the practice of sports. The point is that a hypoxic chamber is a work in progress and
that the moral judgment of this technology on how it seems to occupy a quite different social
space compared with the idea of athletes running in mountains is neither accurate nor
relevant. Moreover, the development of this technology is only likely to become more
"seamless" in the way that I mentioned earlier [06168].

In short, it is possible for a performance-enhancing technology to be of no detriment to the
spirit of sport, but simply involve a reskilling of the activities an athlete undertakes in order to
remain competitive. The intrinsic value of sports – the skills required to bring about sporting
performance – are unaffected by hypoxic chambers. At the very most, their use will raise the
standard of sporting achievements, which is precisely what gives elite sports their unique
social value. While it is inevitable that circumstances arise where an athlete is simply
introduced to a new performance-enhancing technology, it is crucial to remember that every
part of that technology's development has involved members of the athletic community. Indeed, as is true of other technologies, it is likely that open access to this innovation will lead to a more nuanced culture of use [06168].
PLATELET-RICH PLASMA

Biomedical sciences have made major advances in understanding how tissues repair, and the signalling mechanisms required to achieve this goal are progressively being dissected. Advances in the understanding of tissue repair mechanisms and the pivotal role of growth factors have stimulated the use of platelet-rich therapies by orthopaedic surgeons and sports physicians, mainly with the aim of stimulating and enhancing tissue healing. Autologous activated platelets retained in fibrin matrices are used as a source of molecular signals that control cell fate, including cell growth, cell differentiation and the synthesis of diverse functional proteins. Thus far, platelet-rich technologies have spawned additional ambitious endeavours, including surgical and non-surgical treatments in sports orthopaedics. Reconstruction of anterior cruciate ligament and tendon surgery and treatment of joint injuries, tendinopathy or muscle tears are but a few examples of the potential applications of this technology in the field of orthopaedic sports medicine. In the present article, some of the most important therapeutic applications using these approaches – especially preparation rich in growth factor technology – are presented, as are some of the limitations, anti-doping concerns and future challenges in this field. In view of a general state of confusion, the concept of platelet-rich plasma needs rigorous definition associated with well characterized products and re-administration procedures. There is evidence that reconstruction of anterior cruciate ligament and tendon surgery combined with preparation rich in growth factor technology enhances healing and functional recovery; clinical evidence is also appearing in the literature regarding treatment of tendinopathies and osteoarthritis. Currently, the challenge lies in conducting randomized, controlled clinical trials to determine the essential qualities of these technologies. If anti-doping agencies clarify their regulatory guidelines, robust studies in athletes are expected to emerge. Although much research work lies ahead, the current knowledge points to a future in which platelet-rich therapies will continue improving existing conventional approaches to treatment of sports injuries.

Autologous platelet-rich plasma (PRP) is perceived to accelerate healing in musculoskeletal injuries. PRP is increasingly used in situations that require rapid return-to-play, which, in the professional sports arena, translates to fame and money. Human blood platelet counts are approximately 200,000/ml. PRP is an autologous concentration of human platelets above this in a small volume of plasma. Reports vary regarding the platelet concentration and different growth factors present in the PRP concentrate. Also, there are many preparation protocols, kits, centrifuges and methods to trigger platelet activation before use. The same is true for application methods, including using injectable activated PRP liquid concentrate versus implanting a fibrin scaffold, optimal timing of injection and the specific volume to use. Almost every major manufacturer in the orthopaedic and sports medicine world markets a different commercial kit. Some claim to produce a better quantity and quality of PRP than their competitors from the same amount of blood from the same patient. Costs vary tremendously: a commercial kit yields a PRP concentrate at the cost of several hundred dollars, but inhouse non-automatised techniques produce a PRP concentrate for approximately US$10. Each method to concentrate platelets leads to a different product with different biology and potential uses, with a high variation (3 to 27-fold) in growth factor concentration and in the kinetics of release. Most techniques yield a PRP concentrate of approximately 10 percent of the blood volume taken (e.g. 20 ml of whole blood would result in approximately 2 ml of PRP). These differences might be of relevance to clinical management, although they have not been systematically studied. PRP preparations containing only moderately elevated platelet concentrations may be the ones to induce optimal biological benefit, with lower platelet concentrations leading to suboptimal effects, and higher platelet concentrations to inhibitory effects. Other authors have stated that the
“therapeutic dose” of PRP would be at least four to six times higher than the normal platelet count. To complicate things, the actual growth factor content is not well correlated with the platelet count in whole blood or in PRP, and there is no evidence that gender or age affects platelet count or growth factor concentrations [10360].

A few studies have categorised the different platelet concentrates according to the presence or absence of white blood cells (WBC): either pure platelet rich plasma (P-PRP), in which WBC have been intentionally eliminated from the PRP, or leucocyte and platelet-rich plasma (L-PRP), possibly from the inability of the kit to differentiate between the WBC and the PRP layers. A positive or negative effect of WBC cannot be generalised to all tissues and clinical conditions. This issue requires further investigation, as the WBC content in the preparation injected has never been systematically studied. It is known that neutrophils promote additional muscle damage soon after the initial injury, but there is no direct evidence that neutrophils play a beneficial role in muscle repair or regeneration. This exacerbation of injury and/or delay in muscle regeneration may be of major importance for injuries managed with PRP. This, together with the improved homogeneity of P-PRP and its reduced donor-to-donor variability, supports some PRP production techniques that claim to be clinically superior. L-PRP injected for soft tissue injuries might induce more local pain than P-PRP. Platelets by themselves do reduce pain. L-PRP reduces postoperative pain, although here the contribution of the WBC to the overall effect observed remains unclear [10360].

Platelets contain many biologically active factors, including many of the proteins responsible for haemostasis, synthesis of new connective tissue and revascularisation. They can stimulate a supraphysiological release of growth factors to jumpstart healing in chronic injuries, or speed up an acute injury repair process. The idea behind PRP treatment is that all stages of the repair process are controlled by a wide variety of cytokines and growth factors acting locally as regulators of the most basic cell functions, using endocrine, paracrine, autocrine and intracrine mechanisms. More than 95 percent of presynthesised growth factors are secreted within 1 h of activation from the granules. After the initial burst of PRP-related growth factors, platelets synthesise and secrete additional growth factors for the remaining 7–10 days of their lifespan. Typically, blood, such as the haematoma formed in a muscle tear, contains approximately 94 percent red blood cells (RBC), a small amount of platelets (6 %) and less than 1 percent leucocytes. The rationale for PRP therapy lies in reversing the blood ratio by decreasing RBC, which are less useful in the healing process, to approximately 5 percent, and increasing the platelet amount to 94 percent to stimulate recovery. The main growth factors in the PRP concentrate are the transforming growth factor-beta1, platelet-derived growth factor, vascular endothelial growth factor, epithelial growth factor, hepatocyte growth factor and insulin-like growth factor 1. Most of these growth factors play key roles in tendon, muscle, ligament, cartilage and bone healing by stimulating angiogenesis, epithelialisation, cell differentiation–replication–proliferation and the formation of extracellular matrix [10360].

