ENCYCLOPEDIA OF ANTI-DOPING

IN AN ERA OF EVIDENCED BASED MEDICINE

Scientific literature made available 2006 through 2013

Selected and edited by

Åke Andrén-Sandberg

From the Department of Surgery, Karolinska Institutet at Karolinska University Hospital, Huddinge, S-141 86 Stockholm, Sweden
EDITOR’S PREFACE (AND SEARCH ALGORITHM)

The scientific literature also in small medical fields like doping is today enormous – and it is not possible to keep updated unless making strong and focused efforts. The present review is an attempt to make it easier for those fighting doping to keep updated. From the beginning it was foremost an effort to make the reviewer updated, but hopefully it can be used also of others with the same interest, i.e. those who believe in fighting doping with the aim to eradicate it – or at least make doping so difficult that nobody can succeed with it. However, it should be emphazised that this compilation of data will still is a personal review, which means that the selection of presented articles have been up to the reviewer, and probable another author might have made at least some other choices.

The definition of “doping” has varied over the use, not least because it is difficult to combine what really is enhancing performance in sport from a theoretical point of view with what is practical – caffeine, children’s medicine when they have caught a cold, and alcohol are good example of this. Moreover, there is an ongoing evoluation all the time which gives new possibilities but also new problems, e.g. gene doping. Today the used definition of “doping” is very anti-intellectual: “What WADA put on the list of forbidden substances and methods is doping”. In this book the limitis is more generous, as not only the WADA lit is used as an inclusion criterium, but also not forbidden but often discussed substances and methods are covered. The biggest part of the discussed items is dietary supplements, but there are also other substances that might or might not be clasifie as doping substances. Unfortunately the borders of doping are ill defined – and with times it is even more difficult to define. This is why this book has defined anti-doping from the athlete point of view: the aim of this encyclopedia is to include what is discussed as performance enhancing substances and methods, irrespectively if they are working or not.

So, why bother to compile a lot of articles and tease serious individuals interested in sports and sports medicine to wast time on even a superficially look through these texts? The answer to that is that even if each abstract of an article can be rightly criticised the total body of abstracts tell a more important story. This body tells something on what the present issues are in the part of sports medicine that deals with doping, what it is worked with scientifically on these issues in today, and what the thoughts of the researchers were when they wrote their reports. It also tells something where the edge of our knowledge is situated presently, and from that we can better understand what we can expect in the nearest future. So, a recommendation may be to read each paragraph with considerable scepticism, but enjoy them all together as new bricks in our scientific wall and hopefully find that together with the next bricks we will have a chance of reaching the next – higher – level that is more easy to understand. It is all the knowledge together that counts much, much more than every single article.

Moreover, as interested in clinical anti-doping I am proud tog breg that I am interested in a field of medicine that can be included under the heading of evidence based medicine. The anti-dopers are not just beliving and guessing; we can base our recommendations on scientific facts!

There must be made some limitations, otherwise a review in this form should not be possible to write due to lack of time and lack of brain capacity, and probably not possible to read either. Regarding the limitations, first of all the writing here will be based on the abstracts of the articles in almost all cases for practical reasons. This is also in line with the aim of the review: not to report all what has been published, but rather to give an introdutional sample
that hopefully will make the reader eager to read the whole article or articles: this should be regarded as "a taste of anti-doping in the last years".

A second limitation is that most of the selections has been made through PubMed; a few other sources have also been scrutinized, but then more occasional and not systematically. The medical subheadings (MeSHs) always used are (but some more have been used occasionally):

Doping, testing, medical history, biological passports, inadvertent doping, mass spectrometry, liquid chromatography, gas chromatography, isoelectric focusing, anabolic androgenic substances, rhabdomyolysis, designer drugs, AICAR, testosterone, nandrolone, dehydroepiandrosterone (DHEA), stanozolol, boldenone, boldione, bolandiol, methyltestosterone, methyltestosterone, adrenosterone, androstenediol, androstenedione, hydroxyandrostenedione, trenbolone, metandienone, finasterid, norbolethone, phytoecdysteroids, designer steroids, aromatase inhibitors, exemestane, dehydrogenase inhibitor, selective androgen receptor modulator (SARM), estrogens, oral contraceptives, aromatase inhibitors, selective estrogen receptor modulator (SERM), toremiphene, raloxifene, anti-estrogens, tamoxifen, blood doping, red blood cells, total hemoglobin mass, reticulocytes, erythropoietin (EPO), darpoinet, NESP, epoetin delta, hematide, perfluorocarbon, hemoglobin-based oxygen carriers (HBOCs), hemopure, plasma volume expanders, dextran, hydroxyethyl starch, hydroxyethyl starch (HES), glucose solution, saline solution, Ringer lactate solution, albumin, plasma protein fraction, gelatins, alpha-keratose, pullulan, levan, acetyl starch, polyvinylpyrrolidone, glycerol, polyethylene glycol, platelet-rich plasma, growth hormone, insulin-like growth factor i (IGF-1), insulin, human chorionic gonadotropin, clomiphene, luteinizing hormone, mechanical growth factors, AGRP, caffeine, theobromine, ephedrine, pseudoephedrine, methylephedrine, modafinil, methylphenidate, amphetamine, methamphetamine, methylamphetamine (MDMA), mephentermine, metamfepramone, mmephradene, tuaminoheptane, mesocarb, sydnocarb, strychnine, belfluorex, sibutramine, beta2 adrenergic agonists, asthma in sports, exercise-induced bronchoconstriction (EIB), salbutamol, terbutaline, procaterol, clenbuterol, methoxyphenamine, beta-blockers, angiotensin converting enzyme (ACE) inhibitors, diuretics, thiazides, mannitol, epistestosterone, desmopressin, glucocorticosteroids, ACTH, sildenafil, morphine, cannabis, cocain, ecstasy, gamma-amino butyric acid (GABA), gamma-butyrolactone (GBL), gamma hydroxybutyrate (GHB), beta-hydroxy-beta-methylbutyrate (HMB), gamma-oryzanol and ferulic acid, alcohol, nicotine, non-steroidal anti-inflammatory drugs (NSAIDs), peroxisome proliferator-activated receptor, nutritional supplementation, dehydration, exercise-associated hyponatremia, bicarbonate, carbohydrates, mouth rinse, carbohydrate gel, milk, ribose, galactose, fructose, nergy beverages, sport drinks, Red bull, proteins, branched-chain amino acids (BCAA), arginine, ornithine, leucine, tryptophan, taurin, cystein, cystine, theanine, glutathione, glutamine, alanine, methionine, carnosine, citrulline, asparagines, spartame, glycine, alpha-ketoglutarate, alpha-ketoisocaproate, whey protein, fat, medium-chain triglycerides, fish oil, omega-3 fatty acid, calcium, copper, boron, chromium, zinc, magnesium, selenium, vitamins, N-Acetylcysteine, antioxidants, creatine, carnitine, melatonin, methylhexaneameine, luthiatione, lecithin, inoleic acid, gamma-linolenic acid, conjugated linoleic acid, leptin, inosine, glucosamine, dietary nitrates, methylsulphonylmethane, melamine, probiotics, green tea, ginseng, ginko, garlic, macroalgae, quercetin, Teribulus terrestris, Arnica, Rhodiola rosea, Cissus quadrangularis, Cordyceps sinensis, bee pollen, Actovigin, colostrum, gene doping, medical ethics

most often combined with Sport, Sports or Exercise.
This MeSHs will lead to a lack of some articles that might be of interest, e.g. in doping physiology, doping biology and social aspects of doping, but the border has to be set somewhere.

Yet another limitation is that this is a clinical oriented review and the term **human** has been used in the search algorithm. Therefore almost all "preclinical" articles have been neglected; i.e. molecular biology, cell lines studies and whole animal studies are not included except exceptionally (when the authors could not resist the temptation to review also them). This is not because the preclinical issues are not interesting, but because they are so numerous, and because it is much more difficult to evaluate the importance of them.

Note that one aim of this collection of articles has been to file them in a way that the editor and reader can find reports on the same issues close to one another. However, rather often an article may be classified under more than one heading. In these cases the editor has had to make a choise; if it was the best choise possible will be up the reader to judge.

Another "problem" is how to evaluate the quality of the reports. In the best of worlds the reports with highest quality should be given more space, and those with low quality should maybe just get a short note. However, this is an extremely difficult task and this book's editor has almost surrendered; there is almost no quality control, except for those that have an outstandingly poor quality – they have been omitted ruthlessness. However, most of the quality control has been left to the readers.

Why is then all the text on dietary supplements included? There are four reasons for this:

- they are so widely used in the same rings of athletes where doping substances are attempted
- they are not seldomly discussed as if they were part of doping
- most of them is worthless (but rather expensive)
- some of them can be of value in the right dose and right setting (and there is science behind)

When presenting quarterly reviews, annual reports and this encyclopedia I sometimes am criticized for just rewriting what others have just written. I can just agree with them; the only thing I have done is to gather what others have worked with nothing more, nothing less. The only thing I have contributed with is that I have made other's work more available and easier to compare with what others have done. Maybe it is not som much, but I am proud of what I have done.

I am sometimes also asked why it is included so much on dietary supplements, as many of them in without effect and "unscientific." The reason to include them is, however, easy: they are present out there among the athletes and are compared to the doping agents if the antidopers want it or not. Also, one must admit that the border between what is allowed and what is not is not always logic or semantically right. For example water, carbohydrates may be important for athletic performance in some cases, and if too much is given it might even be harmful, i.e. they might fulfill the criteria for doping agents. However, the most important reason to include them is to make them "less mysterious" – if there is any science on the dietary supplements it would be nice to spread that also to them who consider to use them. In most cases it will lead to a drain of money from the pocket of the athletes, in a few cases the dietary supplements will be harmful, and in most cases they are only irrelevant.

All of the text – including tables etc – has been written in Microsoft Words, as this is the most spread mode for communicating with computers. This means that all words and all tables can be search throughout the text; for example the references can most easily be looked for this way. This is also why some of the reference figures have 0 or 00 as the first figures. Also, there is a "Content in the book" but no pages. This is because it is ment to be a book on a computer, and if so different persons and computers make there formatation different.
Also, the book is growing every third month, which makes impractible to give pages, and then change them four times a year would be a waste of time. Please instead use the content-part for selecting the words for the “search” mode – that is how it was planned to be used.

Lastly, the language has not been checked by someone who is English spoken. Instead the text is written by a person who at his very best is speaking Swinglish. The written language could have been presented more properly by a real translater, but the cost for that luxury was too high. Accept therefore that there is a place also for “bad English” in science as long as it can be understood. Maybe some of the sentences or words make you smile a little, but remember than that my Swedish probably still is much better than your English …

This encyclopedia shall be looked upon as a “living” book. This means that it will continuously be added new articles to as they are published and get available – and I hope this can be continued for the foreseeable future. Then I re-edit it by putting articles in a place where they better fit, put in new subheading etc. the most difficult thing is then to compress the text and take away som of what is said twice, three times or more. I love every word, and cry a little bit inside when I have to omit a sentence here or there, just as if they were my friends. Despite that, the compression is in the end necessary and will be done. Gradually, but not without tears. However, the reference list will never have any references taken away, as the meaning of the encyclopedia is to direct the reader to the full articles.

There are chapters that are more difficult to handle regarding re-editing than others. The worst part is by far those that deal with laboratory techniques. The author have difficulties in understanding the issues and even more difficult to classify the different techniques. Also, the chapter on ethical question is difficult to handle, but for another reason: ethic has so little facts and som much of it needs a lot of words – unless you try to describe ethics in black and whit (which this reviewer refuses to do). So, for the moment you have to stand with these drawbacks, or help the reviewer to come up with something better.

This means that the plan is to follow up with quarterly reports during coming years (it is then the quarter when the review was made available through PubMed that counts, not the month it was actually published) and then to include the reports from each quarter in an annual report that is then taken into this encyclopedia – which then is gradually re-edited. This also means that there is probably always a later version by the author than that you have in your hand now. However, if you send me a mail I am happy to send you that latest (not the last) version.

Is this all that has been published on doing? No, certainly not, there is much more out there. However, what is gathered in this book is probably a good deal of what has been published as full articles (no abstracts included), and hopefully all that has been of real importance. If someone find more that should be included, please let me know. If we are of the some opinion I will of course include it as soon as possible.

It I probable that my reporting system can be presented better than what is done here is, but how this is done is not so easy for the author, who like the way he has done it. So, welcome with comments, criticism, or cheers – but if they fail to appear, the next quarters, the next annual report, and the encyclopedia will have the same dispositions as the present. This means that also you have a responsibility for the future!

Welcome to contact!

EDITOR’S PREFACE (AND SEARCH ALGORITHM)

ABBREVIATION

BACKGROUND FOR TODAY’S DOPING PROBLEMS
Definitions of doping
A background for understanding performance-enhancing drugs in sports
Judging cheaters in different domains

Overview
Little symptoms and signs
Socio-psychological background to doping
To move borders …
Much to win

Ergogenic potential of AAS
Testosterone/epitestosterone (T/E ratio)
Isotope ratio mass spectrometry (IRMS)
Synthetic androgens
Androgen bioassays
Indirect androgen doping
Estrogen blockers
Androgen precursors
Gonadotropins
Boosting in paraolympics
Possible lack of effects of doping
Cognitive doping
Brain stimulation techniques
What can be done with brain stimulation?
Can it be detected? What are the risks?
Ethical issues

Effect of international results during the anti-doping era
100 meter and 5000 meter
100 meter in Olympic Games

Is doping-free sport a Utopia?

DOPING AND ANTI-DOPING HISTORY
Overview
Specific dates
Early (modern) history
History of anabolic steroids
Detection of testosterone
The era of anabolic steroids
US professionals
Anabolic steroid prodrugs in the US
Designer drugs
BALCO

History of blood doping
Early testing strategies for blood doping
History of detection of recombinant erythropoietin and derivates
Background to the athlete biological passport
History of doping with growth hormone
History of doping with caffeine
History of doping with ephedrine
History of doping with cannabis
History of doping with alcohol
History of doping with gamma-Hydroxybutyric acid (GHB)
History of biomarker approach regarding doping
History of gene doping
History of athlete biological passport

Methodology for investigation of doping in the society
A support vector machine
Performance profiling
Controls at random
Errors in drug testing
Incongruity of data
Theoretical testing
Self-reporting
Testing as a way of decreasing intent for doping
Fatigue as a limit for test performance
Economical aspects
Chemoinformatics-based classification of prohibited substances
Need of excretion studies
Preanalytical variability
Chemical and physical manipulations of doping tests
Designer drugs in Japan
Testing efficiency
Anti-doping research opportunities
Economy
Measurement uncertainty in anti-doping quantitative analysis
Placebo
  Medical history of placebo
  Powerless placebo
  Lack of effect of flavor
  Ethical issues
  Concluding remarks on placebo
Statistical aspects
  Wald test
  Bayesian statistics
  Decision limit (CCalpha) and detection capability (CCbeta)
Prediction of future doping

ATHLETE BIOLOGICAL PASSPORT (ABP)
Overviews and background
Individualized statistics
Personalized monitoring of biomarkers for doping
  Technical specifications necessary
  Still an interpretation
An international tool
Three complementary items of ABP
Hematological parameters
  Hemoglobin mass
  Animal studies
  Biking
  Possible variables
Erythropoietin
Steroid profile for athlete biological passport
Confounding factors
  Plasma osmolality
  Stability of athlete blood passport parameters during air freight
  Gastroenteritis
Also for research
Law issues
Software
Passports in practice
  Erythropoiesis stimulating agents
  Testing during cycle tournament
  Positive cases in biking
Continuous evaluation of the ABP

SOCIO-MEDICAL ASPECTS ON DOPING
Semantics in doping
Political and economical aspects of anti-doping
Social and socio-medical issues
  Social psychological determinants
  Psychological background
Subjective effects
Expectation of the doped
Rejuvenation
Interaction between athletes and coaches
Sports addiction
Motivational and social cognitive predictors of doping
Motives for use
Elite athletes' attitudes, beliefs, and knowledge
Attitude of elite cyclists on doping
Young athletes attitudes towards doping
Other athletes' attitudes regarding doping
Attitudes against dopers
Body image and attitudes toward male roles
Polypharmacy
Concomittant use of other substances
Neuropharmacy addiction
Connexion to use of dietary supplement
Complementary and alternative medicine (CAM)
Connexion to eating habits
Concomittant symptoms and signs
Performance versus recreational drugs
Health promoting effects of sports
Lifestyle alteration
Prediction of later life-style
Risk factors for doping
Psychiatric comorbidty diseases
Sponsoring of sports
Information to dopers
Medical practitioners' knowledge, attitudes and beliefs
Contagiousness of doping
Economical aspects
Importance of sports medicine as a medical speciality
Impact of national programs
Staffing protocols in high-performance sport
Law issues

- Heart rate recovery
- Myocardial fibrosis caused of anabolic steroids
- Left ventricular myocardial dysfunction and cardiac hypertrophy
- Cardiac (autonomic) dysfunction
- Vascular reactivity
- Cholesterol changes
- Impaired exercise-induced cardioprotection of antioxidant enzymes
- Sudden death
- Altered lipid profile
- Abnormal plasma lipoprotein
- Trombocyte function
- Hypercoagulability
- Arterial thrombosis
- Thrombosis
- Pulmonary embolism
- Endothelial cells
- Increased ilintima-media thickness
- Aortic elasticity
- Arterial hypertension
- Other vascular effects
- Experimental
- Cardiovascular effects of low androgens
- Summaries of effects of anabolic steroids on the heart

Increased risk of diabetes

Effects on the brain
- Brain development
- Cerebral infarction
- Brain nerve growth factor
- Decreased memory
- Mania
- Effects on GABA
Rewarding systems
Monocygotic twins
Sleeping pattern
Psychologic and psychiatric effects
Agression and violence
Association with criminality
Suicide risk
Addiction
Withdrawal effects
Treating psychiatric effects of steroid use
Cognitive deficits

Liver changes due to sex hormones (anabolic steroids and oral contraceptives)
Overview
Metabolism of anabolic steroids in the liver
Enzyme elevations
Cholestatic liver disease
Non-alcoholic fatty liver disease (NAFLD)
Peliosis
Hepatocellular adenoma and carcinoma
Hepatocellular necrosis.
Spontaneous hepatic rupture

Anabolic steroids and reproductive system and male infertility
Physiology of reproduction-endocrinology
Anabolic steroid-induced hypogonadism in young men
Azospermia
Histopathology
Impact on semen quality
Aneuploidies and ultrastructural changes in spermatozoa
Case report

Reproductive-endocrine effects in women
Skin
Acne
Hirshutism
Androgenic alopecia (baldness)

Effects on the immune system
Infection risks after injections of anabolic steroids
Injection policies

Bone
Effect on bone density

Influence on muscle and tendon injury and injury healing
Muscle healing in power-lifters
Tendon adaptation
Compartment syndrome in upper limb

Rhabdomyolysis
Renal effects
Gynecomastia
Other side effects
Thyroidal effects
Hematological
Hypercalcemia
Effect on gingival tissues
Effect on inflammation
In basket ball players
Side effects in elderly
Other infections
Genotoxicity (cancer risks)

Fatal events
Multiple organ failure

Side effects of topical anabolic steroids
Influence on reaction on pain
Long-term effects on social-medicine demography
Swedish data
Increased mortality in former users of anabolic steroids
Tour de France (1947-2012)

TESTOSTERONE
Theoretical, overviewing, aspects
Normal values

Problems in evaluating serum testosterone values
Half life
Testosterone/epitestosterone concentration ratio (T/E)
Free testosterone/cortisol ratio
Time-course of testosterone action
Stability in the urine
Testosterone prohormones
Seasonal variations
Ethnic differences in steroid-related diseases
Urinary levels of testosterone and epitestosterone in a Korean male population
Status of lean elite athletes
Levels in male Olympics
Older men
Women
Testosterone after use of chlorinated swimming pools
Testosterone prohormones
Salivary testosterone (and testosterone to cortisol ratio)

Biological action
Hypothalamic-pituitary-gonadal (HPG) axis
Brain
Heart
Tendon
Muscle
Breast
Liver
Testosterone deficiency
Opioid-induced androgen deficiency (OPIAD)

Effect of magnesium on testosterone levels
Testosterone and motivation to compete
Psychological influence on testosterone levels
Influence of psychosocial environment
Victory or defeat
Home or away game
Spectators

Influence of stress on testosterone (and other anabolics) levels
Hormone profile in men
Hormone profile in women
Influence of fasting (Ramadan)
Circadian rhythm
Genetic influence (polymorphism)
Influence of exercise on testosterone levels
   In trained and in not-trained
   Effects of hard exercise
   Effect of endurance training
   Effect of resistance training
   Effect of different types of training
   Effect of different short-time types of exercise
   Explosive performances
   Active recovery versus passive recovery
   Influence of red color
   Pre-game free testosterone concentrations and outcome
   Pre-game testosterone level: home advantage
   Effect of testosterone on myoblasts
   Testosterone levels after concussions
   Effect of soccer
   Effect of golf
   Overreaching
   Older men
   Females
   Effects in a young female
   Adolescents
   Biking
   Response to marathon running
Effects on immune system
Testosterone and age
   Aging athletes
Effects of long flights
   Influence of space flights
Effects of diet on testosterone metabolites
   Influence of zinc
In hypogonadal men
Testosterone level as an indicator of gender
Transdermal testosterone
   Topical preparations
   Transdermal preparations
   Gels and solutions
Effect of postexercise ethanol ingestion
Effect on cocaine’s vascular effects
Interaction with NSAIDs
Influence on gastric ulcer precursors
Side effects
   Cardiovascular disease
   Diabetes
Laboratory techniques
   Testosterone versus epitestosterone
   TLC-densitometry method
   Mobility spectrometry separations
   Analysis of the transcriptome
Experimental

NANDROLONE
Physiology

Effects on mitochondria
Effect on dynorphin A in the brain

Metabolism

Protein disulphide isomerase (PDI)
Diagnostic metabolites
Effects of the menstrual cycle
Influence on hypothalamic-pituitary-adrenal axis

Effect on muscles
- Effect of training
- Effect on healing of muscle injuries
- Positive effect on nerve regeneration

Side effects
- Effect on male fertility
- Cardiotoxic effects
- Harmful effects on brain axons
- Harmful effects on learning capacity

Effect on hypertension
Effect on peripheral nerve injury
Effect on growth hormone
Effect of small doses on stress response
Aortic adaptations to exercise
Nandrolone-mediated testosterone reduction during alcohol intoxication
Impact of nandrolone on biosynthesis of steroids
Effects of nandrolone on recovery of denervated muscle

Genotoxic effects
Upregulation of aromatase expression
Endogenous or exogenous origin of nandrolone
Significance of 19-norandrosterone in athletes' urine

Laboratory techniques
- Liquid chromatography/tandem mass spectrometry
- Cyclic, differential pulse and square-wave voltammetry
- Gas chromatography-tandem mass spectrometry

Experimental

**BOLDENONE, BOLDIONE AND BOLANDIOL**

Overviews
Boldenone potency compared with other anabolic steroids
Effect on reproductive functions
Possible endogenous origin
Urinary samples contaminated with faecal boldenone
Influence of renal function
Metabolism of 1-ene-steroids
- Stenbolone
- Quinbolone
- Boldione

Experimental
Laboratory techniques
- Conjugated and unconjugated
- In cattle

**DEHYDROEPiANDROSTERONE (DHEA)**

Physiology
Metabolism
Molecular and cellular mechanism of DHEA
Effects of DHEA on body composition, bone metabolism, and skin
Role of DHEA in sexual function

Normal values related to age
Influence of menstrual cycle
In women

Efficacy in performance enhancement
Effects of walking training

Effects on asthma
DHEA metabolites activate estrogen receptors
DHEA in vascular disease

Adverse effects
5-androstene-3beta,7beta,17beta-triol
Laboratory techniques
Current medical recommendations

OTHER SPECIFIED ANABOLIC ANDROGENIC STEROIDS
Oxandrolone
Stanozolol
Methyltestosterone
Biomarkers
Side effects
Laboratory techniques
Desoxymethyltestosterone (DMT)
Metabolism
Methyltestosterone
Testing
Fluoxymesterone
Dihydrotestosterone (DHT, androstanolone)
Dehydroepiandrosterone
Diurnal secretion
Deposterone
Dromastanolone
Adrenosterone
Androstenediyl
Metabolism of 1-androstenediol and 1-androstenedione
3alpha-Androstanediol
Androstenedione
Hydroxyandrostenedione
Androst-4-en-3-one-based steroids
Dehydrochloromethyltestosterone
Fluoxymesterone
Desoxymethyltestosterone
Keto-androgens
Trenbolone
Experimentally
1-Testosterone
Metabolism
Metenolone
Metandienone
Metabolism
Laboratory tests
Mestranolone
Norbolethone
Phytosterols
Phytoecdysteroids
17-hydroxyandrosta-3,5-diene ("Syntrax Tetrabol")
Yeast transactivation system
Designer steroids
Tetrahydrogestrinone (THG)
YK11
Delta6-methyltestosterone
Methylstenbolone
Methyl-1-testosterone (M1T)
Laboratory techniques
Reductase inhibitors
Finasterid
Aromatase inhibitors
Exemestane
Anastrozole and exemestane
Formestane
Metabolism of keto and hydroxy steroids
Dehydrogenase inhibitor
Transsexuality

SELECTIVE ANDROGEN RECEPTOR MODULATOR (SARM)
Background
Steroidal ligands and their clinical applications
Arylpropionamide-based SARMs
SARMs produced by fungus
Andarine
New SARM compounds
Laboratory techniques

ESTROGENS AND FEMALE SPORTS
Ethnic variations
Urinary estrogens and androgens during pregnancy
Endogenous versus exogenous estrogens
Sex-hormone binding globulin
Testosterone
Prolonged aerob exercise
Urinary steroids in exercise
Salivary testosterone in exercise
Hyperandrosteronism in women
Effects of menstrual cycle
Effects of exercise on the female reproductive system and sex hormones
Effects of strength training
Comparison of baseline free testosterone between elite and non-elite female athletes
Effect of stretching
Effect of estrogens on muscle regeneration
Influence of IGF-1
Influence of age on muscle mass in women
Gestrinone
Estrogen blockers
Effects in men
Experimental
Oral contraceptives
  Effect of bone mass
  Influence of oral contraceptives on tendons and ligament
Influence of SERMs on steroid metabolism
Folinic acid supplementation
Laboratory techniques
  Selective estrogen receptor modulator (SERM)
    Toremiphene
    Raloxiphene
    Laboratory techniques

AROMATASE INHIBITORS
  Tamoxifen
  Exemestane
  Aminoglutethimide
  Formestan

BLOOD DOPING
  Overviews
  Prevalence of blood doping
  Biochemical markers of hypoxia
  Theoretical aspects on energy transfer in the body
    Hemoglobin mass and physical performance
Erythropoiesis
  Effects of marathon
  Effects of training in juniors
Red blood cells
  Effect of iron on performance
  Testing of blood
  Freezing red blood cells
  Effect of endurance training on erythrocyte deformability
Hemoglobin and hematocrit
  Seasonal variations of hemoglobin
  Regulation of red blood cell mass
  Circadian rhythm
  Stability of hemoglobin under testing conditions
  Statistical models for blood cell survival
  Preanalytical mixing of whole-blood specimens
  Blood parameters during endurance exercise
  During flights
Total hemoglobin mass
  Within-subject variation in hemoglobin mass
  Influence of exercise
  A stable parameter
  Influence of travelling
  Influence of erythropoietin
  Laboratory technique
Reticulocytes
  Sports anemia
  Influence of erythropoietin
  Blood drawing
Measurement
diurnal variation
biological variability
kinetics of reticulocytes production in humans
reported reticulocyte values in athletes
gender effects on reticulocytes
stability of reticulocytes
effects of exercise on reticulocytes
reticulocytes in doping
neocytolyis

polycythemia
blood conservation and transfusions
blood transfusions in general
autologous transfusion
adverse events
plasma markers for testing
screening for homologous blood transfusions
screening for autologous blood transfusions
mRNA
dNA testing
response to foreign erythrocytes
effects of blood withdrawal and reinfusion on biomarkers
laboratory problems
robustness of measurements after storage of blood
reticulocytes
whole blood transfusion
detection of homologous blood transfusion
capillary electrophoretic separation
intravascular hemolysis
evaluation of blood parameters

erthropoietin (EPO)
overview
physiology
different ways of action
erythropoietin and the heart
a neuroprotective agent
neovascularization
psychological effects
influence of N-acetylcysteinin
interactions with androgens
effects of exercise on erythropoietin molecules
effect of endurance training
effect on performance
effects of erythropoietin on serum hepcidin and serum iron bioavailability
new biomarkers
theoretical aspects of detection blood doping with erythropoietin
micro dosing
excessive dosing
enzymatic desialylation
laboratory techniques
hepcidin as a marker
microRNAs
confounding factors for erythropoietin detection
Available erythropoietins
CERA, a continuous erythropoietin receptor activator
Darpoietin/NESP
Epoetin delta (Dynepo®)
Hematide®
Non-EPO-related erythropoiesis stimulating agents
Synthetic peptide-based EPO receptor agonist
EPO-Fc fusion protein
New erythropoietin-like drug principles
Adverse effects of erythropoietin
Novel erythropoietin doping strategies
Detection rate
Detection of misuse of erythropoietin in competitive sports and laboratory testing

Effects outside the bone marrow
Economy
Experimental

Blood substitutes, in general
Perfluorocarbon emulsions
Efaproxiral
Ex vivo erythrocyte generation
Irradiation of red blood cells
Enhancement of oxygen transfer
2,3 DPG
Hypoxia-inducible factor
Hemoglobin-based oxygen carriers (HBOCs)
Allosteric modulators of hemoglobin
New products
Laboratory techniques
Hemopure®
Hematide/Peginesatide
Hypoxia-inducible factor (HIF) stabilizers
Cobalt salt as erythropoietic agent

Phthalates
Granulocyte colony-stimulating factor (G-CSF)
Other blood products
Actovegin

Intravenous fluid use in athletes
Discussion on dangerous dehydration in sports
Oral versus intravenous fluids
Exertional muscle cramp prevention
Preexercise fluid requirements
IV volume expanders
Rehydration

Plasma volume expanders
Dextran and hydroxyethyl starch
Hydroxyethyl starch (HES)
Glucose solution
Saline solution
Ringer lactate (or acetate) solution
Hypertonic crystalloid solution
Albumin
Plasma protein fraction
Plasma
Gelatins
alpha-Keratose
Combined solutions (hypertonic crystalloid/colloid)
Pullulan
Levan
Acetyl starch
Polyvinylpyrrolidone
Mannitol
Glycerol
Polyethylene glycol
Newer plasma expander

Intravenous rehydration
Hyponatremia

CREATED HYPOXIA
Nomenclature

Achilles tendon
Muscle injuries

GROWTH HORMONE
Overviews
Recombinant human growth hormone
Epidemiology and demographic factors
Adolecents
Children
Women

Prevalence
Side effects

Physiology
- Molecular and metabolic mechanisms
- Promoters of secretion
- Influence of nutrition
- Influence of testosterone on GH
- Immunofunctional and traditional growth hormone
- Effects on circulation
- Fett-substrate metabolism
- Glucose-substrate metabolism
- Effects on muscle mass and strength,
- Body fat, extracellular water, and thermoregulation.
- Interactions with thyroid hormones and sex steroids
- Hypothalamo-pituitary-adrenal (HPA) axis
- Growth hormones secretagogues
- The GH-IGF-I axis and exercise in normal subjects
- Supraphysiological GH and exercise performance
- Influence of training on GH response
- Influence of carbohydrates and proteins
- Influence on glucose homeostasis
- Influence on cardiovascular system
- Effect on IGFBP-4 and -5
- Influence of alcohol
- Effects on other variables
- Effects on respiration

Side effects
Clinical use
- Delivery methods
Use in weightlifters
- Biomarkers for use (other than IGF-1)
  - GH2000
  - Intra-individual variability
  - Effect of training of the analyse results
- Theories for detection of doping with growth hormones
  - Isoform approach to detection abuse
Possible ethnic differences
- Pharmacokinetics and pharmacodynamics of GH
Metabolism of GH
- Effect on red blood cells
- Positive association with estrogens in men
- Negative effects on collagen synthesis
- Idiopathic adult growth hormone deficiency
- Effect on memory
- Gene expression in peripheral blood
- GH-receptor antagonists
- Growth hormone releasing peptides
Legal framework
- Effect of dietary supplements on GH levels
- Effects of hypertemia on GH levels
- Effects of exercise on GH levels
  - High intensity versus high volume endurance training
  - Eccentric exercise
  - Effects in immobilisation
Effects of GH on performance in sports
   Endurance
   Resistance exercise
   Sprint
   Muscle strength
   With and without carbohydrate + protein
   Slow eccentric exercise velocity
   Tendons
   Meta-analysis
   In women

Impact of injuries
Boxers
Horse growth hormones
Detection of different brands
Laboratory techniques
   The isoform methods
   With nano-technology
   Stability of GH during testing procedures
   Monoclonal antibodies
   Electrophoresis and mass spectrometry
   Immunoaffinity purification
   Immunoassays
   Freeze-thaw cycling
   Intra- and inter-laboratory validation
   Tests for GH deficiency

Ethics of use of growth hormone in sports

INSULIN-LIKE GROWTH FACTOR I (IGF-1)
Polymorphism
Physiology
In peripubertal females
Effects of training
   Resistance exercise
   Training with calorie restriction and sleep deprivation
   In Kenyans
Local administration
IGF-1 in deer antler
Markers for IGF-1
Laboratory techniques
Detection
   Variation in measurements
   In saliva

INSULIN
Amino acid-stimulated insulin secretion
In weightlifting
   Effects of leucine on post-exercise muscle protein synthesis
   Protein hydrolysates
   Whey
   Effects of insulinotropic nutritional mixtures on insulin secretion
   Effects of insulinotropic nutritional mixtures on post-exercise muscle anabolism
   Protein shake
   Effects of post-exercise hyperinsulinaemia on fat oxidation and de novo
Anti-inflammatory effects of insulin
Laboratory techniques

**OTHER DEFINED PEPTIDE HORMONES**

*Gonadotropins*
- Human chorionic gonadotropin
- Chorionic gonadotrophin (CG) and luteinizing hormone (LH)
- Clomiphene
- Release of GnRH
- Luteinizing hormone
- Natural agonists

*Secretagogues: gonadotrophin-releasing hormone*

*Myostatin*
- Effect of psychological stress
- Experimental

*Mechanical growth factors*
- Stretching
- Antibodies against human MGF E-peptide
- Fibroblast growth factor (FGF) and mechano growth factor (MGF)

**AGRP**

**CAFFEINE**

*Overviews*
- History of coffee drinking
- Presence of caffeine in society
- Epidemiology of use
  - Self-reported consumption
  - Emergency medicine residents' use of psychostimulants

*Athletes' knowledge of effects of caffeine*

*Factors influencing serum caffeine concentrations*

*Bioavailability of coffee*

*Caffeine dosages versus effects*
- Duration of effect
- Administration mode
- Dosage versus endurance cycle time
- Use as a flavor
- Potential adverse effects

*Physiological effects of caffeine*
- Effect on EMG frequency variables
- Effect on energy expenditure
- Effect on glucose homeostasis

*Molecular effects*
- Blocking of adenosine receptors
- Coffee polyphenol caffeic acid

*Analgesic effect*

*Users versus non-users*

*Metabolism*

*Mobilization of fat*
- Effects on performance after a fat meal

*Effects on blood pressure*

*Effect on cardiac blood flow*
- Caffeine-reduced myocardial blood flow during exercise
Dose-dependent neuromuscular effects
Effect of caffeine on delayed onset muscle soreness
Effects on performance
  Effect versus measurable levels
  Effects on the brain
  Effects on mood and vigilance performance
  Effects on endurance
  Effects on short term performance
  Effects on skill performance
  Effects on resistance training
  Effects of performance of chronic use
  Effects on cycling
  Effects on muscles
  Effects of neural recovery
  Effects in children
  Effects on tennis
  Effects on rugby
  Effects on weight-lifting
  Effects on rowing
  Effects on iron-man
  Effect on field hockey
  Effect on sedentary men
  Effects on basket
Caffeine in central fatigue
  Ratings of perceived exertion
Caffeine levels before and after the removal of caffeine from the doping list
Caffeine in diabetes
Combination with creatinine
Combination with ephedrine
Caffeine versus pseudoephedrine
Combination with albuterol
Combination with sodium bicarbonate
Combination with sodium citrate
Combination with carbohydrates
  Caffeine at low muscle glycogen availability
  Caffeinated mouth-rinse
  Effect on individuals with negative energy balance
Combination with epigallocatechin
Combination with taurine
Combination with ecstasy
Caffeine versus theobromine
Caffeine in asthma
Influence on circadian rhythms
Influence on biomonitoring data
Impact on pain perception
Impact on testosterone levels
Impact in hot environments
Impact on immunology
  Immunoendocrine effects
Effect on hydration
Effect on urea formation
Caffeine with carbohydrates
Caffeine with phosphatidylserine
Lack of effect on oxidative stress
Modulation of oxidative stress markers in the liver of trained rats
Impact on the inflammatory response
Impact on glycogen accumulation
Impact on ventilation
Impact on sweating
Impact on delayed-onset muscle soreness
Impact on postexercise oxygen consumption
Impact on potassium levels
Impact on glutamine acid
Impact on sex-hormone binding globulin
Effects after a withdrawal period
Effects on arousal
Moderated effect of anxiety
Psychological effects
Caffeinated versus decaffeinated coffee
Hematological side effects
Experimental
Caffeine and taurine
Interaction with amitriptyline
Muscle metabolism
Effect of fat free weight
Practical recommendations
Caffeinated “energy shots”
Caffeinated chewing gum
Caffein gel
Guarana

OTHER STIMULANTS
Ergogenic effects
Theobromine
Theobromine and theophylline
Ephedrine
Chinese preparations
Use in women

Side effects
  Heart
Laboratory techniques
  Measurement in hair
Experimental

MELATONIN
As marker for training
Effect on performance
Effects on strenuous exercise
  Experimental
Jet lag
Salivary
Experimental
  Influence on plasma glucose
  Combination with imipramine

SILDENAFIL (VIAGRA®)
MORPHINE
Decreased sensitivity after exercise
Dermorphine

RECREATIONAL DRUGS: CANNABIS, COCAINE, ECSTASY AND GAMMA-BUTYROLACTONE (GBL)
Cannabis
- Overviews
- Long-term use
- Epidemiology of use of cannabis
- Mechanism of action
- Synthetic cannabinoids
- Medical use
- Duration of detection in blood
- Effects
- Influence on psychomotor performance
- Cannabis use in sports
- Influence of nandrolone on cannabinoid dependence
- Cannabis in urine
- Does cannabis have a doping effect?
- Endogenous
- “Spice”
- Occasional or frequent smokers
- Side effects
- Laboratory technique

Cocaine
- Environmental factors important for abuse
- Effects
- Cocaine in sport
- Side effects
- Laboratory techniques

Methylenedioxyxymethamphetamine (MDMA; Ecstasy)
- Together with Ecstasy
- Metabolites
- Laboratory testing

gamma-Aminobutyric acid (GABA)
- Influence of anabolic steroids

gamma-Butyrolactone (GBL)
- gamma-Butyrolactone and gamma-butyrolactone
- gamma-Butyrolactone and 1,4-butanediol

gamma Hydroxybutyrate (GHB)
- Metabolism and neuromodulatory properties

Other negative aspect of GHB
GHB abuse
GHB detection
Laboratory technique
beta-Hydroxy-beta-methylbutyrate (HMB)
Metabolism
HMB safety
Effects on skeletal muscle damage, protein breakdown, and recovery
Effects of training status
Duration of supplementation, dose, and timing
The effects on skeletal muscle hypertrophy in healthy untrained and trained adults
HMB in athletes training in an energy restricted state
HMB supplementation in youth and adolescent populations
HMB supplementation in aging and masters athletes
HMB improves indices of aerobic performance, fat loss, and energy metabolism
Proposed mechanisms of action
Skeletal muscle regeneration
Skeletal muscle proteolysis
HMB in young trained subjects
HMB in trained versus untrained subjects
HMB mixed with other molecules in young trained subjects
HMB mixed with other molecules in young untrained subjects
Dose and safety of treatment
HMB versus glucocorticoids
Attenuation of muscle loss during sustained energy deficit
Influence of HMB on protein synthesis
Influence on free acids
Laboratory testing
Experimental
Summarised aspects of HMB in sports
1,4-Butanediol (1,4-BD)
gamma-Oryzanol and ferulic acid

ALCOHOL
Epidemiology
Motives and attitudes for alcohol use by athletes
Mechanism of action
Studies on alcohol and performance
Practical effects of energy drinks on alcohol priming
Effects of ethanol on glycogen metabolism
Hydration and thermoregulatory function
Effects of acute alcohol consumption on neuromuscular function.
Effects of acute alcohol consumption on recovery from a match
Effects on brain’s white matter
The aftermath of alcohol use

Energy intake
For team sports
For power sports
For endurance sports
For young soccer players
Response to long distance running (energy needed)
Food provision during Olympic Games
General recommendations
  - Nutrition for sprinters
  - Nutrition for runners
  - Nutrition for triathlon and marathon
  - Nutrition for football players
General recommendations regarding the use of dietary supplements
Recommendation of the International Society for Sports Nutrition
  - Energy need
  - Carbohydrate
  - Protein
  - Strategic eating and refuelling
  - Vitamins
  - Minerals
  - Water
  - Convenience supplements
  - Muscle building supplements
  - Creatine
  - Essential amino acids (EAA)
  - Beta-hydroxy beta-methylbutyrate (HMB)
  - Branched chain amino acids (BCAA)
  - alpha-Ketoglutarate (alpha-KG)
  - alpha-Ketoisocaproate (KIC)
  - Ecdysterones
  - Growth hormone releasing peptides (GHRP) and secretagogues
  - Ornithine-alpha-ketoglutarate (OKG)
  - Zinc/Magnesium aspartate (ZMA)
  - Glutamine
  - Isoflavones
  - Sulfo-polysaccharides (myostatin inhibitors)
  - Boron
  - Chromium
  - Conjugated linoleic acids (CLA)
  - Gamma oryzanol (Ferulic acid)
  - Prohormones
  - Tribulus terrestris
  - Vanadyl sulfate (Vanadium)
  - Green tea extract
  - Phosphatidyl choline (Lecithin)
  - DHEA and 7-Keto DHEA

NUTRITIONAL.SupPLEMENTS: WATER, CARBOHYDRATE, PROTEIN, AND FAT

Hydration
  - In adolescents
  - Effects on environment and persons around for drinking habits
  - Sweating
  - Hydration assessment
  - Dehydration
Hyperhydration
Muscle problems in hypohydration
Modifying factors for hypohydration
Diet
Fluid replacement before exercise
Fluid replacement during exercise
Drinking pattern during different parts of activity
Different commercial available sport drinks
Dehydration despite favorable conditions for fluid intake
Gastric emptying
Fluid restriction increases GI permeability
Effects of hypohydration on performance
Drinking pattern during sports
Hydration in marathon
Water and carbohydrates
Water and electrolytes
Alcoholic beverage for treatment of dehydration
Oral salt supplementation

Exercise-associated hyponatremia
Use of NSAID
Pathophysiology
Arginine vasopressin (AVP)
Sweating
Clinical features
Prevention of EAH
Therapy of EAH

Bicarbonate
Physiology
Effect on exercise
Effect on symptoms from the stomach
Sodium bicarbonate and sodium citrate

Energy need
Meal frequency

Carbohydrates
Glucose homeostasis in athletes
Effect on perceived exertion
Effect on endurance exercise
Effect of pre-exercise carbohydrate-loading on endurance performance
Effect on combat sports
Effect on tennis
Effect on football
Effect on sleep onset
Mouth rinse with carbohydrate solutions
Influence on testosterone levels
Intake recommendations
Can low carbohydrate high fat provide fuel for sport?
Carbohydrates and protein
Carbohydrates plus whey
Carbohydrates with fat
Milk carbohydrate and protein
Carbohydrates and caffeine
Carbohydrates and electrolytes
Influence of age and pubertal status on substrate utilization
Carbohydrate gel
Milk
Chocolate milk
Raisens
Fruits and vegetables
Cornstarch
Hydroxypropyl-distarch
Honey-sweetened beverage
Low-carbohydrate diets and performance
Carbohydrate loading effect of menstrual-cycle phase
Effects of carbohydrate beverage ingestion on the salivary IgA
Carbohydrate in young adolescents
Glucose polymers
Carbohydrate effect on oxidative changes
Increased lactate (decreased lipolysis) due to carbohydrates
Lactate
Sucrose
Ribose
Galactose
Galactose and fructose
Multiple transportable carbohydrates
Carbohydrates in tennis

Energy beverages/Sport drinks
Science on “sports drinks”
With caffeine
With carbohydrate, protein and antioxidants
With other nutrients
Effect on exercise performance
Energy drinks and their role in energy expenditure and weight loss
Gastric emptying
Safety considerations
Consumption pattern
Beverage after aerobic activity
In school children
Adverse effects
Sweet, non-alcoholic beverages
Red bull
Canada
USA
Effects of cold drinks

Proteins
Recommended daily allowance in athletes
High protein feeding
Egg white protein
Whey
Wheat germ
Soy-protein
Combination of sago and soy-protein
Wheat gluten hydrolysate
Building muscles in fed and fasted state

Protein drinks
Effect on endurance and muscles
The effects of protein intake timing in relation to strength training
Proteins before exercise
Protein-rich intake for recovery after exercise
Needs in older, training subjects

Peptides
Amino acids
Branched-chain amino acids (BCAA)
  BCAA plus arginine
Neutral amino acids
  Effect on performance
  Effects on muscle soreness
Arginine
  Combined with ornithine
  Combined with citrullin
Leucine
  4-hydroxyisoleucine
L-tryptophan
Taurin
Cystein and cystine
Cystine/theanine
Glutathione and glutamate
Glutamine
  Studies in intensive care units
  Glutamine, athletes, and immunity
  Glutamine, muscle function, and athletic performance
Alanine
  L-alanine
  beta-Alanine
  Alanine plus creatine
Methionine
Threonine
Tryptophan
Tyrosine
Valine
CBEX
Carnosine (beta-alanyl-l-histidine)
  With and without sodium bicarbonate
  Effect of training
Citrulline
Aspartate and asparagine
Aspartame
Glycine
Glycine-arginine-alpha-ketoisocaproic acid
alpha-Ketoglutarate
alpha-Ketoisocaproate
Prolin
Amino acids and creatine
Fat
  Medium-chain triglycerides
  Maximal lipid oxidation
  In cyclists
Fish oil
  Omega-3 fatty acid
Multi-ingredient performance supplements (MIPS)
NUTRITIONAL SUPPLEMENTS: TRACE ELEMENTS, VITAMINS AND OTHER OXIDANTS