Most early studies concentrated on purified isolated growth factors that were known to play a specific role in tissue healing. Only in the past decade has it been recognised and put into practice that the need to target various signalling pathways requires the administration of a balanced combination of mediators, as isolated growth factors would not be able to satisfy the multiple requirements of the injured tissue. PRP has been used to enhance the healing of meniscus defects and muscle injuries, and stimulate chondrocytes to engineer cartilaginous tissue, reduce pain and produce better and more balanced synovial fluid in arthritic knees, improve outcomes after total knee arthroplasty and subacromial decompression, accelerate bone formation, stimulate the healing of an anterior cruciate ligament injury central defect, its primary repair or its reconstruction, improve the outcome of operated ruptured Achilles tendons, reduce pain in chronic tendinopathies and prevent and reverse intervertebral disc
degeneration. It is remarkable that very few randomised controlled trials have been performed, and even fewer trials are adequately powered, use appropriate outcome measures and have decent follow-up [10360].

The 2008 “Aspetar Consensus”, organised by the World Anti-doping Association (WADA) and the International Olympic Committee to debate possible conflicts with the WADA code, discussed the use of PRP in muscle injuries, concluding that further research is necessary. “The application of the WADA Therapeutic Use Exemption (TUE) process is the preferred approach when wishing to utilise growth factors technology in elite athletes, however the ability of the TUE committee to appropriately evaluate such applications is inhibited by the current level of scientific evidence.” The position statement concludes that “WADA will not be in a position to evaluate its clinical utility for either assessment of TUE applications or the prohibited list.” In section S2 of the Aspetar Consensus, concerning any autologous product that contains growth factors, the only actual factor mentioned in connection with PRP is insulin-like growth factor 1, which, while present in PRP, is systemically subtherapeutic by a factor of 500; only 1 percent of it is unbound, available and active, with a half life of 10 minutes [10360].

Another concern is that PRP might produce genetic instability, potentially leading to neoplasms. Growth factors act on cell membranes rather than on the cell nucleus, and activate gene expression by internal cytoplasmic signal proteins, which promote normal, not abnormal, gene expression. Growth factors are not directly mutagenic, and act through gene regulation and normal wound healing feedback control mechanisms. Furthermore, the systemic effects on circulating growth factors from a local PRP injection showed a very brief reduction of blood growth factors. The modalities of use of PRP vary. The use of non-steroidal anti-inflammatory drugs in the early post-injection period may exert an inhibitory effect on healing, and the use of local anaesthesia at the injection site is controversial. Extrarticular injections are performed under ultrasound guidance, and it is suggested that the haematoma, if present, should be evacuated and replaced with PRP [10360].

Regarding platelet-rich plasma, the sceptics point out that, given the well concerted healing cascade that has evolved over millions of years, it is not easy to understand how a single or even a few injections of a cocktail of growth factors at variable, and at present not well codified, times from the injury will produce a lasting beneficial effect on a wide variety of conditions. Despite the hype of the technique and its biological plausibility, the anecdotal nearly miraculous recovery reported in the lay press in some famous athletes, and the myriad of extremely favourable retrospective and prospective studies published, level I investigations are lacking [10360].

Platelet-rich plasma is defined as autologous blood with a concentration of platelets above baseline values. Platelet-rich plasma has been used in maxillofacial and plastic surgery since the 1990s; its use in sports medicine is growing given its potential to enhance muscle and tendon healing. In vitro studies suggest that growth factors released by platelets recruit reparative cells and may augment soft-tissue repair. Although minimal clinical evidence is currently available, the use of platelet-rich plasma has increased, given its safety as well as the availability of new devices for outpatient preparation and delivery. Its use in surgery to augment rotator cuff and Achilles tendon repair has also been reported. As the marketing of platelet-rich plasma increases, orthopaedic surgeons must be informed regarding the available preparation devices and their differences. Many controlled clinical trials are under way, but clinical use should be approached cautiously until high-level clinical evidence supporting platelet-rich plasma efficacy is available [09180].

Biomedical sciences have made major advances in understanding how tissues repair, and
the signalling mechanisms required to achieve this goal are progressively being dissected. Advances in the understanding of tissue repair mechanisms and the pivotal role of growth factors have stimulated the use of platelet-rich therapies by orthopaedic surgeons and sports physicians, mainly with the aim of stimulating and enhancing tissue healing. Autologous activated platelets retained in fibrin matrices are used as a source of molecular signals that control cell fate, including cell growth, cell differentiation and the synthesis of diverse functional proteins. Thus far, platelet-rich technologies have spawned additional ambitious endeavours, including surgical and non-surgical treatments in sports orthopaedics. Reconstruction of anterior cruciate ligament and tendon surgery and treatment of joint injuries, tendinopathy or muscle tears are but a few examples of the potential applications of this technology in the field of orthopaedic sports medicine. In the present article, some of the most important therapeutic applications using these approaches - especially preparation rich in growth factor (PRGF) technology – are presented, as are some of the limitations, anti-doping concerns and future challenges in the field. In view of a general state of confusion, the concept of platelet-rich plasma needs rigorous definition associated with well characterized products and re-administration procedures. There is evidence that reconstruction of anterior cruciate ligament and tendon surgery combined with PRGF enhances healing and functional recovery; clinical evidence is also appearing in the literature regarding treatment of tendinopathies and osteoarthritis. Currently, the challenge lies in conducting randomized, controlled clinical trials to determine the essential qualities of these technologies. If anti-doping agencies clarify their regulatory guidelines, robust studies in athletes are expected to emerge. Although much research work lies ahead, the current knowledge points to a future in which platelet-rich therapies will continue improving existing conventional approaches to treatment of sports injuries [09181].

In Europe and the United States, there is an increasing prevalence of the use of autologous blood products to facilitate healing in a variety of applications. Recently, it has been learned more about specific growth factors, which play a crucial role in the healing process. With that knowledge there is abundant enthusiasm in the application of concentrated platelets, which release a supra-maximal quantity of these growth factors to stimulate recovery in non-healing injuries. For 20 years, the application of autologous PRP has been safely used and documented in many fields including; orthopedics, sports medicine, dentistry, ENT, neurosurgery, ophthalmology, urology, wound healing, cosmetic, cardiothoracic, and maxillofacial surgery. One article introduces the reader to PRP therapy and reviews the current literature on this emerging treatment modality. In summary, PRP provides a promising alternative to surgery by promoting safe and natural healing. However, there are few controlled trials, and mostly anecdotal or case reports. Additionally the sample sizes are frequently small, limiting the generalization of the findings. Recently, there is emerging literature on the beneficial effects of PRP for chronic non-healing tendon injuries including lateral epicondylitis and plantar fasciitis and cartilage degeneration [09182].