Iron
Boron
Calcium
Cobalt
Copper
Chromium
Magnesium
Potassium
Selenium
Vanadium
Zinc
Zinc monomethionine aspartate
Phosphate
Nitrate
Vitamins, in general
Vitamin B
Vitamin D
Vitamin D and muscle tissue
Vitamin D recommendations (intake and desirable levels)
Vitamin D status of athletes
Vitamin D and athletic performance
Summer versus winter
Experimental
Vitamin A
Coenzyme Q10
Folate
Vitamin K
Vitamin C
Optimal vitamin C intake for athletes
Vitamin C and E
Effects on running
Side effects
Vitamins A, C, and E
Vitamin E
Dietary antioxidants, in general
Theoretical aspects on the cellular level
Redox state in athletes
In rugby players
Resveratrol
Resveratrol and quercetin
N-Acetylcysteine
Allopurinol
Other antioxidants
Cognitive performance
Flavonoids (including quercetin)
Astaxanthin
In handball
alpha-Tocopherol, ascorbic acid, and beta-carotene
Catechins
In chronic obstructive pulmonary disease
Experimental
Hydroxycitrat
Applephenon

NUTRITIONAL SUPPLEMENTS: OTHER DEFINED CHEMICAL SUBSTANCES AND METHODS

Creatine
Effects of creatine supplementation on physical performance
Effects of creatine on anaerobic exercise
Effects of creatine on aerobic exercise
Effects of creatine supplementation on skeletal muscle hypertrophy
Effect on plasma levels of pro-inflammatory cytokines
Effects of creatine on glycogen stores
Effects on blood lactate
Effects on kidney function
Effects on inflammatory markers
Side effects of creatinine
Dosing protocols applied in creatine
Commercially available forms of creatine
Creatine in combination with other supplements
Safety and side effects of creatine
In muscle wasting
Effects of statins
Creatine monohydrate and conjugated linoleic acid
Creatine kinases
Influence on glucose metabolism
Creatine and whey protein
Cognitive effects of creatine
Use in women
Effect on myostatin
Children
Creatine purity
In taekwondo
Effect on tennis
Effect on ice-hockey
Effect on sprint running
During sleep deprivation
Side effects
Creatine and bicarbonate
Experimental

Carnitine
Effect on post-resistance-exercise (RE)
Side effects

Methylhexaneamine (DMAA)
Glutatione
Choline bitartrate plus acetylcholine
Chondroitin/glucosamine
Lecithin
Linoleic acid
gamma-Linolenic acid
Conjugated linoleic acid
Leptin
Inosine
Glucosamine
“Fat burners”
L-arginine alpha-ketoglutarate (AAKG)
Blend supplements
Nutritional support to maintain proper immune status during intense training
Electrolytes
Dimethylglycine
Dietary nitrates
Dihydroxyacetone phosphate and pyruvate
Methylsulphonylmethane
Melamine
Nootkatone
Octacosanol and policosanol
Superoxygenated water
Non-pharmacological therapy
Acupuncture
Cryostimulation
Cooling
Sublingual, ergogenic spray

**NUTRITIONAL SUPPLEMENTS: FROM PLANTS AND ANIMALS**

**Herbs**
- Ergogenic theory
- Herbal weight loss supplements

**Prebiotics**
**Probiotics**
- Probiotic intervention studies in athletes

**Bluberries**
**Wolfberry (goji berry)**
**Green tea**
**Black tea**
**Ginseng**
**Ginkgo biloba**
**Garlic**
**Macroalgae**
**Spirulina (microalgae)**
**Phosphatidylserine**
**Quercetin**
**Capsaicin**
- Soldiers
- Mice

**Pycnogenol**
**Kava kava (Kava)**
**St. Johns wort**
**Yucca**
**Teribulus terrestris**
**Arnica**
**Rhodiola rosea**
- Lack of effect on marathon running

**Cissus quadrangularis**
**Hydroxycut**
**GENE DOPING**

**Overviews**
- The science behind gene doping
  - Definitions and history
  - Gene transfer approach to therapy
  - Therapeutic gene transfer vectors introduced into human beings
  - Reversing the effects of transplanted genes
- Medical uses of gene therapy
- Animal use of gene doping
- Genes versus environmental influence
- Gene therapy versus gene doping
- Epigenetics
- Evolving definitions
  - RNA interference
- Genetic enhancement
  - In vivo gene doping
  - Ex vivo gene doping
- Possibilities for gene doping
  - Gene-based doping for muscle function
  - Gene-based doping for oxygen delivery to exercising tissues
  - Further possibilities of detecting gene doping
- Doping targets
  - Glucose metabolism
  - Red blood cell activity/delivery
  - Skeletal muscle size, strength and endurance
  - Vascular endothelial growth factor
  - Fibroblast growth factor
  - Preventing pain (endorphin and enkephalin)
  - alpha-Actinin 3
  - Peroxisome proliferator-activated receptor-delta
  - Cytosolic phosphoenolpyruvate carboxykinase
  - Gene doping with intracellular molecules
- Options for gene doping
  - Gene doping targets
- Candidate genes for athletic gene doping
Hematopoietic/vascular systems
Hypoxia inducible factors
Vascular endothelial growth factor
Actin-binding peptides
Angiotensin-converting enzyme
Insulin-like growth factor
Myostatin
Peroxisome proliferator-activated receptor delta
Endorphins
Erythropoietin gene transfer
Polymorphism
Experimental
Sport as a case study
Risks and complications of gene doping
  Gene silencing
  Immune reaction
  Integration
  Infection of germ cells
  Expression
  Storage and usage
  Long term
  Uses of gene therapy
Potential strategies for detection of gene doping
  Detection of erythropoietin gene doping
  Muscle biopsy
  Blood monitoring
  Genetic activity tests
  Protein fingerprints
  Genetic barcodes
Laboratory techniques for detection of gene doping
  Direct methods
  Indirect methods
  Transgene and nonviral vectors in blood
  PCR-based detection of gene transfer vectors
Regulation of gene doping
  The ethics of gene doping
    Bioethical concerns
    Definition of enhancement
    Genetic enhancement
    The thin line between therapy and enhancement
    Specific ethical questions

ETHIC ISSUES IN DOPING AND ANTI-DOPING
The history of anti-doping ethics
War on doping versus war on drug
  Doping is here to stay
  "Everybody take doping drugs"
Arguments for doping and their ethical anti-arguments
  Human nature
  Regulation could improve safety
  Spirit of sport
  Argument against doping in sports
Escalating problems
Engineered athletes
Bans can work
What justifies anti-doping?
Alternatives to current anti-doping strategy
A continuing discussion is needed
The reasons for anti-doping rules
Sports as part of the society
Doping as a sign of dehumanization
Making sport possible
Technology introduced but changing the sport
Increased participation and spectatorship
Alternate conceptualizations
Ethical aspects of “harm” in sports
Harm to the athlete
Harm to other athletes
Harm to society
Ethics of the athletes regarding doping
Sports Federations’ attitudes
Litigation in sports medicine
Physician’s role in doping
The challenge of working in sports medicine
Environmental factors
Case reports of the doctor’s fault but athlete’s verdict
Rumanian gymnast
Serbian handball player
Russian basketball player
French basketball player
Spanish basketball player
Regulations
Aims of the regulations
Legislative structures on enhancement
Courtroom medicine
Evidence-based doping?
Motherhood goes with gold?
Legitimacy of ban on cannabis and cocaine
The complexity of anti-doping
The ethics of doping
Education in moral judgment of participants in team sports
Professionalism and the ethics of the sports physician
Conflicts of interest: the need to minimize
Need to recognize the limits of athlete’s autonomy
The need to maintain informed consent
Confidentiality in doping
Patient confidentiality
Fairness in sports
Criticism of the fairness of the testing procedure
The WADA mission
Sport and the history of ethics in sports medicine
Multiple obligations
Attitudes on anti-doping
Hypotheses on background of doping
Youth and adolescents
Environmental factors
Anti-doping programmes
The life-cycle model of performance enhancement
A gold medal but also death in 5 years’ time?

Prevention of athletes from harm
On cheating
Different shades of blood doping
The grey zone of undiscovered doped
Enforcement of anti-doping policy today
Smart drugs (“brain doping”)
Performance-enhancing drugs create an uneven playing field
Everybody else is taking them
Performance-enhancing drugs are dangerous
Drug use would be almost impossible to control
Danish ban on gyms not adhering to doping-tests

Cannabis
Gender as more than a binary quantity
On how to make illegal drugs less dangerous
Hidden assumptions and inherent contradictions in anti-doping policy
Setting a good example
A level playing field
Protecting the health of athletes
Preserving the integrity of sport
Policy implications

Research on doping substances
WADA’s statement

Ethical codes
A code of ethics with a foundation in evidence
The complex environment of elite sport
Multiple obligations
Sharing personal information about athletes with others
Risk taking by athletes
Aims for a new code of ethics
Practicalities and negotiating the politics

Scientific cooperation
The formal ethics of research with human subjects
The ethical principles used by review bodies
Further amendments

Sport as an occupation
Legislation of drugs aimed for doping
“Naturalness” in sports
An example for the society

Law versus ethics
International doping policy: the WADA and the WADC
Public law versus sport’s law
Guilt, negligence and liability
Privacy

Physician’s responsibility
Self-reporting on doping

Hypoxic tents
Pain medication
Injection therapy with local anaesthetics
Injection therapy with local corticosteroids
Concluding remarks
Publication ethics

VETERINARY
Bacterial hydrolysis of urine without doping substances
Contaminated food for animals
Screening
Anabolic steroids, general
  Anabolic steroids in dogs
    In hair
  Differentiation between endogenous steroids and synthetic homologues in cattle
Testosterone
  Testosterone and nandrolone
19-nortestosterone
Nandrolone
1-Testosterone
Stanozolol
Methyltestosterone and mestranolone
Mesterolone
Methandienone
Boldione, boldenone and boldenone esters
Trebolone and estradiole
Fluoxymesterone
Growth hormone
Selective androgen receptor modulators (SARMs)
Erythropoietin
  Horse
  Dog
Darbepoetin
Insulin
Seven peptide hormones
Relaxine
Thyroid hormones
Hydrocortisone
  Topical glucocorticoids
Clenbuterol and hydrocortisone
Clenbuterol
THG
Theobromine
Flurbiprofen
Phenylbutazone
Salicylic acid
Prednisolone
Bupivacain
Levamisole
3,4-Methylenedioxypyrovalerone (MDPV)
Glycopyrrolate
Dermorphine
Capsaicin
Acepromazine
Antioxidants
Vitamin E
Myo-inositol trispyrophosphate (ITPP)
Alpha-cobratoxin
Quaternary ammonium drugs
Ethanol

Laboratory techniques
  Direct-injection differential-gradient LC-LC coupled to hybrid tandem MS/MS
  Stable carbon isotope analysis
  Solid-phase extraction and liquid chromatography-mass spectrometry
  Liquid chromatography – Orbitrap mass spectrometry
  Proteomics et al
  In hair
  Identifying individual horses urine by single-nucleotide polymorphisms (SNPs)
  TB-500
  Primary hepatocytes as a bioassay
  Molecularly imprinted polymer applied to the selective isolation of urinary steroids
  Single-nucleotide polymorphism assay
  Orbitrap
  Protein biomarkers

Other aspects on forensic medicine
Horses (in general)
  Drug metabolism in horses

CRE  cyclic AMP response element
CRM  certified reference materials
CrM  creatine monohydrate
CRM  certified reference materials
CRP  C-reactive protein
CS  citrate synthase
CS  cage-switching stress
CS  creatine supplementation
CSA  cross-sectional area
CSIA  compound-specific isotope analysis
CT  computed tomography
CT  calcaneal tendon
CTAB  cetyl trimethyl ammonium bromide
CTX  C-terminal telopeptide of type-I collagen
CV  coefficient of variance
CV  cardiovascular
CVD  cardiovascular disease
CVF  collagen volumetric fraction
CVP  central venous
CVST  cerebral venous sinus thrombosis
CW  Caucasian women
CWI  cold-water immersion
CYP  cytochrome P
CZE  capillary zone electrophoresis
CZE-UV  capillary zone electrophoresis-UV absorbance detection
D  deletion
DA  dopamine
Da  Dalton
DAD  diode-array detector
DALDA  Daily Analysis of Life Demands for Athletes
DAM  N,N-dimethylamphetamine
D-AMPH  d-amphetamine
DART  direct analysis in real time
DAT  drug and alcohol testing

</table>
FTICR  Fourier transform ion cyclotron resonance
FT-ICR/MS  Fourier transform ion cyclotron resonance mass spectrometry
FTIR  Fourier transform infrared
F20TPP  meso-tetrakis(pentafluorophenyl) porphyrin
FV  fruits and vegetables
FW  fat weight
FW  flavored water
FWHM  full-width at half maximum
GA  gastrocnemius
GABA  gamma-aminobutyric acid
GABAAR  gamma-aminobutyric acid receptor
GAKIC  glycine-arginine-alpha-ketoisocaproyl acid
GAL  galactose
Gas  musculus gastrocnemius
GASP-1  growth and differentiation factor-associated serum protein-1
GBL  gamma-butyrolactone
GBR  gamma-aminobutyric acid (GABA)/benzodiazepine receptor complexes
GBS  global positioning system
GC  glucocorticoid
GC  gas chromatography
GCC  gas chromatography combustion
GC/C/IRMS  chromatography/combustion/isotope ratio mass spectrometry
GC/GC/TOF/MS  two-dimensional gas chromatography coupled to time-of-flight mass spectrometry
GC/HRMS  gas chromatography-high-resolution mass spectrometry
GC/GC  two-dimensional gas chromatography
GC/GC/TOFMS  two-dimensional gas chromatography with time-of-flight mass spectrometry
GC/IT/MS  gas chromatography-ion trap-mass spectrometry
GC/MS  gas chromatography/mass spectrometry
GC/MSD  gas chromatograph-mass spectrometer
GC/MS/MS  gas chromatography-tandem mass spectrometry
GC-NCI-MS/MS  gas chromatography-negative chemical ionization-tandem mass spectrometry
GCoaTOFMS  gas chromatography/electron ionization orthogonal acceleration time-of-flight mass spectrometry
GCS  glutamylcysteine synthetase
GCS  Glasgow Coma Scale
G-CSF  granulocyte colony-stimulating factor
GC/TOF/MS  gas chromatography time-of-flight mass spectrometry
GD  gastrointestinal distress
GET  gas exchange threshold
GF  growth factor
GFP  green fluorescent protein
GFP  general factor of personality
GFPQ  General Factor of Personality Questionnaire
GFR  glomerular filtration rate
GGT  gamma-glutamyl-transferase
GH  growth hormone
GHB  gamma-hydroxybutyric acid
GHBP  growth hormone binding protein
GHD  growth hormone deficiency
GHR  growth hormone receptor
GHRH  growth hormone-releasing hormone
GHRP  growth hormone releasing peptides
GHS  growth hormone secretagogue
GHV  gamma-hydroxyvalerate
GI  gastrointestinal
Gl  glycemic index
GIH  glycerol-induced hyperhydration
GIP  glucose-dependent insulinotropic polypeptide
GL  glycemic load
GLA  gamma-linolenic acid
GLC  gas-liquid chromatography
Gln  glutamine
GLP  glucagon-like peptide
Glu  blood glucose
GLUC  glucose-maltodextrin
GLUT  glucose transporter
GLUT4  glucose transporter 4
GMFI  geometric mean fluorescence intensity
GnIH  gonadotropin inhibitory hormone
GNP  gold nanoparticle
GnRH  gonadotrophin-releasing hormone
GOS  galacto-oligosaccharides
GP  General Practitioner
GP  glucose polymer
GP  growth promoters
GPA  growth-promoting agents
GPA  grade point average
GPCR  G protein coupled receptors
GPER  G protein-coupled estrogen receptor
GPLC  glycine-propionyl-L-carnitine
GPR30  G protein-coupled receptor-30
GPx  glutathione peroxidase
GR  glutathione reductase
GPS  global positioning systems
GPx  glutathione peroxidase
GR  glutathione reductase
GR  glucocorticoid receptor
GS  glycogen synthase
GS/GS/TOFMS  gas chromatography coupled two time-of-flight mass spectrometry
GSH  glutathione
GSH-Px  glutathione peroxidase
GS-MS  gas chromatography-mass spectrometry
GSSG  glutathione disulphide
GT  glutamyl-transferase
GTC  green tea catechins
GTE  green tea extract
GTN  gastrocnemius
GVL  gamma-valerolactone
GXT  graded exercise tests
HA  hepatic adenomas
HABA  2-(4-hydroxyphenylazo)benzoic acid
HAD  hydroxyacyl-CoA dehydrogenase

</table>
BACKGROUND FOR TODAY’S DOPING PROBLEMS

More than two thousand years ago, naked athletes competed at the Olympic games in ancient Athens for eternal fame and an olive branch. Today, most athletes run, jump or swim not only for fame and honour but also for money – after all, a gold medal is the ticket to lucrative advertising contracts. Not surprisingly, professional sports now resemble high-tech races in which any technological trick is used to gain milliseconds to set the next record. This involves not only designing faster bobsleds, racing bikes or shark-skin swimsuits but also pushing the physical abilities of athletes by using the latest medical and biological research.

Since ancient times, unethical athletes have attempted to gain an unfair competitive advantage through the use of doping substances, even though the methods and drugs have varied over time. Nowadays a list of doping substances and methods banned in sports is published yearly by the World Anti-Doping Agency, and what is on that list is defined as doping irrespectively if enhance performance or not. A substance or method might be included in the list if it fulfills at least two of the following criteria:

- enhances sports performance
- represents a risk to the athlete’s health
- violates the spirit of sports.

This list, yearly updated to reflect new developments in the pharmaceutical industry as well as doping trends, enumerates the drug types and methods prohibited in and out of competition. Among the substances included are steroidal and peptide hormones and their modulators, stimulants, glucocorticosteroids, beta2-agonists, diuretics and masking agents, narcotics, and cannabinoids. Blood doping, tampering, infusions, and gene doping are examples of prohibited methods indicated on the list. From all these, hormones constitute by far the highest number of adverse analytical findings reported by the antidoping laboratories. Although to date most are due to anabolic steroids, the advent of molecular biology techniques has made recombinant peptide hormones readily available. These substances are gradually changing the landscape of doping trends. Peptide hormones like erythropoietin, human growth hormone, insulin, and insulin-like growth factor I are presumed to be widely abused for performance enhancement. Furthermore, as there is a paucity of techniques suitable for their detection, peptide hormones are all the more attractive to dishonest athletes.

The national attention and economic gains that come with success in professional sports has produced tremendous pressure on modern athletes to win at all costs. In 1994, it was completed a survey of 198 Olympic level athletes. They were asked, if they were guaranteed of winning an Olympic medal and not getting caught would they take a banned substance. One hundred and ninety five of 198 athletes answered yes. When presented with the same scenario, with a guarantee of winning every competition for the next five years, but they would eventually die from adverse effects of the substance, more than 50 percent of the athletes reported that they would still use the substance.

Over the last 20 years systematic doping has become a major threat for elite sport. So far, there is no clear information about the daily practice of doping. Repeated scandals and recent personal statements have added to our knowledge. Several more recent doping agents like Erythropoietin (EPO) and, probably, growth hormone (GH) enhance performance in a highly effective way and, together with the well-known anabolic steroids (AAS), belong to...
the major doping categories. The introduction of EPO has really changed the paradigm in endurance sports allowing a good middle class athlete to become a champion. It is evident that doping practices are influenced by the possibilities of the anti-doping control system. Unethical, criminal medical doctors play a decisive role in the ongoing practice of major doping. Apart from the already mentioned substances AAS, EPO and GH several novel drugs appear on the horizon. They are highly effective and there is no doubt that they will be used in attempts to improve performance. During the last years, doping control systems have also been improved: EPO can now be detected in urine samples and the detection of AAS has also become much more sensitive. However GH hormone detection is not possible at the moment and this remains a major weakness of doping control. Other problems are the control procedures which are far from being optimal. In the future the quality of doping controls will be decisive and not only the quantity; controls will have to be "intelligent". The effective fight against doping in the next years will decide about the survival of elite sport [07003].

The list of drugs prohibited by the World Anti-Doping Agency (WADA) has grown in the last decade. The newer entries into this list include gonadotropins, estrogen antagonists, aromatase inhibitors, androgen precursors, and selective androgen receptor modulators. The use of mass spectrometry has revolutionized the detection of various compounds; however, challenges remain in identifying newer designer androgens because their chemical signature is unknown. Development of high throughput bioassays may be an answer to this problem [10043].

Success in sports is often defined by winning, which drives athletes to use performance-enhancing drugs (PEDs) to gain an advantage over opponents. Over the past 20 years, use of PEDs by Olympic and professional athletes has led to public discussion regarding potential negative health effects and ethical implications of their use. Unfortunately, PEDs are not isolated to professional athletes, as PED use in adolescents has increased dramatically. Many professional organizations, including the American Academy of Orthopaedic Surgeons, have taken a stance against PED use in sports. The AAOS believes neither anabolic steroids nor their precursors should be used to enhance performance or appearance, and that these substances should be banned in all sports programs. Pediatricians and orthopedists are often the first physicians to see these young athletes. It is critical for these physicians to recognize the significance of the problem, have the knowledge to inform adolescents, dissuade them from future use, and provide viable alternatives for meeting performance goals [10435].

Doping incidents infesting high prestige sport events such as the 1998 Tour de France, which was dubbed as the "Tour of Shame" or the 2004 Athens Olympic Games with a sudden double number of positive cases; and the reaction to them (i.e. establishing national anti-doping agencies) indicate that these events may only be the tip of the iceberg. Whilst the adverse analytical findings (positive results) in tests conducted by the World Anti Doping Agency (WADA) remain low around 2 percent, other occasions have revealed an elevated level of substance use. For example, the presence of some kind of drug or supplement was evidenced in 45 percent of the athletes who participated and were tested in the Tour de France 2000. However, the problem seems to be rooted more deeply. The literature supports the assumption that the consideration of and actual use of doping starts well before the athlete reaches his/her best career years as the prevalence of doping, particularly the use of anabolic steroids, is well documented among adolescents and even among pre-adolescent athletes where a steady increase in doping use was observed over the period of four years from age 11 to 15 [07004].

Ergogenic aids (from the Greek, ergon, meaning work) are ingested to enhance energy
utilization in athletes. While there is no scientific evidence to support the usage of these agents for enhancing performance in children and adolescents, using supra-physiological doses may be associated with undesired side effects [07005].

Doping is a problem that has plagued the world of competition and sports for ages. Even before the dawn of Olympic history in ancient Greece, competitors have looked for artificial means to improve athletic performance. Since ancient times, athletes have attempted to gain an unfair competitive advantage through the use of doping substances. A Prohibited List of doping substances and methods banned in sports is published yearly by the World Anti-Doping Agency. Among the substances included are steroidal and peptide hormones and their modulators, stimulants, glucocorticosteroids, β₂-agonists, diuretics and masking agents, narcotics, and cannabinoids. Blood doping, tampering, infusions, and gene doping are examples of prohibited methods indicated on the List. Apart from the unethical aspect of doping, as it abrogates fair-play's principle, it is extremely important to consider the hazards it presents to the health and well-being of athletes. The referred negative effects for the athlete's health have to do, on the one hand, by the high doses of the performance-enhancing agents and on the other hand, by the relentless, superhuman strict training that the elite or amateur athletes put their muscles, bones, and joints [11556].

The fact that athletes routinely use a wide array of substances is well documented as are the potential reasons for use. Whilst performance-enhancing substances are recognised in global as well as local anti-doping prevention programmes, other substances such as alcohol, tobacco and psychoactive drugs constitute a somewhat neglected area in the current idealised anti-doping educational effort. This prevailing approach creates an artificial divide between athletes' lives as sportspersons and private individuals. In reality, athletes constantly navigate their athletically active years on a tightrope between the different expectations they face both as athletes (often being in the spotlight) and as ordinary citizens, and know that failing in one part of their lives could easily result in failures in the other and vice versa. Substances in sports are mainly used for the following reasons:

- enhancing physical capacities (e.g. enhancing endurance, strength, or recovery between exercise sessions)
- psycho-stimulation (e.g. as a way of dealing with psychological stress)
- improving physical appearance (e.g. for achieving a lean figure)

Contemporary sport legislation recognises two types of substances used in sports: non-controlled substances, such as the majority of nutritional supplements, and products that contain prohibited substances (the use of which is often referred to as doping). Nutritional supplementation is defined as a preparation intended to provide nutrients, such as vitamins, minerals, fibre, fatty acids or amino acids, which are otherwise missing or not consumed in a sufficient quantity in the athlete's diet. It is generally accepted that substance use and misuse (SUM) in sports is more common in physically demanding sports (e.g. weightlifting or cycling) than in sports that require advanced specific motor skills (e.g. diving, sailing, table tennis or curling). However, to our knowledge, such generalisation is not sufficiently supported by any systematic comparative analyses of SUM across a variety of sports. Instead, the association of doping with particular types of sports has mostly come from anti-doping testing and the consequential public perception about doping in certain sports such as professional cycling, track and field or weightlifting. The majority of sport activities take place outside of controlled environments, leading to substance use without medical advice or supervision. The mismatch in targets in the anti-doping prevention and deterrence programmes coupled with the limited concern over substances such as alcohol and social drugs raises questions about the suitability of the current anti-doping policy. Whilst both arms of WADA's anti-doping effort represent heroic measures to keep doping out of sports, laboratory statistics shows no
significant change between 2003 and 2009 with the proportion of adverse and atypical findings ranging between 1.50 and 2.12 percent. Self-reports, alternative analyses and epidemiologic estimations indicate that the actual prevalence of doping is greater than this official statistic and ranges up to 40 percent. Although it is difficult to make a direct comparison between the latter and the WADA laboratory report, a recently published report evaluating 7,289 blood samples from 2,737 track and field athletes in the athlete testing pool, using the Athlete Biological Passport approach, estimated the prevalence of blood doping to be at 14 percent overall and between 1 and 48 percent for sub-populations, which supports the results from the epidemiologic studies. Anti-doping policy focuses on preventing selected substance use in situations where such behaviour has been deemed to result in increased athletic performance giving an unfair advantage. Drugs such as anabolic steroids that have long lasting effects and are considered “training drugs” are prohibited both in and out of competition. Other substances, such as alcohol, marijuana and opiates, have only an in situ effect on performance and, thus, are only prohibited in competition. Furthermore, the detection-based doping policy sanctions athletes if there is evidence of a prohibited drug in their body whilst completely disregarding whether the substance found has any performance-enhancing effect on the individual. This narrow view fails to address health concerns that might arise from SUM that happens outside the regulated domain. The main pillars of the current anti-doping approach are fair play, level playing field and equal chance; only those substances that violate these principles are considered with health being secondary. The detection- and sanction-based approach to prevent doping reinforces the priority given to protecting the sport instead of protecting the athletes' health. Future anti-doping policies should address the gaps that currently exist between the testing pool and all athletes including emerging (thus not yet selected for the testing pool) athletes and those training and competing at the sub-elite level; A holistic approach to substance use and misuse that considers athletes' substance use behaviour as a whole should be used in order to prevent doping and preserve not only the integrity of sports but also the athletes' health. Critical analysis of one of the three pillars of the doping ban, namely the protection of the health of athletes, points to the health risks inherently present in elite level sports along with the widespread use of acceptable substances that can also pose health risks. Furthermore, that excessive alcohol or social drug use does not pose infringements upon the anti-doping rules if their use happens outside of competition is a concerning phenomenon among athletes and gym patrons. Both experts and athletes concerned agree that tailored and innovative ways are needed to deliver relevant information on performance-enhancing and illicit drugs to athletes and key stakeholders [11557].

Semantics and definitions of doping

The International Olympic Committee's (IOC) definition of doping is the "use of an expedient (substance or method) which is potentially harmful to athletes' health and/or capable of enhancing their performance, or the presence in the athletes' body of a prohibited substance or evidence of the use thereof or evidence of the use of a prohibited method". There is no mention of intent or of how the substance entered the body. If the substance is in the athlete's body, then he or she is responsible. That is the basis of sanctions for testing positive for a prohibited substance. Sir Arthur Porritt, first chairman of the IOC Medical Commission, noted: "To define doping is, if not impossible, at best extremely difficult, and yet everyone who takes part in competitive sport or who administers it knows exactly what it means. The definition lies not in words but in integrity of character". Such agents are also known as "performance enhancing substances" (PES) or "performance enhancing drugs" (PED). The American Academy of Pediatrics defines these agents as: "...any substance when taken in non-pharmacological doses specifically for the purposes of improving sport performance. A
substance should be considered performance enhancing if it benefits sports performance by increasing strength, power, speed or endurance (ergogenic) or by altering body weight or body composition [10001].

The WADA has defined doping in their World Anti-Doping Code (the “Code”). Under the Code, a violation of one or more of the following rules is considered doping and may result in sanction:

- the presence of a prohibited substance or its metabolites or markers in an athlete’s bodily specimen
- the use or attempted use of a prohibited substance or a prohibited method
- possession of prohibited substances and methods
- administration or attempted administration of a prohibited substance or prohibited method to any athlete
- assisting, encouraging, aiding, abetting, covering up or any other type of complicity involving an anti-doping rule violation or any attempted rule violation.

A substance or method is considered for inclusion on the WADA’s prohibited list if the WADA determines that the substance or method meets any two of the following three criteria:

- medical or other scientific evidence, pharmacological effect, or experience that the substance or method has the potential to enhance or enhances sport performance.
- medical or other scientific evidence, pharmacological effect, or experience that the use of the substance or method represents an actual or potential health risk to the athlete.
- determination by the WADA that the use of the substance or method violates the spirit of sport as described in the “Introduction to the Code”

The current emphasis of prohibition also appears to be based on four factors:

1. Substances within the athlete’s body.
2. Methods that enhance oxygen transfer through blood doping or artificial measures.
3. Altering collected body fluid samples.
4. Genetic manipulation.

The interpretation of the Code is a legal one and largely untested. The broad interpretation of the principles behind the Code would seem to be related to any substance or method that (potentially or actually) enhances sport performance, becomes a health threat to the athlete, or is against the spirit of the sport. If the motivation, and indeed, the imperative, of an athlete is to constantly seek creative ways to improve the sporting performance, what then is the spirit of sport, and what actions are deemed to have violated that spirit? Using a biopsychological perspective, issues of what are acceptable levels of naturally occurring endogenous compounds, what is a method that is not considered doping, and what is the spirit of sport may be discussed especially regarding unnatural amounts of natural substances? Evidence-based medicine requires large sample sizes and preferably randomised-controlled trials to provide statistical evidence of significant effects. The issue of doping, however, is as much an interpretation of the law, as it is about the scientific and statistical evidence. The Code states that “…regardless of whether the expectation of performance enhancement is realistic…” [12015].

The WADA characterises spirit of sport under the Code as:

1. ethics, fair play and honesty;
2. health;
3. excellence in performance;
4. character and education;
5. fun and joy;
6. teamwork; dedication and commitment;
7. respect for rules and laws;
8. respect for self and other participants;
9. courage;
10. community and solidarity.

While these objectives are noble and worthy principles for sport, their abstract nature sometimes creates confusion when applied to the day-to-day realities that athletes face. The Code cites specific issues in the context of the spirit of sport, but these add to the confusion. The WADA states in the Code that the [121015]:
“... use of genetic transfer technology to dramatically enhance sport performance should be prohibited as contrary to the spirit of sport even if it is not harmful...”
and that
“... the potentially unhealthy abuse of certain substances without therapeutic justification based on the mistaken belief they enhance performance is certainly contrary to the spirit of sport regardless of whether the expectation of performance enhancement is realistic...”

**A background for understanding performance-enhancing drugs in sports**

Performance-enhancing drug use is a prevalent problem in sports. It is a problem that has captured the world's attention as the media highlights story after story of athletes who have transformed their bodies over a short period of time, those who have simply defied the aging process in an attempt to prolong a career and those whose careers have been tarnished because of drug use. The baseball investigations and the Mitchell Report of 2007 opened the US’s eyes and gave a glimpse of a secretive underground world. This "world" is much more intelligent and sophisticated than it is given credit for. It was the goal of one article to increase the awareness of the medical provider about the types of steroids and other medications used, the influence these substances have on the athletes, and how and why they use them [12018].

**Judging cheaters in different domains**

The present study examines how individuals judge others who use performance-enhancing drugs in two different domains – the athletic domain and the academic domain. Approximately 1,200 males in their freshman year of college completed a questionnaire that included two scenarios. One scenario described an athlete who misused anabolic steroids to help him succeed at a sporting event. The other described a college student who misused Adderall to help him succeed on his midterm exams. Participants rated the extent to which they thought the target had cheated and the extent to which they felt the substances were necessary for success. Results showed participants believed the athlete was more of a cheater than the student, and this difference got larger as past prescription stimulant misuse increased. Results also demonstrated that participants felt Adderall was more necessary than anabolic steroids for bringing about success. Contributions to the literature on zero-sum and non-zero-sum domains are discussed. Implications for future research and efforts to prevent substance misuse are described [12019].
Overviews

Doping is a phenomenon which in the past years through the various incidences in for example professional cycling has come more and more into the focus of the public interest. Whilst in the young past the problems were to define the term "doping" exactly, today's problem is to prevent adolescents and children of doping. This may partly be achieved by carrying out controls and serious sanctions for doping violations. However, scientific research has also proved that doping usage can be avoided by broad specific prevention measures. In general, the earlier the athletes dope the higher the risk to become addicted later on in life to other legal or illegal drugs. To get closer to a doping-free sport it is important to analyse the prevalence of doping regarding youth-, competitive-, high performance and recreational sports to find more specific ways for prevention. Moreover it may be rewarding to examine also other aspects of doping abuse, risks of addiction, the legal situation, current strategies in the fight against doping to enhance chances of further doping prevention opportunities. By means of this data an all-embracing view should be given over the current situation, problems and prospects [10002].

The drive toward success in sports and the need for a cosmetically acceptable appearance have driven many adolescents to take a wide variety of doping substances. The consumption of these chemicals in the hope and hype of improved sports performance, fueled by the easing of government restrictions on their proof of safety and efficacy, has resulted in an explosion of so-called ergogenic products available to the youth. Agents that have been used include anabolic steroids, anabolic-like agents, designer steroids, creatine, protein and amino acid supplements, minerals, antioxidants, stimulants, blood doping, erythropoietin, beta-blockers, and others. The use of these agents has considerable potential to cause physical and psychological damage. Use and misuse of drugs in this sports doping process should therefore be discouraged. Clinicians providing sports medicine care to youth, whether through anticipatory guidance or direct sports medicine management, should educate their young patients about the hype and hyperbole of these products that may keep them out instead of in the game at considerable financial cost to the unwary consumer [10003].

Testosterone is the principal male sex hormone. As with all natural steroids, it is biosynthesized from cholesterol. Phase I metabolism employs some very specific enzymes and pathways. Phase II metabolism and excretion follow more general patterns. The effects of testosterone are twofold: anabolic and androgenic. Because of its anabolic effects, testosterone is frequently abused in sports. Because of its endogenous nature, testosterone doping is difficult to detect. The standard procedure is based on the evaluation of the urinary steroid profile. Conspicuous samples then are submitted to compound-specific \(^{13}\text{C}/^{12}\text{C}\) analysis. Synthetic and endogenous steroids differ in this measure. However, numerous xenobiotic compounds have been derived from testosterone. The modifications typically aim at a reduction of the androgenic properties while maintaining the anabolic potential. Most of these compounds have been withdrawn from the legal market but are despite that found to be illicitly added to otherwise inefficient nutritional supplements. These products represent a major problem to doping control. Recently, also clinical trials with selective androgen receptor modulators have been started in a hope to get more anabolism and less androgenic effects [10004].

Little symptoms and signs

Abuse of doping substances has become increasingly widespread among athletes also at sub competitive and recreational level, due in part to the lack of controls in form of doping tests. Hypertension and the many other side effects related to the illicit use of prescription
drugs pose a substantial but often underestimated threat to public health. The symptoms are recognized late and are then mostly repressed or misjudged. Since the abuse is concealed to the doctor when help is finally sought, it might result in extensive and expensive tests that can seldom lead to an effective treatment. Two case reports were presented to elaborate on this issue [10005].

**Socio-psychological background to doping**

Sporting competition in the society has become the spectacle that mobilises and brings together the greatest number of people throughout the world, with the corresponding cultural and economic influence that this implies. As a result, the desire for athletic prowess has led sportspersons to undergo intense training programs and to consume substances that improve their performance, at times having recourse to doping techniques. At present, doping is the result of a combination of social, individual, physiological and cultural factors, which affect not only professional, but also amateur sportspeople. In order for the control and eradication of doping to be efficient, it is necessary to understand the problem and the substances that are most employed, amongst which special mention is merited by hormonal substances due to the complexity of detecting them and their possible repercussions on health [06012].

**To move borders …**

Human performance, defined by mechanical resistance and distance per time, includes human, task and environmental factors, all interrelated. It requires metabolic energy provided by anaerobic and aerobic metabolic energy sources. These sources have specific limitations in the capacity and rate to provide re-phosphorylation energy, which determines individual ratios of aerobic and anaerobic metabolic power and their sustainability. In healthy athletes, limits to provide and utilize metabolic energy are multifactorial, carefully matched and include a safety margin imposed in order to protect the integrity of the human organism under maximal effort. Perception of afferent input associated with effort leads to conscious or unconscious decisions to modulate or terminate performance; however, the underlying mechanisms of cerebral control are not fully understood. The idea to move borders of performance with the help of biochemicals is two millennia old. Biochemical findings resulted in highly effective substances widely used to increase performance in daily life, during preparation for sport events and during competition, but many of them must be considered as doping and therefore illegal. Supplements and food have ergogenic potential; however, numerous concepts are controversially discussed with respect to legality and particularly evidence in terms of usefulness and risks. The effect of evidence-based nutritional strategies on adaptations in terms of gene and protein expression that occur in skeletal muscle during and after exercise training sessions is widely unknown [08002].

The creed of the Olympics states: “The important thing in the games is not winning but taking part. The essential thing is not conquering, but fighting well”. As noble a goal as this is, it has little to do with the reality of the modern sports world. Athletes today are expected and encouraged to seek every possible way to improve their performance, including specialised training, hi-tech design of equipment and apparel, scientific and medical support, including the use of nutritional supplements [08003]. Being a high performing athlete is nowadays a profession that requires dedication, long-term commitment and sacrifice [08004], whereas a great concern to sport governing bodies is the chemical alteration of athletic performance. The intriguing question is then what compels athletes to risk their health or reputation for
outstanding sports performance, how high price the athlete is willing to pay, and what factors make athletes vulnerable to doping and at which point of their careers [08005]. New, more powerful and undetectable doping techniques and substances are now abused by professional athletes, while sophisticated networks of distribution have developed. Professional athletes are often the role models of adolescent and young adult populations, who often mimic their behaviors, including the abuse of drugs [08006].

Breaking of borders
To explore how current substance use, including the use of sports supplements and illicit drugs, may impact upon a person’s future intentions to use anabolic-androgenic steroids (AAS) 214 exercising males (mean age, 30 years; range, 17-61 years) recruited from 5 gymnasia in Sydney, Australia, completed a web-based survey. The survey contained questions relating to sport supplement use, illicit substance use, reasons for currently not using AAS, and reasons for intending to use AAS in the future. Participants completed a structured interview schedule that included questions regarding licit and illicit substance use, reasons for non-AAS use, and, where appropriate, reasons for intended future AAS use. Sixteen percent of the sample indicated that they would use AAS in the future. Reasons for future AAS use included increasing muscle size (80 %), improving appearance (74 %), and increasing strength (57 %). Four-fifths (80 %) of the sample reported use of sports supplements, with vitamins and protein supplements commonly reported (83 % and 67 %, respectively); more than one-third (36 %) reported use of creatine in the past 6 months. Half (52 %) of the sample reported use of illicit substances in the preceding 6 months, with amphetamines and cannabis commonly reported (66 % and 62 %, respectively). Significant predictors of intending to use AAS included past 6-month use of creatine and knowing AAS users. The authors concluded that the use of sport supplements and/or illicit substances may remove barriers for the future use of such drugs as AAS [09011].

Much to win
Athletes are rewarded for winning at virtually every level of competition. Second place is viewed as the “first loser”. A coach’s job security is directly related to his team’s success, not that they are simply “fighting well”. Given this reality, it is not surprising that athletes and coaches will sacrifice and risk a great deal in order to obtain a competitive edge and enhance performance at all costs. Performance enhancement in Olympic and professional sport has now become a medical, ethical, and legal problem for modern athletes and athletic organizations. This is primarily due to the amount of money associated with winning in today’s sports industry. Multimillion dollar contracts, appearance fees, international endorsement and sports merchandising represent a billion dollar industry that offers today’s athletes, their sponsors and entourage previously unheard of financial gains. Driven by the millions of dollars now routinely available for winning a sporting event, unethical pharmacists, medical professionals, trainers and sports organizations have worked secretly, and at times without their athletes’ consent, to develop sophisticated doping programs where performance is optimized, often at the risk of the athletes’ health. Now, these same doping programs are moving out of the professional sports market to our youth and other at-risk populations at alarming rates [08006].

Modern sports and the media’s misplaced fixation on fame, fortune and winning at all costs have unintentionally created a growing market for doping substances. These substances, once only abused by elite athletes, are clearly spreading into schools and health clubs worldwide. They are being accepted by a whole new generation of young customers who see reports daily in the newspapers of sports icons accused of abusing drugs only to continue playing, breaking records and claiming fortunes. These same performance-enhancing drugs...
are also abused by adolescents and weekend athletes and non-athletes who have wider behavioral and health risk problems. In addition, these drugs are now being abused by male and female adolescents for cosmetic purposes in an attempt to achieve the "cut" and sexy look promoted by the media [08006].

Ergogenic potential of AAS

It was in 2005 described physiological changes that occurred in a Tour de France cyclist as he matured from 21 to 28 years of age during the period of 1992 to 1999. This cyclist has recently admitted to using performance-enhancing drugs: erythropoietin, red blood cell reinfusion, testosterone, cortisone, and human growth hormone. The main physiological improvements he displayed over this 7-year period during which the author was testing him were an improved gross mechanical efficiency and a reduced body weight. It is also worth noting that four of the five laboratory-based physiological testing sessions were performed in the precompetitive season or with reduced training, although one session was conducted at the end of the competitive season. It is not possible to know the extent to which his drug use might have improved his gross mechanical efficiency because there have not been direct studies conducted to the author’s knowledge. Erythropoietin and/or red blood cell reinfusion would seem to be taken acutely during the competitive season to boost blood volume during a race, although it is conceivable that erythropoietin could be taken as a training aid. However, it seems unlikely that this cyclist had elevated blood volume at the time of physiological laboratory testing. Furthermore, it is unlikely that an elevated blood volume would improve gross mechanical efficiency, because studies that have acutely infused red blood cells into athletes have not reported changes in efficiency measured from open circuit spirometry. Since publication of the 2005 paper, there have been several reports of champion athletes displaying improved efficiency of movement. The world record holder in the women’s marathon, Paula Radcliffe, displayed a remarkable 15 percent improvement in running economy between 1992 and 2003. Therefore, there is growing evidence that mechanical efficiency can improve with chronic training. However, we cannot be absolutely certain that the improved gross mechanical efficiency and reduced body weight displayed in the subject of the 2005 paper was not somehow influenced by his reported drug use [0021].

Although AAS have been used in sports for ergogenic purposes for decades, many believed that the improved performance seen with AAS was due to their influence on motivation and aggression. It took landmark studies from Bhasin et al to prove that testosterone dose-dependently increases muscle mass, maximal voluntary strength, and power and that these improvements are correlated with circulating testosterone concentrations. There are multiple mechanisms that lead to this anabolic response. Androgens are known to increase fractional muscle protein synthesis and increase the size of both type I and type II muscle fibers. Studies have also shown that testosterone directs the pluripotent mesenchymal stem cell toward myogenic lineage rather than adipogenic lineage. Some clinical trials of testosterone replacement in hypogonadal elderly men have also shown improvement in muscle strength. Because androgens improve maximal voluntary muscle strength, it is understandable that a high rate of androgen use is seen among weight lifters and other power athletes. However, the use of androgens in endurance events, e.g. bicycling, is not based on scientific evidence because androgens have not been shown to improve whole body endurance. There are two types of androgen doping: direct and indirect. Direct doping involves exogenous administration of both natural and synthetic androgens. Indirect doping refers to using compounds that increase the production of endogenous testosterone (estrogen receptor antagonists or aromatase inhibitors), androgen precursors (dehydroepiandrosterone (DHEA), androstenedione), and gonadotropins [13003].
Testosterone/epitestosterone (T/E ratio)

To circumvent the detection of synthetic androgens, athletes have resorted to doping with testosterone. Hence, the detection of illegal use depends upon distinguishing between endogenous and exogenous testosterone. There are two main detection methods available. Epitestosterone (17alpha-hydroxy-4-androsten-3-one) is a 17-epimer of testosterone that is also secreted by the Leydig cells of the testes. It was first described in 1947 as an androgen metabolite; however, the first direct evidence of its urinary excretion was seen in the 1960s. It is biologically inactive, and there is no interconversion between testosterone and epitestosterone. Although its production rate is less than 5 percent of testosterone, its urinary excretion is 33 percent that of testosterone. It is mainly excreted in the urine as a glucuronide; however, a small amount is also excreted as a sulfate. Due to its rapid clearance, excretion rates of testosterone and epitestosterone are similar, making the urinary T/E ratio approximately 1. Because there is no interconversion between the two compounds, administration of exogenous testosterone results in an increase in the T/E ratio. Measurement of T/E ratio in a large number of athletes has shown that generally the ratio remains below 6. This initially led the IOC to adopt the cutoff threshold of 6 to consider the test as positive. However, it was later recognized that genetic differences in various populations may influence T/E ratio. Some athletes have low endogenous epitestosterone production rate; hence, their T/E ratio always exceeds 6. To the contrary, a deletion polymorphism in uridine diphosphate glucuronyl transferase 2B17, an enzyme that facilitates epitestosterone excretion, lowers T/E ratios (especially in Asian populations). Considering these genetic variants, the IOC recently lowered the T/E cutoff ratio to 4. Hence, any value above 4 is considered suspicious. To complicate matters, some athletes may mask the use of exogenous testosterone by coadministration of epitestosterone. In such cases, the exogenous use of epitestosterone is detected by elevated concentrations of its urinary metabolites. Generally, in athletes not using AAS, the T/E ratio remains fairly constant. Hence, monitoring T/E ratio serially in the same athlete is occasionally performed to detect any change that may suggest illicit use [13003].