Circulation-derived cells play a crucial role in the healing processes of tissue. In early phases of tendon healing processes, circulation-derived cells temporarily exist in the wounded area to initiate the healing process and decrease in number with time. It was assumed that a delay of time-dependent decrease in circulation-derived cells could improve the healing of tendons. In one study, it was injected platelet-rich plasma (PRP) containing various kinds of growth factors into the wounded area of the patellar tendon, and compared the effects on activation of circulation-derived cells and enhancement of tendon healing with a control group (no PRP injection). To follow the circulation-derived cells, we used a green fluorescent protein (GFP) chimeric rat expressing GFP in the circulating cells and bone marrow cells. In the PRP group, the numbers of GFP-positive cells and heat-shock protein (HSP47; collagen-specific molecular chaperone)-positive cells were significantly higher than in the control group at 3 and 7 days after injury. At the same time, the immunoreactivity for types I and III collagen
was higher in the PRP group than in the control group at early phase of tendon healing. These findings suggest that locally injected PRP is useful as an activator of circulation-derived cells for enhancement of the initial tendon healing process [09183].

Mechanical stimulation improves the repair of ruptured tendons. Injection of a platelet concentrate (platelet-rich plasma, PRP) can also improve repair in several animal models. In a rat Achilles tendon transection model, 1 postoperative injection resulted in increased strength after 4 weeks. Considering the short half-lives of factors released by platelets, this very late effect calls for an explanation. It was studied the effects of platelets on Achilles tendon regenerates in rats 3, 5 and 14 days after transection. The tendons were either unloaded by Botulinum toxin A (Botox) injections into the calf muscles, or mechanically stimulated in activity cages. No Botox injections and ordinary cages, respectively, served as controls. Repair was evaluated by tensile testing. At 14 days, unloading (with Botox) abolished any effect of the platelets and reduced the mechanical properties of the repair tissue to less than half of normal. Thus, some mechanical stimulation is a prerequisite for the effect of platelets at 14 days. Without Botox, both activity and platelets increased repair independently of each other. However, at 3 and 5 days, platelets improved the mechanical properties in Botox-treated rats. Platelets influence only the early phases of regeneration, but this allows mechanical stimulation to start driving neo-tendon development at an earlier time point, which kept it constantly ahead of the controls [09184].

It was described the therapeutic utilization of separated and isolated autologous growth factors in semiconservative treatment of type III injury to the ankle ligamentous complex. Eleven patients, two women and nine men, with acute injury to the lateral ligamentous complex of the ankle were treated by plasma rich in growth factors (PRGF) infiltration. The injured patients were clinically examined and standard forced inversion radiographs were made using topical anesthesia. Autologous PRGF activated with calcium chloride was used to infiltrate the injured tissues. The treatment was followed by immobilization of the joint and its subsequent rehabilitation. Clinical examination of injured tissues was carried out at 4 and 6 weeks of follow-up, using stability assessment tests and functional radiography of the ankle. Physical therapy included standard procedures, but faster regeneration of the soft tissues allowed for more exercises. The average time of healing was 5 weeks. Five patients showed no signs of instability at 4 weeks after therapy and could return to their previous sports activities. One patient had lateral ankle instability at 5 weeks and therefore the therapy continued with prolonged immobilization and then rehabilitation at a slower pace. According to the authors presence of growth factors facilitates the healing and remodeling of soft tissues and regeneration may begin before leukocytes infiltrate the affected site. At a relatively low level of interleukins, the inflammatory phase of healing is suppressed, pain is reduced and the process of reparation and regeneration is accelerated [08291].

Tendon and muscle injuries are common in elite and weekend athletes. Treatment of these injuries in both groups is rapidly evolving. In this context, platelet-rich plasma (PRP) has emerged as a potential solution. PRP is a fraction of whole blood containing concentrated growth factors and proteins. These cytokines direct tissue healing through autocrine and paracrine effects. The number of basic science, animal, and human investigations of PRP for tendon and muscle injuries worldwide has risen sharply in recent years. These studies are helping clinicians better understand the mechanisms of PRP and are guiding novel treatment protocols. In one paper, the value of PRP as a treatment for acute or chronic tendon and muscle disorders is Explorer [08292].

In recent years there have been rapid developments in the use of growth factors for accelerated healing of injury. Growth factors have been used in maxillo-facial and plastic surgery with success and the technology is now being developed for orthopaedics and sports
medicine applications. Growth factors mediate the biological processes necessary for repair of soft tissues such as muscle, tendon and ligament following acute traumatic or overuse injury, and animal studies have demonstrated clear benefits in terms of accelerated healing. There are various ways of delivering higher doses of growth factors to injured tissue, but each has in common a reliance on release of growth factors from blood platelets. Platelets contain growth factors in their alpha-granules (insulin-like growth factor-1, basic fibroblast growth factor, platelet-derived growth factor, epidermal growth factor, vascular endothelial growth factor, transforming growth factor-beta) and these are released upon injection at the site of an injury. Three commonly utilised techniques are known as platelet-rich plasma, autologous blood injections and autologous conditioned serum. Each of these techniques has been studied clinically in humans to a very limited degree so far, but results are promising in terms of earlier return to play following muscle and particularly tendon injury.

The use of growth factors in sports medicine is restricted under the terms of the World Anti-Doping Agency (WADA) anti-doping code, particularly because of concerns regarding the insulin-like growth factor-1 content of such preparations, and the potential for abuse as performance-enhancing agents. The basic science and clinical trials related to the technology are reviewed, and the use of such agents in relation to the WADA code is discussed [09185].

PRGF (plasma rich in growth factors) had been introduced with much basic and some clinical research for maxillofacial surgery by Dr Eduardo Anitua in Vitoria, Spain. After first having published impressive results from his own research field, his group followed up with the first studies in sports medicine as well. In 2007, Peter AM Everts from Eindhoven in The Netherlands defended his impressive thesis on “Autologous platelet-leucocyte enriched gel. Basics and efficacy,” where he used the system to support soft tissue and bone healing. Finally, a method that will accelerate the healing of muscle, tendon, bone and cartilage injuries, shorten the rehabilitation time after musculoskeletal injuries and rejuvenate sleeping cells? is it not perfect? Well, it seems that even though more is better, much more may not be so good, at least not in every term of the word. The issues of preparation procedure, with or without leucocytes, volume of autologous blood, the concentration of growth factors, method of delivery, dose and frequency, the effect of local anaesthesia and anti-inflammatory medication are all unresolved issues. Even more importantly, the risks of side effects have not been fully elucidated, even though it all looks good at this stage. To discuss the use of PRP in a clinical setting, and the need for further research, the International Olympic Committee (IOC) assembled an expert group in May 2010 to critically review the current state of PRP treatment among athletes, aiming to provide recommendations for clinicians, athletes and individual sports governing bodies. The purpose of this consensus paper was furthermore to review the evidence for the clinical effectiveness of PRP, its ergogenic potential and safety, and attempt to reconcile any possible disparity between its increasing popularity and the underlying science supporting its use. Firm recommendations on the effectiveness of PRP in the clinical setting to support the healing processes of muscle, tendon, ligament and cartilage injuries cannot be given. Results of clinical studies on PRP are difficult to interpret, as the methodological quality of published investigations varied substantially. More attention should be paid to the use of solid methods when designing, performing and reporting clinical trials. The final recommendation of the IOC consensus group is to proceed with caution in the use of PRP in clinical practice of sports medicine. The group believes that more work on the basic science needs to be undertaken and that greater rigour should be implemented in developing robust clinical trials to demonstrate the efficacy of PRP [10474].

In 2008, the International Olympic Committee (IOC) published a consensus document on the importance of molecular mechanisms in connective tissue and skeletal muscle injury and healing. This document predicted an increase in the use of autologous growth factors, as it
has indeed happened following that publication. Platelet-rich plasma (PRP) (also referred to as platelet-rich in growth factors, platelet-rich fibrin matrix, platelet-rich fibrin, fibrin sealant, platelet concentrate) is now being widely used to treat musculoskeletal injuries in sports and draws widespread media attention despite the absence of robust clinical studies to support its use. Of the few studies on the effectiveness of PRP in clinical settings published, very few are of sufficient methodological quality that would enable evidence-based decision-making. PRP and its variant forms were originally used in clinical practice as an adjunct to surgery to assist in the healing of various tissues. PRP in an injectable form has been used for the management of common muscle, tendon and cartilage injuries. Currently, PRP is not considered as a drug or a therapeutic substance, and so it does not have the usual regulatory requirements that would generally be needed for a substance used in regular clinical practice [10432].

In broad terms, PRP may be defined as a volume of the plasma fraction of autologous blood having a platelet concentration above baseline, and is therefore a concentrated source of autologous platelets. Platelets contain a number of growth factors that play an important role in the healing of injured tissue. PRP is prepared from a volume of autologous blood using extracorporeal blood processing techniques such as blood cell savers/separators, table-top devices (centrifuges) and filtration methods. This volume may contain variable concentrations of red and white cells depending on the specific preparation technique that is used. Not only can PRP be prepared in a variety of methods, but it can be administered in various forms; this diversity is reflected by the number of terms used to describe the product. These variations will inevitably influence the composition and potential effectiveness of the biologically active material. Allogenic fibrin glue was originally described in 1970, and is formed by polymerising fibrinogen with thrombin and calcium. The first reference in the scientific literature to the use of PRP in clinical practice dates back to 1987, when PRP was used as an autologous transfusion component after open heart surgery to prevent the need for a homologous blood product transfusion. In 1990, an autologous fibrin gel (fibrin sealant or fibrin glue) was introduced; a biomaterial with haemostatic and adhesive properties. In 1999, the first autologous PRP prepared from a small quantity of blood was described. Despite limited scientific support, musculoskeletal practitioners began using PRP for the management of cartilage problems as early as 2003. The use of PRP in many fields of medical practice has recently expanded rapidly, with many articles being published. This results in part from its relative ease of use, relatively low cost and a strong commercial industry investment, with the yet unsubstantiated promise that it may prove to be highly effective. In particular, in athletes with sporting injuries, especially in elite athletes where there is a relative urgency to facilitate a rapid return to competition, the use of PRP has expanded rapidly [10432].

Platelets are cytoplasmic fragments of megakaryocytes that are formed in the bone marrow. They are the smallest of the blood components, with an irregular shape and a diameter of 2-3 µm. They lack nuclei, but contain organelles and structures such as mitochondria, microtubules and three forms of granules (alpha, beta and gamma). The alpha-granules, bound by a membrane, are formed during megakaryocytes maturation and are about 200 to 500 nm in diameter. There are approximately 50 to 80 granules per formed platelet. They contain more than 30 bioactive proteins, many of which play a role in haemostasis or tissue healing. However, the entire and exact function of these proteins remains to be elucidated. These proteins are accumulated in alpha granules, and platelets contain distinct subpopulations of α granules that undergo differential release during activation, a potentially important point in understanding how PRP is activated and acts. Platelets contain, synthesise and release large amounts of biologically active proteins that promote tissue regeneration. Researchers have identified more than 1100 types of proteins inside platelets or on their surface. The most commonly studied platelet proteins include platelet-derived
growth factor (PDGF), transforming growth factor (TGF-β), platelet-derived epidermal growth factor (PDEGF), vascular endothelial growth factor (VEGF), insulin-like growth factor 1 (IGF-1), fibroblastic growth factor (FGF), epidermal growth factor (EGF) and cytokines including proteins such as platelet factor 4 (PF4) and CD40L [10432].

The basic premise of PRP use in clinical practice is to facilitate the application of autologous plasma and platelet-derived proteins, in addition to developing at the desired location a fibrin scaffold that can act as a temporary matrix for cell growth and differentiation to assist repair in the injured tissue. PRP can be prepared in a laboratory, an operating theatre or an appropriate room in the outpatient clinic from blood collected in the immediate pretherapeutic period. A sterile technique is followed when blood withdrawing, preparing and applying PRP. PRP can be applied percutaneously or during an open surgical procedure as fluid injections, gel or releasate serum, or mixed with other biological active materials such as bone and ligament grafts. During open procedures, PRP is activated to form a gelatinous mass to facilitate ease of application. During closed procedures, more applicable to sporting injuries such as soft tissue muscle and tendon injuries, PRP is injected by a syringe in a fluid form. It is recommended that the injections are administered under ultrasound guidance, thus ensuring the exact location of the product placements. Platelets begin to actively secrete these proteins within 10 min of clotting, and more than 95 percent of the presynthesised growth factors are secreted within 1 h. After the initial burst of growth factors, the platelets synthesise and secrete additional growth factors for the remaining several days of their life span. When using anticoagulated PRP, activation is critical, as clotting results in the release of growth factors from the α-granules (degranulation) of the platelets. PRP may be activated immediately before application. Alternatively, activation can occur in vivo, that is, with or after the injection in the tissue of interest. There is no consensus on the timing of PRP activation, or even whether activation is necessary at all. Furthermore, there is currently no consensus on whether the PRP is better activated in vitro and placed in vivo, or whether we allow the local environment (in vivo) to activate. In vitro, the application of PRP enhances gene expression of the extracellular matrix proteins, collagen production and tenocyte proliferation. Studies demonstrated the mitogenic activity of PRP, and also that stimulated tenocytes synthesise important growth factors such as VEGF and HGF, suggesting a beneficial effect for the management of tendon injuries by inducing cell proliferation and promoting the synthesis of angiogenic factors during the healing process [10432].