Isotope ratio mass spectrometry (IRMS)

If the T/E ratio is abnormal, the WADA requires additional confirmation by gas chromatography combustion IRMS, which involves measurement of $^{13}$C/$^{12}$C isotope ratio in testosterone. This method is based on the fact that the percentage of $^{13}$C (a naturally occurring isotope of carbon) in endogenous testosterone (synthesized in the body from carbon sources derived from animals and plants) is higher than in synthetic testosterone. Hence, synthetic testosterone has a lower $^{13}$C/$^{12}$C ratio. During the IRMS, the steroids are separated by gas chromatography and oxidized to carbon dioxide in a combustion chamber. The ratio of $^{13}$CO$_2$/$^{12}$CO$_2$ is monitored in an isotope ratio mass spectrometer. A lower $^{13}$C/$^{12}$C ratio suggests exogenous testosterone administration. In addition to testosterone, IRMS is also used to distinguish endogenous from exogenous nandrolone, dihydrotestosterone, and DHEA [13003].

Synthetic androgens

The availability of synthetic androgens has not only provided more options for the athletes but at the same time circumvents their detection by the doping authorities because chemical signatures of many of these compounds are not readily available. Norbolethone has been credited as the first designer androgen that was identified in the 1960s. In 2002, its chemical signature was identified after it was detected in an athlete’s urine. In 2003,
tetrahydrogestrinone was identified. It is a derivative of gestrinone (a progestin); hence, it is both a potent androgen and progestin. In 2005, a third designer androgen was identified as desoxymethyltestosterone. In addition to these androgens, SARMs have recently gone to clinical trials and have the potential for abuse in various sports. Various bioassays are being employed in the detection of these designer androgens [13003].

**Androgen bioassays**

Bioassays are functional assays that are employed to determine the bioactivity of a compound. Hence, they measure potency of a substance. The unit of bioactivity is defined as the lowest concentration at which a functional response is measured. This unit is then compared with known bioactivity of a standard compound (such as testosterone or dihydrotestosterone). The main advantage of these bioassays lies in their ability to detect even those androgens whose chemical structure is unknown, hence making this an ideal tool to detect novel designer androgens (unlike RIA and mass spectrometry that require the chemical signature of the steroid to be known). Bioassays can be divided into in vivo and in vitro assays. The former involves evaluation of in vivo responses of androgenic stimulation such as the growth of capon comb or changes in weight of androgen-dependend tissues (levator ani, seminal vesicles, etc.) in castrated male rats. These assays are time consuming and expensive. Hence, in vitro assays are used more commonly because they are faster, relatively inexpensive, and can simultaneously screen a large number of test samples. The in vitro assays are of three types [13003]:

- **Receptor binding assays**: These assays evaluate the ability of a substance (test sample) to bind to the androgen receptor in the presence of a known radioactive ligand for the receptor. Hence, the displacement of the radioactive ligand from the androgen receptor by the test sample correlates with its bioavailability.

- **Cell proliferation assays**: These assays involve measurement of bioactivity of an unknown substance by its ability to proliferate androgen-dependent cell lines, e.g. human prostate cancer cell line (LNCap). Although sensitive, these assays are not entirely specific for androgens.

- **Reporter gene assays**: In these assays, the bioactivity of a compound is measured by the degree of expression of the reporter gene. These assays can be performed in either yeast (usually Saccharomyces cerevisiae) or mammalian cells. In short, the process entails choosing a host cell line that does not express an endogenous androgen receptor. The next step involves introduction of two plasmids into the cell line: an expression plasmid for constitutive expression of androgen receptor in the cells and a reporter plasmid in which the androgen response element sequences drive the expression of a truncated form of firefly (Photinus pyralis) luciferase. The latter serves as the reporter gene. The amount of luciferase expression is proportional to the bioactivity of the compound being tested in the sample and is measured by luminometry. These assays have now been optimized for high throughput screening. Hence, a large number of samples can now be tested with reporter gene assays.

**Indirect androgen doping**

Indirect doping refers to strategies employed by athletes that result in a sustained increase in endogenous testosterone production and is tailored to circumvent the banning enforced on the administration of natural or synthetic androgens by WADA. These strategies include [13003]:

---

99
- estrogen blockers such as estrogen receptor antagonists (antiestrogens) or aromatase inhibitors
- androgen precursors such as DHEA and androstenedione
- gonadotropins.

**Estrogen blockers**

The rationale for using estrogen antagonists and aromatase inhibitors stems from the fact that estrogen is a more powerful negative regulator of hypothalamic-pituitary-gonadal axis than testosterone itself. This is evident in men with congenital aromatase deficiency where both androgens and gonadotropins are elevated and exogenous estrogen replacement suppresses them. Although less than 1 percent of daily testosterone produced is aromatized to estradiol, it has 100-fold higher molar potency than testosterone. Hence, the reflex rise in endogenous testosterone as a result of estrogen blockade may result in myotrophic effects, although the rise in serum testosterone concentrations is modest (50-65 %). Hence, both estrogen receptor antagonists and aromatase inhibitors have been put on the list of banned drugs by WADA. The original antiestrogens were the nonsteroidal drugs like clomiphene and tamoxifen that bind to both estrogen receptor alpha and beta. Since then, newer nonsteroidal agents have become available such as raloxifene, toremifene, and droloxfene. The newest steroidal estrogen analog that has come to market is fulvestrant. Aromatase is an enzyme that is a product of CYP19 gene and is responsible for converting testosterone to estradiol. Aromatase inhibitors completely and irreversibly inhibit this enzyme, which results in a decrease in estradiol synthesis. Aminoglutethimide was the first steroidal drug in this class. Since then, more specific and potent steroidal aromatase inhibitors have become available such as testolactone, atamestane, and exemestane. The nonsteroidal aromatase inhibitors include anastrozole, letrozole, and vorozole. Recently, mass spectrometric methodologies have become a formidable tool in identifying both estrogen blockers and aromatase inhibitors. Hence, a sensitive and robust assay is now available to circumvent indirect doping by these agents [13003].

**Androgen precursors**

This class of agents includes drugs like androstenedione and DHEA. Androstenedione is a prohormone that is produced in the gonads and the adrenals in both sexes. It is synthesized from DHEA and is converted to testosterone by 17beta hydroxysteroid dehydrogenase. On the other hand, DHEA is predominantly secreted by the adrenal glands. Both these compounds were sold over the counter in an uncontrolled fashion as dietary supplements for almost two decades under the Dietary Supplement Health and Education Act. It was only recently that the US Congress added androstenedione to the list of banned steroids. To the contrary, the IOC prohibited the use of these agents more than a decade ago (DHEA in November 1996 and androstenedione in December 1997). Androstenedione at a dose of 300 mg results in a significant increase in serum testosterone levels, whereas a dose of 1500 mg results in an increase in lean body mass and muscle strength. Similarly, one study showed that DHEA at high doses (100 mg) also results in an increase in muscle strength. Hence, the banning of both these prohormones by the IOC is justified because they do carry ergogenic potential. Each of these hormones results in an increase in T/E ratio, which is then followed by confirmation of $^{13}\text{C}/^{12}\text{C}$ ratio with IRMS. In the case of androstenedione, another mode of confirmation is by measuring its metabolite, 4-hydroxyandrostenedione, by mass spectrometry or IRMS [13003].

**Gonadotropins**
Another form of indirect doping is the use of gonadotropins such as LH or human chorionic gonadotropin (hCG), both on the WADA’s list of prohibited drugs for male athletes. The latter is a dimeric glycoprotein containing an alpha- and a beta-subunit that is normally produced by the human placenta. Its alpha-subunit is similar to other glycoprotein hormones such as FSH, LH, and TSH. It undergoes glycosylation with sialic acid residues that prolongs its half-life and makes it a long-acting analog of LH. Clinically, recombinant LH or hCG is used to stimulate spermatogenesis and endogenous testosterone production in men who have central hypogonadism and desire fertility. Not only are hCG and LH expensive, requiring injections several times per week, but the evidence that they improve muscle strength is sparse. A small randomized placebo-controlled study of older men showed that hCG therapy resulted in an increase in serum testosterone levels and lean body mass; however, it failed to improve upper or lower body strength (61). In addition to its presumed ergogenic effects, subjects abusing AAS also use hCG to avoid detection of exogenous testosterone by stimulating endogenous testosterone production and preventing testicular atrophy. Because hCG doesn’t alter T/E ratio, this methodology is not useful in the detection of indirect doping with hCG. The detection of hCG is initially performed with immunoassays, and if positive, confirmation is carried out with immunoextraction and mass spectrometry. hCG is not banned in female athletes because there is no evidence suggesting that it improves muscle mass and strength. Furthermore, there is an ethical dilemma because positive hCG may reveal underlying pregnancy and is therefore considered an invasion of privacy. Detection of LH is accomplished by immunoassays [13003].

GnRH is synthesized in the hypothalamus, and it is transported from there via the hypothalamic-pituitary portal venous microcirculation to stimulate the gonadotrophs, resulting in LH and FSH production. For this, GnRH must be secreted in a pulsatile fashion (peaks every 60–90 min). Continuous administration of GnRH desensitizes the gonadotrophs, resulting in down-regulation of GnRH receptors. This results in suppression of testosterone to castrate levels (after an initial flare) and forms the basis of therapy for prostate cancer. Pulsatile administration of GnRH via pumps is performed in clinical settings in men who have a hypothalamic cause of hypogonadism; however, serum testosterone levels achieved are generally within the therapeutic range. Hence, GnRH administration doesn’t result in sustained production of supraphysiological testosterone levels. For these reasons, GnRH and its analogs are not banned by WADA. However, mass spectrometry-based assays have been developed to detect the use of exogenous GnRH. Under normal circumstances, only fragments of GnRH may be detectable in the urine. Hence, a urinary concentration of intact GnRH of at least 20 pg/ml is considered unambiguous evidence for surreptitious use of the hormone [13003].

For decades, scientists have been trying to dissect out the anabolic and androgenic properties of androgens. The discovery of SARMs was a result of the constant quest for achieving tissue selectivity mainly so that the anabolic effects of these compounds on muscle and bone can be achieved without any risk to the prostate. This tissue selectivity is of tremendous importance in the elderly who have a higher incidence of prostate-related events. This was finally accomplished in 1998 when it was developed the first SARM. This compound was derived from androgen receptor antagonists like flutamide and bicalutamide. Over the years, four groups of SARMs have been synthesized. These include arylpropionamides, bicyclic hydantoins, quinolines, and tetrahydroquinolines. Based on their anabolic properties in musculoskeletal tissues, in January 2008, WADA added SARMs to its prohibited list. Because SARMs possess enormous structural heterogeneity, their detection remains a daunting task. However, most of the available SARMs can be detected either by liquid or gas chromatography tandem mass spectrometry [13003].
**Boosting in paraolympic**

“Boosting” is defined as the intentional induction of autonomic dysreflexia (AD) by athletes with a spinal cord injury (SCI) at or above the level of T6 for the purpose of improving sports performance. Boosting has been shown to confer up to a 10 percent improvement in race time. Additionally, to compete in a hazardous dysreflexic state, whether intentional or unintentional, would present an extreme health risk to the athlete. For these reasons, the International Paralympic Committee strictly bans the practice of boosting, and has developed a protocol to test for its presence. Testing was performed at three major international Paralympic events. Education regarding the dangers of AD was provided to athletes and team staff. Testing was conducted on athletes from the relevant sport classes: Athletics (wheelchair racing classes T51/T52/T53) and Handcycling (H1). Key parameters included the athlete’s demographics (gender, country of origin), classification and blood pressure measurements. An extremely elevated blood pressure was considered to be a proxy maker for AD, and a systolic blood pressure of ≥180 mm Hg was considered a positive test. A total of 78 tests for the presence of AD were performed during the three games combined. No athlete tested positive. The number of athletes tested, by classification, was: 6 in Athletics T51, 47 in Athletics T52, 9 in Athletics T53 and 16 in Handcycling H1. Of those tested, the average systolic and diastolic blood pressures were 135 mm Hg (range 98-178) and 82 mm Hg (range 44-112), respectively. All athletes were compliant with testing. No athletes were withdrawn from competition due to the presence of AD. Testing for the presence of AD in paralympic athletes with SCI prior to competition has been carried out for the first time at three major international paralympic competitions. There have been no positive tests thus far. Knowledge gained during these early testing experiences will be used to guide ongoing refinement of the testing protocol and the development of further educational initiatives.

**Possible lack of effects of doping**

Doping is a serious issue bedevilling the sporting arena. It has consequences for athletes’ careers, perception of sports in the society and funding of sports events and sporting organisations. There is a widespread perception that doping unfairly improves results of athletes. A statistical study of information on best lifetime results of top 100 m sprinters (males better than 9.98 s, females 11.00 s), over the period of 1980-2011 was conducted. Athletes were divided into categories of "doped" (n=17 males and 14 females), based on self admission, the confirmed detection of known doping agents in their bodies or doping conviction, and "non-doped" (n=46 males and 55 females). No significant differences (unpaired t-test) between dopers and non-dopers were found in their average results: male "dopers" 9.89 s identical with 'non-dopers' 9.89 s, females 10.84 s and 10.88 s respectively. Slopes of regressions of best results on dates for both 'dopers' and 'non dopers' were not significantly different from zero. This indicates that no general improvement as a group in 100 m sprint results over a quarter of a century occurred irrespective of doping being or not being used. Since there are no statistical differences between athletes found "doping" and the others, one of the following must be true: (1) "doping" as used by athletes so detected does not improve results, or (2) "doping" is widespread and only sometimes detected. Since there was no improvement in overall results during the last quarter of the century, the first conclusion is more likely. Objectively, various "doping" agents have obvious physiological or anatomical effects. These may not translate into better results due to the clandestine use of doping that prevents its scientific structuring. Perception of the effectiveness of doping should be reconsidered. Policy changes may be required to ensure the continued fairness and equity in testing, legislation and sports in general.
Cognitive doping

A growing concern in today's society is the consumption of substances to increase physical or cognitive performance. For example, the use of drugs such as anabolic steroids in professional sports has long been a concern. In order to combat physical doping in professional sports, the World Anti-Doping Agency (WADA) annually lists banned substances. Besides illicit or banned drugs, athletes also consume legal and freely available substances such as analgetics, caffeine, and other ergogenic aids (e.g. creatine, vitamins, minerals, carbohydrates, proteins), which may also improve physical performance. Cognitive doping can include illicit substances (e.g. cocaine) and prescription drugs (pharmacological neuroenhancement) such as stimulants (e.g. methylphenidate and amphetamines), antidepressants, beta-blockers, or modafinil, which are primarily designed and used for the treatment of diseases. Prevalences for the use of such cognitive-enhancing substances range from 1.2 to 35 percent among German and American students, and are estimated to be 20 percent among readers of the journal Nature, 20 percent among surgeons, and 5 percent among office workers in Germany. Besides illicit and prescription drugs, the use of legal and freely available substances such as ginkgo biloba or caffeinated drinks (e.g. coffee, energy drinks) are also a matter of debate although their ergogenic potential is still unknown. It is of particular concern that these nutritional supplements have been shown to fail tests of safety, purity, and quality of ingredients and may contain prohibited substances. One study assessed, for the first time, prevalence estimates for physical and cognitive doping within a single collective of athletes using the randomized response technique (RRT). Furthermore, associations between the use of legal and freely available substances to improve physical and cognitive performance (enhancement) and illicit or banned substances to improve physical and cognitive performance (doping) were examined. An anonymous questionnaire using the unrelated question RRT was used to survey 2,997 recreational triathletes in three sports events in Germany. Prior to the survey, statistical power analyses were performed to determine sample size. Logistic regression was used to predict physical and cognitive enhancement and the bootstrap method was used to evaluate differences between the estimated prevalences of physical and cognitive doping. 2,987 questionnaires were returned (99.7%). 12-month prevalences for physical and cognitive doping were 13 and 15 percent, respectively. The prevalence estimate for physical doping was significantly higher in athletes who also used physical enhancers, as well as in athletes who took part in the European Championship in Frankfurt compared to those who did not. The prevalence estimate for cognitive doping was significantly higher in athletes who also used physical and cognitive enhancers. Moreover, the use of physical and cognitive enhancers were significantly associated and also the use of physical and cognitive doping. The use of substances to improve physical and cognitive performance was associated on both levels of legality (enhancement vs doping) suggesting that athletes do not use substances for a specific goal but may have a general propensity to enhance. This finding is important for understanding why people use such substances. Concerning a potential gateway for cognitive doping, the prevalence estimate for cognitive doping was significantly higher in athletes who used cognitive enhancers than those who did not. Since we do not know which type of substance was used first by the athletes – legal and freely available or illicit substances – these data do not strongly support the gateway theory that the use of cognitive enhancers is the first step for cognitive doping. Consequently, more effective prevention programs against substance abuse and doping could be developed [13023].

Doping may be defined, broadly, as the use of unauthorised means to increase performance in sport. Doping is most commonly associated with the use of drugs. It was discussed some recent advances in neuroscience that suggest that the skills and abilities underpinning sports performance can be enhanced using technologies that change the activity of the brain. These factors may include motor learning, enhanced muscular strength or reduced fatigue,
or even changes to mental state or concentration. The devices needed to generate these
effects are already available, and are currently in use in laboratories or clinics to produce
short- or long-term changes in performance. It was argued that brain stimulation, or
neurodoping, will become a key technology for the future of sport and sports medicine. It will
be suggested that neurodoping may have different uses in different sports, and it was argued
that each sport must determine whether neurodoping should be considered as cheating, or
should be considered a legitimate aid to training or performance [13024].

Brain stimulation techniques

Two main brain stimulation techniques are available. Transcranial magnetic stimulation
(TMS) involves the discharge of brief magnetic pulses through a stimulating coil held against
the subject’s head. This rapidly-changing magnetic field induces electric currents in the brain
tissue near to the centre of the coil. The immediate effect of this is to generate action
potentials in those cells, followed by a refractory period as the cell recovers. The fire-
and-recover pattern is most visible when a TMS pulse is triggered over the hand area of
primary motor cortex: muscle activity of the contralateral hand, measured with electromyo-
graphy, shows a burst (called the motor-evoked potential) followed by relative quiescence
(called the silent period). Recent developments in the application of TMS have involved
temporally patterning the pulses delivered by the stimulator to induce both inhibitory and
excitatory effects in the target brain area (called thetaburst stimulation). These effects outlast
the stimulation phase by several tens of minutes, with the possibility of longer-term
reorganisation of brain activity if the stimulation is applied at regular intervals. Transcranial
current stimulation (tCS) comes in two common variants. Transcranial direct current
stimulation (tDCS) involves passing a weak electric current from a negative electrode
cathode) to a positive electrode (anode). The magnitude and polarity of the electric field at
the brain surface near the electrodes determines its effect: cells in the vicinity of the anode
will tend to increase in excitability, through a process thought to involve a modulation of the
resting membrane potential of the cells; conversely, cells near the cathode become less
active through the same process. Transcranial alternating current (tACS) uses a similar
principle, except that the current alternates at a specific frequency. Researchers typically
apply tACS with a frequency related to functionally-relevant oscillatory brain potentials, such
as might be seen with electroencephalography. tCS has a number of advantages over TMS.
The technology is cheaper and more portable. Indeed, wireless tCS stimulators are now
commercially available, and websites exist that give instructions for home-made tCS
stimulators. TMS is, however, a more focal technique, with a relatively small area of the brain
being affected by the sti13ulation, whereas the electric field induced by tCS spreads across
the whole brain surface [0024].

What can be done with brain stimulation?

It is foreseen two domains where neurodoping may potentially change performance in sport.
These divide into immediate gains from increasing cortical excitability versus longerterm
gains from stimulation during training. In the “acute” phase following stimulation, participants
have demonstrated enhanced motor skills including: improved time-to-fatigue, response time,
and tremor suppression. The effect of tDCS is maximal shortly after the end of stimulation
and declines over roughly a 20- to 60-min period, depending on the stimulation parameters.
The effects of theta-burst TMS last for a similar length of time, but with the peak of effect
some 5 min after the end of stimulation. So, it is possible to envisage a time when an athlete
might take a “hit” of stimulation before shooting a pistol or setting off on a ski slalom. A
second use of neurodoping might be in skill acquisition. Skills learned in the context of
anodal tDCS are acquired more rapidly, and reproduced more accurately, than those learned
without. Sports performance at the highest levels require good technique and good timing. These are skills learned during training, so enhancing the efficiency of learning during the training phase will be of greater benefit at competition time. It has been suggested that an athlete could use these techniques to make training more efficient and thereby gain an advantage. It is possible that neurodoping will add little to the performance of elite athletes. Most studies of brain stimulation recruit non-expert, healthy participants from the community of the laboratory (in practical terms, university students) and test in conditions where performance is likely to be changed but not reach its maximum. Elite athletes who are already performing close to the physical limits of the human body may not gain from the potential benefits of brain stimulation. Further research is needed to explore whether neurodoping and elite performance are compatible [13024].

Can it be detected? What are the risks?

There is no known way to detect reliably whether or not a person has recently experienced brain stimulation. A modern technique for analysing brain composition is magnetic resonance spectroscopy (MRS), which can detect changes in the concentration of neurotransmitters and related metabolites. Theta-burst TMS appears to affect inhibitory processing by gamma-amino butyric acid (GABA) while not affecting excitatory processing involving glutamate. Anodal and cathodal tDCS modulate GABAergic and glutamatergic processing differently. When looking specifically at the brain region targeted by TMS or tDCS, the changes in brain chemistry are of the order of 10 percent in metabolite concentration, and require carefully controlled conditions to pick out the signal from the noise. Several factors mean that MRS is unlikely to be of practical utility in detecting neurodoping [13024].

Ethical issues

There is an argument that human enhancement of any type is not wrong in sport or in any other context. It has been argued that enhancing performance with drugs is analogous to an act of creativity whose only limit should be the safety of the participant. So, by this argument, regulating pharmacological enhancers places an unnecessary constraint on the limits of human achievement. Allowing drug enhancement would simply add another option for athletes who wish to choose among all the available means of improving their overall performance. While the analogy with the kind of neuroenhancement is not perfect, nonetheless brain stimulation offers a potential adjunct for immediate performance or for training and should be considered as if it were another form of drug doping. A related question about the use of human enhancement is whether the performance shown by the person is “authentically” theirs. If a neuro-enhanced sprinter is faster in reacting to the starter’s pistol, is that advantage hers or should the stimulator be given the credit? It was recently argued that brain training with tDCS enhances the person’s own latent cognitive abilities and increases the efficiency of a training programme. Thus, brain stimulation mediates a person’s ability but does not enhance it in the strictest sense. A third argument is practical: as discussed above it is not possible, as far as is known, to determine whether a person has or has not had brain stimulation. Each sport determines its own rules. It would be suggested that each sport determines whether neurodoping poses a risk to its ethos. For example, performance in a sport such as pistol-shooting would be greatly improved by tremor reduction, so governing bodies should decide whether shooters should be prevented from using tACS during or immediately before competing to reduce tremor, just as beta-blockers are banned in many sports. Conversely, a tennis player’s performance in a match is heavily influenced by the probability of regularly getting the first service in, which is a skill learned in training and therefore potentially susceptible to neurodoping [13024].
Effect of international results during the anti-doping era

100 meter and 5000 meter

The introduction of doping substances and methods in sports triggers noticeable effects on physical performance in metric sports. Here, we use time series analysis to investigate the recent development in male and female elite sprinting performance. Time series displaying the average of the world's top 20 athletes were analyzed employing polynomial spline functions and moving averages. Outstanding changes in performance over time were statistically analyzed by Welch's t-test and by Cohen's measurements of effect. For validation we exemplarily show that our analysis is capable of indicating the effect of the introduction of in- and out-of-competition doping testing on women's shot put as well as the effects of the market introduction of erythropoietin (EPO) and the introduction of EPO and continuous erythropoiesis receptor activator (CERA) testing on 5000 m top 20 male performances. Time series analysis for 100 m men reveals a highly significant drop by more than 0.1 s from 2006 to 2011 with a large effect size of 0.952. This is roughly half of the effect size that can be found for the development of the 5000 m performance during the introduction of EPO between 1991 and 1996. While the men's 200 m sprinting performance shows a similar development, the women's 100 m and 200 m sprinting performances only show some minor abnormalities. It was discussed why the striking sex-specific improvement in sprinting performance is indicative for a novel, very effective doping procedure with insulin-like growth factor-1 (IGF-1) being the primary candidate explaining the observed effects [13068].

100 meter in Olympic Games

The introduction of doping substances and methods in sports triggers noticeable effects on physical performance in metric sports. Here, we use time series analysis to investigate the recent development in male and female elite sprinting performance. Time series displaying the average of the world's top 20 athletes were analyzed employing polynomial spline functions and moving averages. Outstanding changes in performance over time were statistically analyzed by Welch's t-test and by Cohen's measurements of effect. For validation we exemplarily show that our analysis is capable of indicating the effect of the introduction of in- and out-of-competition doping testing on women's shot put as well as the effects of the market introduction of erythropoietin (EPO) and the introduction of EPO and continuous erythropoiesis receptor activator (CERA) testing on 5000 m top 20 male performances. Time series analysis for 100 m men reveals a highly significant drop by more than 0.1 s from 2006 to 2011 with a large effect size of 0.952. This is roughly half of the effect size that can be found for the development of the 5000 m performance during the introduction of EPO between 1991 and 1996. While the men's 200 m sprinting performance shows a similar development, the women's 100 m and 200 m sprinting performances only show some minor abnormalities. It was discussed why the striking sex-specific improvement in sprinting performance is indicative for a novel, very effective doping procedure with insulin-like growth factor-1 (IGF-1) being the primary candidate explaining the observed effects. It is known that human growth hormone (hGH) has been abused in professional sports since the 1980s, disregarding its appearance on the World Anti-Doping Agency (WADA) list for banned substances. For modern elite athletes, especially for cheating sportsmen and women, growth-promoting effects play an important role and can be induced by various substances. One study demonstrates that hGH administration in recreationally trained athletes results in statistically significant improvements in sprint capacity. IGF-1 is known for evoking growth-promoting effects and for its direct anabolic impact on skeletal muscle. At least some of the hGH deployed anabolic actions are exerted through triggering the generation of IGF-1.
However, so far no clinical trials have demonstrated a beneficial effect of IGF-1 administration on athletic performance. IGF-1 acts in endocrine, autocrine, and paracrine modes on skeletal muscle. Exogenous administration of IGF-1 causes powerful anabolic actions similar to the effects of hGH. Due to limited experience with long-term administration of exogenous IGF-1, only side-effects from short-term usage have been documented in clinical trials. Next to edema, arthralgia, headache, and jaw pain especially hypoglycemia should be mentioned. Furthermore, it is appealing to use IGF-1 in combination with other drugs like hGH, insulin, and anabolic steroids, as the combined application most likely provides an enormous potential to improve performance. Consequently, IGF-1 is included in the WADA list of banned substances, but its abuse by elite athletes is assumed to be lower than for hGH, because of its lower availability due to the lack of a natural resource from which IGF-1 could be harvested. Nevertheless, IGF-1 will be more attractive to use than hGH, since testing for hGH is improving. Preparations containing IGF-1 were first approved for the American market in August 2005 by the US Food and Drug Administration (FDA) for the treatment of growth failure in children. Therewith the possibilities to acquire and abuse IGF-1, despite the lack of a natural source, have been increasing even more. The results from the time series analysis disclose a time decreasing trend in male short-distance running that started around 2005/2006. Over 100 m, elite athletes underwent a large effect (0.952) in the last five years that is clearly displayed by both approaches: spline and moving average. The last six years over 200 m entailed an effect size of 0.481. In women's track and field sprinting, an effect is also detectable over 100 m. However, the moving average is at the same level in the beginning and the end of the regarded interval and over 200 m there is no effect noticeable after 2004. These explicit developments can be discussed to be associated with doping, but it is important to mention the existence of other possible or additional explanations. Simultaneously with the time decreasing trend over 100 m for men, we noted that more athletes from the West Indies entered the annual top 20 lists. Thus changing conditions concerning training for these populations of athletes could contribute to the stated developments. When taking doping into consideration as a plausible explanation, several different substances have a strong enough physiological effect and therefore could be related to this development. HGH may still be used as presently no robust long-term testing method for the detection of hGH administration exists. Unfortunately it is also possible that new synthetic ‘designer steroids’ have been developed that cannot be detected by the tests currently available. Additionally the list of other substances that could possibly improve sprinting performance is long. Next to hGH, IGF-1 and ‘designer steroids’ another example would be oestrogen receptor antagonists. However, it was argued in the following that among the substances that were recently introduced to the market, IGF-1 is a very important candidate that could explain the observed development in sprinting performance. The mechanism of IGF-1 with its beneficial actions concerning physical performance presupposes its abuse, alone and in combination with other agents, in track and field. 2008 is the year in which we first noted a significant change over 100 m, but IGF-1 was approved in 2005. Interestingly, we detected the first sign of an EPO effect in 1992, although it entered the American market in 1989. In one opinion, athletes first need to get acquainted with drugs they want to abuse. Its handling is usually only known for medical purposes. So the doping-related application of the drug and its incorporation in the training process take some time to be optimized. Additionally, examination of the number of athletes that ran the 20 fastest times of each year over 100 m shows a fall from ten in 2005 to four in 2006 and eleven athletes ran the fastest times in 2011. It was believed that this progression illustrates a slow integration: IGF-1 abuse started with a small amount of athletes and now is integrated in the world elite of track and field sprinters. Induced by the effect detected over the women's 100 m, it was suspected female athletes to be using IGF-1, too. Even so, it seems to be less beneficial for women, because there is no parallel effect over 200 m. Furthermore, athletes usually try to deliver top performances in Olympic Games years. Over the women's 100 m and 200 m, 2008 – the year of the Olympic Games in Beijing – is the minimum. In contrast,
the men have their minima in 2011 and there is a local maximum in 2008 over 200 m. A study showed that women responded with a smaller increase in IGF-1 levels, although they received a larger dose of hGH compared to men. So far it is not known whether treatment with IGF-1 leads to sex differences in the related physiological response. However, sex differences can be found for serum levels of IGF-1. IGF-1 would not be the only doping substance with different effects depending on sex. For example, our analysis of women’s and men’s shot put shows greater effects for female shot putters. Considering the whole period from the introduction of anabolic steroids to the beginning of out-of-competition controls, it was computed an effect size of 3.482 for men from the earlier effect onset in 1961 to 1988 and 5.154 for women from 1966 to 1988. Franke and Berendonk mentioned that enormous effects, especially in female athletes, were noticed in the 1970s during the systematically organized doping efforts of the German Democratic Republic. Anabolic steroids and EPO are the best-known doping substances and the portrayed examples account for enormous effect sizes. Anabolic steroids had an effect of 3.177 over ten years in the women’s shot put and EPO 1.925 over a five-year period in the men’s 5000 m. Both were abused in a variety of sports disciplines. Nowadays blood doping, including potential abuse of EPO, is widespread among athletes regardless of the progress in testing. This is well in line with our notion that the introduction of EPO testing had no profound effect. In comparison, out-of-competition testing for anabolic steroids led to a clear decrease in performances displayed through the arithmetical mean of the 20 best athletes of each year. The effect sizes that was computed for short-distance running from 2001 to 2011 are not as large, but still enormous enough to animate other athletes to misuse IGF-1. In our opinion, IGF-1 could definitely also be effective concerning track and field in the jumping disciplines, although analysis of long-jump and high-jump did not display any recent significant developments, but future examination might. Thus, the official introduction of the recently developed test procedure for IGF-1 could prevent the expansion of the abuse of IGF-1 in professional sports [13069].

Contrary to that statement, when analyzing men’s 100 m performance at the Olympic level, the winners (average 86.36 kg) have outweighed the rest of the finalists (77.72 kg) dating back thirty years. This phenomenon is also consistent when comparing the medal winners (80.45 kg) versus non-medal winners. Contrary to the claims made by the author’s there have been statistically significant improvements over the last quarter century in elite performance of the 100 m dash, both in the men’s and women’s division. A separate one-way ANOVAs compared the 100 m finals times for men and women from the Olympic Games over the past 20 years with Bonferroni post hoc analysis when appropriate. There were significant differences observed for men and women. Post hoc analysis revealed men’s times from 2012 were significant lower than 1992 and 2000; with 2008 also being lower than 1992. Women’s times from 2012 were lower compared to 2000. This holds true for not only the medal winners of the Olympic Games, but also of the participants in the finals as a whole [13070].

It is believed that the remarkable improvements observed in the 100 and 200 m are mostly due to the performance of one single athlete, Usain Bolt, who has repeatedly broken the world record of these sprint disciplines in 2008 and 2009, by lowering the limits by notable coefficients of 0.984 and 0.993, respectively. Since the dramatic drop of the polynomial lines is almost entirely due to the performance of one athlete, it cannot be attributed to an entire group of athletes. This phenomenon has been recently defined as the Usain Bolt effect, and has been attributed to stature and reduction in stiffness as a consequence of the increased contact time and lower step frequency, which both result in an advantage in relative power development and mechanical efficiency. This would not support the theory of improvement by doping but – rather – the well known possibility of “extreme outliers” that seldom occur in a normal distribution of athletes, and may remarkably account for an improvement in records. A second important aspect is that Usain Bolt, the athlete who has dramatically improved both
100 and 200 m world records, has never been found positive during anti-doping controls, either in- or out-of-competition, by whatever anti-doping authorities. Until opposite evidence can be provided, this is the only reliable proof that we have that the world records were broken by a fair athlete. Then, it is also questionable to assert that the use of hGH and/or IGF-1 explains the effect on 100 m performance between 2006 to 2011, since it has been clearly acknowledged that athletes have been abusing hGH for its anabolic effects since the early 1980s, whereas the first test was not introduced until 2004. Accordingly, it is much more likely that the abuse of hGH had been commonplace before 2006, and not afterwards. An identical consideration can be made on the potential abuse of IGF-1, since this substance appeared much earlier than 2006 on the black market [13071].

Is doping-free sport a Utopia?

The impressive legend of 7-time Tour de France winner Lance Armstrong has died, replaced by an equally impressive legacy of shameless lying and cheating on a grand scale, team doping orchestration and discipline on and off the road, and conspiracy to fool the world while earning tens of millions of dollars. But, the harsh reality is that the doping-control system did not catch arguably the biggest, boldest, and most brazen drug cheat in the history of sport. Hundreds of analytical doping tests performed over nearly a decade in state-of-the-art laboratories failed to reveal his charade. And the same system failed to catch any of his teammates as long as they were on his team. Riders have confessed under oath how easily the tests could be manipulated. Doping testing failed miserably. A federal investigation compiling 1000 pages of evidence and testimony from 26 different cycling teammates and support staff finally caught Armstrong. All of this evidence is now public. If one of the world’s most visible athletes evaded detection despite “500 doping tests” (probably the real number was about half that) over all those years while the whole world watched and the doping-control officials took blood and urine samples, why should we have any confidence that the situation is better today? In numbers, the power-to-weight ratio for the best cycling climbers in the world on their hardest, most decisive climbs rose from about 5.8 W/kg in the late 1980s and early 1990s quite rapidly to ≥6.3 W/kg by the mid-1990s and remained there to the mid-2000s, before beginning to fall again to 5.8 to 6.0 W/kg in the most recent tours. This anecdote suggests that EPO plus consumption/injection of anabolic agents facilitating accelerated recovery may have been “worth” as much as a about 10 percent increase in sustainable power over climbs of 30 to 40 minutes. The Festina doping scandal of 1998 seemed to scare the peloton straight in 1999, because climbing power (otherwise) inexplicably dropped about the same 10 percent, before rising again in 2000 and thereafter. That is a measurable, chronologically preciseblip that adds some contrast to the doping fingerprint. With the exception of doping-positive Alberto Contador, the fastest climbs in Tour history were performed during the 1996-2006 time window, with slower climbing times since by the best climbers and the Tour de France winners in the last 2 years [13028].

Armstrong’s doping violations were detected by antidoping laboratories on several occasions, but these results appear to have been systematically swept under the rug at a higher level. A broomshaped checkbook may have been used, as evidenced by large “financial contributions” by Armstrong to the International Cycling Union (UCI). This would mean not that doping testing systematically failed but that the system was corrupt. This is a second small piece of evidence that the drug labs can go a long way toward keeping cycling and all sports cleaner, provided that the sport-governing bodies they serve are 100 percent clean. A third source of encouragement amid all the gloom is that the culture of collective “tight lips” among athletes has collapsed. In addition to a substantial increase in positive tests since 2006, a large share of a generation of top cyclists has confessed their doping
practices. A long-standing code of silence has now been broken. Effective doping on the immense scale uncovered with Team US Postal (and subsequent versions of Team Armstrong) exemplifies how critical the cooperation of athletes, sport scientists, doctors, and coaches is to achieving the combined goals of extensive and effective doping on one hand and detection avoidance on the other. Good sport science and the open dissemination of research and best-practice methodology in all aspects of athlete preparation have probably contributed to making the race to the top of the international podium more expensive. The top-20 medal-winning countries are winning a smaller share of the total medals in the Olympics, from 90 percent in 1992 down to 75 percent in 2012. This is great for sport and in part a result of better sport-science support in a larger number of countries, all along the path from talent identification to physiological and technical development, to performance peaking, to race management. The difference between a gold medal and finishing out of the medals is smaller than ever before. Good sport science can make the tiny difference between gold and fourth place on a given day. At the world-class level, the performance-enhancing effects of doping clearly exceed what cutting-edge sport science can achieve with further optimization of training programs, recovery methods, etc. For the sake of sports, it must be hoped that good sport science, and not just good chemistry, matters more in the future [13028].
DOPING AND ANTI-DOPING HISTORY

Overviews

Though we may still sing today, as did Pindar in his eighth Olympian Victory Ode, "... of no contest greater than Olympia, Mother of Games, gold-wreathed Olympia...", we must sadly admit that today, besides blatant over-commercialization, there is no more ominous threat to the Olympic games than doping. Drug-use methods are steadily becoming more sophisticated and ever harder to detect, increasingly demanding the use of complex analytical procedures of biotechnology and molecular medicine [13001].

The use of drugs to enhance physical performance has occurred since the beginning of recorded time. Ancient Greeks at emushrooms and sesame seeds to enhance performance, and Roman gladiators used stimulants to increase endurance. In modern sports, documentation of the abuse of performance enhancing drugs appeared in the early1900s, when athletes ingested stimulants (caine, amphetamines, ephedrine, and strychnine) to alleviate fatigue and increase focus. Anabolic-androgenic steroids (AAS) are now the most common illicit drugs used to enhance performance at the modern Olympic Games along with stimulants, primarily by weight lifters and athletes in track-and-field. The AASs are a group of synthetic derivatives of testosterone with both androgenic, anabolic, and masculinizing (androgenic) effects. In 1889, physiologist Charles E. Brown Seuard reported improvement in a variety of his body functions (strength, intellect, and force of urine stream) following the injection of an extract of testicles from the dog and guinea-pig. The primary natural male hormone, testosterone was first isolated from the testis of bulls in 1935 by Davidet al. Butenandt and Hanisch and Ruzicka et al independently synthesized testosterone in the same year, and both chemists received the Nobel Prize in 1939 for their work. Most of the AASs were developed during the 1950s when chemists attempted unsuccessfully to separate the anabolic and androgenic properties of these testosterone derivatives. Nandrolone, the 19-nor analog of testosterone was the first anabolic steroid with sufficient dissociation of androgenic and anabolic properties to justify introduction into clinical practice during the 1950s. Dr. John Ziegler, an American physician- weight lifter, administered AASs to 3 future American weight lifting champions after learning of the success of AAS-using Russian weight lifters at the 1954 World Championships. In 1958, the US Food and Drug Administration (FDA) approved the use of methandrostenolone (Dianabol) for the treatment of hypogonadism, resulting in the increased availability of this steroid. By the mid-1960s, the use of AASs to enhance performance in sports spread, particularly among weight lifters and other strength athletes. An estimate done was that a third of the US track-and-field athletes in the 1968 pre-Olympic training camp were using AAS. From 1966 until the collapse of the German Democratic Republic in 1990, hundreds of East German physicians and scientist performed doping research and administered prescription drugs as well as unapproved experimental drug preparations to adult and adolescent athletes of both sexes. In 1963, the Council of Europe defined doping in sports as a result of the death of a Danish cyclist at the 1960 Olympics, the death of a UK cyclist at the Tour de France, and the prevalence of potentially life-threatening drugs in sports. In 1964, the International Olympic Committee (IOC) unanimously voted to ban doping in sports. By 1967, the IOC established a Medical Commission with responsibilities to prohibit doping, to develop the Olympic Movement Anti-Doping Code, and to formulate a list of prohibited substances. In 1974, the IOC banned the use of AASs, and testing for AASs by immunoassay screening and gas chromatography-mass spectrometry confirmation began in 1976. In 1984, the use of testosterone was also banned. From the 1960s through the 1980s, the German Democratic Republic established a systematic doping program for thousands of their athletes that included the use of
parenteral preparations of epitestosterone propionate to avoid detection of illicit AASs. In 1988, the IOC stripped Ben Johnson of his Olympic gold medal and world record in the 100-meter dash for using an AAS. In the same year, the distribution of possession of AAS with intent to distribute without a valid prescription became a felony, when US Federal Food, Drug, and Cosmetic Act (FFDCA) was amended as part of the Anti-Drug Abuse Act. In 1990, the Anabolic Steroids Control Act defined an AAS as any drug or hormonal substance chemically and pharmacologically related to testosterone (other than estrogens, progestins, and corticosteroids) that promotes muscle growth. These synthetic compounds became DEA schedule III drugs as defined by the US Controlled Substances Act. Later, this act was amended by the Anabolic Steroid Control Act of 2004; on January 20, 2005, the amended Controlled Substance Act added both anabolic steroids and prohormones to the list of controlled substances, making possession of the banned substances a federal crime. In response to continuing demand for illicit AASs, designer AAS appeared as a means to avoid detection of these illicit drugs. An example was the synthesis of tetrahydrogestrinone from the palladium-charcoal catalyzed hydrogenation of gestrinone by the Bay Area Laboratory Cooperative, an American nutritional supplement company. However, analyses and legal action resulted in the banning of several athletes as a result of the use of these synthetic steroids. Subsequently, major league baseball revamped their AAS policy calling for a 50-game ban for first-time offenders (up from 10 days), a 100-game penalty for second-time offenders (up from 30 days), and a life time ban for a third positive test. Previously, a baseball player could be suspended for life only after the fifth positive test [13002].

The earliest records of doping in sport come from the Ancient Olympics games when athletes are reported to have taken figs to improve their performance. With the advent of modern pharmacology in the 19th century, many athletes began to experiment with cocktails of drugs to improve strength and overcome fatigue. As this practice was not illegal, there are good records of the lengths athletes would go to in order to win. Alongside the benefits, came the dangers and following several fatalities, a code to ban performance enhancing drugs was gradually developed. Growth hormone was first isolated from the human pituitary gland in the 1950s. Its anabolic effects were soon recognised and athletes had begun to abuse it by the early 1980s, at least a decade before it was used therapeutically by adult endocrinologists. A number of high profile athletes have admitted using growth hormone. Detection of its abuse has been challenging and the lack of an effective test has undoubtedly encouraged its abuse. Only now are methodologies being developed that should stem this tide [09001].

Doping is as old as sport itself. The word itself is likely derived from the Dutch word, dop, the name of an alcoholic beverage made from grape skins used by Zulu warriors to enhance their prowess in battle. In the 20th and 21st centuries, various agents have been used: alcohol, caffeine, strychnine, amphetamines and then after World War II anabolic/androgenic steroids and more recently some of the peptide hormones including insulin, erythropoietin, human GH, and a host of other growth factors. Anabolic/androgenic steroids remain a mainstay in the performance enhancement drug arena given that they are really the only major class of steroids that are unequivocally anabolic with salutary effects on athletic performance. The arms race will continue as long as designer steroids are produced, tested in vitro, and then, for the more difficult parameter, that they and their metabolites will not lead to a positive test at the doping control laboratory [11554].

Sporting associations have stated that the fundamental aims of doping controls and anti-doping policies are to [06101]:

- uphold and preserve the ethics of sport
- safeguard the physical health and mental integrity of the players
- ensure that all competitors have an equal chance.
The word doping is probably derived from the old Dutch word dop, which was the name of an alcoholic beverage made of grape skins used by Zulu warriors to enhance their prowess in battle. Ancient Greek athletes are known to have used special diets and stimulating potions to fortify themselves. Strychnine, caffeine, cocaine, and alcohol were often used by cyclists and other endurance athletes in the nineteenth century. Thomas Hicks ran to victory in the Olympic marathon of 1904 in Saint Louis with the help of raw eggs, injections of strychnine, and doses of brandy administered to him during the race. The term “doping” progressed into mainstream use in the early twentieth century, originally referring to drugging of racehorses. The practice of enhancing performance through foreign substances or other artificial means, however, is as old as competitive sport itself. By the 1920s it had become evident that restrictions regarding drug use in sports were necessary. In 1928 the International Amateur Athletic Federation became the first international sport federation to ban the use of doping (use of stimulating substances). Many other international federations followed suit, but restrictions remained ineffective as no tests were performed. The death of Danish cyclist Knud Enemark Jensen during competition at the Olympic Games in Rome 1960 – the autopsy revealed traces of amphetamine and nicotinyl tartrate – increased the pressure for sports authorities to introduce drug tests. In 1966 the International Cycling Union and the Fédération Internationale de Football Association (FIFA) were among the first international sports federations to introduce doping tests in their respective world championships. In the following year the International Olympic Committee (IOC) instituted its Medical Commission and set up its first list of prohibited substances. Drug tests were first introduced at the Olympic Winter Games in Grenoble and at the Olympic Summer Games in Mexico in 1968 after the urgency of anti-doping work had been highlighted by another tragic death, that of cyclist Tom Simpson during the 1967 Tour de France. A reliable test method to detect anabolic steroids was finally introduced in 1974 and the IOC added anabolic steroids to its list of prohibited substances in 1976. This resulted in a marked increase in the number of drug disqualifications in the late 1970s, notably in strength related sports such as throwing events and weightlifting. Blood boosting or blood doping, which involves removal and subsequent reinfusion of the athlete’s blood in order to increase the level of oxygen-carrying haemoglobin, has been practised since the 1970s. The IOC banned blood doping as a method in 1986. Anti-doping work was complicated in the 1970s and 1980s by suspicions of state-sponsored doping practised in some countries. The most famous doping case of the 1980s concerned Ben Johnson, the 100 metre runner who tested positive for stanozolol (anabolic steroid) at the 1988 Olympic Games in Seoul. Johnson's case focused the world's attention to the doping problem to an unprecedented degree. In 1998 a large number of prohibited medical substances were found by the police in a raid during the Tour de France. The scandal led to a major reappraisal of the role of public authorities in anti-doping affairs. As early as 1963, France had been the first country to enact anti-doping legislation. Other countries followed suit, but international cooperation in anti-doping affairs was long restricted to the Council of Europe. In the 1980s there was a marked increase in cooperation between international sports authorities and various governmental agencies. Before 1998 debate was still taking place in several discrete forums (IOC, sports federations, individual governments), resulting in differing definitions, policies, and sanctions. One result of this confusion was that doping sanctions were often disputed and sometimes overruled in civil courts. The Tour de France scandal highlighted the need for an independent international agency, which would set unified standards for anti-doping work and coordinate the efforts of sports organizations and public authorities. The IOC took the initiative and convened the World Conference on Doping in Sport in Lausanne in February 1999. Following the proposal of the Conference, the World Anti-Doping Agency (WADA) was established on 10 November 1999. On 5 March 2003, at the second World Conference on Doping in Sport, some 1200 delegates representing 80 governments, the IOC, the International Paralympic Committee, all Olympic sports, national Olympic and Paralympic committees, athletes, national anti-doping
organisations, and international agencies supported the World Anti-Doping Code as the basis for the fight against doping in sport. The Code entered into force on 1 January 2004. On 19 October 2005, the World Anti-Doping Code was adopted at the 1st International Convention against Doping in Sport by the General Conference of UNESCO at its plenary session. Some 184 countries have signed the Copenhagen Declaration on Anti-Doping in Sport, the political document through which governments show their intention to implement the World Anti-Doping Code by the ratification of the UNESCO Convention [06002].