In addition to healing ability, PRP may also contain antibacterial effects that could demonstrate clinical benefits. PRP or platelet-leucocyte rich plasma prepared by two-step centrifugation of whole blood contains high concentrations of platelets and leucocytes. Both platelets and leucocytes play an important role in antimicrobial defence by performing opsonophagocytosis, chemotaxis and oxidative microbialic activity. Furthermore, platelets and leucocytes can release a variety of small cationic peptides (antibacterial peptides) that, upon contact with pathogens, exert bactericidal activity via a non-oxidative mechanism. Another potential advantage is that in vitro and in vivo data have shown that these peptides possess potent microbicidal activities with minor cytotoxicity for relevant mammalian cells. Thus, PRP may act in cooperation with the host immune defence system to defend invasion of pathogens. There are no published applications of the antibacterial effect of PRP in sports medicine. The antibacterial effects of PRP are transient, lasting for only 2-6 h. In summary, the antimicrobial effect of PRP and its use in clinical practice is, as its role in healing and repairing cells and tissue, yet to be fully elucidated. However, there could be a future use for PRP in both the prophylaxis of infection, in particular for surgical wounds, and as adjuvant to normal treatment regimes [10432].

Muscle strain and contusion injuries are common in sports, and result in time loss from training and competition. In many sports, particularly the football codes, muscle injuries are
the single largest cause of time loss from injury. Historically, the management of muscle injuries has involved the use of various stretching and strengthening regimes underpinned by a graduated return to activity and subsequent return to sporting competition. These management strategies lack sound scientific support. The rapid return to functional activity and minimisation of recurrence is the goal of any management intervention. In the past, there has been little direct intervention. However, to facilitate an earlier return to sporting competition and with less risk of injury recurrence, invasive techniques using various substances are currently being considered for use. These include traumeel (a homeopathic anti-inflammatory), actovegin (protein-free extract obtained from filtered calf blood), growth factors such as IGF-1 and PRP. None of these proposed interventions, however, have any evidence base for their use in the treatment of muscle injuries. While the use of recombinant growth factors for muscle injuries has a strong theoretical and scientific basis, cost, side effects and prohibition by World Anti-Doping Agency (WADA) contraindicate their use in athletes. While acknowledging that the mode of delivery of growth factors (bolus vs sustained release) may impact significantly upon the clinical outcome in injured muscle tissue, the recognised physiological benefits of recombinant growth factors include the enhancement of muscle regeneration and minimisation of scarring. By contrast, while anecdotally being widely used in elite sport, the use of PRP for acute muscle injuries has little scientific support with very few studies in either animals or athletes. While not strictly PRP, one study investigated the potential of autologous growth factors to enhance recovery from muscle strain injury using autologous conditioned serum (ACS). By injecting 5 ml of autologous ACS, they compared the return to play time of 18 professional athletes with muscle strain injuries treated with ACS, with 11 athletes treated with traumeel and actovegin. While the authors report a significant reduction in return to play time for the treated group (16 vs 22 days), the large number of methodological concerns, including choice of control, lack of randomisation, lack of blinding and potential bias of the MRI, limits its interpretation. In summary, at present there is little scientific support for the use of PRP for the management of muscle strain injuries. This provides challenges for clinicians hoping to utilise this technology to treat this common sporting injury. Optimal timing, dose, volume, frequency, content and postinjection rehabilitation techniques require future clarification in order to provide any coherent guidelines, and future research should address these areas. However, as basic science supports the use of specific growth factors in muscle regeneration with minimisation of muscle scarring, further investigation of the utility of PRP injection is warranted.

Despite the morbidity associated with tendon problems in athletes and an abundance of therapeutic options, management is far from scientifically based, and many of the therapeutic options in common use lack scientific support. Although tendon biopsies show an absence of inflammatory cell infiltration, anti-inflammatory agents (non-steroidal anti-inflammatory drugs and corticosteroids) are commonly used, but their efficacy and effectiveness are dubious. In most instances, the rate of success using anti-inflammatory agents, defined as an improvement of symptoms and return to sport, is in the region of 65 percent, and the time to return to sport ranges from several weeks to several months. PRP is one treatment that is considered option for management of chronic tendon injuries in athletes, with a positive effect of PRP on tendon healing having been established in several animal studies. In one of these studies, PRP was percutaneously injected into the transected rat achilles tendon. This increased tendon callus strength and stiffness by about 30 percent after 1 week, and mechanical testing indicated an improvement in maturation of the tendon callus when compared with controls. Another study showed that locally injected PRP in the rat patella tendon increased the activation of circulation-derived cells and the immunoreactivity for types I and III collagen at the early stages of tendon healing. Finally, the osteoinductive effect of PRP on tendon-to-bone healing was evaluated on a sheep infraspinatus repair model using MRI scan and histology. This study demonstrated an increased formation of new bone and fibrocartilage at the healing site. In summary, there is a lack of well-designed studies to
support the use of PRP in clinical settings in the management of tendon injuries. More research on basic science and the clinical application of PRP needs to be undertaken before there is any comprehensive recommendation for PRP administration in injured human tendons. For each individual athlete and circumstance, a risk/benefit analysis should be performed before embarking on this as yet scientifically unproven therapeutic modality [10432].

Based on long-term clinical experience and thousands of patients being treated, the use of PRP is safe. In musculoskeletal tissues, although no long-term clinical studies with PRP exist, a large number of patients have been treated worldwide. Recently, Wang-Saugusa et al reported that no adverse effects were observed when plasma rich in growth factors was infiltrated in more than 800 patients, many of whom suffered from knee osteoarthritis. As, theoretically, PRP is an autologous preparation, immunogenic reactions or disease transmission should be prevented. However, development of antibodies against clotting factors V and IX leading to life-threatening coagulopathies has been reported. To date, there is no compelling evidence of any systemic effect of local PRP injection. Furthermore, there are no scientific reports suggesting potential cause–effect relationships between growth factors present in PRP and carcinogenesis. Some potential arguments for these considerations include the limited need of PRP injections in clinics (as PRP is not chronically administered) and the short in vivo half-lives and local bioavailability of growth factors produced by PRP [10432].