Drug use by athletes to improve performance is not a new practice. As early as BC 776, the Greek Olympians were reported to use substances such as dried figs, mushrooms, and strychnine to perform better [06003].

Anti-doping efforts started in earnest after the 1960 Olympic Games in Rome. During a team time trial, 23-year-old Danish cyclist Knud Enemark Jensen collapsed, fractured his skull and died. An autopsy reportedly found traces of amphetamine and a blood-vessel dilator in his system. Although the drugs might not have caused his death, the episode forced cycling officials to take a closer look at doping. The UCI banned some performance enhancers, and in 1967 the International Olympic Committee established a commission to ferret out doping in sport. The task is thankless: anti-doping agencies thwart one cheating strategy, only for another to emerge. The 1972 Olympic Games in Munich, Germany, ushered in testing for stimulants, but athletes had moved on to undetectable, naturally occurring hormones, such as testosterone. Anti-doping authorities now measure the ratio of testosterone in the blood to a related molecule called epitestosterone. In response, some athletes have reportedly found ways of regulating epitestosterone to keep the ratio in check. For cycling and other endurance sports, human recombinant EPO fuelled a doping revolution. EPO is a natural hormone that promotes production of oxygen-carrying red blood cells. The first synthetic, or recombinant, version was developed by the biotechnology company Amgen in Thousand Oaks, California, and in 1989 it was approved by the US Food and Drug Administration to treat anaemia. It also offered cyclists an easy endurance boost that helped them to excel in gruelling stage races. The drug is nearly identical to the hormone naturally churned out by the kidneys, so was impossible to detect. It is also easier to administer than blood transfusions, which had been used to the same effect. Typically, red blood cells account for 40-45 percent of the blood, but in the heyday of EPO doping, some riders were showing up at starting lines with haematocrits of more than 60 percent. The UCI instituted a “no-start” rule, disqualifying riders if their haematocrits on the morning of a race were above 50 percent for men and 47 percent for women. So cyclists began diluting their EPO-boosted blood with saline solution to keep their haematocrits below the threshold. The drug companies that produce EPO have helped anti-doping laboratories to develop direct tests based on subtle biochemical differences between the recombinant molecules and the natural form. The first of these was approved for use in 2000. But athletes increasingly obtain knock-off forms produced in China and India, and researchers have struggled to keep up [11415].

The use of doping agents, once restricted to professional athletes, has nowadays become a problem of public health, since it also concerns young people and non-competing amateurs in different sports. The use is also diffused in social life for improving physical appearance and enhancing performance and even dietary supplements assumed to improve performance often contain anabolic steroids. While decades ago the so-called “classical doping agents” (like stimulants and narcotics) were used, to-day anabolic steroids are more widely diffused. Anabolic steroids are synthetic substances prepared by introducing modifications in the molecular structure of testosterone, the main natural androgenic anabolic steroid that forms in testes interstitial cells. The first report concerning the use of anabolic
steroids by an athlete who searched for increased weight and power dates 1954. In 1974 the misuse of anabolic steroids in sports was banned by the International Olympic Committee and control tests were implemented in 1976 Montreal Olympic Games through radioimmunoassay analysis: the technique, however, only allows for unspecific detection of a limited number of exogenous steroids. Over the years, always new doping substances are synthesized and, as a consequence, the list of prohibited compounds is continuously updated and new suitable analytical methods for their detection and determination in biological matrices are continuously required. In doping control analysis the knowledge of steroid metabolism pathway in human body is of primary importance and the analytical methods must permit the simultaneous detection and determination not only of the forbidden precursor agents but also of their metabolites. In addition, the potential presence and amount in the biological samples of species that can interfere in the analysis should be evaluated. Also the several anabolic steroids, specifically designed to circumvent doping control, put on the market have been incorporated in the list of the prohibited substances of the World Anti-Doping Agency (WADA). In WADA list steroids figure in three main classes, namely anabolic steroids, corticosteroids and substances with anti-estrogenic properties. It must be strongly reminded that assumption of doping agents not only leads to athletes the possible failing of doping tests but causes important health risk and WADA prohibited list establishes criteria to highlight the alteration of the natural steroid profile caused by exogenous administration [12001].

**Specific dates**

Some important dates in the history of anti-doping [11416]:

1928  The IAAF becomes the first federation to ban doping

1966  The IAAF, the Union Cycliste Internationale (UCI), and the Fédération Internationale de Football Association (FIFA) introduce urine drug tests in their respective championships

1967  The International Olympic Committee (IOC) institutes its Medical Commission and sets up the first list of prohibited substances

1968  Drug tests introduced at the Olympic Games

1970s  Marked increase in the number of doping-related disqualifications after the introduction by the IOC of anabolic steroids to its list of prohibited substances

1980s  Introduction of out-of-competition testing

1986  Blood transfusion banned by IOC

1990s  rEPO included in the IOC’s list of prohibited substances

1990s  Introduction of blood tests

1999  WADA is established

2004  The World Anti-Doping Code is adopted worldwide

2005  United Nations Educational, Scientific and Cultural Organization (UNESCO)
adopts the International Convention against Doping in Sport

The drugs-in-sport problem first came to prominence in the 1960s with the use of amphetamines among professional European cyclists. At the same time, steroids were becoming widespread in the United States and Eastern Europe. As money flowed in commensurate with an unprecedented media interest, sport began to globalise in the 1980s, and its commercial value increased exponentially. A number of high-profile drugs scandals occurred in the 1980s, culminating in the Ben Johnson affair in 1988. The consequent media feeding-frenzies encouraged a number of sporting bodies to introduce anti-doping regulations. Plagued by constant allegations of drug use in international sport, along with the Tour de France drug crisis of 1998, the IOC led the push for the establishment of an agency with the responsibility for managing and enforcing global anti-doping policy. WADA was born in 1999 and has become a global force in the war on drugs-in-sport. WADA's success in establishing an international drug code has been underpinned by three developments. First, WADA is funded jointly by the IOC and a group of national governments. This has provided the agency with both capital and influence. Secondly, WADA has secured a series of international declarations that have commended and ratified the policy code it has developed. Thirdly, WADA policy has recently been approved by the United Nations Educational, Scientific and Cultural Organisation (UNESCO) as an international convention. These achievements have consolidated WADA’s position as the central international agency for regulating drug use in sport [10312].

Despite the fact that doping is not a new phenomenon in sport, enhancing performance through artificial means has only been banned since the 1960s. Doping as a potential danger to the modern Olympic movement was recognized in the '50s and officially acknowledged ten years later by the creation of a list of banned substances. After an agonizing period over athletes' amateur status, performance enhancing drugs have taken over as the major basis for tension and concern within the Olympic movement since 1972. Researchers seem to agree that doping is unwelcome in sport. However, opinions are divided between doping being a serious deviance one must fight against and doping as undesirable but unavoidable consequence of the institutionalized sport. Notably, the reason behind banning doping initially was the growing concern about athletes' health. Doping only became established as unethical after that point [07004].

The seriousness of the doping problem is reflected by the recent increase in organised effort to combat doping in sport. The first step toward a globalised effort was the creation of the Anti-Doping Code of the World Anti-Doping Agency (WADA) in 1999 as an organisational level response to the Festina Scandal at the Tour de France, parallel to the European Union's (EU) pledged support in the fight against doping. The first report (known as the HARDOP report) was commissioned in 1998 and published in 1999, followed by targeted research projects under the EU's Competitive and Sustainable Growth run under 5th Framework Programme. The globalised effort was recently manifested in the creation of the International Convention Against Doping in Sport by the United Nations Educational, Scientific and Cultural Organization (UNESCO). The UNESCO convention is the first legally binding international framework setting out the responsibilities of national governments and is currently signed either as ratification, acceptance, approval or accession by 65 countries [07004].

**Early (modern) history**
The use of drugs and ergogenic substances to augment athletic performance, commonly referred to as doping, has evolved along with sporting events. Ancient Olympic athletes consumed mushrooms, plants, and herbs in an attempt to gain a competitive edge. The modern Olympic Games made their debut in 1896, and mixtures of cocaine, ephedrine, and strychnine were used to enhance performance [08007].

Alfons Bukowski (1858-1921) is commonly regarded as the pioneer of anti-doping research. In 1910, he developed a method to detect alkaloids in horse saliva. One hundred years later, this is a good moment to remember Bukowski, an outstanding Polish pharmacist, often mistakenly represented in world literature as a Russian chemist. It is also an occasion to mention that the real driving force in the history of doping were events related to horse rivalry [10313].

In the 1904 Olympics, marathon runner Thomas Hicks used a mixture of brandy and strychnine and nearly died. Mixtures of strychnine, heroin, cocaine, and caffeine were used widely by athletes, and each coach or team developed its own unique secret formulae. This was common practice until heroin and cocaine became available only by prescription in the 1920s. During the 1930s, it was amphetamines that replaced strychnine as the stimulant of choice for athletes. In the 1950s, the Soviet Olympic team first used male hormones to increase strength and power [08006].

History of anabolic steroids

Almost half a century before the discovery of androgens, Brown-Sequard (the father of andrology) had recognized that the contents of testicular extracts could improve libido, energy, and muscle strength. After synthesis of testosterone, Boje was the first to suggest that sex hormones may enhance physical performance. Although the most well-known phase of AAS abuse in Olympic history is that of the Soviet weight-lifting team in the 1952 and 1956 Olympic Games, it is believed that some German athletes were given androgens even during the 1936 Berlin Olympics. The introduction of AAS among the American athletes is attributed to Dr. John Ziegler (a physician-member of the US Weight-Lifting Team) who learned about the use of AAS by the Russian team in 1954 during his trip to weight-lifting championships in Vienna. Upon his return, Dr. Ziegler experimented with testosterone on weight lifters in the York Babel Club in Pennsylvania. That is considered to be the beginning of AAS abuse in sports in the United States, which later spread from high-intensity strength-training games to sports such as field athletics, baseball, swimming, etc. The two common patterns of AAS abuse are “stacking” and “cycling.” Stacking involves the use of two or more androgens in progressively increasing doses over a short period of time. Cycling refers to the intermittent use of AAS where use of steroids is followed by a drug holiday. The practice of “cycling” is based on the notion that drug holidays prevent desensitization to large doses of androgen [13003].

The first report concerning the use of anabolic steroids by an athlete who searched for increased weight and power dates 1954. In 1974 the misuse of anabolic steroids in sports was banned by the International Olympic Committee and control tests were implemented in 1976 Montreal Olympic Games through radioimmunoassay analysis: the technique, however, only allows for unspecific detection of a limited number of exogenous steroids [13004].

Detection of testosterone
The history of AASs is a tale that has its roots in ancient "endocrinology." More than 6000 years ago, farmers noted an enhanced ability to domesticate animals after castration. Years later, the medical theories of "humoralism" developed. This doctrine was based on a theory that attempted to explain diseases based on imbalances among the four humors: sanguine, choleric, melancholic, and phlegmatic. In addition, ancient Egyptians and Romans believed that testicles and animal penises held special healing powers. Ancient Greek athletes used a wide variety of alleged performance-enhancing drugs, such as plant extracts and testicular extracts. These early theories and practices marked the beginning of future discoveries. John Hunter (1728-1793) was a Scottish surgeon who was later appointed as Surgeon General for the British army. He made many noteworthy contributions to science, including contributions to the understanding of digestion, fetal development, venereal diseases, dentistry, and lymphatics. He conducted the first testicular transplant in 1786 in which he removed a testicle from a rooster and implanted it into a hen. However, it was not until 1849 that Arnold Adolf Berthold (1803-1861) found evidence of a "bloodstream substance" from roosters that affected their appearance and behavior. His theory was correct, but it was not widely accepted by his contemporaries. Berthold was a professor at the University of Göttingen, and he performed experiments on roosters while he was a curator at a local zoo. He observed the impacts of castration and the reimplantation of testicular tissues on roosters. Once castrated, the roosters' combs decreased in size, they lost interest in the hens, and they lost their aggressive male behaviors. Those effects were reversed after reimplanting testicular tissues or extract, despite denervation. Despite these findings, other researchers did not cite Berthold's work for nearly 50 years [07007].

Perhaps the most well-known researcher of anatomy and physiology was Charles Edouard Brown-Sequard (1817-1894). Brown-Sequard, a prominent French physiologist and Harvard professor, was one of the founders of modern endocrinology. He had a strong interest in endocrinology, and he studied adrenal glands, testes, thyroid, pancreas, liver, spleen, and kidneys. He is probably most famous for his auto-experimentation with testicular substances (extracted from guinea pigs and dogs), the results of which were published in 1889. He reported increased strength, mental abilities, and appetite and even claimed that the process relieved constipation and increased the arc of his urine stream. Although no one is sure why he experienced these effects, his experiment caused others to investigate the testicular substance as a possible cure for various ailments, such as diabetes, tuberculosis, epilepsy, paralysis, gangrene, anemia, influenza, arteriosclerosis, Addison's disease, hysteria, and migraine headaches. He encouraged testing of his testosterone products by providing free samples to physicians. Unfortunately, with such widespread use, shoddy researchers subjected animals and humans alike to high risks for infection and inflammation. Austrian physiologist Oskar Zoth was the first person to propose injecting athletes with a hormonal substance, as published in his 1896 paper describing how the use of an "extract" improved muscular strength and the "neuromuscular apparatus," thus potentially improving athletic performance. He and his physician partner, Fritz Pregl (1869-1930), self-injected testosterone extracts from bulls and measured the strength of their middle fingers by plotting them on "fatigue curves". They won the Nobel Prize in chemistry in 1923 [07007].

Substances referred to as "chemical messengers" were discovered in 1902 by English physiologists and professors, William Maddock Bayliss (1860-1924) and Ernest Henry Starling (1866-1927), at University College London. Bayliss' research team was the focus of an animal rights controversy in 1903 – the Brown Dog Affair – in which Bayliss was alleged to have performed a live dissection of a brown dog in his laboratory. He, of course, denied the accusation and won a civil suit, donating the money to the University for further research; he even wrote articles promoting the humane treatment of animals. Other accomplishments included contributions on shock, digestive system, and endocrinology; being knighted in 1922; and authoring four editions of Principles of General Physiology. Starling officially
coined the term “hormone” in 1905 when giving a Croonian Lecture (prestigious lectureships) titled “The Chemical Control of the Functions of the Body” to the Royal College of Physicians. The term “hormone” means “to urge on” or “impulse or arouse” in the sense of “to set in motion” in Greek. Years later, reports suggested that a Cambridge physiologist, William B. Hardy, actually suggested the term “hormone” to Bayliss and Starling. In 1911, Andre Pezard first noted a direct relationship between the amount of testicular extract injected into a rooster and the size of his comb [07007].

An Austrian physician, Eugen Steinach (1861-1944), developed the “Steinach operation,” an “autoplastic” treatment for the “middle-aged and listless”. The 20-minute operation involved ligation of the vas deferens, often at the most proximal position to the testicle. This allegedly increased testosterone production. He believed that the incision produced a “back pressure” on the testicle, thus increasing testosterone production by the interstitial cells. He also implanted testicular tissue grafts between the peritoneal muscles. He reported that his patients were able to regrow hair, had better erections with less premature ejaculation, and had increased libido. Despite little clinical evidence of his claims on “rejuvenation,” the results of his operations, at best, likely were due to the power of suggestion; however, he performed this procedure on some famous patients, including Sigmund Freud and William Butler Yeats. He also discovered, by transplanting male sex glands into females and vice versa, that guinea pigs developed sexual behaviors of the opposite sex. Later research proved that sex hormone injections have no effect on sexual orientation but that high doses of testosterone may increase sexual desire. In 1913 in Chicago, Victor D Lespinasse (1878-1923), a urologist, claimed that he cured a patient who had sexual dysfunction by transplanting a testicle from a donor. He removed the organ, made three transverse slices, and inserted them into muscle tissue around the patient's scrotum. His most famous patient was Harry F. McCormick (husband of Edith Rockefeller), whose case was described in The New York Times. Five years later, the first journal of Endocrinology was published. In the 1920s, Sergio Voronoff, a Russian-French physician and surgeon, made a fortune from removing testes from animals (including the controversial monkey and chimpanzee gland transplants by way of vivisection, sparking campaigns from animal rights groups and satirical cartoons and books on the subject) and transplanting them into men. The chimpanzee tissue was not implanted inside the scrotum but instead in the tunica vaginalis. He concluded that his experiments with testicular transplants helped to relieve pain and provided a sense of well-being [07007].

It was apparent to researchers that some substance circulating in the blood was responsible for their findings; however, it was not until 1929, when a German chemist and professor, Adolf Butenandt (1903-1995), isolated the first sex hormone, that a new path of discovery was initiated. He isolated estrone from the urine of pregnant women and later isolated 15 mg of androsterone (“andro” = male, “ster” = sterol, “one” = ketone) from 15,000 L of urine from a local policemen. Over the next few years, researchers found that the hormones isolated from the testes were more androgenic than were those isolated from urine. Perhaps the most famous, and perhaps unethical, research of “organotherapy” occurred in the 1920s and 1930s at San Quentin prison in California where Leo Stanley transplanted the testicles from executed prisoners into impotent prisoners. He had a limited supply, so he turned to substituting a variety of animal gonads (from ram, sheep, goat, deer, and boar) to treat men who suffered from senility, epilepsy, and paranoia. Over the years he performed hundreds of operations. During the 1930s, three pharmaceutical companies each hired research teams to isolate the testicular hormone. The term testosterone (“testo” = testes, “ster” = sterol, “one” = ketone) was coined in 1935 by Karoly David and his research team. Ernst Laqueur isolated testosterone from bull testes. The research team was funded by the pharmaceutical company Organon in Oss, The Netherlands. Later that same year (on a team funded by Schering Corporation in Berlin, Germany), Butendant and Gunir Hanisch published “A
method for preparing testosterone from cholesterol" in a German journal. Only a week later, Leopold Ruzicka (who synthesized androsterone in 1934) and A Wettstein published “On the artificial preparation of the testicular hormone testosterone (andro-sten-3-one-17-ol)” in Helvetica Chimica Acta and applied for a patent. Butenandt and Ruzicka won the Nobel Prize for chemistry in 1939. Butenandt spent a large part of his career studying the sex hormones and their relationship with one another. His work laid the foundation for the production of cortisone [07007].

In the late 1930s, experimentation using humans involved testosterone propionate (slow-release derivative) and methyl testosterone (oral form that was slower to metabolize). Most of the research at that time was focused on treating hypogonadism in men (inducing and maintaining secondary sexual characteristics and treating impotence). Charles D Kochakian discovered an increase in protein anabolic processes, thus opening the door for the treatment of a variety of disorders by restoring tissue and stimulating growth. In 1939, it was reported that daily topical application of testosterone by females enlarged the clitoris and increased sexual desire. The use of synthetic testosterone skyrocketed after publication of the book “The Male Hormon”e by Paul de Kruif in 1945, which made claims of increasing libido and boosting athletic performance. Testosterone was a proposed treatment for menorrhagia, dysmenorrhea, estrogen-derived breast cancers, and other breast conditions. It was reported to help relieve pain, increase appetite, and promote a “sense of well-being.” Despite these claims, physicians remained reluctant to begin widespread use among women because of the virilizing side effects. Most of the profits from sale of this substance were obtained by way of the black market [07007].

In 1849, Arnold Berthauld, a curator of a zoo in Germany, observed that castrated roosters ceased to fight, crow and mate, that their combs and wattle regressed, and that these symptoms were reversed by re-implantation of their testes. In 1889, Charles-Edouard Brown-Sequard, a French physician and Harvard professor, announced that his vigor and sense of well-being were transiently but markedly restored after injecting himself with testicular extract from guinea pigs and dogs. These observations led to trials of animal and human clinical research. In 1935, testosterone was identified as 17beta-hydroxyandrost-4-en-3-one (C19H28O2), a solid polycyclic alcohol with a hydroxyl group at the 17th carbon atom [12008].

A landmark discovery was made in 1889 when Dr Brown-Sequard announced at a scientific meeting in Paris that he had found a substance that reversed his 72-year-old body’s ailments. He reported having injected himself with the extract of dog and guinea pig testicles under the assumption that these organs had “internal secretions that acted as physiologic regulators.” This bold statement was confirmed with the discovery of hormones in 1905 and the isolation of testosterone in 1935 [06003].

The first characterized androgen was androsterone, which was isolated from urine. Shortly thereafter, in 1935, the characterisation and synthesis of testosterone was done by Butenandt and Ruzicka [06004]. The characterization and synthesis of testosterone resulted in the 1939 Nobel Prize in chemistry for them [12005].

The era of anabolic steroids

In 1923 Bob Hoffman formed the famous York Barbell Company in the United States. A dominant figure in US weightlifting, he published the “Strength and Health magazine” and sold health and food supplements in his gym. As a weightlifting coach, his success led to him being named the head coach of the US Olympic weightlifting team. At the 1954 World Championships in Vienna, he met with a Soviet colleague who told him of a synthetic form of
testosterone developed by the Nazis which produced dramatic improvements in strength and power. He and his colleagues contacted Ciba Pharmaceuticals in pursuit of synthetic testosterone. Ciba had conducted a number of studies on the use of synthetic testosterone in pain patients and the physically disabled. This resulted in the development of danazol, which rapidly became a doping substance abused by weightlifters [08008].

Anabolic androgenic steroids (substances similar to the hormone testosterone) were used already directly after World War II by Soviet athletes to increase muscle mass and power in weightlifting and bodybuilding events. When the Berlin Wall fell, the East German government's program of performance enhancement by meticulous administration of steroids and other drugs to young athletes was exposed. These well-documented and controlled hormonal doping experiments on adolescent athletes by the East German Sports Medical Service at Kreischa and Leipzig yielded a crop of gold medalists (mostly young females as they responded more dramatically to male hormones). Some of these athletes later suffered severe medical abnormalities, including premature death [08009].

The first reports of athletes using anabolic steroids searching for an increase in weight and power appeared in 1954. After that there has been an increasing use of doping substances by athletes. Furthermore, it was found that not just stimulants were being used but also anabolic androgenic steroids (AAS). However, the banned list did not include those substances. Therefore, the IAAF banned them and developed an immunological method for their detection. It was used for the first time at the European Athletic Championships in Rome in 1974. No cases were found as the method was still immature, but the IAAF initiative paved the way for the IOC who banned steroids in time for the 1976 Games and found eight cases at the Montreal Games with an improved method. The IAAF experience soon showed the need for strict procedures to be applied at every stage of a doping control, including the laboratory analysis. Therefore, the Federation started to work out procedural guidelines for doping controls as well as specific requirements for laboratories that were used for the analysis of doping-control samples. Some heads of laboratories were not so happy since they felt that their competence was questioned, but in 1979 the IAAF decided to only recognize analytical results from laboratories that met the specific requirements. The “Accreditation of Doping Control Laboratories” was born. Subsequently, two years later, the IOC adopted the IAAF system, and for a couple of years laboratories were jointly accredited by the IAAF and IOC. In 1986 the IOC took over full responsibility for the accreditation program. Today, doping-control laboratories are accredited by WADA [12005].

The 1960s through 1980s were the golden age of anabolic steroid use in sports. After learning that the success of the Russian weightlifting team was in part due to their use of testosterone, Dr. John B Zeigler began experimenting with Dianabol (methandrostenolone) on weightlifters at the York Barbell Club in 1958. The weightlifters became strength and conditioning coaches in a variety of other sports in the United States and spread use of anabolic steroids to other sports, such as American football. The German Democratic Republic operated a state-supported anabolic steroid doping program that produced many medals in the 1970s and 1980s, especially for women in swimming and track and field. The doping program, and its health effects for the women, was the subject of an excellent review by Franke and Berendonk and a television special by the Public Broadcasting Service. Ben Johnson of Canada had anabolic steroids detected in his urine at the 1988 Olympic Games in Seoul, and he was stripped of his gold medal. While increased muscle mass was the goal of early doping with steroids, since the late 1990s steroids in Olympic sport have been primarily used to enhance recovery to allow more frequent and more intense workouts. Testosterone is also largely responsible for the larger red blood cell (RBC) mass in men as opposed to women, so it has benefits beyond its effect on muscle. Other anabolic steroids have a similar effect on RBC production [12006].
Soon thereafter in the 1950s, Russian weightlifters began to outpace American Olympians through performance-enhancing injections. Attempting to make up lost ground, the then US Olympic physician teamed with chemists to produce an anabolic steroid for the Americans, now known as Dianabol. In the decades that followed, steroids and stimulants spread throughout sports, and in 1959, the first reported case of a high school football player’s taking steroids surfaced. In the 1960s, the International Olympic Committee banned steroid use and began formal drug testing in the ensuing decade. During the 1980s, the reported positive test results ranged from 2 to 50 percent, depending on whether the tests were announced or conducted at random. At the 1988 Seoul Olympics, the first gold medal in track and field was stripped when the Canadian sprinter Ben Johnson lost his 100-m victory after failing drug tests. Then, in 1994, an often-referenced survey was conducted by Goldman when aspiring Olympians were asked 2 simple questions. The first was, “If you were offered a banned performance-enhancing substance that guaranteed that you would win an Olympic medal and you could not be caught, would you take it?” Remarkably, 195 of 198 athletes said yes. The second was, “Would you take a banned performance-enhancing drug with a guarantee that you will not be caught, you will win every competition for the next 5 years, but will then die from adverse effects of the substance?” Still, more 50 percent of the athletes said yes. This survey made it clear that modern athletes often approach their sports with a “win at all costs” mentality [06003].

In 1954, the first reports appeared of athletes using anabolic steroids searching for an increase in weight and power. As a result, the misuse of anabolic steroids in sports led to a ban by the International Olympic Committee of these substances in 1974 and testing was implemented on a large scale at the 1976 Montreal Olympic Games via radio-immunoassays. In 1994, the Drugs Supplement Health and Education Act (DSHEA) was approved in the United States and several new steroids were commercialized as nutritional supplements. Initially these new steroids were precursors of testosterone, commonly referred to as “prohormones”. Late 2004, the US Congress approved the Anabolic Steroid Control Act (ASCA), restricting the sale of anabolic steroids as nutritional supplements. However, by 2004 a range of prohormones derived from other steroids, including 19-nortestosterone, boldenone and even 17alpha-alkylated steroids were available as over-the-counter preparations [06004].

The evolution of the history of testosterone therapies is as interesting as the history of its development. Erectile dysfunction is one of the most researched ailments treated with testosterone, although any positive effects are questionable. In men with absent to low circulating levels of testosterone, treatment with testosterone increased libido, improved erectile function, and helped to maintain secondary sexual characteristics. In men with normal or mild hypotestosteronemia, studies have not shown consistent response to therapy. Those treated were reported to have increased sexual interest, increased arousal, increased frequency of intercourse, and nocturnal erections. In the early twentieth century, there was much interest in the hormonal influence of testosterone on sexuality and sexual preferences. It even was prescribed to “treat” homosexuals because it was theorized that male homosexuals had higher estrogen levels [07007].

Testosterone has even played an important role in various ailments affecting women, such as treatment for some metastatic breast cancers. Approximately one third of breast cancers are hormone dependent and respond to androgen therapies. Other uses for testosterone are as postmenopausal hormone replacement therapy, for sexual dysfunction (by increasing libido), and for increasing bone density. Some clinical case studies showed an increase in appetite, lean muscle mass, and strength and an improved overall sense of well-being. Before the use of erythropoietin and bone marrow transplants, testosterone was used to help
treat anemia (i.e. chronic renal failure/hemodialysis). Psychiatrists prescribed anabolic steroids from the 1930s to the 1980s to treat psychoses, depression, and melancholia. Testosterone has been used as an adjunct in people with growth hormone deficiency or in boys with pubertal delay [07007].

Body builders and athletes began using testosterone to increase muscle mass and to intensify training protocols on the West Coast of the United States in the late 1940s and early 1950s. The US Food and Drug Administration approved methandrostenolone in 1958. In the 1950s, Soviet Union and East German Olympic athletes were using AASs. They later found their way into the hands of Olympic competitors, including track and field athletes from many countries. Paul Niehans wrote the 1960 book "Introduction to Cellular Therapy", in which the main emphasis was on testicular secretions. He believed that testicle cell injections increased testosterone derivative excretion. Some of Paul Niehans' famous patients included Pope Pius XII, Bernard Baruch, and Aristotle Onassis. In 1974, the International Olympic Committee banned the use of testosterone and its derivatives. AASs were widely abused in a variety of sports, including volleyball, cycling, swimming, soccer, and bobsledding. Testosterone was studied using different forms. Scientists quickly learned it was ineffective, and even toxic (like 17 alpha-methyl testosterone), when taken orally; instead, it was synthesized into tiny pellets that were inserted subcutaneously. Longer-acting injectable forms of testosterone were synthesized in the 1950s (i.e. testosterone enanthate). Over the following decade, the hormone was modified into derivatives that possessed more anabolic qualities. In the 1970s, oral testosterone undecanoate was synthesized; however, it did not fare well in the oral form because of hepatic clearance and hepatotoxicity. Transdermal scrotal patches were derived in the 1990s. These allowed physiologic levels of testosterone to be acquired. Nonscrotal skin patches were developed, and testosterone gels were marketed. Today, there are short-acting buccal forms as well as the long-acting injectable testosterone undecanoate [07007].

By the early 1990s, several pharmaceutical companies had stopped producing AASs. It was about at this time that the black market sales of AASs and counterfeit products increased secondary to the ease of Internet shopping and availability. Authentic steroids, as well as placebos and unpurified forms, were sold and abused. The US Congress placed anabolic steroids into the schedule III category of the Controlled Substance Act (CSA) in the Anabolic Steroid Control Act of 1990. This act included testosterone and all related chemical or pharmacologic substances that promoted muscle growth. Corticosteroids, progestins, and estrogens were not included in this act. The Anabolic Steroid Act of 1994 was an amendment to the CSA. It placed anabolic steroids as well as their precursors on the controlled substance list. Possession of the drugs without a prescription was now a federal crime. Studies of the effects of supplemental testosterone on aging men in the 1990s suggested an increase in word memory, special cognition, increased libido, decreased bone resorption, and increased lean body mass and strength. McKinlay reported in the Journal of Urology that testosterone does not treat impotence. In theory, prostatic tissue, including cancer and benign prostatic hypertrophy, can be stimulated by testosterone, but no compelling evidence has been reported that suggests an increased risk [07007].

Androgenic-anabolic steroids (AAS) have been misused by athletes at the Olympic Games, both before and after they were prohibited in sport in 1974. Systematic doping with AAS occurred in the German Democratic Republic from 1965 to 1989 which assisted that country to win many medals at Olympic Games, especially in female events. Currently, androgenic-anabolic steroids are the most frequent category of prohibited substances detected in the urine of athletes both globally and at the last two Summer Olympic Games. Scientific confirmation that AAS are effective in enhancing sports performance was difficult because ethical approval was difficult for research involving male subjects taking massive doses of
androgens as some athletes and bodybuilders did. Methods to detect androgenic-anabolic steroids have evolved gradually over the past three decades and currently, despite an impressive array of sophisticated analytical equipment and methods, anti-doping authorities and analytical scientists continue to face challenges as have occurred from the use by athletes of designer AAS during the past few years. The future development and use of selective androgen receptor modulators can be anticipated to pose problems in the years ahead. Endocrinologists should be aware that on occasions, replacement testosterone therapy may be authorized in sport as a therapeutic use exemption (TUE) [08060].

Definitive proof of anabolic steroid abuse in sports was not possible prior to the introduction of combined gas chromatography/mass spectrometry (GC/MS). It was now given a report of the early history (1960-1980) of GC/MS and radioimmunoassay, and how these techniques were utilized in the first years of steroid doping control in athletics. There were several key individuals and research groups involved in the early technical developments, and their essential contributions have been acknowledged. The Oakland USA laboratory was the first IAAF (International Association of Athletic Federations) sanctioned site to do steroid GC/MS steroid analysis resulting in athletes being disqualified from competition. This gave notable successes, including the only East German female competitor ever suspended during the tenure of the DDR (Deutsche Demokratische Republik). By the early 1980s, in anticipation of the Los Angeles Olympic games, dedicated year-round sports testing facilities had been established and part-time amateurs could step aside [08125].

High levels of anabolic-androgenic steroids abuse have been attributed to professional football players, bodybuilders, weight lifters, and track and field throwers since the 1960s. The exceptional athletic performance of the East German female swimmers in the 1976 Montreal Olympics brought further public attention to AAS athletic use. It was not until the 1980s, however, that the medical community admitted that these substances were effective. Since that time, the pervasive use of AASs by professional athletes has garnered significant media attention, culminating most recently in the ongoing investigation of the use of illegal performance enhancing drugs by some of baseball's top players. “Juiced”, a book by Jose Canseco, details his steroid use and the widespread use of anabolic steroids in Major League Baseball [07008].

US professionals

Despite years of aggressive anti-doping testing by international sports federations such as those for cycling, athletics and soccer, steroid abuse scandals involving high profile athletes continue to be front page news across the globe. Professional sports in the United States were not subject to extensive anti-doping programs, as players’ unions and collective bargaining agreements prevented such extensive testing to be put into place. However, they did establish limited anti-doping programs, as the professional sports organizations recognized the potential of doping to harm athletes and their sport. In 1998, when Mark McGuire, an American baseball player, broke Roger Marris' home run record, it was revealed that he had been taking a supplement containing a precursor to nandrolone, a steroid. At that time Major League Baseball did not ban steroids and did not believe that steroids were a problem within the league. However, subsequent government investigations and former players revealed that steroid abuse was a problem in the League, which resulted in a limited steroid testing program [08006].

Anabolic steroid prodrugs in the US
The potential performance-enhancing benefits of testosterone precursors were brought to the attention of the public and athletic community in the US in 1998 when Major League Baseball player Mark McGwire set the home run record and openly admitted to using androstenedione. Sales skyrocketed by 500 percent, and many supplements containing prohormones became available in the United States market. Questions and concerns of contamination with other supplements arose but their purity was unknown because these supplements were not regulated by the FDA. Also, their popularity was fueled by the misperception that nutritional supplements are natural, and, therefore, safe. In 2004, after much controversy and debate, the US Department of Health and Human Services (HHS) and the FDA announced a crackdown on companies that manufacture, market, and distribute products containing androstenedione. They recognized the potential serious adverse health risks that were similar to those associated with AASs. As part of their concern about its safety, the FDA and HHS sent warning letters to 23 companies asking them to stop distributing dietary supplements that contained androstenedione and warned them that enforcement actions would be taken if they did not comply. As a result of this action, the Anabolic Steroid Control Act of 2004 was passed. This act added the steroid precursor androstenedione to the list of schedule III controlled substances in the United States. Schedule III substances have limited medicinal use, require a prescription from a licensed physician, and allegedly can threaten public health without government regulation. DHEA was not added to the controlled substance list; industry lobbyists contended that it had proven effective as an antiaging supplement and that its risks were minimal [07009].

**Designer drugs**

Synthetic organic chemistry can be traced back to 1865 when Friedrich August Kekule published two theoretical papers on the structure of aromatic organic molecules. Paul Ehrlich postulated in the early 1870s that differences in chemoreceptors between micro-organisms, parasites, and cancer cells from those in host cells could be exploited for therapeutic purposes. In the absence of current ligand-based and receptor-based molecular design techniques, there were limited approaches to identify minor structural changes in biologically active compounds that would enhance selectivity and/or potency of therapeutic molecules. Hamett made the first significant contribution relating structure to activity of small organic compounds with his study correlating electronic properties of organic acids and bases with reaction rates and equilibrium constants, focusing on benzoic acid derivatives. Moving beyond the linear free energy relationships provided by the Hammett equation, the next major development was the introduction of quantitative structure-activity relationships (QSAR) by Corwin Hansch et al. in two seminal papers in the early 1960s, providing a new tool to systematically relate molecular descriptors (electronic, steric, topological, and hydrophobic indices) to biological activity. These early efforts concentrated on naturally occurring plant hormone mimics, and relied on statistical analysis of published accounts of the biological activity of phenoxyacetic acid derivatives and other plant growth regulators. Electronic indices were found insufficient for QSAR of biological systems; rather, a measure of lipophilicity (classically measured as an octanol-water partition coefficient) was essential to predict targeting of compounds to specific tissues, cells or organelles, and subsequent biological activity. John Topliss developed a method to automate QSAR; however, it is of limited utility in many experimental systems and ignores possible interactions between multiple substituents. QSAR remains a dynamic tool for drug design and optimization. Approximately 15 years ago, pharmaceutical companies realized that existing screening libraries were inadequate for newly developed high-throughput efforts for lead drug design. The challenge has been to balance size and structural diversity of new libraries against screening cost, while maintaining affinity and selectivity against a portfolio of targets. Two major approaches have emerged: fragment-based screening (FBS) and diversity-oriented synthesis (DOS). Despite major advances in chemical screening and synthesis, discovery of...
new drugs is difficult, expensive, and the efficacy of target-based drug discovery has been questioned [11555].

**BALCO**

Although a general topic of interest in the 1990s, designer drugs first made international headlines in 2003 with the Bay Area Laboratory Co-operative (BALCO) scandal involving the widespread use by athletes of tetrahydrogestrinone (THG). This simple reaction created a potent agonist for androgen and progesterone receptors whose presence could not be detected by standard multiple reaction monitoring (MRM) methods used by anti-doping laboratories for steroid detection. Subsequent characterization of this steroid derivative led to US federal prosecution of many involved with BALCO, culminating in March 2011, with the most high profile case so far, involving the former San Francisco Giant (US Major League Baseball) Barry Bonds [11555].

**History of blood doping**

Blood transfusions as a means for improved endurance were researched as early as 1947 by Pace and coworkers. Transfusion of 500 ml of allogeneic erythrocytes on four consecutive days reduced the pulse rate during exercise in simulated hypoxia. However, even though the methods would not meet today’s standards; this was the first of many studies to confirm the possible performance enhancing effect of blood transfusions. Accordingly blood transfusions in sports were later banned by the International Olympic Committee (IOC) in 1986 [13005].

Lasse Viren, a Finnish long distance runner who won gold medals at the 1972 and 1976 Olympic Games in the 5,000 m and 10,000 m, is believed to be among the first athletes to have used blood transfusions to improve performance. It should be noted that this technique was not banned at the time and although the ethical debate on the topic was in full swing, it was only in 1986 that the International Olympic Committee banned blood transfusions. Other than the anecdotal evidence from the Nordic distance runners, there are other reports on more systematic use of transfusions in the context of major sporting events in the 1980s. Notably, it is well established that a large part of the US cycling team was involved in a systematic blood doping program that earned them unprecedented success at the 1984 Olympic Games in Los Angeles. There is also some evidence that blood transfusions were an integral part of the doping regime used for the enhancement of performance for athletes from the Eastern bloc (Soviet Union, East Germany) at that time. Nevertheless, it can be assumed that because of the logistic requirements of blood withdrawal and reinfusion, the technique was not widespread, as the technical necessities were only available to a small number of athletes, but nevertheless available to certain elite athletes [13006].

The blood doping situation changed dramatically with the commercial introduction of recombinant human erythropoietin (rhEPO), the human hormone that regulates the erythropoietic system in the organism. EPO was first isolated in the 1950s. The gene for human erythropoietin was successfully cloned in 1983, and the first recombinant erythropoietin (rhEPO) was approved by the FDA for treatment of anemia in renal failure in 1989. One year later the IOC banned the use of erythropoietin (EPO) [13005].

Studies investigating the effect of rhEPO on performance were soon published and demonstrated positive effects on maximal oxygen uptake of 6-12 percent. Although the authorities rapidly banned rhEPO, the easy access to the substance and the huge impact on performance resulted in widespread abuse of rhEPO during the 1990s/2000s. It is believed
that this substance had a considerable impact on the development of peak performances in all endurance sports during these years and there are even scientific attempts to prove this for several sports on the basis of performance analysis. The abuse was facilitated by the fact that no detection method was readily available at that time. From a practical point of view, the impact of rhEPO on performance in endurance sports is best illustrated by a quote from Greg Lemond, an American cyclist who won the Tour de France in 1986 and 1989, i.e., before rhEPO became available, recalling the 1991 race: “I was the fittest I had ever been, my split times in spring training rides were the fastest of my career, and I had assembled a great team around me. But something was different in the 1991 Tour. There were riders from the previous years who couldn’t stay on my wheel who were now dropping me even on modest climbs.” These words accurately describe how rhEPO changed the entire world of endurance sport in the following decades and divided the athletes’ performance primarily between rhEPO users and non-users [13006].

Logically, following widespread abuse from the 1990s onwards, doping scandals involving rhEPO or blood transfusions have shaken the world of sport on a regular basis, culminating recently with the investigation of Lance Armstrong, who subsequently admitted the use of both rhEPO and blood transfusions throughout his career. Although, it is therefore common belief that many recent doping cases were not unveiled by conventional anti-doping testing, but rather by police investigations or admissions from athletes or staff, thus non-analytical approaches, anti-doping laboratories were able to detect about 400 cases testing positive for rhEPO between 2003 and 2011 (World Anti-Doping Agency (WADA) statistics). Analytics have therefore come a long way in the detection of blood manipulation in sports and still outperform police investigations by 10 to 1 [13006].

Blood transfusions, as a method to enhance endurance performance, first gained attention after the Olympic games (OGs) in Mexico City in 1968. Before these OGs, evidence was presented that a lowered atmospheric pressure would decrease performance in all athletic disciplines dependent on a high level of sustained oxygen uptake. This was indeed confirmed in Mexico City, where all winning times in running races above 800 m were significantly worse than the world records at that time. This highlighted the impact of the oxygen delivery to the working muscles as a limiting factor during whole body endurance exercise. It also became evident that runners hailing from higher altitudes tended to be superior to competitors from lowlands because they had “thick blood” with high hemoglobin content. A relatively straightforward way to increase the hemoglobin concentration (Hb), and, hence, oxygen delivery to the muscles is, thus, by blood transfusions. This was documented in the classic study by Ekblom et al from 1972 where a high correlation between Hb and performance capacity after blood withdrawal and reinfusion was presented. An overnight increase in Hb by 13 percent caused by the reinfusion of 3 units of stored autologous blood resulted in an increase in maximal oxygen uptake and physical performance capacity of 9 percent and 23 percent, respectively. The method of transfusing blood in a sport setting was hereafter dubbed “blood doping” by the media, and its potent effect on athletic performance was quickly noted in the sports community. Blood doping was used already at the OG in 1972 by a Finnish steeplechaser, and during subsequent OGs, several athletes admitted having used blood doping. Not until after the OG in Los Angeles in 1984, where the US cycling team used blood doping and won 9 medals after not having won a medal in cycling for 72 years, the method (both homologous and autologous transfusions) was prohibited by the International Olympic Committee, although no method was available to detect its use. Because of its logistic advantages compared with blood transfusions, human erythropoietin (rhEPO) became the preferred blood boosting method by athletes after it had been available. At the OG in Sydney in 2000, two tests for rhEPO were introduced: a “direct test” that was able to distinguish rhEPO from endogenous molecules by isoelectric focusing and an “indirect test” based on changes in blood parameters caused by rhEPO administration.
Because of the introduction of these tests, old-fashioned blood doping reentered the scene. At the Salt Lake City Winter OG in 2002, discarded blood transfusion equipment was found at the headquarters of the Austrian cross-country skiers. After DNA testing, 2 skiers were disqualified. Although testing for homologous blood transfusions had been performed at the Lillehammer OG in 1994 by use of antigen testing cards, it was not until 2004 at the OG in Athens that a test had been validated and implemented. At this event, the gold medal winner of the men's time trial in cycling was first tested positive, but because the backup sample (B-sample) was frozen and, thereby, the red blood cells (RBCs) destroyed, no doping offense could be proven. After he failed further doping tests at the 2004 Vuelta a España, the rider was suspended for 2 years [12009].

The word “doping” was used in the 1860s to describe a drug used for horse racing that consisted of opium and narcotics. With human athletes, “blood doping” originally referred to a process whereby athletes increased their oxygen-carrying capacity by receiving blood transfusions from previously donated blood to increase their hematocrits a few days before competition. The first report of blood doping in a controlled experiment was reported in 1947. Today, “blood doping” is used more synonymously with cheating of any kind, including any of the various blood-boosting methods or classes of ergogenic aids that are available to athletes. Advances in genetic medicine have allowed athletes to raise their level of sophistication significantly by using PESs that are virtually undetectable. In June 1989, the first rHuEPO product was marketed in the United States. It was isolated and purified from Chinese hamster ovaries and reproduced using DNA recombinant techniques. The popularity and effectiveness of rHuEPO in elite endurance athletes is demonstrated by a long list of anecdotes associated with its misuse during international competition. When the average speed of the cyclists racing in the Tour de France began to increase suddenly during the 1990s, rumors of rHuEPO use began to circulate. The gene that produces EPO was cloned in 1985, and rHuEPO was available in Europe by 1987. Between 1987 and 1991, more than 20 Dutch and Belgian cyclists died at rest – some of them while sleeping – as a result of unexplainable cardiac arrest. Between 1997 and 2000, 18 more cyclists died from pulmonary embolisms, stroke, and myocardial infraction. Finally, suspicions of rHuEPO use in professional cyclists competing in Europe were confirmed during the 1998 Tour de France; boxes of ampules containing rHuEPO were found in team vehicles and the personal rooms of riders from many of the biggest and most successful teams. It became embarrassingly clear that rHuEPO use in elite professional cyclists was organized, widespread, and sophisticated. The International Olympic Committee (IOC) added rHuEPO to its list of banned substances in 1990, even though all forms of blood doping had been officially prohibited since 1984. Despite justified suspicions of rHuEPO use in cycling and the inability of current methods to detect its use, in 1997, the governing body of the International Cycling Union (UCI) enacted hematocrit cutoffs for male (50 %) and female (47%) cyclists while more reliable methods of detection could be developed. The hematocrit cutoffs were based on existing normative data on elite athletes, taking into consideration the expected effect of dehydration, in an attempt not to exclude athletes with normal variations but to protect athletes from danger. Anyone over that limit would be considered “unfit to race” and could not compete for 2 weeks, although they were not subjected to official sanctions. To circumvent this, an athlete could inject rHuEPO every 2 to 3 days over 3 to 4 weeks, along with some form of iron supplementation, to get a desired effect and then reduce the dose to match the basal rate of endogenous EPO production to maintain one’s hematocrit just below the “legal limit.” During the 2000 Sydney Olympics, the IOC approved the use of a test developed by the Australian Institute of Sport to detect rHuEPO users [07010].

Shortly after the discovery of blood circulation by the English physician William Harvey in 1628, the first empiric blood transfusion was attempted. There is therefore a long history of blood doping, conventionally originating with the anecdote of athletes being encouraged to
drink reindeer blood or something like that to achieve extraordinary performances. Although the earliest proof of improved sport performances after blood transfusions was provided already in 1947, the first evidence of blood doping came later, in 1972, when a controlled experiment clearly showed a considerable increase in performance of athletes undergoing autologous transfusion of packed RBCs from an earlier venesection. Since then, there are consistent records of athletes experimenting with blood transfusions who achieved incredible success in competitions. Besides the first anecdotal reports, this technique became fairly popular during the 1980s and was widely used by distance runners, cyclists, and skiers, particularly during the 1980 and 1984 Olympics. Although no reliable test had been devised for unequivocal detection, the International Olympic Committee (IOC) officially banned blood doping after the 1984 Olympics. In the same year, the USA Olympic Committee declared that seven cyclists, including four medallists, out of 24 athletes of the national team who participated in the Olympic Games, used transfusions. Years later, following the implementation of reliable strategies for detecting doping with recombinant erythropoietin and analogues, blood transfusions, which had fallen out of favor, made a strong comeback. In March 2002 at the Salt Lake City Olympics, the IOC investigated the discovery of discarded blood transfusion equipment at the quarters of the Austrian cross-country skiers. Following DNA testing, two Nordic skiers (who had been placed in the 40s, and not the Austrian team’s three medallists) were disqualified and had their results cancelled. For the same reason, some professional cyclists, one of whom nearly died after being injected with poorly stored blood, were found guilty and suspended in 2004 [06005].

The suspension of several professional road cyclists from the 2006 Tour de France could represent the tip of the iceberg, with more than 200 athletes in different sports disciplines implicated in an international doping probe including blood transfusions and exogenous hormone administration. In an apartment building in Madrid occupied by a doctor, Spanish police discovered clandestine equipment for international performance enhancement, seizing more than 200 450 mL blood bags, along with records and several other doping substances, which allowed investigators to finally match code names of athletes with their highly detailed doping records. This sophisticated pan-European doping ring either treated athletes locally or arranged the transport of stored blood through a system of couriers to athletes at race sites. Hence, based on the riders named in this one investigation, the problem is endemic [06005].

**Early testing strategies for blood doping**

Originally, the only means to test for doping by blood transfusion was the adoption of arbitrary thresholds for hematocrit and/or hemoglobin. Blood doping practices were suspected when blood tests showed hemoglobin values exceeding 175 g/L for men and 155 g/L for women (International Ski Federation), and hematocrit values above 0.50 for men and 0.47 for women, with reticulocytes < 2 percent (according to the International Cycling Union). Athletes with random values exceeding such limits were prevented from racing in official competitions. Nevertheless, such a questionable strategy involved several drawbacks, including the difficult interpretation of several hematological parameters because of wide inter-individual variability, the possible occurrence of false positive results that would have penalized clean athletes with naturally increased values, and the possibility to arbitrarily expand or titrate the RBC mass up to the allowable threshold [06005].

The obvious alternative to homologous blood transfusions is autologous blood transfusions (ABTs). In 2006, just before the Tour de France, a large Spanish doping scandal evolved, known as Operación Puerto. A doping ring involving several physicians was uncovered by the Spanish police, and more than 200 autologous blood units belonging to professional athletes were found in freezers and refrigerators for subsequent reinfusion. Detailed doping
calendars from individual athletes were published, and the modus operandi of involved athletes and their physicians was uncovered. From these calendars, it became evident that besides the massive abuse of a wide range of different performance-enhancing drugs and masking agents, ABTs were used during important competitions. The procedure of blood withdrawal and reinfusion was performed numerous times for each individual athlete during the year by using specialized equipment for phlebotomy and storage. Typically, blood was withdrawn after competitions and reinfused few days before 1-day races or before and during multiple-day competitions. Since then, athletes testing positive for other substances have confirmed the ongoing abuse of ABT today [12009].

Increasing delivery of oxygen to the active muscles and making energy efficiently from the oxygen is the most effective way to increase performance. Increasing the number of RBCs is the most effective way to increase aerobic performance. The US pursuit cycling team unexpectedly won gold at the XXIII Olympic Games in Los Angeles. It was later revealed that they transfused blood and that some of the cyclists had suffered severe transfusion reactions. The advent of recombinant protein therapeutics in the late 1980s ushered in a new era for dopers. The lay press speculated that the deaths of 18 European cyclists were related to the availability of recombinant human erythropoietin (rhEPO). rhEPO stimulates the production of red blood cells in the bone marrow, resulting in increased red blood cell mass. The development of a test for rhEPO caused the athletes to change the route of administration from subcutaneous to intravenous, decrease the dosage, and increase the frequency of administration in order to avoid detection. At the Salt Lake City Games in 2002, three winter endurance athletes had Aranesp (darbepoetin-alpha), a novel erythropoietin stimulating protein, detected in their urine samples – 7 months after approval in the European Union and 5 years before the FDA approved its medical use in the United States. Information gathered from investigations confirms that with the advent of tests for prohibited peptides and proteins like EPO, some cheating athletes changed to autologous blood transfusions to increase RBC mass [12006].

History of detection of recombinant erythropoietin and derivates

Direct detection of a forbidden substance in a biological matrix such as urine or blood obtained from an athlete is the classical forensic approach to prove doping. This approach has long been the sole strategy, only fine-tuned by improving the sensitivity of the analytical detection methods and by optimizing the timing of testing. The basic principle of the direct detection of forbidden substances relies on the fact that these substances are different from the normal constituents of the human organism. With the introduction of recombinant drugs such as rhEPO, this principle was not valid anymore, as the recombinant constituent was virtually identical to the endogenous version of the substance. Thus, at first, doping tests could not differentiate between the natural, endogenous and the artificial, exogenous recombinant version of the drug. This has, for a long time, been a major difficulty for the testing laboratories. In 1995, it was described a method to separate the natural from exogenous EPO through electrophoresis, but other laboratories could never replicate their results and the described method never reached the stage of validation. Only in 2000, thus more than 10 years after the estimated beginning of rhEPO abuse in sports, the first practicable and validated test to directly detect rhEPO in urine was published. This test relied on a difference in glycosylation between the endogenous and the exogenous EPO molecules, which resulted in different migration characteristics during isoelectric focusing (IEF). The recombinant EPO was industrially harvested from transfected hamster kidney or ovarian cells and, owing to the difference in cell organelles, a minor posttranslational difference in glycosylation between the rhEPO (made by the hamster cells) and the endogenous EPO (made by the human kidney cells) occurred, although the amino acid
sequence is identical. The rhEPO molecules are less negative and will thus move differently from endogenous EPO in an electric field, which can be demonstrated using the IEF. Further developing the approach of Wide, IEF is then followed by double blotting, which addresses the problem of non-specific binding of the EPO molecules. Although relatively cumbersome, the method soon identified the first athletes testing positive, namely Roland Meier and Bo Hamburger, both cyclists. Ironically, Hamburger was later acquitted by the court of arbitration of sports on formal grounds (i.e. a lack of harmonization of the positivity criteria for the EPO tests between laboratories was identified). This issue has since been addressed and strict positivity criteria apply, based on acceptance, identification, and stability principles. rhEPO positive samples, for example, have to show at least three acceptable, consecutive bands in the basic area and the two most intense bands measured by densitometry must be in the basic area. When the analysis is performed in blood (serum/plasma) the intensity of those bands must be approximately twice or more than any band in the endogenous area. Many laboratories nowadays use computer-based classification algorithms to guarantee objectivity in this context [13006].

At the 2000 Olympic Games in Sydney, the Australian WADA-certified laboratory first launched a sophisticated anti-doping test for erythropoietin that required both urine and a blood sample. Over 300 tests were performed for erythropoietin for the first time in Olympic history but no positives were reported. This could be due to the fact that the technology for the test was new and questions still existed about the assay [08006].

Hypotheses on erythropoietin doping practice
It has been noted that recombinant erythropoietin (rEPO) appeared in Europe in 1987, and the unusual deaths began soon thereafter. From 1987 to 1991, up to 20 competitive cyclists died suddenly and unexpectedly. Autopsy results were elusive, but cycling authorities said the deaths were from “heart attack,” “cardiac arrest,” or “cardiac failure.” However, about 15 of the deaths seemed to fit a profile that suggested another explanation: They were young and improving fast, “rising stars” who died not during a race but at rest before or after a race. The rationale for abusing rEPO in competitive cycling is that by raising the hematocrit without unduly raising blood viscosity, one can enhance aerobic performance by enhancing oxygen delivery to muscles. By 1990, the first experiment on the effects of rEPO on athletes had been done, and the lead researcher was quoted to the effect that rEPO might enable an elite athlete to shave 30 s off a 20-min racing time. The problem is that the higher the hematocrit, the greater the risk of clots. Blood clots are the proximate cause not only of pulmonary emboli but also of many strokes and heart attacks. Coagulability hinges partly on blood viscosity, which is set by the plasma fibrinogen level, the deformability of red cells, and the hematocrit. Hematocrit also influences platelet adhesion, the first step in arterial thrombosis. Hematocrit, then, modulates the flow, fluidity, and coagulability of blood. As hematocrit increases toward 60 percent as in mountaineering, for example, blood clots can become a menace [13066].

In 1991, a warning appeared in a prestigious medical journal on how fast hematocrit can rise with large doses of rEPO and how rEPO abuse by athletes could drive hematocrit to “dangerously high levels."By 2007, after esteemed studies in patients with renal disease, cancer, and other major illnesses tied higher dosing of rEPO to greater risk of death from thrombotic events (heart attack, stroke, or venous thromboembolism) or heart failure, the Food and Drug Administration issued a black box warning on these risks from rEPO. Even this did not end the abuse of rEPO by athletes or the deaths. Cyclists continued to dope, dupe, and die [13066].

Sudden deaths in Swedish orienteers
A spate of deaths in orienteers paralleled the cycling deaths. Suddenly, among young, elite orienteers (but in no other Swedish sports), the death rate spiked to 1 percent a year for 3 years in a row. From 1989 to 1992, seven elite-level orienteers, all from the same small area of central Sweden, died during or after competitions or training. They knew one another and occasionally trained together. All performed very well shortly before they died; some placed near the top in national competitions. The last, Melker Karlsson, 24, was a rising star who died after a training run and sauna. His death was the final straw that led to a meeting of Swedish health experts to probe potential causes and solutions. As in the cyclists, the deaths were considered “cardiac,” and a popular hypothesis was a transmissible myocarditis, ascribed first to Chlamydia and then to Bartonella. Their supporting evidence, however, is not compelling and does not dissuade skeptics, from speculating that a culprit in this spate of sudden deaths in top Swedish orienteers was abuse of rEPO [13066].

Cyclists
Evidence from many believable anecdotes, from sworn testimony to the United States Anti-Doping Agency (USADA), and from police raids at the 1998 Tour de France and before the 2006 Tour de France shows that cyclists continue to abuse rEPO. Indeed, top South African cyclist David George was caught on rEPO (and admitted it) in August 2012. The culture of competitive cycling dies hard; despite the deaths and the black box warning, rEPO abuse in cycling has endured for 25 years. In his affidavit to USADA, Stephen Swart, a teammate of Lance Armstrong in 1994 to 1995, said that their Motorola Team used rEPO for the 1995 Tour de France, and that most riders, including Lance Armstrong, had a hematocrit over 50 percent. It is widely reported that Marco Pantani abused rEPO and had a hematocrit of 60 percent in a 1995 race. As noted in Tyler Hamilton’s recent tell-all book, Bjarne Riis won the 1996 Tour de France on rEPO, and his peak hematocrit was an astonishing 64 percent. For cyclists who abuse rEPO, there may be a thin line between winning and dying. Alas, the deaths continue. From early 2003 to early 2004, eight more European cyclists died, and up to five fit the profile of a likely rEPO death. Notable were French cyclist Fabrice Salanson, 23, found dead in his hotel room just hours before he was to start the Tour of Germany, and Belgian cyclist Johan Sermon, 21, who went to bed early to rest up for a planned 8-h training ride the next day, but was found by his mother dead in bed at dawn. In early 2009, the promising Belgian cyclist Frederick Nolf, 21, died at night in his Ritz Carlton hotel room, after the fourth stage of the Tour of Qatar. He went to bed laughing and happy and never woke up. No autopsy was done. How the autopsy results on Salanson were described to the press may come closest to the truth in this long, sad saga. Dr Jan Dressler of the University of Dresden Medical Institute said the death was probably caused by the heart enlarging and the coronary vessels failing to pump enough blood [13066].

Background to the athlete biological passport
In an investigation of samples obtained as part of routine International Ski Federation blood-testing procedures in participants at the World Ski Championships, abnormal hematological profiles, defined as those deviating from the 1989 Nordic Ski World Championships and the IOC Erythropoietin 2000 project data set, were identified in 36 percent of the skiers tested and finishing within the top 50 places in the competitions. In addition, 50 percent of medal winners and 33 percent of those finishing from 4th to 10th place had highly abnormal hematological profiles. In contrast, only 3 percent of skiers finishing from 41st to 50th place had highly abnormal values. Although these data cannot be immediately associated with blood doping practices, including blood transfusions, and it is very unlikely that blood doping would be less common in other endurance sports, the present situation is highly suggestive of a phenomenon that is not being controlled by the ongoing antidoping testing program. In fact, it has been hypothesized that a combination of blood transfusion and recombinant human erythropoietin administration could also be used by such athletes [06005].

132
History of doping with growth hormone

In 1998 at the Tour de France that French customs arrested Willy Voet, a physiotherapist of the Festina cycling team, for the illegal possession of needles, syringes and over 400 bottles containing erythropoietin, human growth hormones, steroids, amphetamines, narcotics and stimulants [08006].

Ben Johnson also admitted to using human growth hormone along with steroids during investigations after his disqualification in Seoul. The abuse of growth hormone in sports seems to be escalating, with large caches of needles and vials of hGH being confiscated at sporting events worldwide. Six months prior to the 2000 Olympic Games, a pharmacy in Sydney was broken into and 1,575 multiple dose vials of growth hormone were taken while nothing else was touched. Also, on their way to Australia, the Chinese swimming team was detained, as needles, syringes, and vials of human growth hormone were found by customs officials in their baggage [08006].

hGH is a naturally occurring hormone produced by the anterior pituitary gland and is one of the major hormones influencing growth and development. Harvey Cushing discovered the hormone in 1912 and isolated it from human and monkey cadaver brains in 1956. Two years later it was used to treat dwarfism in children by injection. The unfortunate development of Creutzfeldt-Jakob disease, a degenerative brain disorder, in boys who were treated with cadaver growth hormone led to the discontinuation of all products derived from the human pituitary gland. Because of this ban, the abuse of hGH was rare in sport until the middle to the end of the 1980s. In 1985 Genentech received approval from the US FDA to market Protropin® for children with growth hormone deficiency. This was the first recombinant DNA form of growth hormone (rhGH) that was safer than cadaver extracts used in the past. Recombinant DNA technology made the production of pharmaceutical grade growth hormone easier and cheaper. Most human growth hormone used in medicine and diverted to sports doping is now obtained by recombinant technology, and is simply referred to as hGH (but it may also appear as rhGH or HGH) [08006].

Growth hormone (GH) is an important and powerful metabolic hormone that is secreted in a pulsatile pattern from cells in the anterior pituitary, influenced by several normal and pathophysiological conditions. Human GH was first isolated in the 1950s and human derived cadaveric GH was initially used to treat patients with GH deficiency. However, synthetic recombinant GH has been widely available since the mid-1980s and the advent of this recombinant GH boosted the abuse of GH as a doping agent. Doping with GH is a well-known problem among elite athletes and among people training at gyms, but is forbidden for both medical and ethical reasons. It is mainly the anabolic and, to some extent, the lipolytic effects of GH that is valued by its users. Even though GH's rumour as an effective ergogenic drug among athletes, the effectiveness of GH as a single doping agent has been questioned during the last few years. There is a lack of scientific evidence that GH in supraphysiological doses has additional effects on muscle exercise performance other than those obtained from optimised training and diet itself. However, there might be synergistic effects if GH is combined with, for example, anabolic steroids, and GH seems to have positive effect on collagen synthesis. Regardless of whether or not GH doping is effective, there is a need for a reliable test method to detect GH doping. Several issues have made the development of a method for detecting GH doping complicated but a method has been presented and used in the Olympics in Athens and Turin. A problem with the method used, is the short time span (24-36 hours) from the last GH administration during which the test effectively can reveal
doping. Therefore, out-of-competition testing will be crucial [08238].

Today, many medical interventions that begin as treatments for disease often expand into therapies that reduce disability, lessen disadvantage, or even confer advantage. Forces that propel profitable drugs, devices, and procedures dominate over considerations of efficient and equitable distribution of resources. This dominance is fueled by industry-physician collaborations often biased by prior assumptions, reliant on surrogate outcomes, and advantageous to marketing. Interventions are justified by "medicalization" of physiologic variations (e.g. short stature) as defects or disease, and nudged into "standard practice" by key opinion leaders. The story of recombinant human growth hormone (hGH) treatment of short stature is one vivid example, but others (e.g. expansion of drug treatment to "optimize" cholesterol profiles, bone health, psychological well-being) can be found throughout medicine. In the new obesity era, lessons learned from the hGH era will be needed to keep the field of pediatric endocrinology empowered to make the key clinical decisions, and free of unintended consequences for patients and runaway health care inflation for society [11469].

After testing over 1,000 samples, the first adverse analytical finding of growth hormone came in February 2010 when the British Rugby League player, Terry Newton, tested positive. Since then, several other positive tests have been reported including the announcement in September 2010 from the Canadian Center for Ethics in Sport that Matt Socholotiuk, a University of Waterloo football player, had tested positive for GH use on 31 March 2010. The following year, Colorado Sky Sox first baseman Mike Jacobs became the first baseball player to test positive for GH and was subsequently suspended for 50 games by Minor League Baseball. In 2011, Andrus Veerpalu, an Estonian Olympic gold medal winning skier, tested positive for GH. However, he pleaded his innocence and challenged the laboratory finding in the Court of Arbitration for Sport who subsequently acquitted Veerpalu on 25 March 2013 as the court was not convinced that the threshold for considering an adverse analytical finding was sufficiently reliable to uphold the doping conviction; nevertheless, the court stated "that there are many factors in this case which tend to indicate that the Athlete did in fact himself administer exogenous hGH" [13007].

History of doping with caffeine

From 1962 to 1972 and again from 1984 to 2003 caffeine was on the WADA banned list, with a concentration >12 microg/ml in the urine considered as doping. Caffeine has been demonstrated to be ergogenic at doses lower than those doses that result in a urine concentration of 12 microg/ml, and higher doses appear to exhibit no additional performance-enhancing effect. During the second banned period, many athletes tested positive for caffeine. The sanctions ranged from warnings up to 2 year suspensions (maximum penalty, usually only 2-6 months). Since 2004, caffeine has been removed from the prohibited list, however, it is still part of WADAs monitoring program (stimulants but in competition only) in order to monitor the possible potential of misuse in sport. According to WADA, one of the reasons caffeine was removed from the Prohibited List was that many experts believe it to be ubiquitous in beverages and food and that having a threshold might lead to athletes being sanctioned for social or dietary consumption of caffeine. Furthermore, caffeine is metabolized at very different rates in individuals and hence urinary concentrations can vary considerably and do not always correlate to the dose ingested. In addition, caffeine is added to a wide range of popular food products such as coffee, tea, energy drinks and bars, and chocolate [13008].
History of doping with ephedrine

Ephedra is a Chinese shrub which has been used in China for medicinal purposes for several thousand years. The pure alkaloid ephedrine was first isolated and characterised by Nagai in 1885. It was then forgotten until it was rediscovered by Chen and Schmidt in the early 1920s. Its actions on the adrenoceptors could be classified into separate alpha and beta effects – a defining moment in the history of autonomic pharmacology. Ephedrine became a highly popular and effective treatment for asthma, particularly because, unlike adrenaline (until then the standard therapy), it can be given by mouth. Ephedrine as a treatment for asthma reached its zenith in the late 1950s, since when there has been a gradual and inevitable decline in its therapeutic use. From mainstream medicine, ephedrine moved into the twilight zone of street drugs and nutritional supplements. Ephedra and ephedrine products are now banned in many countries, as they are a major source for the production of the addictive compound methamphetamine (crystal meth) [11001].

Ephedrine is not only efficacious in the treatment of numerous ailments, but also has a long history of misuse. Research was needed to examine ephedrine policy over time in order to determine potential regulatory flaws that allowed misuse to continue. One review is based on primary literature derived from systematic searches of historical and scientific archives, as well as grey literature. Ephedrine managed to pass through numerous regulatory loopholes within seventy years. Despite warnings of misuse over the latter half of the century, ephedrine, and its herbal source, ephedra, were regulated in a piecemeal fashion and remained easily available to the public. Health authorities have struggled to control ephedrine, as an amphetamine "look-alike," as a methamphetamine precursor, as a dietary supplement, and as a medication. Despite being a potentially dangerous stimulant, under-regulation was perhaps more problematic than the substance itself. Tighter control of all ephedrine products, drugs and dietary supplements alike, might have prevented adverse outcomes and allowed this substance to remain available in a safer manner. Stringent regulation of all ephedrine products is necessary to prevent misuse and to protect the public's health [11002].

History of doping with cannabis

The medical properties of cannabis have been known for many centuries. The first documented use of cannabinoids for medical purposes dates back to 2800 BC in the Chinese herbarium Pen-ts'ao, a herbal pharmacopoeia describing many drugs among which cannabis, which was referred to as "ma", meaning “chaotic”. Pen-ts'ao described the pain-relieving, stupefying and hallucinogenic properties of cannabis and recommended cannabis for constipation, malaria, gout, rheumatism, and menstrual anomalies. Cannabis therapeutic use was introduced in Western medicine during the first half of the nineteenth century by the Irish physician William Brooke O'Shaughnessy (1809–1889), who studied forensic toxicology and chemistry at the University of Edinburgh in Scotland. He conducted a number of experiments in animals and proved that cannabis was safe even at high doses; thus, he extended the use of cannabis to patients suffering from rheumatism, seizures, and tetanus [12006].

The International Olympic Committee included cannabis in the banned substance list beginning in 1989 and since 2004 the World Anti-Doping Agency has prohibited its use for all sports competition. Cannabinoids are substances prohibited in-competition only [0009].
The class of cannabinoids has been subject of much debate concerning its relevancy for sports drug testing, fuelled by the increase of the urinary threshold for the main cannabis metabolite 11-nor-delta9-tetrahydrocannabinol-carboxylic acid (THCCOOH) from 15 ng/mL to 150 ng/mL (being effective since 11 May 2013) while the MRPL for cannabimimetics remained at 1 ng/mL as well as prevalence studies demonstrating the widespread availability and misuse of cannabis and its synthetic analogs. Since the raise of the urinary threshold for THCCOOH came unexpected, studies from early 2013 concerning improved/accelerated quantification approaches have become obsolete, even though the principle is certainly still valid 130009].

History of doping with alcohol

Alcohol is prohibited in-competition only and it is prohibited in the following sports: aeronautic, archery, automobile, karate, motorcycling and powerboating. Until 2010, modern pentathlon was also included in this list. The limit (blood tests) eligible for a doping violation is 0.10 g/L [13008].

History of doping with gamma-Hydroxybutyric acid (GHB)

Occurring naturally in many parts of our body from the brain to heart, to most muscles, kidneys and brown fat, gamma-hydroxybutyric acid or GHB for short was first synthesized in 1960s by Laborit in an attempt to study the effects of GHB and GABA, producing a compound that would interfere with beta oxidation and cross blood–brain barrier. It was later discovered that GHB was an endogenous compound and an endogenous metabolite of GABA. GHB was thus discovered in search for therapeutic GABA analogs. Since its discovery, GHB has played many roles in the laboratory. It was used to create an absence seizure model. GHB was also shown to have tissue-protective effects in the setting of myocardial infarction, stroke, sepsis, small bowel ischemia, hypovolemic shock, ionizing radiation and oxygen free radicals. Despite promising beneficial effects, GHB has not found widespread clinical use. In the 1960, GHB was used as a general anesthetic agent but fell out of favor due to an association with abnormal electroencephalographic (EEG) patterns in animals. In the year 1980, GHB could be bought in health food stores and the use began to rise amongst body builders as it was believed that taking this drug could improve muscle mass or improve exercise performance. While GHB has been present in laboratories and therapeutic trials for years, it has recently become a public health issue as a drug of abuse. Hence in the year 1990, FDA imposed ban over the counter sale of the drug throughout the United States. Simultaneously from 1997 to 1999, several states and countries passed laws to control the sale and consumption of GHB and finally designated it as a Schedule 1 substance in the United States in the year 2000 [13010].

History of biomarker approach regarding doping

In the late 1990s, as a first step, “no start” rules were introduced with the official objective to protect the health of the athletes when certain blood markers exceeded definite limits (e.g. hematocrit (Hct) above 50 percent or hemoglobin (Hb) above 17 g/dL (International Cycling Union, UCI) or Hb above 17.5 g/dL in men and 16.0 g/dL in women (International Ski Federation, FIS). In this time, the widespread use of rhEPO can be assumed on the basis of indirect evidence; e.g. in elite cross-country skiers extreme Hb values up to 20 g/dL were common between 1994 to 1996 but disappeared after the “no start” rule was introduced in 1997. Yet, mean Hb values continued to rise, suggesting the further use of artificial methods
with fewer extremes. It became obvious that the use of upper limits of definite blood values may result in athletes who would titrate rhEPO to approach the target Hb or Hct without exceeding it [13006].

Plasma volume fluctuations resulting from changes in posture, exercise, and training, altitude exposure, season as well as storage conditions influence concentration-based blood values such as Hct and Hb and thus represent a major limitation of their use with absolute limits. Additionally, cheating athletes may manipulate abnormally elevated Hb and Hct values by intravenous infusions of normal saline leading to hemodilution. On the other hand, even clean athletes may be declared unfit as Hb and Hct in a normal distribution may exceed the given limits. The panel of indirect markers was extended and more evidence was gathered on the effect on blood values of rhEPO administration in training athletes. It was suggested the use of a combination of indirect markers of altered erythropoiesis (reticulocyte Hct, serum EPO, soluble transferring receptor, Hct, %macrocytes) in a multivariate statistical model for detection of rhEPO during a possible administration phase (ON models) and after recent cessation of rhEPO use (OFF models). The sensitivity of these models was improved with larger numbers of subjects and resulted in the introduction of the so-called second-generation blood tests of which the OFF-hr model, a score combining Hb and %retics, is part of the current ABP according to the WADA ABP operating guidelines. Although OFF-hr was originally described for the detection of rhEPO use, it is also sensitive to other forms of blood doping such as blood transfusion [13006].

The application of these models by sports authorities and anti-doping organizations was problematic despite their scientific impact. The OFF-hr model was used by certain sports federations as another ‘no start’ criterion. Yet, infringements of the “no start” rule were equal to failing a “health test” but not considered a violation against WADA’s anti-doping code and therefore only yielded short mandatory interruptions of competition, e.g. 2 weeks. As even these improved biomarkers were only compared with a population-based reference range in a cross-sectional setting (e.g. universal limit of Hct above 50 %, OFF score greater than 122), it already seemed likely in 2000 that a longitudinal, individual hematologic profile, the so-called hematologic passport, could be advantageous to prevent and perhaps detect blood doping. Various attempts were made to define the natural within-subject and between-subject as well as analytical variability to use longitudinal measurements as an instrument against blood doping [13006].

**History of gene doping**

Gene therapist Ted Friedmann and multiple Olympic gold medallist Johann-Olav Koss were the first to describe the possibility of misusing the techniques and experiences of gene therapy in the athletic arena. In 2006, before the Turin Winter Olympic games, the president of the World Anti-Doping Agency (WADA), Dick Pound, called gene doping “the new threat that is now a reality.” Although Pound did not expect gene doping to pose a problem in Turin, he indicated that it could be a problem at the Summer Games, 2 years hence in Beijing. In fact, the problem did not materialize in China, in 2008, nor at the London 2012 Olympics, as far as the then available detection measures could determine [13011].

**History of athlete biological passport**

To detect cellular components of blood and those pharmacological agents that are too large to be excreted in urine, blood collection and analysis was begun in 2008. The Hematological
Module of the WADA Athlete Biological Passport uses the predictive model of Pottgiesser et al to monitor hematological marker changes within an individual. The fact that intraindividual variations in a number of blood (and urine) parameters are lower than interindividual variations has been used in the clinical chemistry laboratory since the 1970s. Blood is also analyzed for recombinant proteins, such as GH variants and biomarkers [12006].

**Doping in the Olympics**

*The ancient Olympic games*

The first instance of an athlete doping in competition is unclear, although there are examples of sportmen from the Greek era using natural substances to gain an advantage. The Olympic games, founded in 776 B.C. (date of the earliest recorded Olympic competition) in Olympia as a tribute to the gods but also to celebrate the virtues of athletic competition, peaceful coexistence and the magnificence of athletics, constitute Olympia’s perennial contribution to the world, this symbolized by the eternally burning Olympic flame. We may still sing today, as did Pindar in his eighth Olympian Victory Ode, “... of no contest greater than Olympia, Mother of Games, gold-wreathed Olympia...” [12002].

The ancient Olympic games were (almost) men only affairs. Successful athletes were highly honoured, and, perhaps for this reason, skulduggery was not unknown. For example, it is red in Wikipedia that “Sotades at the ninety-ninth Festival was victorious in the long race and proclaimed a Cretan, as in fact he was. But at the next Festival he made himself an Ephesian, being bribed to do so by the Ephesian people. For this act he was banished by the Cretans” [12003].

*Olympic nationalism*

In July 1912, the Boston Medical and Surgical Journal celebrated “American Supremacy,” noting that the “overwhelming success of the American athletes at the current Olympic games in Stockholm is as interesting physiologically as it is nationally gratifying. Although Sweden won the most medals, athletes from the United States won the gold medal count by the thinnest margin, 25 to 24.” The large population of the United States “is more mixed of all races, and we should therefore be able to select the best strains and breed the best mixtures.” American athletes were “better nourished and conditioned” than their competition, “which again should conduce to racial physical superiority.” To top it off, “the intensity of our national disposition leads our athletes to train much more eagerly and consistently, and with a keener professional intentness for winning.” Though eugenic undertones have faded, physicians have maintained their interest in the Olympics. The strobe of the quadrennial competitions illuminates dramatic changes in medicine and sport [12004].

*The first Olympic tests*

The first Olympic drug testing took place at the 1968 Games in Grenoble and Mexico City, but it was the Munich Games in 1972 that marked the introduction of a comprehensive testing program. Approximately 7000 athletes participated and just over 2000 samples were collected and analyzed for various types of stimulants. Since then the testing program has expanded for each (summer) Games, both in number and percentage-wise, and at the 2008 Beijing Games where 10,500 athletes took part, 4770 samples were collected. By then, the number of banned substances to be analytically identified had increased significantly. The IOC, however, had limited possibilities to conduct an efficient anti-doping activity as they
Doping during the modern Olympics

Athletes have always sought to outperform their competitors and regrettably some have resorted to misuse of drugs or doping to achieve this. Stimulants were taken by the first Olympic athletes to be disqualified in 1972. Although undetectable until 1975, from the 1950s androgenic anabolic steroids were administered for increased strength and power followed in the 1990s by erythropoietin for enhanced endurance. Both are highly effective doping agents. As analytical science validated improved techniques to identify these drugs, Olympic athletes, including many medallists were caught and disqualified. When the International Olympic Committee (IOC) prohibited beta blockers (beneficial in shooting), diuretics (assist weight classified athletes) and glucocorticosteroids, some athletes with genuine medical conditions were denied legitimate medical therapy. To overcome this, in 1992 the IOC introduced a system known now as Therapeutic Use Exemption (TUE). One paper discussed Olympic athletes who have been known to dope at past Games and some medical indications and pitfalls in the TUE process [12007].

The resolut fight during the Olympic games against doping in sports commenced as a result of the death of a Danish cyclist during the Rome Olympic Games in 1960 - directly seen by millions of people viewing TV. The International Olympic Committee (IOC) established a Medical Commission (IOC-MC) which had the task of designing a strategy to combat the misuse of drugs in Olympic Sport. It's today a far cry from the horror that ensued when drug testing was first introduced for the 1968 Winter and Summer Olympic Games and an athlete was busted, for of all things, drinking beer: the Swede modern pentathlete Hans-Gunnar Liljenwall was stripped of a bronze medal for dipping into the local cerveza at the Mexico City Summer Games [08012].

At the 2000 Olympics, 10 athletes were caught doping, including 6 medalists, while a record 27 athletes were caught doping at the 2004 Olympics. In total, 84 athletes, including 28 medal winners, have been caught doping at Summer Olympics, 37 of whom were weightlifters, the most notorious of sports amongst dopers. The Winter Olympics have generally witnessed fewer tests and fewer doping busts. Since 1968, only 13 athletes, including 6 medal winners, have been caught doping. Seven of them were cross-country skiers and 4 were hockey players. According to the International Olympic Committee there have been 84 infractions for doping since 1984, including such bizarre incidents as one in 2004 in which an Irish equestrian administered an antipsychotic drug to his horse. By Olympic Games, the failed, missed, refused or falsified test (and medals forfeited) have been [08012]:

<table>
<thead>
<tr>
<th>Year</th>
<th>City</th>
<th>Failed (Missed, Refused, Falsified)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1968</td>

</tr>
</tbody>
</table>
The Winter Olympics have generally witnessed fewer tests and fewer doping busts. Since 1968, only 13 athletes, including 6 medal winners, have been caught doping. Seven of them were cross-country skiers and 4 were icehockey players.

In total, 84 athletes, including 28 medal winners, have been caught doping at Summer Olympics, 37 of whom were weightlifters, the most notorious of sports amongst dopers. By country, the number of medals forfeited as a consequence of drug testing up to 2004:

- Bulgaria 7
- USA 6 (3 gold and 2 bronze from Marion Jones)
- Hungary 3
- Germany 2
- Sweden 2
- Canada, Russia, Poland, Ireland, Romania, Finland, Mongolia, Greece, Spain, Armenia, the Netherlands & Ukraine 1

By sport 12 medals have been forfeited in weightlifting, 5 in athletics, 2 each in equestrian, wrestling and cycling, and 1 each in judo, modern pentathlon and rowing.

The increased number of positive tests is in part a function of the increased number of tests administered at each game. At the 2000 Olympics, about 2000 doping tests were administered. That number grew to 3700 by the 2004 Olympics. The increasing number is largely a result of the expansion of the rules governing who gets tested. In the past, the top 4 finalists in an event and 1 other athlete chosen randomly were subjected to tests. However, in Beijing, the top 5 athletes were tested in addition to 2 chosen at random in each final. As well, random tests will be conducted throughout earlier stages of competition. Beginning in 2000, Olympic athletes were also subject to pre-Olympic, out-of-competition testing to detect substances consumed prior to competition that wouldn't later appear on a test. Blood testing was introduced on a limited basis at the 1994 Winter Olympics and at the 2000 Summer Olympics. It is the International Olympic Committee itself that administered and monitored athlete testing in Beijing, not the World Anti-Doping Agency. The latter focuses on policies, regulations and monitoring the 33 facilities worldwide that have been approved for testing athletes' samples [08012].

Some International Sport Federations (IF) and National Sports Federations followed suit when the anti-doping process started, but progress was modest until the world's best male sprinter (Ben Johnson, Canada) was found doped with anabolic steroids at the Olympic Games in Seoul in 1988. Further progress was made following the cessation of the cold war in 1989 and in 1999 public authorities around the world joined the Olympic Movement in a unique partnership by creating WADA, the World Anti-Doping Agency, which has doubtless been the start of a new anti-doping era [08013].

The Olympics in medical journals

Even before Pierre de Coubertin revived the Olympics in 1896, lore from the ancient games circulated in the medical literature. An 1851 essay in the Boston Medical and Surgical
Journal about the power of mind over body described “the old Greek who died on the spot from excess of joy on seeing his three sons crowned with laurel at the Olympic games” (1851). Oliver Wendell Holmes invoked this same episode in his valedictory to Harvard medical graduates (1858). Other authors drew competing lessons from the Olympic legacy. One warned that excessive athletic training diverted energy from mental development, leaving adolescents “listless and stupid”: “It was especially remarked by the Greeks that no one who in boyhood won the prize at the Olympic games ever distinguished himself afterwards” (1867). An 1891 review, in contrast, expressed the hope that educators would learn from the ancient techniques and improve athletic training in U.S. schools [12004].

When the modern games began in Athens in 1896, physicians only slowly became interested – and mostly in marathons. Heat and humidity tormented marathoners in St. Louis in 1904: only 14 of 27 finished. The winner Thomas Hicks, who sustained himself during the race with strychnine sulfate, five eggs, and brandy, required the care of four physicians in the aftermath. Heat caused problems again in London and Stockholm. When the games resumed in Antwerp in 1920, athletes were subjected to physical examinations. The United States sent its first team physician – one who had fenced in Stockholm – to the Paris games in 1924. Medical scrutiny has continued ever since [12004].

Physicians have been interested in the Olympics for many reasons. In the 1920s, they probed the limits of human physiology. One group studied the Yale heavyweight rowers who won gold in Paris. An ingenious contraption revealed that at their racing speed – 12 mph – the eight men produced four horsepower, a 20-fold increase over resting metabolism (1925). A 1937 study published in the Journal showed that athletes at the 1936 Berlin games consumed 7300 calories each day. Sometimes the venue itself became the issue. The United States threatened to boycott the Berlin games until Hitler relented and allowed black and Jewish athletes to compete. Ignoring these tensions, the Journal, which had published a favorable review of Nazi health insurance in 1935, advertised the exhibits and lectures on “Medical Theory and Practice in the New Germany” that had been organized for physicians who visited the Olympics (1936). Boycott politics surfaced again when the Journal’s editor, Arnold Relman, visited the Soviet Union in 1980. Relations had been strained by tensions over the Soviet invasion of Afghanistan and the United States’ threat to boycott the Moscow games. Other venues created medical concerns. Roger Bannister, who eventually became a neurologist after being the first person to run a mile in under 4 minutes, “thoroughly disapproved” of holding the 1968 games at high altitude in Mexico City. And indeed, several hundred athletes collapsed at those Olympics, from migraine, shock, syncope, or emotional excitement. Fears of local pathogens emerged before the Olympics in Seoul (Japanese encephalitis) and Barcelona (multidrug-resistant strep). Each warning met with vehement rebuttal. Olympic events now attract millions of visitors and require careful medical and public health planning [12004].

The safety of Olympic sports has remained an enduring concern. The French Academy of Medicine appointed a committee before the 1924 Paris games “to study the effects of modern athletics on the human system.”. The resulting tests “revealed an alarming number of cases of athletic heart.” Subsequent studies from the 1920s (on athletes from the 1928 Amsterdam games) through the 1990s (on 310 Italian Olympians) have produced conflicting evidence on the question of whether intense physical training can cause cardiac hypertrophy. Some sports received special scrutiny. On the eve of the Atlanta games in 1996, a scathing review likened women’s gymnastics to child abuse, arguing that although “elite gymnastics can provide a profoundly meaningful experience for the athletes,” it could also “result in serious, life-endangering physical and psychological disabilities.” Citing injuries, eating disorders, and social problems, the authors warned that “talented youngsters at every competitive level should be supported rather than crippled by their sport as they enter...
adulthood” [12004].

A different kind of medical scrutiny emerged in the 1950s. Commenting on a symposium about “Pheidippidian physiology,” a 1957 editorial highlighted the recent dramatic improvements in performance at track and field events. What explained “these epidemics of broken records”? The editorial considered possible contributions from training, diet, antibiotics, and motivation but focused on “a speculative explanation”: “that amphetamine is being used by some athletes to help them break otherwise unassailable records.” Such practices, if they were in fact occurring, were both dangerous and “ethically undesirable.” Each passing decade brought new scandals about performance-enhancing drugs. After the U.S. Olympic Committee admitted that seven cyclists (including four medalists) had received blood transfusions at the Los Angeles games, a Sounding Board article in the Journal in 1985 condemned this practice. Not only was the practice dangerous, especially in light of the emerging AIDS epidemic, but also it “represents an attempt to use a medical therapy to provide athletes with an unfair competitive advantage.” When Ben Johnson was stripped of his gold medal at the Seoul Olympics, the Journal reviewed the medical risks and legal consequences of anabolic steroids in 1989. Erythropoietin came next. A Dutch physiologist wrote in the Journal that “the next Olympic Games have already been nicknamed the ‘Hematocrit Olympics,’” and physicians' obligation seemed clear: “the medical profession has a responsibility to consider carefully these untoward consequences of scientific progress.” [12004].

Performance-enhancing drugs have cast a long shadow on the modern Olympics. Whether the agents are the strychnine, heroin, cocaine, and morphine that athletes used in Athens in 1896 or the amphetamines, steroids, and erythropoietin that some use today, the dilemma remains the same. As a sports medicine specialist noted in 2004, the “attraction of performance-enhancing drugs is simply that they permit the fulfillment of the mythical promise of boundless athletic performance – the hubristic “faster, higher, stronger” motto of the Olympic Games.” The ensuing systems of medical surveillance have led, inevitably, to “a new type of competition,” in which some athletes try to stay one step ahead of the authorities [12004].

There are several historical journal article in the Boston Medical and Surgical Journal (1851-1925) and in the follower New England Journal of Medicine after that [12004]:

Boston Medical and Surgical Journal
1858. Holmes OW. Valedictory address. 58:149-59.
1867. The abuse of physical exercise. 77:425.
1891. Hartwell EM. The principal types of physical training compared. 125:641-4.
1924. French Academy of Medicine names committee to study effects on the human system of modern athletics. 190:397.

New England Journal of Medicine

Canada

It is now a long time since the Ben Johnson scandal at the Olympics in Seoul, Korea, drew attention to the issue of doping. In the scandal’s aftermath, an independent organization now known as the Canadian Centre for Ethics in Sport was established to develop a national antidoping program. It has served as a model for other national antidoping organizations. Still, 55 Canadian athletes violated antidoping rules in the past 3 years: 27 used “recreational” drugs such as marijuana, and 28 took performance-enhancing drugs, most often anabolic steroids or stimulants [08014].

Formation of the IOC Medical Commission

In 1961 the International Olympic Committee (IOC) created a Medical Commission (IOC–MC) at its 59th Session in Athens, Greece. The decision was triggered by the death of the Danish cyclist Knud Enemark Jensen during the road race for teams at the Rome Olympic Games the year before. He was said to have taken some stimulating drug, but was also reported to have suffered from heat exhaustion and dehydration. Probably a combination of all this caused his death, but this has never been officially confirmed. At any rate, the IOC could no longer ignore the use of stimulants that had obviously been in place in certain sports for quite some time. The creation of the IOC-MC marked the start of the modern era of the anti-doping campaign. The Commission was requested to propose a strategy for combating the use of performance-enhancing drugs in Olympic sports. It took quite a while to
analyze the situation and recruit the necessary competence. Not until the 1967 IOC session were some concrete proposals presented such as a list of forbidden drugs (stimulants) in Olympic sport and drug testing at the coming Games. Therefore, 1967 is often referred to as the start of the IOC-MC [12005].

**Formation of the World Anti-Doping Agency**

Probably the most serious challenge for the anti-doping fight during the 1970s and 1980s was the unwillingness of most countries and international federations to join the fight. There were several reasons, namely: the costs; the lack of competence; the negative image should a top athlete in their own country or sport test positive; and, the Cold War. The East Germans used success in sport as a political weapon and other countries had followed suit, although in a less sophisticated way. Officially, sports leaders were against doping, but far too many only paid lip service and some were even sabotaging the fight. When the Cold War faded following the political events in 1989 and the years that followed, the anti-doping fight gained increased support. In 1999 the public authorities actually joined the fight by accepting the invitation of the IOC to form WADA together [12005].

In 1999, the IOC recognized that an effective fight against doping required cooperation between sport and government. The First World Conference on Doping in Sport resulted in the formation of the WADA in 2000, which was charged with harmonizing the international antidoping efforts. WADA has developed a World Anti-Doping Program, which has been adopted by all Olympic sports. In order for governments to ratify an equivalent to the World Anti-Doping Program, it was necessary to develop the International Convention Against Doping in Sport through the UN Educational, Scientific, and Cultural Organization. To date, over 160 countries, including the United States, have approved the convention [12006].

**Formation of Court of Arbitration (CAS)**

During the late 1970s and early 1980s, one athlete after another who tested positive challenged the IAAF before national courts and the Federation spent a lot of money on court trials. In an attempt to take care of the problem of escalating legal costs the IAAF included in its constitution an “Arbitration panel” as the highest authority to settle disputes within athletics. This could not prevent athletes from bringing their cases before national courts, but the Arbitration panel served as deterrent. This happened in 1982 and a year later the IOC created the Court of Arbitration for Sport (CAS), which today is included in the WADA Code as the final appellate body on doping matters. There are examples of enormous legal costs following an athlete’s positive sample. The IAAF was ordered by a district court in USA to pay USD 27.4 million in damage compensation to the 400 m world-record holder Harry “Butch” Reynolds after their panel had disqualified him for steroid doping in 1990. The decision was overruled by the Circuit court, and the Supreme Court refused to hear the case. Thus, after several years of legal battle Reynolds lost the case (and money) but the IAAF also lost a lot of money. The winners were the lawyers on each side. In recent years, WADA successfully defended the testosterone analysis before CAS after it had been challenged by the Tour de France winner Floyd Landis following his positive test. The defense cost WADA about USD 2 million. The ever-increasing legal costs are a major challenge for sports organizations and a true threat to the anti-doping fight [12005].

**Out-of-competition testing**
The next challenge was to convince the world of sport that doping controls at competition only is not sufficient. Since AAS are taken during training periods in order to promote the building of muscles and strength, doping controls will also have to be conducted during training – so-called out-of-competition controls. Such controls had been in place in Norway and Sweden since the early 1980s but when the idea was brought to a broader international sports community it was met with great resistance. A majority saw it as an unacceptable intrusion into the athlete’s private life. However, the Ben Johnson scandal at the Seoul Games in 1988 made the skepticism fade and in 1990 the IAAF, as the first international federation, started testing out-of-competition after the necessary rules had been passed by the 1989 IAAF Congress. Today, out-of-competition testing is compulsory in the WADA Code, and any national anti-doping organization or international federation that does not conduct such testing will be declared noncompliant with the Code and possibly face serious consequences. The IAAF ambition to clean up its sport resulted in the identification of doped athletes, some very famous [12005].