In 2010, PRP was specifically mentioned in the prohibited list for the first time. Intramuscular PRP injections were prohibited. All other routes of administration, such as intra-articular, intra- or peritendinous were permitted and required only a declaration of use. Note that specific purified or recombinant growth factors (eg, IGF-1, VEGF, PDGF) are explicitly prohibited elsewhere in the list. Growth factors are permitted only when part of platelet-derived preparations from the centrifugation of autologous whole blood. There was concern by the WADA List Expert Group that growth factors contained in PRP may stimulate muscle satellite cells and increase muscular size and strength (beyond normal healing). However, the different PRP formulations and treatment methodologies, as they exist now, have not been found to increase muscle growth beyond return to a normal physiological state. There are some animal studies that show faster muscle regeneration and recovery to full function following experimentally induced injury, but no enhancement of performance beyond normal. There is a suggestion, but no compelling evidence, of systemic effects. The risk of adverse reactions (fibrosis, infection, carcinogenesis) are theoretical and have not been documented clinically. The use of PRP injections for therapeutic purposes only does not violate the spirit of sport. The prohibition for intramuscular injections of PRP has been deleted in the 2011 Prohibited List. PRP is now permitted by all routes of administration [10432].

There is a limited amount of basic science research on the influence of PRP on the inflammation and repair of connective tissue and skeletal muscle. There is an even greater paucity of well-conducted clinical studies on the use of PRP to manage sport injuries. For clinicians, the generalisability of basic science must be tempered by clinical studies that inherently contain factors controlled for in basic science experiments. For these reasons, the design of robust clinical studies is essential for conclusions to be assigned sufficient validity to be used in clinical practice. Although PRP has been in clinical use for decades, some basic science issues still require further investigation. Several techniques are available to prepare PRP; however, there is no evidence of standardisation of preparation (in terms, for example, of length and speed of centrifugation) and use of PRP. In addition, different methods of preparation may produce different platelet concentrations such as storing the PRP for differing lengths of time before use, using different anticoagulants and variable degrees of other cells such as red and white cells in the PRP preparation. It is therefore
possible that each preparation method may lead to a different product with different biology and potential uses. As stated, all these variables may produce PRPs in which the amount and type of growth factors are different. Therefore, a classification system for different PRPs should be developed and should be used to define the PRPs used by different research and treatment groups. For clinical applications, based on different clinical conditions, the best time to inject PRP must be determined according to the different tissues and body districts. The kinetics of cytokine release from various PRPs with/without other biomaterials needs further investigation, as this may ultimately determine the best time for injection for a given PRP formulation. Furthermore, the tissue-specific effects of PRP should be compared, as the underlying cellular and molecular processes for a particular tissue healing may be markedly quite different. For instance, muscle and bone healing need vascularisation. However, a high degree of vascularisation may not be required for tendon and articular cartilage injuries. In fact, it is plausible that the effect of PRP on a given tissue is influenced by the microenvironment within that tissue, and therefore PRP activation may not be required prior its use. Lastly, the optimal use of PRP for regenerative medicine is still under investigation. Although application of the PRP may enhance mesenchymal stem cell proliferation and migration, exposure of cells to PRP may also limit differentiation of those cells into the appropriate cell lineages. The question arises in this consensus statement as to whether clinicians should use a treatment with very little scientific evidence supporting its clinical efficacy and with limited evidence supporting its safety. Medical ethics is anchored by the concepts of beneficence (doing good) and non-maleficence (do no harm). Medical ethics includes the concept of patient autonomy (self-determination). Western medicine tends to hold to the principle that patients can determine their treatment themselves, even if beneficence or non-maleficence is not proved. For the doctor, non-maleficence is the principal determinant of medical practice. While limited, current evidence suggests the use of PRP to be safe, and therefore the non-maleficence principal is probably upheld; however, there are few if any studies that document adverse or serious adverse events, and there are no studies at all looking at long-term effects. As there is little scientific evidence that PRP injections are of clinical benefit, beneficence is at this time not proven. Current medical ethics generally allows clinicians to make an individual choice to prescribe treatments that have not shown beneficence as long as the treatment is non-maleficient. With respect to PRP, its increasing popularity appears to have outreached in some respects the principle of medical ethics and the usual conservatism that new treatments are taken up by the clinicians. Part of the answer to this would be that PRP is presently marketed and widely perceived as a natural healing method with the implications of minimal maleficence [10432].

Platelet-rich plasma (PRP) is a new technology focused on enhancing the healing response after injury of different tissue types. PRP is prepared by withdrawal of patients’ peripheral blood and centrifugation to obtain a highly concentrated sample of platelets, which undergo degranulation to release growth factors with healing properties. It also contains plasma, cytokines, thrombin, and other growth factors that are implicated in wound healing and have inherent biological and adhesive properties. The prepared concentrate is then injected back into the patient at the site of morbidity. This may be intrasional, intra-articular, or surrounding the involved tissue bed. PRP preparations have been used therapeutically in various medical fields from implantology to vascular ulcers, with a more recent evolution and promising results in the field of sports medicine and arthroscopy. Sports medicine patients desire a rapid return to their preinjury level of function, and PRP may have certain applications that will speed recovery in cases of tendon, ligament, muscle, and cartilage disorders. In particular, anterior cruciate ligament reconstruction has shown better autograft maturation, improved donor site morbidity, and pain control, in addition to improved allograft incorporation. By acceleration of the biological integration of the graft by use of PRP, patients may undergo faster, more intensive rehabilitation programs and return to sports more rapidly. Because of its autogenous origin, easy preparation, and excellent safety profile, the advent
of PRP has opened another therapeutic door for sports medicine physicians and orthopaedic surgeons. Future directions of PRP include improving the results of arthroscopic and related surgery, in addition to delineating correct dosage, timing, and quantification, as well as ideal techniques of PRP application [10131].