**History of therapeutic use exemptions (TUE)**

The introduction of what today is known as therapeutic use exemption (TUE) was far from smooth. It started in the mid-1980s when a Swedish athlete asked the nation’s anti-doping organization for permission to use testosterone as replacement therapy following the removal of both his testes (unilateral cryptorchism as a newborn followed by cancer in his remaining testis as a teenager). It was granted with the remark that it was only valid within Sweden. Soon thereafter a similar case (bilateral testicular torsion) occurred in Australia. At the 1988 Olympic Games two athletes were allowed by the IOC-MC to use banned substances (corticosteroids for inflammatory bowel disease and diuretics for nephrotic syndrome). The permissions were granted although no clear rules existed. Some Commission members, therefore, suggested that such rules be worked out. Other members were against, arguing that athletes should not be allowed to use prohibited substances. If they were in such need they should quit sport. In 1992, however, a proposal was presented to the IOC-MC with strict criteria for “permitted use of prohibited substances” and the formation of a group that should evaluate applications for such use of IOC-MC. The proposal was accepted, and a “Medications Advisory Committee (MAC)” started its operation at the Barcelona Games in 1992. Although MAC’s authority was limited to the Olympic Games it became an advisory body for international federations and national anti-doping organizations. MAC worked under strict anonymity and, actually, in secret. The fear was that if MAC became generally known it would result in a flood of requests and abuse of the system. When the IOC Juridical Commission reviewed the 1999 edition of the IOC Medical Code they first refused to include the concept of “permitted use”. Only after pressure from the IOC-MC was it added as a brief ‘addendum’. When WADA was about to be formed, however, the IOC-MC requested that the concept of permitted use be accepted and clearly explained in the coming rules. Today TUE is an important part of the WADA Code [12005].

When the IOC undertook the first extensive doping controls (>2000) at the 1972 Munich Olympics, the only drugs that were prohibited were stimulants and narcotics. Androgenic-anabolic steroids (AAS) were prohibited prior to the 1976 Olympics, although endogenous steroids such as testosterone could not be identified. During this period, there was no discussion about athletes needing a Therapeutic use exemptions (TUE). However, after diuretics, beta-blockers and systemic glucocorticosteroids (GCS) were added to the IOC’s Prohibited List in the 1980s, significant interference occurred in the availability of essential medications to manage medical conditions in elite athletes. Around 1987-1988, two male
athletes without testes, one in Sweden and the other in Australia, sought to continue their testosterone replacement therapy and participate in their sport. Both were granted national approval. At the 1988 Calgary Games, an ice hockey player was approved to take oral GCS for inflammatory bowel disease (IBD) and later that year in Seoul, a rower with nephrotic syndrome was approved to continue her diuretic therapy and participate. Both were ad hoc decisions taken by all members of the IOC-MC, some of whom were not medically qualified. In February 1991, it was presented a paper “Permission for athletes to use drugs contained in the IOC List of Banned Classes” to the IOC-MC. This detailed the following criteria that should be met to approve any such application by an Olympic athlete [13013]:

- The athlete would experience significant impairment of health if the prohibited medication was withheld
- No enhancement of performance could result from the administration of the prohibited substance as medically prescribed
- The person would not be denied the prohibited substance if he/she was not a competing athlete
- No available permitted or practical alternative can be substituted for the prohibited substance
- Retrospective approval would not be granted

Independently, and at the same IOC-MC meeting, professor Manfred Donike presented a paper on “Replacement therapy” which focused on testosterone in anorchia. An interim Medications Advisory Committee (MAC) was appointed (D Catlin, A Ljungqvist and K Fitch, Convenor) and requested to develop guidelines to implement the proposal. This was undertaken and included [13013]:

- The complete medical details including the history, clinical findings and investigation must be submitted
- The necessity to administer the prohibited medication including the dosage, route and frequency of administration must be certified by a suitably qualified medical specialist
- The medical necessity to administer the prohibited substance cannot be the result, wholly or partially, of prior use of a drug from the banned classes or banned methods
- Additional investigations requested by the MAC will be undertaken at the athlete’s or his/her National Olympic Committee’s (NOC) expense
- Any doctor who provides the MAC with false information will be ineligible to be accredited as an Olympic team doctor or official
- Under no circumstances will permission be given to use any synthetic anabolic steroid

However, the concept had its doubters and it would be another year before the IOC-MC agreed to allow the MAC to start operating prior to the Barcelona Games. However, the IOC-MC Chairman, supported by some Commission members, would not permit any publicity for “fear of abuse of the system”. Hence, only two applications were received for Barcelona 1992. Both were for oral GCS for well-documented IBD and were approved. Each athlete won a medal, although neither was in an individual event [13013].

**Anorchia**

During the early years, MAC members were conscious that they were embarking on a new and potentially controversial undertaking and that their decisions must be able to withstand the closest scrutiny. In the mid-1990s, the MAC compiled the first document that established some circumstances in which certain prohibited substances and methods might be approved to manage specific medical conditions encountered in athletes. A number of conditions and
circumstances for which permission would not be granted were also documented. The classes of prohibited drugs under consideration were diuretics, corticosteroids, beta-blockers and AAS (only testosterone). No exemptions were contemplated for stimulants or narcotics. In 1994, two world-class sailors applied to continue to administer testosterone at the 1996 Olympic Games if selected. Both had anorchia, one a congenital condition and the other surgical due to bilateral malignancies. Having considered these applications, the MAC sought the advice of independent expert endocrinologists who were “blinded” as to the identity of each athlete, his NOC and his medical advisors. Both were approved and although neither athlete qualified at the 1996 Olympic yachting trials, one did compete in Athens 2004 [13013].

**Aplastic anemia**

One unusual request was for erythropoietin in a Winter Olympic athlete prior to the 1994 Lillehammer Games because she had recently been a bone marrow donor for her brother with aplastic anaemia. It was the usual policy of the oncology centre concerned to withdraw and store a unit of blood prior to harvesting bone marrow and reinfusing this postharvest. (This would have been a Prohibited Method.) Owing to not wanting to interrupt her Olympic training programme and the urgency of her brother’s need for a bone marrow donation, this was not undertaken and her haemoglobin fell by 2 g/dl. However, despite the compelling circumstances, the application was rejected [13013].

**Congenital adrenal hyperplasia (CAH) and hypogonadism**

Some early requests included an archer with 21-hydroxylase deficiency (salt losing) congenital adrenal hyperplasia (CAH) seeking oral GCS, which was approved. However, shortly after this, a shooter with 17-hydroxylase deficiency CAH who had been granted national approval was denied permission by her International Federation (IF) to administer GCS and compete internationally. Fortunately, intervention by the MAC reversed this decision and later, she competed successfully at the 2000 Olympic Games. Prior to Atlanta 1996, a female soccer footballer with C1-esterase deficiency hereditary angioneurotic oedema was approved to use danazol daily and participated. In contrast, an aging canoeist who had been prescribed testosterone for alleged hypogonadism and had the backing of his national antidoping agency sought permission to continue this therapy at Atlanta. The MAC advised that this athlete did not have a valid justification and rejected the application [13013].

**Stimulation medication**

A well-publicised case that regrettably reflected that the MAC was compelled to remain “clandestine” was that of an elite 22-year-old 3 m diver whose severe narcolepsy was diagnosed in 1996. Immediately, she sought permission from her NOC and then from FINA to take stimulant medication but was rejected by both bodies. She continued to compete nationally and internationally and won national titles but seemingly was not required to take a doping control until a Grand Prix event in 1999 when she admitted the use of dexamphetamine on the doping control form and tested positive. Despite being advised that her narcolepsy was so severe that she was at major risk of falling asleep on the 3 m diving platform and thus of potential injury, FINA’s Doping Control Panel imposed a 12 month suspension. Intervention by the FINA Medical Commission resulted in the sanction being reduced to 6 months, but on appeal to CAS, this was further reduced to 2 months. Ironically, less than a month after her positive test, FINA modified their doping regulations to permit the use of a prohibited medication in special circumstances. The opinion of the MAC was not sought until shortly prior to her initial FINA hearing and then at the request of her NOC. The MAC had no hesitation in advising that she was entitled to a TUE. This may or may not have
influenced both the FINA Medical Commission and the CAS. Had the IOC informed the stakeholders of the MAC’s existence, this diver would have applied and been approved to take her medication in 1996. Soon after this decision by the MAC, an application was received from a track and field athlete from the same NOC whose narcolepsy had been proven conclusively by sleep studies. On this occasion, the opinion of an independent expert in sleep medicine was sought. This request was granted by the MAC for the recently released but prohibited modafinil – a wakefulness drug [13013].

Danazol

Between 1992 and 2003, the IOC’s MAC (later TUEC) received numerous applications and its recommendations were believed to have been accepted on all occasions. In addition to functioning at the Olympic Games without publicity, the MAC provided advice to as many as 15 IFs and 11 NOCs who sought assistance. Few applications were received that could be deemed to be “opportunistic”, but one from a 33-year-old elite female weightlifter appeared to be. On the advice of a “Longevity Institute” doctor, she sought permission to administer transdermal testosterone following her hysterectomy and bilateral oophorectomies performed for endometriosis. This was in addition to her replacement permitted hormone therapy. The application was rejected because no woman should ever be granted approval to take any AAS except danazol for very strict criteria. From its early days, the MAC decided that no AAS, except testosterone, could be approved for any male athlete and only then with a conclusive diagnosis and if the necessity was confirmed by an independent expert. This policy remains today [13013].

Glucocorticoids and diuretics

In late 1998, approval for oral GCS treatment was granted to a young athlete in the sport of curling who had a successful renal transplant. Earlier that year, he had competed at the 1998 Nagano Olympics with an MAC-approved TUE for furosemide to assist in managing his chronic renal failure. At that time, a condition of approval was that the specific gravity of urine collected in doping control must be 1005 or greater by refractometer. However, improved analytical hardware has made this requirement no longer necessary [13013].

Beta-blocker

A 56-year-old elite international shooter with a history of coronary artery bypass surgery was denied permission to take a cardioselective beta-blocker and compete. Although his medical indication was not questioned, beta-blockers had been demonstrated to produce a 13 percent improvement in shooting performance and this was deemed to contravene the criterion of ‘not enhancing sports performance’. Currently, the status of beta-blockers in shooting remains unchanged, that is, TUEs should not be approved. Prior to Salt Lake City 2002, a bobsledder with low-serum testosterone after a unilateral radical orchiectomy for seminoma was denied permission to administer depotestosterone because of the presence of one intact testicle [13013].

Recognising the concept of TUEs

Many NOCs and IFs did not accept the policy of therapeutic use, first because it was not in the Medical Code of the Olympic Movement, and second, because of ignorance on the part of many sports authorities as to the concepts of therapeutic use. Thus, recognition of the concept of TUE continued to be difficult. In 1998, the IOC’s Juridical (Legal) Committee was incredulous at being advised by the author that TUEs had been approved for 6 years and
criticised the IOC-MC Chairman for denying the MAC and its operation any publicity. But it would be another 2 years before the Juridical Committee would finally permit a one sentence mention of the concept as an addendum to the 2000 edition of the Medical Code of the Olympic Movement. This permitted a small breakthrough when the Anti-Doping policy for the Sydney 2000 Olympics made mention of the principle. Australia is believed to be the first country to have a committee with legislative authority to approve TUEs from August 1999. During the Sydney 2000 Olympic Games, Australia's TUEC organised a meeting of NOCs, IFs and interested persons which recommended that templates of established and proposed criteria for specific TUEs be prepared. This task was undertaken by Australia's TUEC and the templates circulated to attendees for feedback in 2001 [13013].

It was the World Anti-Doping Agency (WADA), not the IOC, that provided global recognition and acceptance of TUE. Strenuous attempts to sell the idea of TUE occurred at the 1999 World Conference on Doping in Sport in Lausanne from which WADA had its origins. Fortunately, two members of the MAC had significant WADA roles from its start and were able to ensure that the principle of TUE was accepted in the World Anti-Doping Code. An International Standard of TUE (ISTUE) was prepared between 2001 and 2003 and became operative when WADA finally assumed global responsibility for doping in January 2004. Significantly, the TUE criteria and guidelines developed by the MAC in 1991-1992 were incorporated virtually unaltered in the initial ISTUE. WADA established a TUE Expert Group in 2004 and members reviewed the Australian TUE templates that had been updated at least annually. These were offered to WADA in 2005 but the offer was rejected. During the last 6 years, WADA has developed advice termed “Medical Information for TUE Committees”, which had a rocky start, but by involving experts in each field, it has become a valuable reference document for TUECs [13013].

Recent Olympic Games

It is difficult to compare TUEs at Olympic Games as changes to the Prohibited List have necessitated TUEs for different substances and methods. Insulin was prohibited prior to Sydney 2000 and 5/8 TUEs approved were for insulin-dependent diabetes mellitus (IDDM). But the number of applications increased significantly after WADA assumed global responsibility for doping from the IOC. At the Games in Athens 2004, 24 TUEs for athletes from 19 NOCs and 15 sports were approved with 9/24 (38 %) being for insulin. An appeal against a rejected application for systemic GCS was heard by WADA and the verdict confirmed that the IOC's MAC, now termed TUEC, had acted correctly. Intravenous infusions were prohibited prior to Torino 2006, although no athlete sought a TUE and 2/4 approved TUEs were for insulin for IDDM. Two applications were considered not to meet the criteria for approval and were discussed with each athlete's Chief Medical Officer (CMO) who accepted the TUEC's rationale and both were withdrawn. In Beijing, the TUEC recognised or approved 39 TUEs, of which nine were for IDDM. These 39 athletes were from 19 NOCs and 19 sports. For the first time, five intravenous infusions were approved. Interestingly, there were two Olympic athletes with well-documented Addison's disease approved for oral GCS. One application for stimulant medication for adult onset attention deficit hyperactive disorder was approved and a second withdrawn when a second opinion was sought, which was IOC's policy and later WADA's [213013].

Between 2002 and 2008, inhaled beta2-agonists (IBA) were managed by an IOC Independent Asthma Panel but not considered to be a TUE. However, in 2009, when WADA included IBAs in the prohibited list, the requirements to approve IBA use were identical to those of the IOC's Asthma Panel. This decision was partially rescinded just prior to Vancouver 2010 but two IBAs remained prohibited, formoterol and terbutaline. These accounted for 94 of the large number of 107 TUEs approved or recognised by the IOC's
TUEC at Vancouver. Of the remaining 13, there were three approvals for insulin for IDDM, two for ADHD and one for an IF infusion. One IF-approved TUE for a female athlete to take dehydroepiandrosterone was a fundamental error since no female athlete should ever be approved to take any AAS except danazol. An appeal to WADA was successful, but WADA rules permitted the athlete 14 days to cease taking this prohibited medication, which allowed her to continue until after the Games. This is unsatisfactory and should be changed.

A number of difficulties were encountered at the recently successful London Olympic Games. From 2004, the IOC’s TUEC had agreed to recognise TUEs for participating Olympic athletes approved by both IF and NADO TUECs after being subjected to close scrutiny. For Vancouver, the IOC was required to use WADA’s Anti-Doping Administration and Management System (ADAMS). This posed a number of problems which were augmented in London with almost four times the number of participating athletes and IFs. First, the IOC TUEC’s access to ADAMS was restricted since members were denied the opportunity to open uploaded medical files to allow them to confirm that an approved TUE had been granted according to established criteria. Second, more than half of the participating 205 NOCs do not upload TUEs onto ADAMS. Third, few NOCs heeded the request to provide the IOC’s TUEC with a list of valid TUEs for their athletes. Finally, much time was spent in fruitlessly examining ADAMS to identify athletes believed to be accredited for London 2012 who may have had current a TUE. Almost all TUEs identified on ADAMS for athletes presumed to be competing in London were either for substances that were currently not prohibited (mainly IBA) or short-term TUEs that were no longer necessary or valid. Clearly, the IOC needs WADA to provide superior access and a more efficient way of ascertaining valid TUEs if ADAMS is to be used at future Olympic Games.

Prior to the opening of the London Olympic Village, CMOs were requested to provide the IOC’s TUEC with details of all valid TUEs for their NOC athletes who would participate at the Games. Only two complied totally and 21 of the 31 preapproved TUEs that were recognised were from these two NOCs. During the Games, two athletes tested positive for prohibited substances and when advised, the NOCs of both athletes confirmed that each had a valid TUE that had not been disclosed. Hence, one must question how many other athletes had TUEs and did not advise the IOC. Although at each Games between 2002 and 2010, between 1/1000 and 1/1500 athletes were known to have IDDM, in London, only three athletes were reported to have a TUE for insulin (1/3500) which begs the question: were there more insulin-dependent diabetic athletes about whom the IOC was never advised? In London, the TUEC approved another 26 TUEs, with as customary most (15) being for systemic GCS and there were six intravenous infusions. One application was considered inappropriate and the CMO was contacted and the reasons provided. The NOC agreed to withdraw the application, institute an alternative permitted treatment and this athlete won a gold medal.

Legislation

In the early 1900s, endurance events lasted for days without rest. Open-water swimming, cycling, and long-distance running and walking athletes used stimulants such as strychnine, heroin, and amphetamine to alter the perception of fatigue. Only later did governments and sport recognize the serious health risks associated with the use of stimulants. The International Amateur Athletics Federation (IAAF; now the International Association of Athletics Federations) banned the use of stimulants in 1928. The amphetamine-related deaths of Danish cyclist Knud Enemark Jensen during competition at the 1960 Olympic Games and British cyclist Tommy Simpson during the 1967 Tour de France illustrated the
seriousness of the problem. In 1966, the cycling, soccer, and track and field international federations began testing for stimulants. The International Olympic Committee (IOC) formed its Medical Commission, which included a Subcommission on Biochemistry and Doping in Sport, in 1967 and tested for stimulants at the 1968 Olympic Games in Mexico City. France adopted antidoping legislation in 1963; the Council of Europe adopted the first international Anti-Doping Convention in 1968 [12006].

Concern regarding the effects of anabolic steroids on athletes resulted in US Congressional hearings in 1988. Anabolic steroids were scheduled under Class III of the Controlled Substance Act in 1990. That same year, the Dubin Commission report, commissioned by the Canadian government because of concerns regarding the use of public money in sport, documented widespread abuse of performance-enhancing drugs and poor testing by Canadian sporting authorities. In 1990, two governmental agencies, the Canadian Sport Anti-Doping Agency and the Australian Sport Drug Agency, were formed to deal with drugs in sports. The second Council of Europe Anti-Doping Convention was signed. A multilateral intergovernmental agreement, the International Anti-Doping Arrangement (IADA) was formed to promote more effective antidoping practices. The IADA group developed an International Organization for Standardization (ISO) Publicly Available Specification (ISO/PAS 188730) for collection of urine samples. This document eventually became the basis for WADA's International Standard for Testing [12006].

USA

The USADA was formed in 2000 by the US Olympic Committee in part to avoid the perception of the “fox guarding the hen house.” In 2001, Congress designated USADA “the official antidoping agency for Olympic, Pan American and Paralympic sport in the United States.” USADA was given authority to develop a comprehensive national antidoping program including testing, adjudication, education, and research. USADA and WADA have jointly worked to advance the science (analytical chemistry, biochemistry, endocrinology, hematology, laboratory medicine, pharmacology, physiology, sports medicine, and toxicology) of detection of doping [12006].

The Bay Area Laboratory Cooperative (BALCO) scandal was one of the early examples of information sharing between law-enforcement and antidoping agencies. BALCO was providing synthetic anabolic steroids not approved by the Food and Drug Administration and designed to avoid detection to a number of athletes including Kelli White, Marion Jones, and allegedly Barry Bonds. Sharing of information between the Internal Revenue Service Criminal Investigations, local law enforcement, and USADA enabled effective prosecution of the cases in criminal and sport venues, as appropriate. Prior to 2004, detection of a prohibited substance or its metabolites or markers was required to be prosecuted for a violation of the antidoping rules. The 2004 edition of the Code recognized other means for proving a case of doping, including any reliable information. USADA's prosecution of the first “nonanalytical positive” case that same year resulted in suspension of the athlete [12006].

Industrialized doping

In 2003, another significant event in the understanding of the institutional nature of doping occurred. A syringe was anonymously sent to a WADA-accredited laboratory in Los Angeles that contained tetrahydrogestrinone (THG), a “designer” steroid that was not known and not on the current WADA prohibited list, made specifically to avoid detection by modern antidoping technologies. This led to a series of investigations resulting in the indictment and
subsequent conviction of individuals running a performance-enhancing program for professional athletes at the BALCO pharmacy in San Francisco [08006].

In May 2006, Spanish police arrested five people and seized a variety of banned performance-enhancing drugs and blood-doping supplies at a Madrid doping clinic. Here, professional athletes would receive medically-supervised injections of hormones and other performance-enhancing drug regimes. The 40-page police report included a clear paper trail of doping procedures on at least 50 professional cyclists. The report was given to the International Cycling Union, which led to the disqualification of 23 professional cyclists, virtually all the top contenders from the 2006 Tour de France. The final of the 2006 Tour was also tarnished, as the champion, Floyd Landis, was found to have a positive anti-doping test for steroids. Landis was stripped of the championship and discharged from his team. At this writing the result is being challenged by Landis and his legal and medical experts, claiming that the test was invalid since several errors were made in the collection, analysis and reporting of the results [006].

In a separate investigation in Paris in 2006, 23 individuals were sentenced to 4 years in jail for trafficking a cocktail of amphetamines and other performance-enhancing drugs known as "Belgium Pot" to professional cyclists. In October of that same year, the cricket world was shocked to learn that two Pakistani fast bowlers, Shoaib Akhtar and Mohammad Asif, tested positive for the steroid nandrolone [08006].

Laboratory testing

Mass spectrometry has played a decisive role in doping analysis and doping control in human sport for almost 40 years. The standard of qualitative and quantitative determinations in body fluids has always attracted maximum attention from scientists. With its unique sensitivity and selectivity properties, mass spectrometry provides state-of-the-art technology in analytical chemistry. Both anti-doping organizations and the athletes concerned expect the utmost endeavours to prevent false-positive and false-negative results of the analytical evidence. The Olympic Games play an important role in international sport today and are milestones for technical development in doping analysis. Mass spectrometry has played an important role in doping control from Munich 1972 to Beijing 2008 Olympics [08015].

One brief note gave also a general overview on the activity of the antidoping laboratories accredited by the World Anti-Doping Agency outlining the evolution, over the last four decades, of the analytical methods and techniques in the detection of prohibited substances and methods. Special emphasis was given to the future trends of the fight against doping in sports, as seen from the perspective of a laboratory scientist, in the wider context of fair play, health protection, and perception of the activity of the antidoping laboratories by the general public [08016].

There were 35 WADA accredited laboratories in 2009. Approximately 3,300 additional samples were analyzed in 2009 compared to 2008, with a slight increase in Adverse Analytical Findings and Atypical Finding, from 1.84 percent (2008) to 2.02 percent (2009).

Anabolic steroids

The initial test for testosterone in urine was developed by Donike and coworkers, who showed that administered testosterone appeared in the urine as testosterone glucuronide. They also showed that for a population of athletes, the ratio of testosterone to
epitestosterone (T/E) had a positively skewed distribution, with a modal ratio of about 1:1. Initially, an athlete sample having a T/E ratio > 6:1 was considered a doping violation. The concept of intraindividual reference ranges (as opposed to population-based reference ranges) was introduced into the T/E test in the early 1990s. Computer programs are now used to compare an athlete's current sample result to their previous sample results. Results that are inconsistent with previous results are investigated and could result in targeted testing or an antidoping rule violation. The measurement of $^{13}$C/$^{12}$C ratios in testosterone and its metabolites has allowed the differentiation of pharmaceutical testosterone from natural testosterone. Donike's group also began the concept of the urinary “steroid profile,” which used a combination of other urinary steroids to increase the sensitivity of the test. Other antidoping research has identified a del/del genotype of UGT2B17 as the cause of a subpopulation of individuals who have low (<0.5) T/E ratios in urine, the use of 11 steroids in urine to improve test sensitivity, new metabolites of testosterone (e.g. testosterone cysteinate) in the urine, and several substances that affect the metabolism and excretion of testosterone [12006].

To measure testosterone in the urine to detect doping is not adequate because of large interindividual and intraindividual differences in urinary steroid concentration. However, the nearly constant ratio of urinary testosterone glucuronide to epitestosterone glucuronide became the basis of a better test. Epitestosterone is the 17alpha epimer of testosterone and has no known physiological function. It is not a metabolite of testosterone [08010]. An upper normal limit of six was calculated for the testosterone/epitestosterone ratio based upon population studies. In 1983 the Medical Commission of the International Olympic Committee (IOC) introduced this value as a criterion for testosterone abuse. Ratios above six should be considered suspicious, and the person concerned should be subjected to further testing. In 2004 the approved upper limit was set at four [08011].

The 2011 WADA list

International anti-doping efforts are harmonized and regulated under the umbrella of the World Anti-Doping Code and the corresponding Prohibited List, issued annually by the World Anti-Doping Agency (WADA). The necessity for a frequent and timely update of the Prohibited List (as the result of a comprehensive consultation process and subsequent consensual agreement by expert panels regarding substances and methods of performance manipulation in sports) is due to the constantly growing market of emerging therapeutics and thus new options for cheating athletes to illicitly enhance performance. In addition, “tailor-made” substances arguably designed to undermine sports drug testing procedures are considered and the potential of established drugs to represent a doping substance is revisited in light of recently generated information. The list that was published and has been authoritative from 1 January 2011 comprising a total of 10 different classes of banned substances (S0–S9), three different groups of prohibited methods (M1–M3), and two classes of drugs (P1 and P2) being banned from selected sports only. In comparison to the 2010 edition of the Prohibited List, few but significant modifications were made. A major novelty has been the installation of the S0 section, which interdicts the use of any pharmacological substance that has not (yet) received approval by governmental health authorities (or where development has discontinued) as a human therapeutic agent. This addendum is particularly important in the light of new drug entities that are not covered by any of the established classes of banned substances, either by their chemical nature or their biological effects. Ryanodine receptor-calstabin complex stabilizers, which have been proven to enhance performance in the laboratory setting are currently undergoing advanced clinical trials but do not represent compounds of S1–S9. These might exemplify such a new category of substances. The section S2 (peptide hormones, growth factors, and related substances) was
modified concerning the examples of erythropoiesis-stimulating agents (ESAs) by explicitly listing hypoxia-inducible factor (HIF) stabilizers, which also represent a considerably heterogeneous emerging class of substances targeted for clinical approval. In contrast to these additions to S2, the use of platelet-derived preparations has been legitimized and the paragraph removed in the 2011 Prohibited List accordingly. The category M2 (chemical and physical manipulation) was extended by a new paragraph (M2.3) that particularly emphasizes the illicit nature of the “sequential withdrawal, manipulation and reinfusion of whole blood into the circulatory system”, a strategy that includes, for example, the so-called UV-activated autohemotherapy (commonly regarded as alternative medicine). M3 (gene doping) was split into three sub-groups that define (1) the transfer of nucleic acids or sequences of these; (2) the use of normal or genetically altered cells; (3) the use of drugs manipulating gene expression with impact on athletic performance as prohibited methods [12016].

**The 2012 WADA list**

As of 1 January, the 2012 Prohibited List International Standard has come into effect, exhibiting minor but relevant alterations from to the previous 2011 version. In agreement with its predecessor, the List comprises a total of 10 different classes of banned substances (S0–S9), three different groups of prohibited methods (M1–M3), and two classes of drugs (P1 and P2). The latter are banned from selected sports only. The major modifications can be observed in the sections: S3 (beta₂-agonists), S4 (hormone and metabolic modulators), and M3 (gene doping). In the S3 group, quantitative consideration of formoterol has been considered with the allowance of a maximum daily therapeutic dose of 36 microg of inhaled formoterol and a urinary threshold of 30 ng/mL. If the determined quantity in urine exceeds this level, an adverse analytical finding is reported followed by penalty, unless the athlete can prove (e.g. by means of a pharmacokinetic study) that the concentrations were reached by the admissible route and daily dosage. The category S4 has been complemented by a new subsection named “metabolic modulators”. These host peroxisome proliferator activated receptor (PPAR)delta agonists such as GW1516 and PPARdelta-AMP-activated protein kinase (AMPK) axis agonists, such as 5-amino-4-imidazolecarboxamide ribonucleoside (AICAR). These were formerly listed among gene doping (M3.3) in the previous list. Following a re-evaluation of the impact of the use of alcohol (P1) and beta-receptor blocking agents (beta-blockers, P2) on the athletes' performance in selected sport disciplines, the interdiction of alcohol was lifted for Ninepin and Tenpin Bowling (in agreement/on request of the Federation Internationale des Quilleurs) and so was the ban of beta-blockers for bobsleigh, skeleton, curling, modern pentathlon, motorcycling, sailing, and wrestling. In order to probe for potential patterns of abuse concerning selected substances that are currently not (or not at all times or at any concentration) prohibited, the established WADA monitoring programme has been expanded. Besides the stimulants bupropion, caffeine, phenylephrine, phenylpropanolamine, pipradrol, pseudoephedrine (< 150 microg/ml), and synephrine and the ratio of morphine over codeine, the prevalence of nicotine, hydrocodone, and tramadol was to be monitored in-competition. Moreover, the (ab)use of corticosteroids in out-of-competition periods is acquiring concern and appears as a new item on the 2012 monitoring programme. Concerning nicotine and its metabolites, a comprehensive compilation of monitoring data was published outlining an alarmingly high prevalence of nicotine use in selected sports disciplines. Further to these explicitly stated drugs, alternative medicine has necessitated greater attention in order to protect both the spirit of sport and the athletes themselves from inadvertent anti-doping rule violations. In continuation of the endeavor to keep pace with the changing trends of doping, manipulation, and innovations and improvements in analytical chemistry, anti-doping laboratories are urged to enhance their
procedures in terms of comprehensiveness, speed, and/or sensitivity. This, in combination with the fact that the International Standard for Laboratories allows for the long-term storage and re-analysis of doping control samples, is considered one of the main aspects causing deterrence to cheating athletes [13012].

The 2013 WADA list

Compared to its predecessor, the 2013 Prohibited List exhibited only few major modifications such as the re-categorization of insulins from S2 (peptide hormones, growth factors and related substances) to S4.5 (hormone and metabolic modulators) and the inclusion of M2.3 (chemical and physical manipulation) into M1.1 (manipulation of blood and blood components) by respective re-wording of the paragraph. In addition, the maximum daily therapeutic dose of 36 microg of inhaled formoterol (S3) was increased to 54 microg, resulting in a permissible urinary concentration of 40 ng/mL (formerly 30 ng/mL). In agreement with prior protocols, an adverse analytical finding is reported (followed by penalty) if the determined quantity in urine, including the measurement uncertainty, exceeds the threshold limit. The finding will be processed as an anti-doping rule violation unless the athlete can prove (e.g. by means of a pharmacokinetic study) that the concentrations were reached by the admissible route and daily dosage. In agreement with or on request of international federations, the interdiction of beta-receptor blocking agents (beta-blockers, P2) was lifted in selected sport disciplines including ninepin and tenpin bowling, aeronautic, boules, bridge, and powerboating. This is a continuation of the process initiated in 2012, where another 7 international federations removed the ban of beta-blockers from their sport [13009].

Category 0

The category S0 of the Prohibited List does not explicitly mention any specific substance; here, any pharmacological compound not covered by the other classes of prohibited substances and methods and without “current approval by a governmental regulatory health authority for human therapeutic use” is considered illicit. Potential candidates for this category are sirtuin-1 (SIRT1) activating drugs such as SRT1720 the characterization, metabolism. In case of the proposed routine doping control application, the mass spectrometer was a QqQ instrument with ESI source operated in positive mode and MRM, while compound characterization was conducted on a quadrupole-time-of-flight (Q-TOF) system [13009].

Monitoring program

In addition to the Prohibited List, WADA has established a monitoring program in order to probe for potential patterns of abuse concerning selected substances that are currently not (or not at all times or at any concentration) interdicted. The “in-competition” monitoring program, which included the stimulants bupropion, caffeine, phenylephrine, phenylpropanolamine, pipradrol, pseudoephedrine (< 150 microg/mL), synephrine, and nicotine as well as the ratio of morphine over codeine, hydrocodone, and tramadol in 2012, was complemented by the analgesic tapentadol in 2013. Further, as in 2012, the (mis)use of corticosteroids in out-of-competition periods has been investigated [13009].

Arne Ljungqvist
Professor emeritus Arne Ljungqvist from Karolinska Institutet, Stockholm, who has served in various high positions in the IOC, International Association of Athletics Federations (IAAF), Swedish Sports Confederation, to mention some of them, has dedicated a great deal of his life to service in sports and sports medicine. Arne Ljungqvist has especially dedicated his career to the fight against doping and to the protection of the health of the athletes. It all started over 60 years ago when Arne became a Swedish senior champion in high jump in 1951, jumping as high as 201 cm. Arne was multi-talented and won also the Swedish junior championships in pole vault and javelin. He was one of the favourites for the Gold medal in the high jump competition in the Olympic Games in Helsinki 1952, but unfortunately could not compete because of an injury that he sustained during a medical student carnival in the autumn of 1951 when a group of us were jumping for the general public in the streets with numerous hard landings on asphalt. Arne had to end his jumping career as his injury could not be cured, and it was not until the 1960s that the diagnosis of patellar tendinopathy could be made. Arne, however, continued his medical studies and soon became very successful. Arne was appointed professor at the Karolinska Institutet in 1972 because of his excellent medical research in the fields of renal and cardiovascular diseases and, later, oncology. He held several high professional positions such as Vice Dean of Medical Faculty, Karolinska Institutet, 1972–1977; Pro-Rector, Karolinska Institutet, 1977–1983; Chairperson, Department of Pathology and Cytology, Karolinska Hospital, 1983–1992; President, Swedish Council of Sports Research, 1980–1992; Dean Swedish School of Sport and Physical Education, 1992–1996; and President of the Swedish Cancer Society, 1992–2001. Interestingly enough, he took time to serve Chamberlain to His Majesty the King of Sweden, 1977-1986 and has since then been Lord in Waiting to His Majesty the King of Sweden. In 1971, Arne returned to sport as he was elected to the Board of the Swedish Athletics Association, where in 1973 he became chairperson. In 1975, he became a member of the Swedish Sports Confederation and was part of the initiation of the Swedish Commission against doping in 1977 with its own doping rules by 1979. During 1989–2001, Arne became the President of the Swedish Sports Confederation and in 1989 a member of the Swedish Olympic Committee. Arne has been a Member of the IOC Medical Commission and in 1994, Arne was elected Member of the IOC. When WADA was founded in 1999, Arne became the Member of WADA’s Foundation Board and Chairperson of WADA’s Health, Medical and Research Committee. Since 2003, Arne has been a Member of WADA’s Executive Committee and since 2008 has been WADA’s Vice President. Arne has been the front-line fighter against doping and his name is today one of the world’s most respected within international sports. Arne’s contributions in the fight against doping are second to none. He has been an athlete himself, which makes him understand the special language that is present in the athletic situation and also in the locker rooms. In his autobiography “Doping’s Nemesis”, Arne gives an unrivalled insider’s view of the biggest dope scandals over the years, including the Ben Johnson and Balco affairs and the history of the Greek sprinters at the Athens Olympics in 2004. Arne’s actions together with the Italian police during the Torino Olympics 2006 against the Austrian team are classic. Doping seems to be steadily on the decline, and there is no doubt that Arne has played a key role in this successful work. Arne’s legacy in the fight against doping is lasting [13014].
ORGANISATION OF ANTI-DOPING

The fight against the use of performance-enhancing drugs in sports has been in effect for nearly 90 years. The formation of the World Anti-Doping Agency in 1999 was a major event because an independent agency was entrusted with harmonization of the antidoping program. In addition to sports governing bodies, governments have endorsed WADA and its programs by signing a United Nations Education, Science, and Cultural Organization Convention on Doping. The first step in the harmonization process was the development of the World Anti-Doping Program. This program consisted of five documents – the Code, the International Standard for Testing, the International Standard for Laboratories, the Prohibited List, and the International Standard for Therapeutic Use Exemptions – which unified the approach of the international federations and national antidoping agencies in applying antidoping rules. For laboratory testing, the International Standard for Laboratories establishes the performance expectations for and competence of laboratories recognized by WADA, including accreditation under ISO/IEC 17025. The antidoping rules are adjudicated by arbitration using the internationally recognized Court of Arbitration for Sport [10006].

An international background to the anti-doping movement

Besides blatant over-commercialization, there is no more ominous threat to sports than doping. Drug-use methods are steadily becoming more sophisticated and ever harder to detect, increasingly demanding the use of complex analytical procedures of biotechnology and molecular medicine. It should also be mentioned in passing that doping is not limited to human sport competitions but is also practiced in animal sports, e.g. equestrian sports. Underlying this distressing phenomenon is regrettably a worldwide pervasive attitude that represents the exact contrary of the original and declared aims of the event as promulgated by de Coubertin in 1903, namely, the aspiration “not to have conquered but to have fought well”. It is important to note that there is frequently differentiation between the official methods employed for anti-doping detection in WADA/IOC laboratories and strategies applied experimentally in various other laboratories. However, laboratories that are not accredited by WADA may apply methods and develop strategies, such as WADA laboratories, in support of the Athlete Biological Passport Program, where all data produced by laboratories can be collated. Over the past few decades, doping has become ever more complex and widespread, increasingly involving exploitation of the fields of endocrine-pharmacology and molecular biology. It thus currently represents not only an individual health hazard but also a menace to society itself, undermining the principles and significance of all the great sports events, and in particular the Olympic games. Faced with this problem, the scientific world is today striving to confront the challenge, in particular in regard to the recent development of hormones abuse, ever more complex methods and new technology being deployed for the task. It is evident that anti-doping policy should proceed to implementation of newly developed analytical methodology and advanced instrumentation as part of a strategy to clearly distinguish between the use of legitimate medication and the use of illicit substances. Furthermore, a multidimensional strategy to counter the scourge needs to be developed combining strict “prohibitionist” measures with preventive-educational programs. Meanwhile, the effort needs also to entail an individualized approach, incorporating counselling on a personal basis, which takes strongly into account the social and psychological background of each athlete. Meanwhile, with regard to athletics, there must be full support of the effort exerted by the WADA to detect banned substances and
compounds so as to eradicate doping, accompanied by legislative changes and longer disqualifications. By continuing to upgrade collaboration with national Anti-Doping Agencies, WADA will be enabled to considerably improve efficacy, thereby gaining ever better control of doping, consequently reducing fraud while, vitally, lessening the health risks incurred by athletes. The prevention of harm to the athlete and the guarantee of fair play should be the target [12011].

The international sports community has recognized for many years the dangers of all forms of doping, but it has been only in the recent past that serious and increasingly effective regulatory mechanisms have been put into place for the detection and control of drug-based doping in sports. It has been clear that, given the opportunity, athletes and their trainers and handlers will resort to many illicit techniques and substances to provide a competitive advantage in sports. One should only remember the pervasive and officially sanctioned and operated doping programs established in East Germany between 1970s and 1980s; how effective these were in the short term, and how harmful these were to the athletes in the long term. It seems very likely that the world of sports will continue to seek out new drugs and stealthy drug delivery methods and even gene-based enhancement to ensure victory in competition. Athletics represents one of the provinces of human activity, most susceptible to the application of existing and future advances in the field of human gene therapy, for the enhancement of nondisease human traits. Modern athletics is as much an entertainment as it is a sport and is sodden with huge amounts of money to assure the victories and records that the public demands. Athletic events are also some of the most powerful instruments for international politics. The prestige, nationalism, and jingoism compel our political institutions to demand victory. Finally, athletes are by nature risk-takers who are driven to compete, excel, and win, even at the cost of injury and other harm to themselves. But even worse, athletes are highly vulnerable to potentially harmful manipulation by dishonest and venal rogue trainers, sports technicians, and sports associations and federations who disregard the ideals of sports and the welfare of the athletes in the interests of victory at all cost. The fact that a sport is already filled with many pervasive drug-based forms of doping should convince even the most skeptical that all current and future advances in pharmacology, sports physiology, and sports medicine, whether based on ever more sophisticated drugs, gene transfer technology, or other still unrecognized technologies, will be applied to the world of sports and will almost certainly occur before the underlying technology is known to be effective and truly safe [06006].

Taking as an example the Tour de France, it can be posited that in the last century, in virtually each year the winner and/or runner-ups were either known to have used doping or strongly suspected of having done so. Aspiring to organize a Tour without doping can therefore be seen as trying to invent a Tour that has never existed before. The difference between earlier and more recent Tours, admittedly important, is the kind of performance enhancing technology that has been made available by the biomedical revolution over the last decades. If in the early days of sports the arsenal of performance enhancing compounds was quite limited, today’s advances of biomedical science have indeed opened up Pandora's box with unlimited possibilities but also increased health risks. Since a doping culture has always been part of cycling it is quite understandable that these new possibilities from biomedical research were, and still are being exploited for performance enhancement practices by cyclists and their entourage. WADA’s claim that a culture of doping-free sport will develop and help attain the eradication of doping in sports remains to be proven; for competitive road-cycling, recent publications suggest that although doping practices certainly have changed, a culture of doping in professional cycling still prevails. A provocative editorial in the journal Nature in 2007 proposed that perhaps the Tour de France should be the first competition to accept pharmacological performance enhancement [12012].
World Anti-Doping Agency (WADA)

To improve the fight against this new potential kind of abuse, the International Olympic Committee (IOC) and national sports federations collaborated in 1998 to establish the World Anti-Doping Agency (WADA), an agency jointly funded by the IOC and cooperating nations and committed to develop programs for detection and control of athletic doping. It carries out its tasks by compiling and constantly updating a list of substances and methods that are inconsistent with the ideals of sports and that should be banned from athletic competition. It is also responsible for developing and validating new, scientifically sound detection assays and implementing effective international programs for in-competition and out-of-competition screening of athletes. The WADA has implemented its program on drug control in sports by issuing and continually updating the world Anti-Doping Code, including a list of banned substances and methods, the latest of which is presented as an appendix to this volume [06006].

One article provided a review of the leading role of the World Anti-Doping Agency (WADA) in the context of the global fight against doping in sport and the harmonization of anti-doping rules worldwide through the implementation of the World Anti-Doping Program. Particular emphasis is given to the WADA-laboratory accreditation program, which is coordinated by the Science Department of WADA in conjunction with the Laboratory Expert Group, and the cooperation with the international accreditation community through International Laboratory Accreditation Cooperation and other organizations, all of which contribute to constant improvement of laboratory performance in the global fight against doping in sport. A perspective is provided of the means to refine the existing anti-doping rules and programs to ensure continuous improvement in order to face growing sophisticated challenges. A viewpoint on WADA’s desire to embrace cooperation with other international organizations whose knowledge can contribute to the fight against doping in sport is acknowledged [12010].

Background

Athletes have a long history of using substances in an attempt to gain an advantage in sporting competitions. The ancient Greeks and Romans used herbs, fungi, poppy seeds and stimulants such as strychnine in order to boost performance. In the modern era, this practice continued mostly with the use of stimulants and narcotics. Sports federations took notice and in 1928 the International Association of Athletics Federations (IAAF) became the first federation to prohibit the use of performance-enhancing drugs (PEDs), although there would be no testing in sport for another 40 years. Amphetamine use was involved in the deaths of cyclists Knud Jensen and Tommy Simpson in the 1960 Olympic Games and the 1967 Tour de France respectively; this spurred the development of the International Olympic Commissions (IOC) Medical Commission, which published the first IOC Prohibited List in 1967. This became the de facto Prohibited List for Olympic Sport Federations. The “Festina affair” (1998 Tour de France), where a team trainer’s car was found to contain a panoply of PEDs, was the catalyst to create a new organisation to harmonise, coordinate and promote the fight against doping in sport in all its forms. The IOC convened the first World Conference in Doping in Sport in 1999, which resulted in the formation of the World Anti-Doping Agency (WADA) [13015].

Pre-WADA history
In the modern era, doping practice continued mostly with the use of stimulants and narcotics. Sports federations took notice and in 1928 the International Association of Athletics Federations (IAAF) became the first federation to prohibit the use of performance-enhancing drugs (PEDs), although there would be no testing in sport for another 40 years. Amphetamine use was involved in the deaths of cyclists Knud Jensen and Tommy Simpson in the 1960 Olympic Games and the 1967 Tour de France respectively: this spurred the development of the International Olympic Commissions (IOC) Medical Commission, which published the first IOC Prohibited List in 1967. This became the de facto Prohibited List for Olympic Sport Federations. The “Festina affair” (1998 Tour de France), where a team trainer’s car was found to contain a panoply of PEDs, was the catalyst to create a new organisation to harmonise, coordinate and promote the fight against doping in sport in all its forms.3 The IOC convened the first World Conference in Doping in Sport in 1999, which resulted in the formation of the World Anti-Doping Agency (WADA) [13015].

The code

WADA is a unique, independent body representing equally sport and the governments of the world. The World Anti-Doping Code is the core document on which anti-doping programmes are modelled. The first version of the Code came into effect in January 2004. There are presently over 600 signatories, including almost all the world's sport federations. The Code applies to Athletes, as defined by their national anti-doping organisations (NADOs) or international federations. Who is considered an athlete for anti-doping purposes may vary widely and a NADO may still test recreational athletes but not apply all elements of the Code, for example, the requirement for whereabouts or advanced therapeutic use exemptions. Athletes may be subjected to sanctions based on possession or trafficking of prohibited substances and not simply due to a positive doping test. However, it is important to be aware that criminal legislation exists in certain countries (e.g. for narcotics) which may be in addition to, or completely separate from, anti-doping sanctions [13015].

The prohibited list

WADA also took over the role of publishing the Prohibited List (List), revised annually since 2004. The List has expanded considerably from the original IOC Prohibited List of the 1960s and contains numerous classes of substances as well as prohibited methods such as blood manipulation. A substance (or method) is considered for inclusion if it meets any two of the following criteria:

- potential for performance enhancement
- detrimental to the athlete's health
- contrary to the spirit of sport

The deliberations on whether to include substances in the List are a highly interactive and consultative process which includes stakeholders and experts. It is impractical to list all known and possible compounds; thus, most of the prohibited classes contain an important clause stating: "...and other substances with similar chemical structure or similar biological effect(s)" [13015].