Autologous platelet-rich plasma (PRP) is perceived to accelerate healing in musculoskeletal injuries. PRP is increasingly used in situations that require rapid return-to-play, which, in the professional sports arena, translates to fame and money. Human blood platelet counts are approximately 200 000/ml. PRP is an autologous concentration of human platelets above this in a small volume of plasma. Reports vary regarding the platelet concentration and different growth factors present in the PRP concentrate. Also, there are many preparation protocols, kits, centrifuges and methods to trigger platelet activation before use. The same is true for application methods, including using injectable activated PRP liquid concentrate versus implanting a fibrin scaffold, optimal timing of injection and the specific volume to use. Almost every major manufacturer in the orthopaedic and sports medicine world markets a different commercial kit. Some claim to produce a better quantity and quality of PRP than their competitors from the same amount of blood from the same patient. Each method to concentrate platelets leads to a different product with different biology and potential uses, with a high variation (3 to 27-fold) in growth factor concentration and in the kinetics of release. Most techniques yield a PRP concentrate of approximately 10 percent of the blood volume taken (e.g. 20 ml of whole blood would result in approximately 2 ml of PRP). These differences might be of relevance to clinical management, although they have not been systematically studied. PRP preparations containing only moderately elevated platelet concentrations may be the ones to induce optimal biological benefit, with lower platelet concentrations leading to suboptimal effects, and higher platelet concentrations to inhibitory effects. Other authors have stated that the “therapeutic dose” of PRP would be at least four to six times higher than the normal platelet count. To complicate things, the actual growth factor content is not well correlated with the platelet count in whole blood or in PRP, and there is no evidence that gender or age affects platelet count or growth factor concentrations. A few studies have categorised the different platelet concentrates according to the presence or absence of white blood cells (WBC): either pure platelet-rich plasma (P-PRP), in which WBC have been intentionally eliminated from the PRP, or leucocyte and platelet-rich plasma (L-PRP), possibly from the inability of the kit to differentiate between the WBC and the PRP layers. A positive or negative effect of WBC cannot be generalised to all tissues and clinical conditions. This issue requires further investigation, as the WBC content in the preparation injected has never been systematically studied. There is no direct evidence that neutrophils play a beneficial role in muscle repair or regeneration. This exacerbation of injury and/or delay in muscle regeneration may be of major importance for injuries managed with PRP. This, together with the improved homogeneity of P-PRP and its reduced donor-to-donor variability, supports some PRP production techniques that claim to be clinically superior. L-PRP injected for soft tissue injuries might induce more local pain than P-PRP. Platelets by themselves do reduce pain. L-PRP reduces postoperative pain, although here the contribution of the WBC to the overall effect observed remains unclear. Over this background, the sceptics point out that, given the well concerted healing cascade that has evolved over millions of years, it is not easy to understand how a single or even a few injections of a cocktail of growth factors at variable, and at present not well codified, times from the injury will produce a lasting beneficial effect on a wide variety of conditions [10132].

One article aimed to provide a comprehensive review of the current literature that pertains to the therapeutic use of autologous platelet-rich plasma (PRP). The basic science literature regarding the role of growth factors in mediating the healing process and the laboratory data from in vitro and in vivo studies that evaluated PRP are reviewed. Subsequently, the current evidence regarding PRP efficacy from animal models, human surgical studies, and human
Clinical studies are presented. A critical analysis of the literature follows, and the article concludes with the authors' perspectives on the state of PRP as a potentially efficacious bioregenerative treatment option for musculoskeletal and sports medicine applications. The relevant articles in this review were obtained via PubMed literature searches for PRP publications that pertain to musculoskeletal and sports medicine conditions. This article is not intended to be a formal meta-analysis [11151].

Growth factor technologies are increasingly used to enhance healing in musculoskeletal injuries, particularly in sports medicine. Two such products; platelet-rich plasma (PRP) and autologous blood, have a growing body of supporting evidence. No previous trial has directly compared the efficacy of these two methods. Growth factor administration improves tissue regeneration in patients who have failed to respond to conservative therapy. Study design A prospective, double-blind, randomised trial. Elbow tendinopathy patients who had failed conservative physical therapy were divided into two patient groups: PRP injection (N=80) and autologous blood injection (ABI) (n=70). Each patient received two injections at 0 and 1 month. Patient-related tennis elbow evaluation (PRTEE) was recorded by a blinded investigator at 0, 1, 3 and 6 months. The main outcome measure was PRTEE, a validated composite outcome for pain, activities of daily living and physical function, utilising a 0-100 scale. At 6 months the authors observed a 66 percent success rate in the PRP group versus 72 percent in the ABI group. There was a higher rate of conversion to surgery in the ABI group (20 %) versus the PRP group (10 %). In patients who are resistant to first-line physical therapy such as eccentric loading, ABI or PRP injections are useful second-line therapies to improve clinical outcomes. In one study, up to seven out of 10 additional patients in this difficult to treat cohort benefit from a surgery-sparing intervention [11152].

To review the evidence for the clinical utilization of autologous plasma products in the management of muscle strain injuries a systematic review using EMBASE and MEDLINE (up to March 2010) was done. There is no level 1, 2, and 3 evidence for the use of autologous plasma products in muscle strain injuries. Furthermore, significant methodological limitations impact on the interpretation of the few published studies in this field. Therefore it can be concluded that although basic science and the use of recombinant growth factors in animal models support the concept of applying growth factors to acute muscle injuries, it is unclear if this evidence can be directly translated to reflect outcomes from platelet-enriched plasma. There remain a large number of unanswered questions, including the principle questions regarding safety and efficacy, which require appropriate scientific investigation. It is incumbent on sports physicians wishing to enhance athlete care, together with researchers, to search for these answers [11153].

Platelet-rich plasma (PRP) is an autologous blood-derived product with an increased concentration of platelets in plasma, which are used to deliver supraphysiological levels of growth factors. Platelet-rich plasma has been used in many fields, including oral, maxillofacial, and plastic surgery. Its use in sports medicine has been increasing after recent evidence and media publicity suggest that it may augment the treatment of muscle strains, as well as tendon and ligament healing. Basic science and animal studies show promising results, but high-level clinical trials have yet to prove its efficacy. With increasing media coverage on the use of PRP in athletes, it is paramount that orthopedic surgeons and sports medicine physicians understand the various methods of preparation and administration, potential clinical applications, and available clinical results to best counsel patients on its advantages and disadvantages [11154].