Some substances have permitted routes of administration, (e.g. glucocorticosteroids are allowed by inhalation or topically). A few substances are permitted but only to a certain threshold level (e.g. pseudoephedrine). The List is divided into substances prohibited in competition only (e.g. stimulants), and those prohibited at all times (e.g. anabolic steroids and erythropoietin). It is irrelevant whether the prohibited substance is synthetic or from botanical
sources or whether it is considered a pharmaceutical product or a dietary supplement. “Strict Liability” means that every athlete is responsible for the substances found in their bodily specimen during a doping control sample analysis. The first line of defence for many cheating athletes has been to claim that the positive test resulted from a tainted dietary supplement. Many of these same athletes later confessed to deliberate ingestion of a prohibited substance. The athlete’s responsibility to explain how a prohibited substance entered his/her body (Strict Liability) has existed for many years, being initially implemented by the IOC. It has withstood the scrutiny of the Court of Arbitration in Sport and civil courts, and is a balance between protecting all athletes by ensuring fair, clean sport and the rights of individual athletes [13010].

**Codes since 2004**

WADA is a unique, independent body representing equally sport and the governments of the world. The World Anti-Doping Code is the core document on which anti-doping programmes are modelled. The first version of the Code came into effect in January 2004. There are presently over 600 signatories, including almost all the world’s sport federations. The Code applies to Athletes, as defined by their national anti-doping organisations (NADOs) or international federations. Who is considered an athlete for anti-doping purposes may vary and a NADO may still test recreational athletes but not apply all elements of the Code, for example, the requirement for whereabouts or advanced therapeutic use exemptions [13015].

**Not only doping testing**

Athletes may be subjected to sanctions based on possession or trafficking of prohibited substances and not simply due to a positive doping test. However, it is important to be aware that criminal legislation exists in certain countries (e.g. for narcotics) which may be in addition to, or completely separate from, anti-doping sanctions. WADA also took over the role of publishing the Prohibited List, revised annually since 2004. The List has expanded considerably from the original IOC Prohibited List of the 1960s and contains numerous classes of substances as well as prohibited methods such as blood manipulation. A substance (or method) is considered for inclusion if it meets any two of the following criteria:

- potential for performance enhancement
- detrimental to the athlete’s health
- contrary to the spirit of sport

The deliberations on whether to include substances in the list are a highly interactive and consultative process which includes stakeholders and experts. It is impractical to list all known and possible compounds; thus, most of the prohibited classes contain an important clause stating: “…and other substances with similar chemical structure or similar biological effect(s).” Some substances have permitted routes of administration, (e.g. glucocorticosteroids are allowed by inhalation or topically). A few substances are permitted but only to a certain threshold level (e.g. pseudoephedrine). The list is divided into substances prohibited in competition only (e.g. stimulants), and those prohibited at all times (e.g. anabolic steroids and erythropoietin) [13015].

**Sanctions of violations**

For an athlete confronted with an anti-doping rule violation, section 10.5 of the Code allows for no sanction, or reduced sanctions, if the athlete can demonstrate no fault or no significant fault. As far as supplements are concerned, simply stating the unknowing ingestion of a tainted dietary supplement is not sufficient – an athlete would have to demonstrate clearly
that every reasonable precaution was taken to avoid ingestion of a prohibited substance [13015].

**Indirect evidence of doping effects: world records**

Progression of world records in athletics is a reliable mean to assess the potentiality of the human body, which also reflects how society has evolved over time and will continue to evolve. It was conducted a quantitative analysis of world records in measurable Olympic events from nine representative disciplines (100, 400, 1500, 10,000 m, marathon, long jump, high jump, shot put and javelin throw) in order to identify progression and trends for the years 1900-2007 from the database of the International Olympic Committee. Overall, the relative improvement of athletic performance was higher in women than in men, being nearly doubled across the different specialities. The biggest increases were observed for javelin throw and shot put, in both men and women, respectively. Conversely, the improvement in race time was directly related to the race distance. It was also observed a consistent significant linear model of world record progression in time, although the improvement has substantially stopped or reached a plateau in several specialities. The observed trend might be explained by a variety of factors, including social and environmental changes, natural selection, advances in training and sport physiology, ergogenic aids and, possibly, doping [08017].

The performance-enhancing effects of doping and the introduction of intensive doping surveillance are especially reflected in the decline in performance in several women's track and field events [08018].

The introduction of doping substances and methods in sports triggers noticeable effects on physical performance in metric sports. It was used time series analysis to investigate the recent development in male and female elite sprinting performance. Time series displaying the average of the world's top 20 athletes were analyzed employing polynomial spline functions and moving averages. Outstanding changes in performance over time were statistically analyzed by Welch's t-test and by Cohen's measurements of effect. For validation we exemplarily show that our analysis is capable of indicating the effect of the introduction of in- and out-of-competition doping testing on women's shot put as well as the effects of the market introduction of erythropoietin (EPO) and the introduction of EPO and continuous erythropoiesis receptor activator (CERA) testing on 5000 m top 20 male performances. Time series analysis for 100 m men reveals a highly significant drop by more than 0.1 s from 2006 to 2011 with a large effect size of 0.952. This is roughly half of the effect size that can be found for the development of the 5000 m performance during the introduction of EPO between 1991 and 1996. While the men's 200 m sprinting performance shows a similar development, the women's 100 m and 200 m sprinting performances only show some minor abnormalities. It was discussed why the striking sex-specific improvement in sprinting performance is indicative for a novel, very effective doping procedure with insulin-like growth factor-1 (IGF-1) being the primary candidate explaining the observed effects [12013].

Doping is a very serious issue bedevilling the sporting arena. It has consequences for athletes' careers, perception of sports in the society and funding of sports events and sporting organisations. There is a widespread perception that doping unfairly improves results of athletes. A statistical study of information on best lifetime results of top 100 m sprinters (males better than 9.98 s, females 11.00 s), over the period of 1980-2011 was conducted. Athletes were divided into categories of “doped” (n=17 males and 14 females), based on self admission, the confirmed detection of known doping agents in their bodies or
doping conviction, and “non-doped” (n=46 males and 55 females). No significant differences (unpaired t-test) between dopers and non-dopers were found in their average results: male “dopers” 9.89 s identical with “non-dopers” 9.89 s, females 10.84 s and 10.88 s respectively. Slopes of regressions of best results on dates for both “dopers” and “non dopers” were not significantly different from zero. This indicates that no general improvement as a group in 100 m sprint results over a quarter of a century occurred irrespective of doping being or not being used. It was concluded that since there are no statistical differences between athletes found "doping" and the others, one of the following must be true: (1) "doping" as used by athletes so detected does not improve results, or (2) "doping" is widespread and only sometimes detected. Since there was no improvement in overall results during the last quarter of the century, the first conclusion is more likely. Objectively, various "doping" agents have obvious physiological or anatomical effects. These may not translate into better results due to the clandestine use of doping that prevents its scientific structuring. Perception of the effectiveness of doping should be reconsidered. Policy changes may be required to ensure the continued fairness and equity in testing, legislation and sports in general [12014].

Anti-doping rules

The ramifications of doping are not limited to topclass athletes who may feel compelled to risk their health for fame and money, but also extend to amateur athletes eager to exhibit superiority in the athletic field. Owing to difficulties in actually proving the intent to cheat, the World Anti-Doping Agency (WADA) enforces a principle of strict liability for positive test results for banned substances. Antidoping laws encompass a broad, continuously updated panel of laboratory tests for the most recent list of banned substances, which includes traditional as well as promising new drugs and techniques that may find actual applications in doping athletes [06005].

The rules

FIFA introduced an anti-doping programme in 1966 at the World Championship, being one of the first international sports federations to do so. The fundamental aims stipulated in the FIFA doping control regulations in 2006 are quite similar to the purpose of the World Anti-Doping Code programme. According to the definition of doping in the World Anti-Doping Code, doping is defined as the occurrence of one or more of the following violations [06002]:

- the presence of a Prohibited Substance or its Metabolites or Markers in an Athlete's bodily Specimen (strict liability rule).
- possession by an athlete at any time or place of a Substance that is prohibited in out-of-competition testing or a Prohibited Method, unless the athlete establishes that possession is pursuant to a therapeutic use exemption granted in accordance with the FIFA Doping Control Regulations regarding the therapeutical use of forbidden substances or other acceptable justification.
- possession of a Substance that is prohibited in out-of-competition testing or Prohibited Method by athlete Support personnel in connection with an athlete, competition or training, unless the athlete support personnel establishes that the possession is pursuant to a therapeutic use exemption as described previously
- trafficking in any Prohibited Substance or Prohibited Method is still a violation of the anti-doping regulations and in most of the law systems an illegal act against the medical preparations law

163
administration or the attempted administration of a Prohibited Method to any athlete, or assisting, encouraging, aiding, abetting or covering up as well as any other type of complicity involving an anti-doping rule violation or any attempted violation.

As set forth in the preamble of the World Anti-Doping Code, the purposes of the World Anti-Doping Program are:

- to protect the athletes’ fundamental right to participate in doping-free sport and thus promote health, fairness, and equality for Athletes worldwide
- to ensure harmonized, coordinated, and effective anti-doping programs at the international and national level with regard to detection, deterrence, and prevention of doping.

Prohibited substances in the context of these regulations are regularly published in the WADA list of prohibited substances (www.wada-ama.org) [06002].

**Strict liability rule**

The reason for the strict liability rule has been comprehensively stated by the Court of Arbitration for Sport, Lausanne in some cases. "It is true that a strict liability test is likely in some sense to be unfair in an individual case, where the athlete may have taken medication as the result of mislabelling or faulty advice for which he or she is not responsible – particularly in the circumstances of sudden illness in a foreign country. But it is also in some sense unfair for an athlete to get food poisoned on the eve of an important competition be altered to undo unfairness. Just as the competition will not be postponed to await the athlete’s recovery, so the prohibition of banned substances will not be lifted in recognition of its accidental absorption. The vicissitudes of competition, like those of life generally, may create many types of unfairness, whether by accident or the negligence of unaccountable persons, which the law cannot repair. Furthermore, it appears to be a laudable policy objective not to repair an accidental unfairness to an individual by creating an intentional unfairness to the whole body of other competitors. This is what would happen if banned performance-enhancing substances were tolerated when absorbed inadvertently. Moreover, it is likely that even intentional abuse would in many cases escape sanction for lack of proof of guilty intent. And it is certain that a requirement if intent would invite costly litigation that may well cripple federations – particularly those run on modest budgets in their fight against doping" [06002].

It is irrelevant whether the prohibited substance is synthetic or from botanical sources or whether it is considered a pharmaceutical product or a dietary supplement. **Strict Liability** means that every athlete is responsible for the substances found in their bodily specimen during a doping control sample analysis. The first line of defence for many cheating athletes has been to claim that the positive test resulted from a tainted dietary supplement. The athlete’s responsibility to explain how a prohibited substance entered his/her body (“Strict Liability”) has existed for many years, being initially implemented by the IOC. It has withstood the scrutiny of the Court of Arbitration in Sport and civil courts, and is a balance between protecting all athletes by ensuring fair, clean sport and the rights of individual athletes [13015].

For an athlete confronted with an anti-doping rule violation, section 10.5 of the Code allows for no sanction, or reduced sanctions, if the athlete can demonstrate no fault or no significant fault. As far as supplements are concerned, simply stating the unknowing ingestion of a
tainted dietary supplement is not sufficient – an athlete would have to demonstrate clearly that every reasonable precaution was taken to avoid ingestion of a prohibited substance. An athlete taking a spiked supplement with intent to dope may claim that he/she did not realise the product contained a prohibited substance. It is difficult to know the intent: nevertheless, the athlete will benefit from the ergogenic effect of the prohibited substance and have an unfair advantage over their competitor. There are many cautionary tales of athletes taking energy boosting supplements before or during the games and subsequently being sanctioned. Many dietary supplements that promise to enhance performance either contain a prohibited substance or are an example of false advertising [13015].

The reality is that a significant percentage (5-20 %) of supplements contains prohibited substances, either by inadvertent contamination or deliberate adulteration, during the production process. This phenomenon has been demonstrated repeatedly, and sporting federations as well as anti-doping organisations continue to impress this warning upon athletes. For example, several athletes have been recently sanctioned over the stimulant methylhexaneamine (MHA), explicitly prohibited since 2009. This was considered to be a dietary supplement from geranium oil, despite the fact that several studies demonstrated that its presence in supplements was not from geranium oil but due to the addition of synthetic MHA. Whether natural or synthetic, athletes need to avoid these types of products [13015].

**The whereabouts rule**

Apart from such special cases, effective doping controls are bonded to out-of-competition tests. Without accurate athlete location information such controls may be inefficient and sometimes impossible. This so-called “whereabouts rule” requires athletes and/or teams that have been identified for out-of-competition control to be responsible for providing and updating information on their whereabouts so that they can be located for No Advance Notice out-of-competition control. The applicable requirements are set by the responsible sport federation or national anti-doping organisation to allow some flexibility based upon varying circumstances encountered in different sports and countries. A violation of this rule may be based on either intentional or negligent conduct by the athlete, but it is known that the whereabouts rule may not be realistic in international team sports, in which players are normally playing for a club far from their home nation [06002].

**Separation of power**

An important legal principle is the separation of power between the anti-doping executive authorities and the disciplinary committee responsible for the administration of anti-doping sanctions. This is to minimise any accusations of bias or conflict of interest in the application of the Code. This principle is applied in a practical sense by having the Doping Control Sub-Committee (representing medical, pharmacological, and medicolegal expertise) dealing with the medical and biochemical aspects of the alleged doping event and, once this issue has been determined, a separate Disciplinary Committee which awards the appropriate sanction in view of the individual circumstances of the athlete concerned [06002].

**Non-approved substances**

Since 2011, this category (S0) of banned substances has been a part of WADA’s prohibited list and encompasses a virtually infinite number of compounds currently not covered by any of the other sections (e.g. anabolic agents, peptide hormones, growth factors and related substances). New representatives of this class of compounds are low molecular weight luteinizing hormone (LMWLH) receptor agonists. Focusing on two series of drug candidates
based on either pyrazole or thienopyrimidine core structures, two model substances were synthesized and used to establish a targeted/non-targeted screening method employing both diagnostic precursor-product ion pair detection and precursor ion scanning. In the absence of metabolism study data, the presence of the intact drug or at least a conserved nucleus must be present to allow the detection using the proposed strategy [12017].

This newly established category of banned substances encompasses a virtually infinite number of compounds with corresponding physicochemical and pharmacological properties; however, only those agents currently not covered by any of the other sections (e.g. anabolic agents, peptide hormones, growth factors, and related substances) are considered relevant for S0. These compounds [016]

- have not received approval for human therapeutic use
- comprise structures not related to any other listed group of banned substances
- exhibit biological effects that are different from all other drugs included in the Prohibited List.

**Therapeutic use exemption (TUE)**

The need for therapeutic use exemptions (TUEs) or the permitted use of Prohibited Substances and Prohibited Methods by athletes to treat significant medical conditions arose when several classes of drugs used commonly in medicine were prohibited in sport by the International Olympic Committee (IOC) during the 1980s. However, although the IOC Medical Commission (IOC-MC) gave qualified support for the concept to formally start at the 1992 Barcelona Olympics, the Commission’s fears that athletes might abuse the mechanism resulted in minimal publicity and its non-inclusion in the Medical Code of the Olympic Movement for 8 years. TUEs would not be widely publicised until the advent of the World Anti-Doping Agency which not only approved the principles of TUEs as developed by the IOC's Medications Advisory Committee (MAC) in 1991, but also introduced the name of TUE. Several changes to the Prohibited List have resulted in TUEs being necessary for substances that were permitted 20 years ago as disclosed in a review of TUEs approved at the 11 Olympic Games that the IOC’s MAC, later the TUE Committee (TUEC), has operated. The IOC and its TUEC played a pivotal role in developing the concept of TUE which is now globally accepted [13013].

Athletes can be allowed to use substances from the prohibited list (the doping list) if they have a medical condition. If so, a Therapeutic Use Exemption (TUE) is required. The boundaries between the use of pharmacological substances due to a medical need and doping are sometimes blurred. Although manipulating the system of TUE granting potentially represents an entry stage for doping, few studies examine how athletes perceive TUE management and relate this to current anti-doping policy. 645 Danish elite athletes (mean age 22) representing 40 sports completed a web-based questionnaire about their experience and perception of TUE (response rate: 43 %). Nineteen percent of the respondents had been granted a TUE. Eighty-five percent of athletes granted a TUE regarded their use of the TUE system as necessary to compete on equal terms with other athletes. Administrative hurdles for TUE prevented 7 percent of athletes from applying. Fifty-three percent of the athletes considered that being "allowed" to dope by means of a TUE was of importance for their (hypothetical) wish to try out doping. Fifty-one percent believed that athletes in their sport received TUEs without a medical need. Athletes granted TUEs had more than twice as high odds to distrust the efficacy of the system than athletes never granted a TUE. The belief that TUEs were misused was especially common among endurance athletes, regardless of them having experience with TUEs or not. Four percent believed it would be okay to receive a TUE without a medical need. The results confirm that TUE is a problem in anti-doping policy. The
fact that distrust in TUE administration increases once an athlete has experience of TUEs represents a challenge for anti-doping policy. We suggest more critical research on TUEs be carried out in order to improve harmonization and increase transparency in the regulations [13020].

Athletes who have either physical symptoms or disease after injury may need to be treated with specific medicines that are on the list of prohibited substances. Therapeutic use exemption may be granted to such players, in accordance with strictly defined criteria-these are presented in this article. Procedures of how to request for an abbreviated or a standard therapeutic use exemption are explained, and data on therapeutic use exemptions are also presented. A therapeutic use exemption (TUE) permitting the use of such a substance or method that is on the prohibited list, may be granted to the player, depending to the clinical situation. An exemption will be granted only in strict accordance with the following criteria [06007]:

- the athlete shall submit an application for TUE no less than 21 days before participating in an event
- the athlete would experience a significant impairment to health if the prohibited substance or method were to be withheld in the course of treating an acute or chronic medical condition
- the therapeutic use of the prohibited substance or method would produce no additional enhancement of performance other than that which might be anticipated by a return to a state of normal health following the treatment of a legitimate medical condition. The use of any prohibited substance or method to increase “low-normal” levels of any endogenous hormone is not considered an acceptable therapeutic intervention
- there is no reasonable therapeutic alternative to the use of the otherwise prohibited substance or method
- the necessity for the otherwise prohibited substance or method cannot be a consequence, wholly or in part, or prior non-therapeutic use of any substance from the prohibited list
- an application for a TUE will not be considered for retroactive approval except in cases where:
  - emergency treatment or treatment of an acute medical condition was necessary
  - due to exceptional circumstances, there was insufficient time or opportunity for an applicant to submit, or the granting body to consider, an application prior to doping control
- confidentiality of information: The applicant shall provide written consent for the transmission of all information pertaining to the application to members of the granting body and, as required, other independent medical or relevant scientific experts. If the assistance of external, independent experts is required, all details of the application will be circulated without identifying the player involved in the doctor's care. The applicant shall also give written consent to the decisions of the granting body to be distributed to the involved medical personnel of other relevant anti-doping organisations under the provisions of the Doping Control Regulations. The members of the granting body involved will conduct all of their activities in strict confidence according to the Hippocratic Oath and the medico-legal and ethical rules of confidentiality.

**Abbreviated TUE**
Abbreviated TUE requests are valid as soon as an approved anti-doping organisation has received the request. Treatment may start immediately after the receipt is confirmed. However, the anti-doping organisation has the right to ask for additional information should the applied indication for glucocorticosteroids or beta-2-agonists appear doubtful. WADA has also decided that for a beta-2-agonist TUE, following a clinical diagnosis of exercise induced or allergic asthma the results of lung function tests have to be submitted to substantiate the clinical diagnosis. This decision of the WADA Medical Committee clearly stresses the importance of sound clinical diagnosis following state of the art assessment to avoid misuse of beta agonists in the absence of clear clinical diagnosis [06007].

**Standard TUE**

In the case of a standard TUE application for which specialist expertise is required, the TUE committee appoints external independent experts for a second opinion to justify the decision. Standard TUE requests are valid as soon as an appropriate anti-doping organisation has sent the player a certificate of approval, except in rare cases of an acute life threatening condition, for which retroactive approval may be considered. TUEs are indispensable for improving medical cover of athletes with health impairments while avoiding anti-doping violations [06007].

**Therapeutic use exemptions (TUEs) at the Olympic Games**

That Olympic athletes, indeed all athletes with documented and significant medical conditions, may seek and be approved to administer a Prohibited Substance or a Prohibited Method and train for and compete in sports is now widely acknowledged and accepted. This is termed a Therapeutic Use Exemption (TUE), although some were granted to Olympic and non-Olympic athletes before this name was introduced in 2001. The International Olympic Committee (IOC), through its Medical Commission (IOC-MC), had a pivotal role in the development of TUE and its TUE Committee (TUEC) has functioned since prior to the 1992 Olympic Games in Barcelona. London 2012 was the 11th Olympic Games at which it had operated. But in its early years, acceptance of the concept of TUEs had many difficulties. However, although the IOC Medical Commission (IOC-MC) gave qualified support for the concept to formally start at the 1992 Barcelona Olympics, the Commission's fears that athletes might abuse the mechanism resulted in minimal publicity and its non-inclusion in the Medical Code of the Olympic Movement for 8 years. TUEs would not be widely publicised until the advent of the World Anti-Doping Agency which not only approved the principles of TUEs as developed by the IOC's Medications Advisory Committee (MAC) in 1991, but also introduced the name of TUE. Several changes to the Prohibited List have resulted in TUEs being necessary for substances that were permitted 20 years ago as disclosed in a review of TUEs approved at the 11 Olympic Games that the IOC’s MAC, later the TUE Committee (TUEC), has operated. The IOC and its TUEC played a pivotal role in developing the concept of TUE which is now globally accepted [13013].

Two decades of experience of TUEs at the Olympic Games have demonstrated that from a semiclandestine procedure in 1992, it has evolved so that currently there are established principles, a robust mechanism to apply and approve or reject applications, globally recognised medical indications and a mutual recognition of appropriately approved TUEs, at least at the Olympic Games. It is gratifying that the IOC’s 1991–1992 pioneering criteria and guidelines have undergone only minor modifications to those of WADA that operated at London 2012. However, despite widespread understanding of the TUE principles and processes, it is essential to continue to strive for superior knowledge of the topic, better
qualified and more experienced TUECs and hopefully a mutual recognition of correctly approved TUEs from experienced TUECs [13013].

Prevalence of use of TUEs in asthmatics

The prevalence of asthma and the use of anti-asthmatic medication is high among elite athletes. Elite athletes require a TUE certificate (Therapeutic Use Exemption) if they require anti-asthmatic medication which is on the prohibited list. The aim of one study was to determine the distribution of Danish TUE certificates and to examine the use of anti-asthmatic medication among Danish elite athletes. A cross-sectional study of all applications for TUE certificates in 2005 was carried out. It was focused on applications including anti-asthmatic medication. All applications resulted in certificates being issued. A total of 694 TUE certificates were issued. Of these, 445 (64 %) concerned anti-asthmatic medication. Short-acting beta-2-agonists (SABA) were the most frequent medication (79 %). Only 2 percent received long-acting beta-2-agonists (LABA) as single therapy. Inhaled steroids were used by 69 percent. Swimmers received significantly higher doses of inhaled steroids compared to all others athletes (1031 microg/day; n=148). The applications for TUE certificates were generally handled by general practitioners (78 %) [08039].

Prioritation in anti-doping

There is debate concerning whether the guiding paradigm for anti-doping policy should be the current legalistic approach or a “harm minimisation” approach prioritising athlete health. This study sought to determine whether a representative sample of Australians prioritises health above other concerns using the World Anti-Doping Code's Spirit of Sport statement which lists the 11 attributes that define the moral basis for anti-doping. A Best-Worst Scaling (BWS) Balanced Incomplete Block Design experiment using 11 choice sets of five Spirit attributes from the set of 11, with the attributes within each choice set in a random order. A representative sample of 168 Australians responded to an on-line survey. The BWS scores defined the relative ranking of each attribute to define an aggregate model and demographically defined models (gender, education, sports participation and sports following). Health was ranked as 7/11 in the aggregate model. Only those who did not follow sport prioritised health (2/11), with other demographic models failing to show a meaningful departure from the aggregate model. It was concluded that Australians ranked health below other attributes in the Spirit of Sport, appearing to prioritise "rule following" consistent with the legalistic approach. This challenges the harm minimisation approach to managing the role of drugs in sport and suggests that rule-following and legalistic approaches to drug use should take precedence over health messages [12031].

Strategy to reduce illicit drug

Australian football

The World Anti-Doping Agency (WADA) prescribes that drug testing is conducted in sports competitions to detect drug use in athletes. This testing includes performance-enhancing drugs as well as illicit substances such as marijuana, amphetamines and cocaine. Illicit drugs are tested for on match days but not on non-match days. Some athletes are known to use illicit substances for recreational purposes, away from competition times and this poses a serious health and welfare issue not addressed by the usual sport drug testing regimes. This paper reports the results of the first 7 years of an illicit drug-testing programme that included
non-match day testing in the elite Australian Football competition, the Australian Football League (AFL). Players in the AFL were tested for illicit drugs both in-competition and out-of-competition. Players were selected for illicit substance tests either randomly or targeted based on previous test history or time since previous test. The number of tests conducted was increased each year from 2005 to 2011 and testing was focused on high-risk times during non-competition periods. There were no positive match day tests. There was a significant reduction in positive tests (19-6) for illicit drugs during non-competition periods over the 7 years. The reduction in positive tests may be related to player education, the greater number of tests conducted and the harm minimisation approach of the illicit drug policy [12032].

**Agreements with the pharmaceutical industry**

With a steady stream of new therapeutic agents – from stimulants to steroids to protein hormones – with potential for abuse in sport entering the marketplace, antidoping scientists and collaborators are continually developing new approaches for detection of prohibited substances and methods. WADA has signed a declaration with the International Federation of Pharmaceutical Manufacturers and Associations, whose members will voluntarily assist in identifying products with doping potential in advance of their introduction into the marketplace [12006].

The misuse of medicines for performance enhancement in sport (doping) is not approved by regulatory agencies, and is illegal in many countries. In addition to the ‘traditional’ doping agents such as steroids, beta-blockers and blood transfusions, the list of agents and techniques used in doping is increasing and now includes newer medicines such as erythropoiesis-stimulating agents and growth hormones. Innovative new medicines are of particular interest as would-be dopers may believe them to be undetectable by current methods. Close collaboration between the biopharmaceutical industry and anti-doping agencies such as the World Anti-Doping Agency is critical to a successful anti-doping strategy. Industry is ideally placed to identify the doping potential of new medicines at early stages and to support early development of detection assays. A strong, united front between the biopharmaceutical industry and anti-doping agencies is essential to counter the misuse of medicines for performance enhancement, as well as to promote fair play and clean sport [12033].

WADA is making significant progress in building relationships within the pharmaceutical and biotech industries. Cooperation, similar to that which now exists with Roche, GlaxoSmithKline and the International Federation of Pharmaceutical Manufacturers Association (IFPMA), will give WADA a head start by working on pipeline compounds that have the potential for abuse in sport [12034].

David A Cowan and Campbell P Barker spoke to Ryan De Vooght-Johnson at Bioanalysis in May 2012 about the partnership between industry and academia for the setup and running of the doping-control laboratory for the London 2012 Olympic Games. David A Cowan is Director of the London 2012 anti-doping laboratory as well as Director of the King's College London Drug Control Centre, the UK's only WADA-accredited anti-doping laboratory, and Head of the Department of Forensic Science and Drug Monitoring. Cowan co-founded the Drug Control Centre in 1978 and became its Director in 1990. He has published extensively in the field of pharmaceutical analysis, especially as it relates to detecting drug administration in sport, and was awarded a personal chair in pharmaceutical toxicology in 1996. Cowan became Head of the Department of Forensic Science and Drug Monitoring at King's College London in 2002. He has served on a number of national and international committees,
including the Council of Europe Working Party Investigating Drug Abuse in Sport that led to the first World Anti-Doping Convention, the Laboratory Representative on the International Olympic Committee's Medical Commission, and WADA's Laboratory Accreditation Subcommittee. He is a member of the Crippen Club for Distinguished Toxicologists. In 1998 he was awarded the IOC Trophy for Sport Ethics by the BOA. He was a founding member of the World Association of Anti-Doping Scientists and became its first President serving on its Executive Board between 2001 and 2004. He was a Visiting Laboratory Director at the Salt Lake City Winter Olympic Games 2002, where the first novel erythropoiesis-stimulating protein (NESP) positive was discovered. He was also a senior advisory scientist at both the Turin Winter Olympic Games in 2006 and the Beijing Olympic Games in 2008. He was also a member of the IOC Medical Commission for the Sydney Olympic Games in 2000 and the Vancouver Winter Olympic Games in 2010. The Drug Control Centre undertook the sample analysis during the 2002 Manchester Commonwealth Games and Cowan was Co-Director of the laboratory for the Commonwealth Games in Kuala Lumpur in 1998. Cowan, who has directed the laboratory at King's College London for many years, was a member of the bid team making the presentation to the International Olympic Committee in February 2005. Campbell P Barker has been leading GlaxoSmithKline's delivery of the London 2012 laboratory services since September 2009. Prior to that time he was Director of Global Strategic Projects in GlaxoSmithKline's Consumer Healthcare business from 2006, and from 1994 to 2006 he worked in R&D for Procter & Gamble. Barker holds a PhD in chemistry from the University of Durham [12035].

Doping controls in practice

Drug testing is now ubiquitous in sport, and it often falls to the team physician to perform a variety of roles including interpreting test results, designing drug-testing programs, acting as medical review officer, and providing therapeutic use exemptions, education, and counseling. Proper understanding of current testing methods for drugs such as anabolic-androgenic steroids, erythropoietin, and growth hormone is essential if the team physician is going to assume these positions. One article outlined the basics of athletic drug testing from the collection process through the interpretation of results to assist the team physician in this field [06008].

International Sport Federations in the protection of the athlete’s health

To determine the priorities and activities of International Sport Federations (IFs) with respect to the promotion of health in their sport and for the general population all 35 IFs participating in Olympic Games in 2014 or in 2016 were asked to rate the importance of 10 indicated topics, and to report their programmes, guidelines or research activities on 16 health-related topics using an online questionnaire (response rate 97 %). On average, the “fight against doping” had the highest priority followed by “health of their elite athlete” and “image as a safe sport”. The topics with the lowest importance ratings were “health of their recreational athlete”, “increasing the number of recreational athletes” and “health of the general population”. All except one IF reported to have health-related programmes/guidelines/research activities; most IFs had 7 or 8 of the listed activities. Eight IFs (24 %) stated to have activities for “prevention of chronic diseases in the general population” but only FIFA and FINA reported related projects. It was concluded that IFs aimed to protect the health of their elite athletes through a variety of activities, however the health and number of their recreational athletes was of low importance for them. Thus, IFs are missing an important opportunity to increase the popularity of their sport, and to contribute to the health of the

171
general population by encouraging physical activity through their sport. FIFA's “Football for Health” and FINA's “Swim for All” projects could serve as role models [13025].

During the Olympics

One article outlines the process of preparation of an anti-doping laboratory in view of the activities to be performed on the occasion of the Olympic Games, focusing in particular on the accreditation requirements of the World Anti-Doping Agency (WADA) and ISO/IEC 17025, as well as on the additional obligations required by the International Olympic Committee, which is the testing authority responsible for the anti-doping activities at the Olympics. Due to the elevated workload expected on the occasion of the Olympic Games, the designated anti-doping laboratory needs to increase its analytical capacity (samples processed/time) and capability by increasing the laboratory's resources in terms of space, instrumentation and personnel. Two representative cases, one related to the Winter Olympic Games (Torino 2006) and one related to the Summer Olympic Games (Beijing 2008), are presented in detail, in order to discuss the main aspects of compliance with both the WADA and ISO/IEC 17025 accreditation requirements [12054].

A brand new 2012 London Olympics anti-doping lab made the headlines worldwide, accompanied by strong anti-doping messages for prospective Olympians and illustrated by an iconic photograph depicting the laboratory's head showing a blood sample to the Minister for Sports and the Olympics. The 4'400 m² laboratory, sponsored by a multinational pharmaceutical company, was operating 24 h/day during the Games, analysing urine and blood samples of one out of two participating athletes while a part of the samples will be stored for eight years, using the threat of future testing technology as a further deterrent [12012].

Biomarkers

Biomarker monitoring can be considered a new era in the effort against doping. Opposed to the old concept in doping control of direct detection of a prohibited substance in a biological sample such as urine or blood, the new paradigm allows a personalized longitudinal monitoring of biomarkers that indicate non-physiological responses independently of the used doping technique or substance, and may cause sanctioning of illicit practices. This review presents the development of biomarker monitoring in sports doping control and focuses on the implementation of the Athlete Biological Passport as the current concept of the World Anti Doping Agency for the detection of blood doping (hematological module). The scope of one article extends to the description of novel biomarkers and future concepts of application [12055].

"Exercisenomics"

Laboratory medicine is complex and contributes to the diagnosis, therapeutic monitoring and follow-up of acquired and inherited human disorders. The regular practice of physical exercise provides important benefits in heath and disease and sports medicine is thereby receiving growing focus from almost each and every clinical discipline, including laboratory medicine. Sport-laboratory medicine is a relatively innovative branch of laboratory science, which can provide valuable contributions to the diagnosis and follow-up of athletic injuries, and which is acquiring a growing clinical significance to support biomechanics and identify novel genomics and "exercisenomics" patterns that can help identify specific athlete's tendency towards certain types of sport traumas and injuries. Laboratory medicine can also provide sport physicians and coaches with valuable clues about personal inclination towards
a certain sport, health status, fitness and nutritional deficiencies of professional, elite and recreational athletes in order to enable a better and earlier prediction of sport injuries, overreaching and overtraining. Finally, the wide armamentarium of laboratory tests represents the milestone for identifying cheating athletes in the strenuous fight against doping in sports [12056].

**Multi-class and multi-analyte test methods**

Traditionally, doping control analytical assays have been drug-class dedicated and tailored to address requirements concerning sample preparation and chromatography/mass spectrometry resulting from specific physicochemical properties of target compounds. Improved analytical instrumentation (particularly based on liquid chromatography-(tandem) mass spectrometry have enabled the development of numerous cost-effective and rapid alternatives, allowing for multi-class/multi-analyte test methods. The trend towards comprehensive and preferably combined targeted/non-targeted screening procedures has been motivated in part in the requirement for analytical approaches to meet the minimum required performance levels (MRPLs) stipulated by WADA. Within the last year, several LC-MS/(MS)-based approaches were published representing options to complement or expand the currently employed methodologies of doping control laboratories. For example, employing targeted multiple-reaction monitoring (MRM), the detection of a total of 61 analytes (plus two internal standards) from urine covering seven classes of prohibited substances (S1–S7) and one agent categorized under M1 was reported. While these assays are all designed to specifically measure amplitudes of target compounds with dedicated precursor-/product-ion pairs and thus gate out all other information (for the advantage of sensitivity and speed), a trend towards combined targeted/nontargeted analytical methods has been recognized over the last few years. Here, particularly LC-MS/(MS) approaches with high resolution/high accuracy mass analyzers such as time-of-flight (TOF) and orbitrap as well as hybrids consisting of quadrupole or ion trap mass selective devices and TOF or orbitraps have been used. The benefit of analytical information being recorded in utmost extent (limited essentially only by sample preparation and/or ionization capability) has been especially recognized and appreciated [12017].

**Statistics**

**London Olympics**

More than 1000 samples were analyzed within a few days after each event for stimulants, steroids, masking agents, recombinant proteins like erythropoietin and growth hormone (GH), and other substances on the World Anti-Doping Agency (WADA) Prohibited List in the London Olympics in 2012 [12006].

**FIFA**

The fight against doping in sport receives considerable media interest and results in much speculation regarding the ability of athletes to compete on a level playing field. Football was one of the sports that took early leadership in this fight when the Fédération Internationale de Football Association (FIFA) introduced doping controls in football in 1970 as part of a wider strategy to ensure that the results of representative matches were a fair reflection of the ability of those taking part. As a result of the collaborative effort between FIFA and regional confederations and their member associations in conjunction with national anti-doping
organisations, more than 20,000 doping controls are performed annually on football players. The overall incidence of positive doping samples for prohibited substances accounts for 0.4 percent of all tests. Most of the positive drug tests are due to cannabis and cocaine, the so-called social drugs. Only a few individual cases (0.07% of the positive tests in 2004) were positive for anabolic steroids, such as nandrolone and testosterone. The majority of doping controls have been carried out in competition. FIFA, the Union of European Football Associations (UEFA), and some of the national anti-doping organisations also perform unannounced, out-of-competition controls at training venues during the football season. Prior to the 2006 FIFA World Cup being held in Germany, unannounced doping controls have been performed in the friendly matches between nations. Doping controls have also been performed during the training camps prior to the opening match on June 2006. All tests to date have proved negative. UEFA has also performed unannounced testing in the 2005–06 football season in all of the teams participating in the UEFA Champions League and UEFA Cup. Ten players were randomly selected from each of the 38 European top professional teams and were subjected to testing. No prohibited substances were found in any of the 380 samples tested. Since 1994, FIFA has followed a similar strategy in international competitions for both men and women. In these tests, two randomly selected players per team are tested after each finals match and a total of 3327 tests have been performed in 32 tournaments to date. Only three samples have tested positive since testing commenced: one for ephedrine, one for cannabis, and one for nandrolone. One sample tested positive for ephedrine during the qualifying matches for the 2006 FIFA World Cup being held in Germany. The incidence of positive tests in FIFA competitions over the past 12 years is 0.1 percent. During the 2000 Olympic Games in Sydney and the 2004 Olympic Games in Athens, none of the football players tested positive for any prohibited substance. The internal surveys of all Olympic team sports federations revealed that none of the team sports athletes tested positive for prohibited substances. The comparison of positive drug tests among different sports is currently not possible as the World Anti-Doping Agency (WADA) presents only adverse analytical findings in their published statistics rather than true positive results. The statistics include “therapeutic use exemptions” as well as elevated (>4) testosterone to epitestosterone (T/E) ratio which may be seen in normal athletes. Football accounts for the majority of doping controls performed worldwide. The current doping statistics demonstrate a very low incidence of positive tests and justifies the assumption that there is no evidence for systematic doping in football and most probably in any of the other Olympic team sports. Although no clear data are available from WADA about the distribution of in-competition and out-of-competition drug testing, it can be assumed that the majority are performed in competition. It has to be remembered that the professional football season in which the footballers are subject to random testing runs for 49 weeks a year in most football playing nations. There are several possible explanations for the low incidence of the positive findings of prohibited substances among football players:

- the stringent drug testing programme occurs during the entire football season in most countries
- football players worldwide understand that prohibited substances in sport will neither improve their physical performance nor their football specific skills and hence are reluctant to use agents that are not effective and subject to possible sanctions
- ongoing education campaigns by FIFA for doctors, administrators, officials and players have encouraged a drug-free culture in football

It is also possible that both in-competition and out-of-competition testing is insufficient to detect drug use. This is unlikely, given the large number of in-competition and out-of-competition drug tests occurring at all levels of professional sport over many years with relatively few positive results. Over the past six years FIFA, realising that the dimension of
misuse of prohibited substances is different from that in individual Olympic sports, has also developed close collaboration with the medical representatives of other Olympic team sports federations, as well as with the International Rugby Board. The medical representatives of these bodies expressed their collective opinion during the WADA meeting in March 2003 in Copenhagen, suggesting a possible revision of the World Anti-Doping Code given the different needs of international team sports federations and the lack of evidence of systematic doping in those sports. Furthermore, given the testing of over 20,000 doping controls in football annually worldwide, it became obvious that a close collaboration had to be developed with the accredited testing laboratories to understand the different examination methods and to keep abreast of new scientific developments. The close collaboration with the laboratories has resulted in these laboratories being considered equal partners in the global strategy against doping. It has also resulted in a number of research studies being performed on controversial issues such as nandrolone metabolism, analysis of the T/E ratio and the influence of age and ethnic differences on testosterone metabolism. It seems likely that the constantly increasing number of drug tests will not alter the incidence of positive findings. Unannounced testing at training grounds following the impressive example of UEFA with the Champions League teams could be introduced in all FIFA confederations to provide more information from possible misuse of prohibited substances between official matches. The absence of any positive tests in the UEFA testing to date makes it unlikely that this strategy will identify a significant number of drug cheats who are currently not being detected. Given these findings, the question that arises is whether there is a need for fundamental change in the strategy to fight doping in football? The FIFA Medical Committee is of the opinion that the educational process has to be intensified with the help of national associations and in particular, through team physicians. Team physicians play a central role in the educational programme as they have direct influence over player behaviour and have the knowledge to advise players, not only on the potential risks to health, but also of the effect that sanctions may have on a player's career if he or she is caught. The 32 team physicians of the 2006 finalists have once again confirmed their unconditional support of FIFA's strategy by signing their joint declaration prior to the 2006 FIFA World Cup Germany. The doping control officer at testing controls can also reinforce the educative aspect of the fight against doping [06009].

The doping control procedure
The full details of the FIFA doping control procedure are set out in the annually updated FIFA Doping Control Regulations (www.fifa.com/en/regulations/regulation/0,1584,9,00.html). With regard to the medicolegal aspects of doping control procedures, the process is as follows:

- once an A sample has tested positive, then the FIFA Doping Control Sub-Committee investigates the documentation of the case and prepares a report for the FIFA Chief Doping Control Officer. The FIFA Chief Doping Control Officer has to verify that the correct doping control procedures have been completed according to the doping control regulations. This process usually involves contacting the testing laboratory as well as the original doping control coordinator where the athlete was tested.
- if the analysis of the A sample is confirmed as positive by the FIFA Doping Control Sub-Committee's report, the FIFA General Secretary shall at once confidentially notify the chairman of the Disciplinary Committee, the Sports Medical Committee and the national association of the player concerned, which shall have the right to request a second analysis using the B sample within 24 hours of being notified.
- if a second analysis is requested, FIFA shall communicate this request immediately to the head of the laboratory where the B sample is being kept. An analysis of the B sample shall be carried out as soon as possible, by personnel who were not directly involved with the analysis of the A sample. The association concerned shall
have the right to have a representative present, in addition to the player concerned. The results of the analysis of the B sample shall be sent immediately to the FIFA Chief Doping Control Officer responsible, by fax or e-mail. If no request for a second test is made, the laboratory shall dispose of sample B after 30 days have elapsed.

In addition to the procedural roles above, the FIFA Chief Medical Officer and the Doping Control Sub-Committee also have to estimate the seriousness of the individual case from the medical point of view as to whether the violation was intentional (partially autonomous but not fully self-responsible), deliberate (fully autonomous) or negligent and examine whether any exceptional circumstances may apply. Finally, a written statement about the medical analysis of the case including an estimation of the medicolegal aspects has to be submitted to the FIFA Disciplinary Committee for consideration of sanctions. In cases where FIFA is asked by a national federation or a confederation to take over the sanction or decide about a sanction for the international level, the same procedure is carried out. The individual case management as outlined above is an integral part of FIFA's approach to doping control and based on Swiss sanction law. This means that there must be evidence that the player is personally guilty of the offence being sanctioned and the unjustness of his behaviour has to be obvious to him. Thus, every sanction inevitably contains a distinctive individual component [06002].

**FIFA Medical Assessment and Research Centre (F-MARC)**

The ongoing media debate surrounding the issue of doping in sport has raised public awareness of a problem that has been steadily developing over many years. This controversy reflects both the rapid development of various sports disciplines as well as the evolution of new doping methods and agents. The Fédération Internationale de Football Association (FIFA) introduced doping controls in football in 1970 to ensure that the results of national and international matches were a fair reflection of the ability of those taking part. Over the past 12 years, the FIFA Medical Assessment and Research Centre (F-MARC) has developed a worldwide network of specialists who are involved in the educational process within the regional football confederations and national associations as one facet of global anti-doping strategies. F-MARC has also been involved in the practical implementation of doping controls for FIFA competitions at all levels. FIFA has developed close collaboration not only with the confederations and member associations, but also with other team sports federations, particularly with the accredited drug testing laboratories. These relationships have helped to understand the extent of doping, which in turn forms the basis of a global, harmonised strategy in the fight against doping in football [06010].

**FIFA's approach to doping in football.**

FIFA's anti-doping strategy relies on education and prevention. A worldwide network of physicians guarantees doping control procedures that are straightforward and leave no place for cheating. FIFA actively acknowledges its responsibility to protect players from harm and ensure equal chances for all competitors by stringent doping control regulations, data collection of positive samples, support of research, and collaboration with other organisations. One article aimed to outline FIFA's approach to doping in football. Data on positive doping samples per substance and confederation/nation documented at the FIFA medical office from 1994 to 2005 are provided. According to the FIFA database, the incidence of positive cases over the past 11 years was 0.12 percent, with about 0.42 percent in 2004 (based on the assumption of 20,750 samples per year) and 0.37 percent in 2005. Especially important in this regard is the extremely low incidence of the true performance
enhancing drugs such as anabolic steroids and stimulants. However, there is a need for more consistent data collection and cross checks among international anti-doping agencies as well as for further studies on specific substances, methods, and procedures. With regard to general health impairments in players, FIFA suggests that principles of occupational medicine should be considered and treatment with banned substances for purely medical reasons should be permitted to enable players to carry out their profession. At the same time, a firm stand has to be taken against suppression of symptoms by medication with the aim of meeting the ever increasing demands on football players. It was concluded that the incidence of doping in football seems to be low, but much closer collaboration and further investigation is needed with regard to banned substances, detection methods, and data collection worldwide [06001].

FIFA introduced doping controls in 1970 to ensure that the results of national and international matches were a fair reflection of the ability of those taking part. The FIFA Sports Medical Committee is responsible for implementing doping controls at all FIFA competitions and also for coordinating with confederations and member associations. The overall management of doping controls is conducted by the FIFA administration (Medical Office and the FIFA Sports Medical Committee). Over the past 12 years, the FIFA Medical Assessment and Research Centre (F-MARC) has developed a worldwide network of specialists who are involved in the educational process within the confederations and national associations as well as in practical performance of doping controls for national, international, and FIFA competitions. The medical doctors/sports physicians, following their Hippocratic Oath as well as their professional and ethical values, play key roles in FIFA’s long term strategy in the fight against doping. Many of these doctors are also team physicians in their national associations. The fight against doping in football focuses on education and prevention with regular in-competition and out-of-competition controls. In past years, approximately 15,000 doping controls were performed annually on footballers, with over 20,000 performed in both 2004 and 2005. FIFA articulated its unyielding position in the fight against doping prior to the world cup competition in both 1998 and 2002 and reinforced its strategy in the FIFA Magazine in March 2004. Physicians demonstrated their strong support of the FIFA long term strategy in its fight against doping before the 2002 FIFA World Cup Japan/Korea. The team physicians of all 32 finalists signed a joint declaration in the fight against doping, supporting FIFA’s decision to introduce routine blood sampling to analyse for blood doping and erythropoietin (EPO). This was a firm message to the football community and demonstrated the excellent collaboration and cooperation between the FIFA Sports Medical Committee and the team physicians taking care of the players before and during the competition. The team physicians of all the finalists of the 2006 FIFA World Cup Germany again reinforced the fight against doping with a joint declaration signed on 5 March 2006 to keep this unique event free of doping [06001].