At present, no drugs are available to hasten restoration of muscle function after injury. Platelet-rich plasma (PRP) therapies may help athletes by promoting muscle regeneration. A systematic review assessing the evidence base for PRP therapies in the management of
muscle injuries was based on a computerized literature search, citation tracking and hand searching for original studies assessing the effect of PRP therapies on skeletal muscle cell biology, skeletal muscle repair, or regeneration in animals or humans was performed. No randomized trials have studied the merits of PRP injections for muscle healing. Clinical studies indicated that PRP therapies may enhance muscle repair after strain or contusion, and laboratory data indicated that they can enhance diverse aspects of myogenesis. However muscle injuries present a complicated picture that includes many components other than muscle cells, such as blood vessels, connective tissue and neural components. The field is relevant but under-researched. No PRP formulation has yet displayed proven solid evidence for the stimulation of healing and recovery after sports muscle injuries. Therefore, major issues, including standardization of formulations and application procedures, need to be addressed to inform clinical studies before recommending best practice guidelines [11155]. Platelet-rich plasma (PRP) has been increasingly used in sports medicine applications. Platelets are thought to release growth factors important in wound healing, including transforming growth factor (TGF-beta1), platelet-derived growth factor (PDGF-AB), and vascular endothelial growth factor (VEGF). However, little is known about the effect of platelet activator choice on growth factor release kinetics. Platelet-rich plasma aliquots were activated with either thrombin or collagen. A control group of whole blood aliquots was clotted with thrombin. Supernatant containing the released growth factors was collected daily for 1 week. Levels of TGF-beta1, PDGF-AB, and VEGF were measured using enzyme-linked immunosorbent assay (ELISA). The use of thrombin as an activator resulted in immediate release of TGF-beta1 and PDGF-AB, while the collagen-activated PRP clots released similar amounts each day for 5 days. The use of collagen as an activator resulted in an 80 percent greater cumulative release of TGF-beta1 from the PRP aliquots over 7 days. Concentrating platelets to 3 times the systemic blood level resulted in a 3-fold higher release of TGF-beta1, 2.5-fold greater release of PDGF, and 5-fold greater release of VEGF when compared with whole blood control clots, but no significant differences in the timing of release were noted. These experiments demonstrated that the choice of platelet activator can significantly influence the release kinetics of cytokines from PRP, with thrombin resulting in an immediate release and collagen having a more sustained release pattern. The level and rate of growth factor release depends on the selected platelet activator, a factor that should be considered when selecting a PRP system for a given application [11156]. Tissue repair in musculoskeletal lesions is often a slow and sometimes incomplete process. In sports patients or professional athletes, the impact of musculoskeletal lesions on life and work is great, and the fast recovery of full efficiency and return to competition is of primary importance. The clinical improvement offered by available treatments is not always sufficient for highly demanding patients to return to their previous level of activity. The search for a minimally invasive solution to improve the status of the chondral surface of the injured joint is therefore highly desirable, especially in these patients. Platelet-rich plasma (PRP) is a procedure that allows to obtain a natural concentration of autologous growth factors. The attractive possibility to use the patients’ own growth factors to enhance reparative process in tissues with low healing potential, the promising preliminary clinical findings and the safety of these methods, explain the wide application of this biological approach. The aim of one review is to analyse the existing published studies to look for scientific evidence in preclinical studies or in the results obtained through PRP application in humans that supports the efficacy of PRP and its use for the treatment of tendinous, ligamentous, cartilaginous and muscular injuries. The analysis of the literature shows promising preclinical results but contradictory clinical findings for the treatment of sport injuries. High-quality studies are required to confirm these preliminary results and provide scientific evidence to support its use [11157].
The International Olympic Committee consensus panel have produced a clear summary of
the current understanding of the basic and clinical science relating to platelet-rich plasma
(PRP) as the body of published literature allows. While there was initially great hope in sports
medicine circles that PRP would become the magic bullet for injuries, recent trials have failed
to provide the conclusive evidence so desired, which is not surprising. The more we learn
about tissue regeneration, the more apparent it becomes how complex a process it is. Tissue
regeneration is not a passive phenomenon, instead it is a highly coordinated interplay of
multiple cell lines at different stages of maturation. Different cellular and humoral
components play their different roles. The process can be likened to the repair of a
collapsed building. Consider muscle injury. The initial cells on the scene, due to bleeding, are
platelets, but they appear to be relatively passively involved – alarm bells that sequester and
awaken the major players. Platelets release chemotactic factors that attract neutrophils to
clear the debris. However, within 24 h macrophages arrive, akin to the foreman, and it is
these cells that appear to regulate the process from this point onwards. If there is any
“brains” or “thinking” to tissue repair, it would seem to be the macrophages doing it. Next
come the actual builders. Fibroblasts are activated to produce a collagen infrastructure,
and satellite cells to form myocytes and finally myotubes, merging to become a single strand of
muscle fibre. So where do “growth factors” come into it? These proteins are simply the
communications being sent between the foreman and his workers. The messages are very
simple – move or stay put, divide or do not divide, live or die, make collagen, etc. In biology
we use the terms chemotaxis, mitosis, quiescence, apoptosis and protein biosynthesis. The
point is this: growth factors are just the messenger molecules used by one cell to send an
instruction to another, they are not the person giving the orders. Unfortunately the language
of growth factors is very different to English. We are used, pretty much, to one word having
roughly one meaning. However, growth factor “words” are more like a tonal language,
Mandarin. In these languages the same word can have multiple different meanings
depending on how you pronounce it. In the same manner, growth factors can produce
varying effects depending on their concentration, time of release, point in cell cycle and
recipient cell. Therefore, trying to pin any one growth factor down to one particular action can
be pointless. For example transforming growth factor beta1 is commonly associated with
fibrosis, but it can also stimulate regeneration or fibrosis, chemoattraction or stasis,
depending on its concentration, target cell, and sequence within the tissue regeneration
process. This is where PRP has the potential to fall down. PRP has variable and inconsistent
content and concentration. There is no consensus on the timing of the injection. What does a
random bolus injection into an injury achieve? Are we sending these effector cells a clear
and coordinated set of instructions with PRP? Or are they being sent a completely confusing
message? It would seem hopelessly optimistic and naive to presume that we are accurately
reproducing biological complexity. Whether or not PRP is eventually proved or disproved in
sports injuries, it is nevertheless a good start. The sports medicine world has woken to the
possibilities of regenerative medicine, and is trying to be scientific in the development of
novel therapies. In the future we will have improved understanding of how the complex and
overlapping processes of tissue regeneration are controlled by coordinating cells, stem cells,
effector cells and the messenger molecules that they employ, and more importantly, how to
manipulate these processes for a beneficial effect [11158].

Full-thickness chondral defects and early osteoarthritis continue to present major challenges
for the patient and the orthopaedic surgeon as a result of the limited healing potential of
articular cartilage. The use of bioactive growth factors is under consideration as a potential
therapy to enhance healing of chondral injuries and modify the arthritic disease process. It
was reviewed the role of growth factors in articular cartilage repair and identified specific
growth factors and combinations of growth factors that have the capacity to improve cartilage
regeneration. Additionally, it was discussed the potential use of platelet-rich plasma,
autologous-conditioned serum, and bone marrow concentrate preparations as methods of combined growth factor delivery. A PubMed search was performed using key words cartilage or chondrocyte alone and in combination with growth factor. The search was open for original manuscripts and review papers and open for all dates. From these searches it was selected manuscripts investigating the effects of growth factors on extracellular matrix synthesis and excluded those investigating molecular mechanisms of action. By modulating the local microenvironment, the anabolic and anticatabolic effects of a variety of growth factors have demonstrated potential in both in vitro and animal studies of cartilage injury and repair. Members of the transforming growth factor-beta superfamily, fibroblast growth factor family, insulin-like growth factor-I, and platelet-derived growth factor have all been investigated as possible treatment augments in the management of chondral injuries and early arthritis. It was concluded that the application of growth factors in the treatment of local cartilage defects as well as osteoarthritis appears promising; however, further research is needed at both the basic science and clinical levels before routine application [11467].