FIFA is a global organisation that unites over 250 million footballers in 207 countries. Around 40 million of these players are female. Currently, confederations, national associations, or both that fall under FIFA’s management, carry out their own doping controls at the competitions they stage. However, the urine or blood samples, or both must be analysed at laboratories accredited by FIFA/World Anti-Doping Agency (WADA). These laboratories send reports on any “chemically positive” A samples to the member associations, and FIFA headquarters for management and WADA for information. Once the FIFA medical office receives a positive A sample report, it requires follow up information from the national association/confederation in question, or both – that is, the results of the possible B sample decision made by the particular disciplinary committee. If the information is not provided, the FIFA disciplinary committee takes appropriate action. Since the 1994 FIFA World Cup in the USA, the FIFA Medical Office has undertaken stringent registration of analysed samples. A new doping control policy for FIFA competitions was introduced at the FIFA U-17 World
Championship in New Zealand in 1999. Since then, during tournaments, two players from each team are randomly selected to undergo doping tests after each match. Between 1994 and 2005, 3327 doping controls (men and women) were performed during three consecutive FIFA world cups (USA, France, Korea/Japan), two consecutive Olympic games (Sydney, Athens) as well as the last Women's World Cup (USA, 2003), the FIFA U-19 in Thailand, the FIFA U-17 World Cup in Peru, the FIFA Confederations Cup in Germany, the FIFA Club World Cup in Japan, the FIFA Beach Soccer World Cup in Brazil, the FIFA U-20 World Cup in the Netherlands, and FIFA World Championship in Futsal, Chinese Taipei, as well as during the World Cup 2006 preliminaries. Only four samples tested positive during this period: one for ephedrine and pseudoephedrine in 1994 one for cannabis and one for nandrolone during the FIFA World Youth Championship 2003 held in the United Arab Emirates, and one for ephedrine in Angola. This reflects an overall incidence of 0.12% positive cases over the past 11 years. The extremely low incidence of positive cases during FIFA competitions indirectly confirms the FIFA long term strategy in the fight against doping: that education and prevention play a key role in keeping high profile competitions free of doping.

It can only be assumed that team sports such as football are not as prone to misuse of performance enhancing substances as are individual sports. During the 2004 Olympic Games in Athens, there were 27 positive cases – all in individual athletes and none in any team sport participants. It might be hypothesised that the close collaboration of the team sport medical committees since the 2000 Olympic Games in Sydney, positively influenced the attitude of fairplay among team sports during the Olympic Games in Athens. Close collaboration between accredited laboratories, the reporting system, and the central control system is an important tool for statistical recording of the extent of doping in football in the future. Although several prominent footballers have tested positive for drugs in recent decades, the true extent of the problem is unknown. Even if we assume that doping is still not a major issue in team sports such as football, any estimation of the problem can be considered as merely an unscientific hypothesis or speculation. To meet the challenges brought about by this situation, FIFA has taken action to develop closer collaboration between the medical committees of the various confederations. In October 1999, the FIFA Sports Medical Committee and the Union of European Football Associations (UEFA) Medical Committee met to discuss the latest sports medicine issues with the aim of not only combating doping but also developing educational programmes designed to meet the fundamental objectives outlined above. Similar meetings have been conducted between the representatives of the FIFA Sports Medical Committee and the medical committees of the Confederation of North, Central American and Caribbean Association Football (CONCACAF) (North and Central America, 2000, 2001), Asian Football Confederation (AFC) (Asia, 2001, 2002, 2005), and Confederation Africaine de Football (CAF) (Africa, 2003, 2004). During 2005, meetings were conducted with the newly established Oceania Football Confederation (OFC) Sports Medical Committee and Confederación sudamericana de Fútbol (CONMEBOL) with the aim of harmonising doping control procedures, improving the understanding of the scientific background of doping, and enhancing the FIFA network of doping control officers (DCOs) who fulfil educational duties as a part of their responsibilities.

According to the statistics of the International Olympic Committee (IOC) (until 2003) and WADA accredited laboratories (as of 2004), approximately 20 750 doping controls are performed annually on football players. The majority of the controls are done in Europe and North and South America. The numbers of doping controls continue to increase in the other confederations. In this respect, FIFA developed its own database to keep records on the substances being reported as positive to allow online control of management of these samples within the different confederations and member associations. During 2004 and 2005, 88 (0.42 % based on the assumption of 20 750 samples per year) and 78 (0.37 %)
positive samples, respectively, were registered at FIFA. The increase is probably because of improved reporting systems used by the laboratories as a result of the implementation of WADA (March 2004). The majority of the positive cases were detected or reported by the European laboratories which receive most of their samples from the European national associations [06001].

The FIFA database will allow a continuous cross-check with the WADA database (ADAMS, Anti-Doping And Management System), once that is operational, not only to control the reporting system of the WADA accredited laboratories, but also to allow prospective studies on sanctions related to the different substances, the severity of the violation, or both. Just before the FIFA World Cup in France in 1998, a number of well known players tested positive for small amounts of nandrolone metabolites in their urine. Nandrolone (chemical name nortestosterone) is an anabolic steroid often encountered in bodybuilding doping cases. In general, this compound is taken in high doses and its degradation products (metabolites) remain detectable in urine for up to several months. Before the 1998 World Cup, FIFA commissioned an independent anti-doping laboratory (LAD) to carry out a collaborative study to obtain a true picture of the situation in football. With the agreement of national and international bodies, every player from every team in the top national leagues in Switzerland (A and B leagues) was tested after a game (356 players in total over two weekends) in collaboration with the Swiss anti-doping committee. The results were compared with those obtained by testing amateur footballers and students. Without revealing anything about the origin of these products, the study showed some players had nandrolone metabolites in their urine after the game. The traces of metabolites in the urine of those players were very small, and all were below the limits of a positive reading. On the basis of this study, FIFA was able to organise the anti-doping programme for the 1998 World Cup with a degree of assurance to provide reliable information to the competing teams to rule out any occurrence of false positive tests. With FIFA’s support, this study into nandrolone and its derivate substances continued. Extraordinary variability in excretion was shown, making the relation between dosage, time delay, and urine concentration critical. Involvement of a world governing body in such a research programme is essential if any worthwhile progress is to be made in this area. The players can also be given the assurance that, scientifically and ethically, they start a match on an equal “playing field” with their opponents as far as doping is concerned [06001].

Future challenges

In 2006, FIFA launched a new developmental programme, the Futuro III. The FIFA Medical Committee undertook to implement the mandate of Mr Joseph S Blatter, President of FIFA, and the FIFA Executive Committee, to educate more than 3000 physicians worldwide in football medicine over the next three years. Anti-doping education is an integral part of the instructional courses, which were launched in February 2006 in Oceania and then held again at the CONMEBOL confederation (South America) in April 2006. The active participation within the instructional courses will entitle physicians to become members of the worldwide network of FIFA medical officers, not only to deal with optimal management and prevention of injuries, but also to act as FIFA doping control officers throughout the 207 member associations of FIFA in collaboration with their national anti-doping organisations. In this respect, FIFA is of the opinion that the doping control programmes have to be carried out by the members of the international sports federations and are obligatory for physicians. There is no need to delegate this important work to commercial companies. The experience of FIFA clearly indicates that employing physicians to perform the doping controls is not only effective but can be done at low cost and most probably will reduce the risk of potential corruption as the physicians have to follow their professional ethical codes of conduct and have medicolegal constraints. Another challenge is the continuous search for identification of new
performance enhancing drugs being distributed on the market via the internet and in this respect medical science, in close collaboration with laboratory experts and the scientific committee of the World Anti-Doping Agency, might help to identify possible new drugs and sanction their misuse accordingly. Arguably the major challenge for the future lies in genetic doping and its detection. There is no doubt that we cannot stop the development of medical science as the development of altered genetic information seeks to benefit the many patients with incurable diseases. Yet it could be hypothesised that this scientific advancement might be misused for performance enhancement in sport. In this regard, the education and cooperation of team physicians forms a crucial link in the chain to prevent athletes adopting such strategies [06009].

The lowering of the threshold for the ratio of testosterone to epitestosterone (T/E) from 6 to 4 has led to intense discussion with the accredited laboratories and raised concerns on behalf of FIFA. According to the FIFA database 2005 none of the samples with elevated ratios between 4 and 6 showed evidence of exogenous intake in the gas chromatography isotope ratio mass spectrometry (GC-IRMS) tests. In face of the logistic impact and additional costs FIFA should strongly advocate detailed statistical analysis of the WADA data, examining the incidence of exogenous intake of testosterone in samples with T/E ratios between 4 and 6. Furthermore, legal difficulties arise in cases where the T/E ratio is between 4 and 6 but GC-IRMS does not verify exogenous intake [06002].

Recent years have shown a constant increase of positive tests for recreational drugs. While this finding reveals rather a social than a doping problem in the sense of the word, an important legal aspect has to be considered too: the consumption of marihuana presents a severe offence against the law in some countries especially in Africa and Asia, even if consumed abroad. Here, the publication of a positive result may lead to serious consequences for the respective player including a prison sentence. Anti-doping bodies should therefore carefully reconsider the unconditioned ban of recreational drugs, preferably based on a juridical expert's opinion [06002].

While the World Anti-Doping Code and the Doping Control Regulations of FIFA offer a comprehensive basis for the fight against doping, the permanent progress in the development of new substances as well as laboratory methods calls for regular review and update of adopted policies. Whereas harmonisation of the strategies of national and international anti-doping agencies is reinforced, the legislation and politics of different countries constitute a permanent obstacle. Any regulation concerning medicolegal aspects should therefore be based on scientific evidence and juridical expertise and has to be supported by close collaboration of national and international bodies [06002].

**WADA-accredited doping laboratories**

In 2013 there were 35 WADA-accredited laboratories. Their locations were [13003]:

EPIDEMIOLOGY OF DOPING

Given the profile of drug use in high-performance sport, it is left to wonder about the use of anabolic steroids in the playgrounds, gymnasia and arenas of our neighbourhoods. However, several years ago, it was noted that the use of anabolic steroids had crept into community sport [014]. A recent survey documented that 3.7 percent of grade 12 Canadian students reported having used steroids [08020].

The use of anabolic-androgenic steroids (AAS) by young athletes has been a primary concern of sports governing bodies because of the implications for unfair advantage in performance and the potential for adverse side effects. Research over several decades indicated a lifetime prevalence of AAS use for adolescent males of 4-6 percent and for females of 1½-3 percent, indicating a problem involving millions of athletes and a potential epidemic of AAS-related pathologies. However, recent studies have questioned the presumption that participation in organised sport is the primary risk factor for AAS use in adolescents as well as the extent estimates of the magnitude of the problem. Increasing evidence indicates that AAS use is associated with non-athletes and is linked to a broader syndrome of problem behaviours rather than efforts to achieve sporting success, and that sports participation may be protective against AAS use. Moreover, employing lifetime prevalence to gauge AAS use limits accurate evaluation of the personal and public health risk as the majority of respondents are not habitual users. Previous studies may have also inflated prevalence values through ambiguously worded survey questions and other design flaws, and few data are available on actual dosages. Prevention efforts need to be focused beyond organised sport and target the general adolescent population rather than athletes and should be founded on interventions with demonstrated efficacy for delinquent, antisocial and self-destructive behaviours rather than the ethical imperative of fair play [10017].

There is evidence to suggest that the prevalence of anabolic-androgenic steroids (AAS) is higher among young people than the general population. The purpose of one study was to examine the proportion of students who reported lifetime and past-year AAS use, explore other drug use among those who reported AAS use, and investigate demographic correlates of AAS use. Data was taken from a cross-sectional survey of a representative sample of Australian secondary students. A stratified two-stage probability sampling methodology was employed and schools were randomly sampled from each Australian State and Territory. A total of 376 schools participated in the survey. Lifetime AAS use was reported by 2.4% of 12-17-year-old students; use was more common among 12-15-year olds then 16-17-year olds. Regardless of age, being male, speaking a language other than English at home, not be at school on the previous school day, and rating own scholastic ability as below average were all associated with a greater likelihood of using AAS in their lifetime and in the past year. Those who reported AAS use also reported the use of a range of other substances, suggesting that AAS use may be part of a broader experimentation with substances. Interventions towards these groups regarding AAS may best be placed within a larger substance use intervention rather than being AAS-specific. In light of the low levels of AAS use among this group, more detailed research into AAS use among adolescent sporting groups may be warranted [10317].

Estimated number of unreported cases

Recent studies have suggested that the use of doping substances and particularly of anabolic androgenic steroids (AAS) is often practised by fitness centre visitors. These studies employed direct interview techniques and questionnaires to assess the estimated
number of unreported cases of doping. Because people hesitate to provide compromising information about themselves, these techniques are subject to response errors. In one study it was applied an alternative interview technique to assess more accurately unreported cases of doping in fitness centres. The investigation employed the randomized response technique (RRT) to reduce response errors. A cohort of 500 people from 49 fitness centres participated in this study. The RRT revealed a high prevalence of doping (13 %). In addition, and most importantly, the present RRT study revealed an alarmingly high prevalence of illicit drug use, specifically of cocaine use, that has been severely underestimated by previous studies. The RRT confirmed previously estimated rates of AAS use assessed by direct interview techniques and voluntary questionnaires, but uncovered a much higher usage rate of illicit drugs among fitness centre visitors. This outcome enabled us to construct a ‘probability’ rating for the use of doping substances in fitness centre visitors. Given its high prevalence and the predominant use of AAS, doping among fitness centre visitors is an issue of extreme relevance for the health care system. The study may help to characterize further doping substance users and to develop and apply prevention and intervention programmes specifically to individuals at high risk [06019].

**Doping in the community**

Prevalence of abuse of androgens in individuals of the general population has reached alarming dimensions. Use of androgens is no longer limited to competitive sports, but has spread to leisure and fitness sports, bodybuilding, and nonathletes motivated to increase muscular mass and physical attractiveness. Alarming studies from Germany demonstrated that members of the healthcare systems provide illegal androgens to 48 percent of abusers visiting fitness centers. The new trend to combine androgens with growth hormone, insulin, and insulinstatic milk protein-fortified drinks may potentiate health risks of androgen abuse. The use of androgens has changed from being a problem restricted to sports to one of public health concern. The potential health hazards of androgen abuse are underestimated in the medical community, which unfortunately contributes to illegal distribution of androgens. Both the adverse effects of current androgen abuse especially in young men as well as the chronic toxicity from past long-term abuse of now middle-aged men has to be considered as a growing public health problem. In the future, an increasing prevalence of androgen misuse in combination with other growth-promoting hormones and insulinstatic milk protein products has to be expected, which may have further promoting effects on the prevalence of chronic western diseases [09018].

The incidence of the abuse of illicit drugs in sport may be a useful indicator of the extent of the phenomenon among the youth population. Many drugs of abuse are included in the WADA (World Anti-Doping Agency) Prohibited List, and are therefore routinely tested for in antidoping controls. This study presents the data obtained in tests carried out in the period 2003- 2007 at the Antidoping Laboratory of Rome, on 44781 samples analysed. The methods used are those developed by the Laboratory for routine antidoping analyses. The percentage of positive test results ranges from 1.1 to 2.0 percent, with a high incidence of stimulants and drugs of abuse. The substance most frequently found is THC metabolite, which accounts for 0.2-0.4 percent of the total, followed by cocaine metabolites, accounting for 0.1 percent. Other stimulants found are ephedrines, carphedon, modafinil, and anorexic compounds such as phendimetrazine and nortenfluramine. No amphetamines or amphetamine-like designer drugs have been detected. These data may be indicative of the widespread incidence of cocaine and cannabis abuse among the young Italian population, bearing in mind that the phenomenon is underestimated in this study, due to the fact that drugs of abuse are investigated only in samples involved in competitive sport, and especially to the fact that people doing such activities take more care of their health and are subject to
greater control in their behaviour and habits with respect to the “normal” population [09019].

Pioneering studies regarding epidemiology of doping in the US were done in the early 1980s, when it was interviewed 3403 male high school seniors nationwide [08021]. The report in 1988 indicated that 6.6 percent of respondents had used steroids and more than two-thirds of the group started using steroids when they were 16 years old or younger. Twenty percent reported that health professionals were the primary source for obtaining steroids and 38 percent used injectable steroids. Pope et al studied 1,010 college men for use of steroids and also reported their findings in 1988 [08022]. The study found that only 2 percent of the respondents reported using steroids. The authors qualified their finding as potentially underestimating the true prevalence of steroid abuse. A review of published reports concluded that 3-12 percent of high school students in the 1990s used steroids, and of the group of abusers about half were adolescent females [08023, 08024]. Contrary to popular belief and supported by Pope's early findings, steroid abuse is not exclusively related to performance enhancement. DuRant et al reported in 1993 that steroid abuse in ninth graders was associated with use of cocaine, injected drugs, alcohol, marijuana, cigarettes and smokeless tobacco [08023]. They then reviewed the 1991 Centers for Disease Control and Prevention Youth Risk Behavior Survey of over 12,272 male and female public and private high school students, and confirmed the earlier finding that there is an association between steroid abuse and multiple drug abuse. In a later review of the 1997 Centers for Disease Control and Prevention Youth Risk Behavior Survey of 16,262 high school students, Miller et al reported no significant correlation in male or female steroid-abusing high school students with physical activity, nor were athletic participation or strength conditioning alone associated with lifetime steroid abuse [08024]. Steroid abuse may also include a wider population of non-athletes who have behavioral problems and may experiment with these now easily available performance-enhancing drugs. Their motivation may not be athletic enhancement, but rather cosmetic and body shaping purposes. To maintain youthful appearances, weekend athletes may experiment with hormones encouraged by "anti-aging" marketing, while adolescent females desirous of the long, lean female media images of "adult women" may use steroids and growth hormone to reduce fat and increase muscle tone [08025].

Drug abuse by adolescents has been investigated in various surveys that reported correlations between age, gender, and activity. However, none of these studies included chemical analyses to help substantiate the statements of participants. In one study, the urine specimens of 964 students (439 females, 525 males; mean age 22 years), who applied to study sports sciences at university, were assessed for anabolic steroids, stimulants, and selected drugs prohibited in sports. In total, 11 percent of the urine specimens provided contained drugs covered by doping controls. The most frequently detected compound was the major metabolite of tetrahydrocannabinol (9.8 %) followed by various stimulants related to amphetamine and cocaine (1.0 %). Indications of anabolic steroid use were found in 0.4 percent of urine samples but originated from contraceptives containing norethisterone. The present study provided unambiguous data on the status quo of drug (ab)use by adolescents hoping for a career related to elite sport or sports sciences. No use of anabolic steroids was detected. However, evidence for stimulants and tetrahydrocannabinol administration was obtained, although not reported by any participant, which highlights the issue of under-reporting in surveys based solely on questionnaires [08026].

The 1999 cross-sectional European School Survey Project on Alcohol and Other Drugs (ESPAD). Data collection by standardized methodology using anonymous self-administered questionnaires completed in the classroom from national probability samples of a total of 18,430 16-year-old high school students from six European countries (Bulgaria, Croatia, Cyprus, Greece, the Slovak Republic, and the U.K.) Besides anabolic steroid use and physical exercise, questionnaire items selected for this study included tobacco, alcohol, and
illicit drug use, indicators of other deviant behavior (self-harming thoughts and behavior, truancy, aggressive behavior), friends' use of steroids, and perceived availability. Backward elimination with likelihood ratio tests was used to select the variables to be retained in a multifactorial model. Interactions of other independent variables with country were checked. Logistic regression analysis of lifetime anabolic steroid users compared to nonusers showed that the odds of lifetime AS use are 1.4 times higher for students who exercise almost daily and 1.8 times higher for boys compared to girls. Significant associations of steroid use were also found with current frequent alcohol use, lifetime use of tranquilizers/sedatives and cannabis, and with the perceptions of friends' use of anabolic steroid and of easy availability of the substance. The authors concluded that findings indicate that daily exercising appears to increase the risk of anabolic steroid use in adolescents. However, a more general pattern of closely interlinked deviant types of behavior, such as other drug use and aggressive behavior, is prominent. Preventive interventions are needed targeted towards adolescents involved in intensive exercise and sport. These should take into account both the idiosyncrasy and setting of the sporting culture and the special characteristics of this group [08027].

Epidemiological confounding factors and false consensus effect (FCE)

The “False Consensus Effect” (FCE), by which people perceive their own actions as relatively common behaviour, might be exploited to gauge whether a person engages in controversial behaviour, such as performance enhancing drug (PED) use. In a study it was assumed that people's own behaviour, owing to the FCE, affects their estimation of the prevalence of that behaviour. It was further hypothesised that a person's estimate of PED population use is a reliable indicator of the doping behaviour of that person, in lieu of self-reports. Over- or underestimation was calculated from investigating known groups (i.e. users vs non-users), using a short questionnaire, and a known prevalence rate from official reports or sample evidence. It is proposed that sample evidence from self-reported behaviour should be verified using objective biochemical analyses. In order to find proofs of concept for the existence of false consensus, a pilot study was conducted. Data were collected among competitive UK student-athletes (n=124) using a web-based anonymous questionnaire. User (n=9) versus non-user (n=76) groups were established using self-reported information on doping use and intention to use PEDs in hypothetical situations. Observed differences in the mean estimation of doping made by the user group exceeded the estimation made by the non-user group (35 % vs 15 % for general doping and 34 % vs 26 % in hypothetical situations, respectively), thus providing preliminary evidence in support of the FCE concept in relation to doping. The presence of the “False Consensus Effect” in estimating doping prevalence or behaviour in others suggests that the FCE based approach may be an avenue for developing an indirect self-report mechanism for PED use behaviour. The method may be successfully adapted to the estimation of prevalence of behaviours where direct self-reports are assumed to be distorted by socially desirable responding. Thus this method can enhance available information on socially undesirable, health compromising behaviour (i.e. PED use) for policy makers and healthcare professionals. The importance of the method lies in its usefulness in epidemiological studies, not in individual assessments [00828].

The false consensus effect (FCE) is the tendency for people to assume that others share their attitudes and behaviours to a greater extent than they actually do. The FCE has been demonstrated for a range of health behaviours, including substance use. The study aimed to explore the relationship between elite athlete's engagement in recreational drug use and their consensus estimates (the FCE) and to determine whether those who engage in the behaviour overestimate the use of others around them. The FCE was investigated among 974 elite Australian athletes who were classified according to their drug use history.
Participants tended to report that there was a higher prevalence of drug use among athletes in general compared with athletes in their sport, and these estimates appeared to be influenced by participants' drug use history. While overestimation of drug use by participants was not common, this overestimation also appeared to be influenced by athletes' drug use history. The results suggest that athletes who have a history of illicit drug use overestimate the prevalence of drug use among athletes. These findings may be helpful in the formulation of normative education initiatives [12028].

The false consensus effect (FCE) is the tendency for people to assume that others share their attitudes and behaviours to a greater extent than they actually do. The FCE has been demonstrated for a range of health behaviours, including substance use. The study aimed to explore the relationship between elite athlete's engagement in recreational drug use and their consensus estimates (the FCE) and to determine whether those who engage in the behaviour overestimate the use of others around them. The FCE was investigated among 974 elite Australian athletes who were classified according to their drug use history. Participants tended to report that there was a higher prevalence of drug use among athletes in general compared with athletes in their sport, and these estimates appeared to be influenced by participants' drug use history. While overestimation of drug use by participants was not common, this overestimation also appeared to be influenced by athletes' drug use history. The results suggest that athletes who have a history of illicit drug use overestimate the prevalence of drug use among athletes. These findings may be helpful in the formulation of normative education initiatives [11012].

Despite the growing body of literature and putative links between the use of ergogenic nutritional supplements, doping and illicit drugs, it remains unclear whether, in athletes' minds, doping aligns with illicit behaviour or with functional use of chemical or natural preparations. To date, no attempt has been made to quantitatively explore athletes' mental representation of doping in relation to illegality and functionality. A convenience sample of student athletes from a large Australian university responded to an on-line survey. Competitive athletes (n=46) were grouped based on self-reported use as follows: 'none used' (30 %), supplement only (22 %), illicit only (26 %) and both supplements and illicit drug use (22 %). Whereas no athlete reported doping, data provided on projected supplement-, doping- and drug use by the four user groups allowed evaluation of doping-related cognition in the context of self-reported supplement- and illicit drug taking behaviour; and comparison between these substances. The False Consensus Effect was found for illicit substance use and was evident as a trend for ergogenic supplement use. It is unclear whether the results point to a relationship between doping and either or neither of the other substances. The results associated with respondents who used supplements suggested that doping estimates may be influenced by ergogenic supplement use. Individuals who used supplements tend to inflate the percentage of individuals who dope but to a much smaller degree than those who use other substances. In addition to these main results, illicit drug use and doping were overestimated. This indicates that, self-report notwithstanding; Australian university athletes may have unrealistic perceptions of illicit drug use and doping. While the pilot nature of this study, especially the small sample, curtails generalisability. The results are therefore interpreted under a generalisability caveat and are intended to inform the broader research program with regard to the observed trends. The presence of the FCE within rather than between substances provides an indication that nutritional supplement use and illicit drug use come from different behavioural domains. Individuals who admitted using one particular type of drug tend to inflate the percentage of individuals who uses the same drug to a much larger degree than those who use other substances. This suggests the FCE could provide an expedient way of identifying when interventions designed to influence one behaviour could influence another. The results indicate that interventions aimed at illicit drug use are unlikely to have much effect on supplement use, and vice versa. Estimates of those who used both
supplements and illicit drugs were more akin to illicit drug users, suggesting illicit drug use may be a dominant behavioural domain. Users of “both” illicit drugs and nutrition supplement gave similar social projections (67%) for illicit drug use to the projected figure of those who use illicit drugs only (74%), compared to a definitely lower estimate (55%) given by nutrition supplement-only users, suggesting that users of ‘both’ may have behaved like illicit drug users due to that domain requiring a different psychological mechanism. For example, users of both may do so as a function of substance use, whereas supplement only users may do so for ergogenic reasons. The dominance of illicit drug use may have implications for the domain specificity of doping behaviour. A reversed pattern was observed for nutrition supplement use projection, where nutrition supplement-only users gave higher estimation (46%) compared to those who use both (34%), thus providing further evidence that in mixed behavioural categories, and the self-anchored behavioural domain is context specific. This pilot study provided an indication that harnessing the FCE might be a fruitful avenue to further examine whether doping behaviour has more in common with illicit drug use or ergogenic supplement use. The pilot nature of the study suggests that doping may be an ergogenic phenomenon, however further testing with an improved research design and sample is needed to establish any such claim. The importance of having a precise picture of the mental representation of doping is underscored by the increasing need for effective anti-doping prevention and intervention. Further research is required to establish if some athletes project their own behavioural tendencies or actual behavior onto other athletes and assume that many others feel or do the same and indeed are using prohibited performance enhancing substances. As a consequence, their own doping tendency or behaviour appears normal and normative, so that they can follow it without compromising their own self-esteem and social acceptance. In this vein, FCE has importance beyond being a useful vector to understanding the position of doping in athletes' minds. These considerations, coupled with the mental representation of doping in athletes' minds, suggest possible intervention strategies to increase compliance with anti-doping initiatives [11013].

One of the key constraints in designing effective anti-doping programs is the lack of conceptual clarity of the psychological mechanisms that influence doping behaviour. For example, preventing doping use in sport on the basis of fair play versus cheating naturally lends to prevention and intervention programs that focus on the ethics of anti-doping and values, coupled with the consequences of being caught – not necessarily limited to sanctions but including dishonour, shame and guilt. Other programs may emphasise the potential hazards and detrimental health effects as consequences of doping use, which are omnipresent, independently from doping testing and sanctioning. In the recent years, a number of athletes have talked publicly about their reasons and motives for doping use, contrasting perceived obligations and duty to perform well with guilt and the shame of lying. Studies conducted among professional athletes, particularly cyclists, offer valuable insight into how athletes perceive doping; and how this perception varies in different contexts. In addition to the fact that many athletes consider doping as part of professional sport, most openly talk about experimentation with non-prohibited substances such as over-the-counter painkillers and non-steroidal anti-inflammatory drugs, caffeine and other non-prohibited stimulants. Nutritional supplement use, which has been considered as a gateway to doping by many is common among emerging and elite athletes and has raised concerns on its own account owing to potentially harmful interactions from combined use and high dosage. The question of whether doping behaviour has the character of illicit substance use, ergogenic substance use, neither or both has been recently raised in connection with anabolic steroids. The ongoing debate is around whether the use of prohibited ergogenic substances aligns with behaviours associated with illicit substance use (e.g. psychoactive controlled drugs) or with nutritional (ergogenic) supplement use. Resolving which behavioural domain doping belongs in athletes' mind provides valuable insight for primary prevention activity. As doping has been categorised as an illicit (illegal) activity, it follows illicit drug models. Thus, the
current anti-doping prevention follows typical demand control models seen for illicit drug use that focus on health education. It may be that the behaviour is functional with regard to its performance enhancing qualities. There is currently little in the way of ergogenic supplement primary prevention. Finally, doping may be an entirely new class of drug use behaviour, requiring a new set of primary prevention activities to be developed [11013].

Previous results investigating social projection in performance enhancing and illicit drug use suggest that projected prevalence of doping and drug use was higher among self-admitted users respectively but absent for nutritional supplement use, and that this social projection was domain specific. Domain specificity refers to an observed phenomenon that admitted doping use came with high estimations of doping use among other athletes with illicit drug use remaining unaffected; and conversely illicit drug users gave higher estimations of illicit drug use among others with estimated doping use remaining unaffected. Although differentiating between cause and effect between social projection and behaviour in data from cross sectional research is impossible, the relationship is clearly present in self-reported data. Interestingly, this phenomenon is only observable within the cognitively controlled information when athletes admitted the use of one or both of these drugs. The importance of the social project lies with the question of whether an elevated and potentially distorted social projection leads to a congruent behavioural choice or resulted from it. The fact that social projection aligns with self-reported behaviour but not necessarily with actual behaviour is intriguing, but more importantly it reveals something about athletes' cognitive processes relating to these substances. Thus, this may be used to gain insight into athletes' implicit mental representation of these, often concomitantly used, substances. Descriptive norms are individuals' perceptions of how common a particular behaviour is. These norms are likely to be affected by some degree of projection (i.e. x % of athletes use doping). In particular, the projection may suffer from a social bias coined the “False Consensus Effect” (FCE) which peoples' perception of their environment (including the behaviours of others) is distorted, thus resulting in a higher estimation. The FCE is a perceptual bias where people who engage in particular behaviours tend to overestimate the proportion of the population who also engage in that behaviour. People who abstain either underestimate or correctly estimate prevalence. For example, marijuana users tend to overestimate the proportion of the population who use marijuana, and non-users are more accurate or underestimate. A further characteristic is that the FCE is domain specific as it works within rather than across different categories or domains of behaviour. Therefore, if doping was an ergogenic phenomenon, users of nutritional supplements should overestimate doping and vice versa (the positive case). Conversely if doping belongs to another domain, then the estimates of doping would occur independently of nutritional supplement use (the negative case). This suggests the relatedness of doping with either illicit or ergogenic substance use behaviours can be determined by emergent patterns of the FCE across behaviours. It may be assumed mutually exclusive categories (i.e. a nutritional supplement user is not a doping user or illicit drug user, etc.). In reality, it is likely that athletes use substances from two or even all three of these substance categories, thus making mixed categories with testable differences in their estimations of drug, doping and nutrition supplement use. For example, athletes construct doping as illicit drug use and therefore athlete illicit drug users also overestimate doping. The legality of the substances may have a confounding influence [11013].

Elites

High use of medication and nutritional supplements has been reported in several sports. To document the use of prescribed medication and nutritional supplements in female and male junior, youth, and adult track and field athletes depending on their sports discipline a
A descriptive epidemiology study was performed. Analysis of 3,887 doping control forms undertaken during 12 International Association of Athletics Federations World Championships and 1 out-of-competition season in track and field was done. There were 6,523 nutritional supplements (1.7 per athlete) and 3,237 medications (0.8 per athlete) reported. Nonsteroidal anti-inflammatory drugs (NSAIDs; 0.27 per athlete, n=884), respiratory drugs (0.21 per athlete, n=682), and alternative analgesics (0.13, n=423) were used most frequently. Medication use increased with age (0.33 to 0.87 per athlete) and decreased with increasing duration of the event (from sprints to endurance events; 1.0 to 0.63 per athlete). African and Asian track and field athletes reported using significantly fewer supplements (0.85 vs 1.93 per athlete) and medications (0.41 vs 0.96 per athlete) than athletes from other continents. The final ranking in the championships was unrelated to the quantity of reported medications or supplements taken. Compared with middle-distance and long-distance runners, athletes in power and sprint disciplines reported using more NSAIDs, creatine, and amino acids, and fewer antimicrobial agents. The use of NSAIDs in track and field is less than that reported for team-sport events. However, nutritional supplements are used more than twice as often as they are in soccer and other multisport events; this inadvertently increases the risk of positive results of doping tests. It is essential that an evidence-based approach to the prescribing of medication and nutritional supplements is adopted to protect the athletes' health and prevent them from testing positive in doping controls [09020].

The aim of one study was to describe qualitatively and quantitatively dietary supplements and medication use in elite athletes. Athletes (n=912) reported medications and dietary supplements taken within 3 days before doping control. It was analyzed data collected from 2006 to 2008, indentified and classified substances. Total of 75 percent athletes reported use of at least one substance, 61 percent took dietary supplements (3.2 per user) and 41 percent took medications. Among users, 21 percent reported the use of six and more different products, and one took 17 different products at the same time. Majority of medication users took non-steroidal anti-inflammatory drugs (NSAID) (25 %), and 22 percent used more than one NSAID. It was found no gender differences in dietary supplements use. Individual sport athletes used more dietary supplements. The study showed widespread use of dietary supplements and drugs by elite athletes in Serbia. Consumption of dietary supplements with no evident performance or health benefits, demonstrated the need for specific educational programs focused on dietary supplements use. Amount, quantity and combination of the reported products raised concern about the risk of potential side effects [09021].

**Use of drugs during the Olympics**

It was gathered data and examined the use by elite Olympic athletes of food supplements and pharmaceutical preparations in total and per sport, country, and gender in the Athens 2004 Olympic Games. Data from two sources were collected: athletes' declaration of medications/supplements intake recorded on the Doping Control Official Record during sample collection for doping control, and athletes' application forms for granting of a therapeutic use exemption (TUE) and through the abbreviated TUE process (aTUE). 24 percent of the athletes tested for doping control declared no use of medications or food supplements. Food supplements (45 %) continue to be popular, with vitamins (43 %) and proteins/aminoacids (14 %) in power sports being most widely used. Nonsteroidal antiinflammatory agents and analgesics were also commonly used by athletes (11 % and 4 %, respectively). Laboratory analysis data reveal that of the aTUEs received for inhaled glucocorticosteroids, only budesonide was detectable in significant percentage (10 %). Only 7 percent of the 445 athletes approved to inhale beta2-agonists led to an adverse analytical finding [09022].
**Student athletes**

There is a general perception that use of performance-enhancing substances (PESs) does not fit the standard profile of substance use. One study sought to determine whether users of PESs report high-risk patterns of alcohol and other drug use and demonstrate risk behaviors associated with problematic substance use. Anonymous self-report questionnaires were administered to a sample of 234 male student athletes. PES users were defined as college athletes who reported past-year use of a broad array of PESs (including stimulants, hormone precursors, and nutritional supplements). Male athlete PES users (n=73) compared with nonusers (n=160) reported more problematic alcohol-use behaviors and more alcohol- and drug-use-related problems. The former compared with the latter was also more likely to report past-year use of tobacco products, marijuana, cocaine, psychedelics, and prescription drugs without a prescription. In addition, PES users demonstrated higher sensation seeking, and greater coping and enhancement motivations for drinking and marijuana use than non-PES users. Although banned PESs are not typically viewed as having a high addiction potential, male athletes who use these drugs may be more likely to participate in other problematic substance-use behaviors. Importantly, the male athletes in this study who reported PES use also participated in substance-use behaviors that can have profound negative effects on athletic performance [09023].

**Adolescents**

The use of anabolic-androgenic steroids (AAS) by young athletes has been a primary concern of sports governing bodies because of the implications for unfair advantage in performance and the potential for adverse side effects. Research over several decades indicated a lifetime prevalence of AAS use for adolescent males of 4-6 percent and for females of 1.5-3 percent, indicating a problem involving millions of athletes and a potential epidemic of AAS-related pathologies. However, recent studies have questioned the presumption that participation in organised sport is the primary risk factor for AAS use in adolescents as well as the extant estimates of the magnitude of the problem. Increasing evidence indicates that AAS use is associated with non-athletes and is linked to a broader syndrome of problem behaviours rather than efforts to achieve sporting success, and that sports participation may be protective against AAS use. Moreover, employing lifetime prevalence to gauge AAS use limits accurate evaluation of the personal and public health risk as the majority of respondents are not habitual users. Previous studies may have also inflated prevalence values through ambiguously worded survey questions and other design flaws, and few data are available on actual dosages. Prevention efforts need to be focused beyond organised sport and target the general adolescent population rather than athletes and should be founded on interventions with demonstrated efficacy for delinquent, antisocial and self-destructive behaviours rather than the ethical imperative of fair play. It has been 50 years since the first report of AAS use by a high school athlete, and since then considerable research has characterised AAS use in young athletes. It appears that illicit use of AAS may be less problematic in young people in organised sport than in the general adolescent population and that prevention efforts would be more effective utilising a public health model rather than one focused on sports-specific concerns such as “fair play”. Yesalis and Bahrke reviewed anabolic steroid use by adolescents up to 1999 and reported that lifetime prevalence in 16 regional studies from 1989-1993 in the USA ranged from 1.6 to 4.4 percent (with higher values for males; in three studies, the prevalence for males was reported as 6.3-6.5 %); in two sets of USA national studies from 1991 to 1997, prevalence ranged from 1.9 to
3.7 percent (with higher values for males), with the values in a third national survey from 1991 to 1994 indicating prevalence from 0.3 to 0.7 percent. The authors’ summary of nine studies from 1990 to 1999 of anabolic steroid use among high school-aged students in a variety of other countries (Canada (three); Sweden (two); South Africa (two); Australia (one); UK (one)) indicated lifetime prevalence ranging from 0.6 to 3.7 percent (with higher values for males). In a review including eight studies (seven from the USA; one from Canada) it was reported prevalence ranging from 1.0 to 5 percent for boys (although two studies reported values of 11 % and 15 %, respectively) and 0.8-2.8 percent for girls (with the same study that reported 15.3 % in boys indicating a prevalence of 6.7% for girls). Of 16 more recent works, six were conducted in the USA (four national samples; two regional studies); nine were in Europe (one trans-European study involving six countries; two national studies (Poland, Norway); six regional (Sweden (three); Norway, Germany, France (one each)); and one regional study from Brazil. As with all of the previously published work on this topic, the majority of new studies differed significantly in their methodology, including the time frame of use (lifetime; previous 30 days; previous 6 months; previous 12 months), sample (middle-school students; high school students; athletes; community-dwelling youth) and source of data (most used researcher-developed questionnaires, although few provided the actual wording of the AAS use questions; internet solicitation). The lack of a standardised approach makes it difficult to compare across studies or acquire an accurate picture of the phenomenon. In Sweden, the Center for Alcohol and Narcotic Information (CAN) questionnaire was used for regional studies in 1995, 1998 and 2000, and indicated prevalence for males of 2.1 percent, 2.9 percent and 1.2 percent, respectively, and for females of 0.2 percent and 0.0 percent (1995 and 1998, respectively). Findings from other studies varied widely. For example, it was reported only 0.8 percent for a national follow-up study of 8508 Norwegian middle and high school students, whereas in another study it was found 3.6 percent for males and 0.6 percent for female high school students in a smaller regional study in Norway [09024].

One article explores the issue of performance-enhancing drug use in adolescent athletes. The article describes current substances that are being used by adolescent athletes, explains their positive and negative effects, examines factors contributing to their increased use in adolescent athletes, and discusses approaches to educating adolescents about alternate means of enhancing their athletic performance. It is hoped that this information will be useful toward encouraging young athletes to pursue, safe, healthy, and natural means of performance enhancement, such as practice and strength training, to improve sports performance in a safe, effective manner [06021].

Ergogenic drugs are substances that are used to enhance athletic performance. These drugs include illicit substances as well as compounds that are marketed as nutritional supplements. Many such drugs have been used widely by professional and elite athletes for several decades. However, in recent years, research indicates that younger athletes are increasingly experimenting with these drugs to improve both appearance and athletic abilities. Ergogenic drugs that are commonly used by youths today include anabolic-androgenic steroids, steroid precursors (androstenedione and dehydroepiandrosterone), growth hormone, creatine, and ephedra alkaloids. Reviewing the literature to date, it is clear that children are exposed to these substances at younger ages than in years past, with use starting as early as middle school. Anabolic steroids and creatine do offer potential gains in body mass and strength but risk adverse effects to multiple organ systems. Steroid precursors, growth hormone, and ephedra alkaloids have not been proven to enhance any athletic measures, whereas they do impart many risks to their users. To combat this drug abuse, there have been recent changes in the legal status of several substances, changes in the rules of youth athletics including drug testing of high school students, and educational initiatives designed for the young athlete. One article summarized the current literature regarding these ergogenic substances.
and details their use, effects, risks, and legal standing [06003].

**Versus those not participating in sports**

One study examined the relationship between high school sports participation and the use of anabolic steroids (AS) and legal performance-enhancing dietary supplements in young adulthood. Additionally, the relationship between the use of AS and legal dietary supplements was explored. Data on approximately 15,000 adolescents from the National Longitudinal Study of Adolescent Health were used. School sports participation was assessed when adolescents were in grades 7-12. AS use and legal performance-enhancing dietary supplement use were assessed six years later. Males were more likely than females to use AS and legal supplements. A sport by gender interaction emerged for the use of AS, indicating that the gender differences in AS use were greater for those who participated in sports during high school. High school sports participation was associated with increased likelihood that adolescents would use legal supplements in young adulthood. Finally, there was a positive relationship between the use of legal dietary supplements and AS use. The study highlights the important role that the social environment during adolescence has on future health behaviors. Results suggest that the sporting context experienced during early adolescence may have lasting effects on the use of performance-enhancing substances. The use of legal performance-enhancing dietary supplements appears to be more prevalent than the use of AS, and there seems to be a positive relationship between the use of AS and legal performance-enhancing dietary supplements [06022].

**Disableds in sports**

Activities concerning the fight against doping with regard to the Paralympic Games have been initiated in 1984, when first doping controls were conducted. The foundation of the International Paralympic Committee exactly 20 years ago (1989) considerably supported systematic sports drug-testing programs specifically designed to meet the particular challenges related to disabled sports, which yielded a variety of adverse analytical findings (e.g., with anabolic steroids, diuretics, corticosteroids, and stimulants) especially at Paralympic Summer Games. In Germany, doping controls for handicapped athletes were established in 1992 and have been conducted since by the National Paralympic Committee Germany and the National Anti-Doping Agency. Also here, various analogies in terms of antidoping rule violations were found in comparison to doping controls of nondisabled athletes. In the one article, available numbers of samples analyzed at Paralympic Summer and Winter Games as well as within the doping control program for disabled sports in Germany were summarized, and particularities concerning sample collection and the doping method termed boosting were presented [09025].

To examine the use of food supplements and pharmaceutical preparations by elite Paralympic athletes in the Athens 2004 Paralympic Games data obtained from athletes' declaration of intake of drugs/supplements recorded on the Doping Control Official Record during sample collection for doping control, and athletes' application forms for granting of a therapeutic use exemption. Sixty-four percent of the athletes tested for doping control declared use of medications or food supplements, and 81 percent of these athletes declared intake of fewer than four preparations. Non-invasive routes of administration dominated. Food supplements (42 %) were popular, and drugs used to treat several pathological conditions noted. Non-steroidal anti-inflammatory agents and analgesics were commonly used (10 % and 6 %, respectively). The prevalence of inhaled beta2-agonist use (5 %) was higher than expected and exceeded that at the Athens Olympic Games. The first
examination of elite Paralympic athletes shows a more rational approach to the use of medication and food supplements, but a similar consumption pattern to that of athletes at the Athens Olympic Games. Because of the dearth of such studies, consumption trends among Paralympic athletes remain unclear. Fewer Paralympic athletes declared the use of medications and food supplements and, in general, a more rational intake pattern was recorded than for Olympic athletes. Drugs used to treat several pathological conditions were recorded, with a higher prevalence of drugs for insulin-dependent diabetes mellitus than in recent Olympic Games. The prevalence of inhaled beta2-agonist use at the Athens Paralympic Games was higher than expected and exceeded that at the Athens Olympic Games. The need to counsel athletes with disabilities on their nutritional needs is confirmed, and close monitoring by healthcare professionals is recommended [09026].

Issues in paraolympics

Autonomic dysreflexia (AD) is unique to individuals with spinal injuries (SCI) at T6 or above and can be voluntarily induced. Although AD improves wheelchair racing performance in some athletes, it also elicits exaggerated blood pressure, which could be dangerous. The International Paralympic Committee considers AD doping and banned its use. Purpose. The purpose of one study was to evaluate AD knowledge, incidence and attitudes (KIA) of Paralympians with SCI. An existing questionnaire was modified to include questions of AD KIA, validated by three experts and piloted with a small sample. It was administered on-line, mailed to members of a scientific network and distributed during the Beijing Paralympic Games. Of 99 participants, 55 percent had previously heard of AD while 39 percent were unaware; 17 percent, all males, had used AD to enhance performance. Participants reported that AD was (1) useful for middle (79 %) and long distance (71 %), marathon (64 %) and wheelchair rugby (64 %); (2) somewhat dangerous (49 %), dangerous (21 %) or very dangerous (26 %) to health. Results were not influenced by age, injury level or injury duration. The findings indicate the need for educational programmes directed towards enhancing the AD knowledge of rehabilitation professionals, coaches and trainers working with spinal injuries individuals [10319].

Paralympic medicine describes the health-care issues of those 4500 or so athletes who gather every 4 years to compete in 20 sports at the Summer Paralympic Games and in five sports at the Winter Paralympic Games. Paralympic athletes compete within six impairment groups: amputation or limb deficiencies, cerebral palsy, spinal cord-related disability, visual impairment, intellectual impairment, or a range of physically impairing disorders that do not fall into the other classification categories, known as les autres. The variety of impairments, many of which are severe, fluctuating, or progressive disorders (and are sometimes rare), makes maintenance of health in thousands of Paralympians while they undertake elite competition an unusual demand on health-care resources. The increased physical fitness of athletes with disabilities has important implications for cardiovascular risk reduction in a population for whom the prevalence of risk factors can be high [12036].

One study reports in detail on the antidoping program of the Paralympic Movement to improve knowledge and optimize intervention programs, including educational and awareness initiatives. Data retrieved from annual statistics reports and historical records are complemented with personal observations. An overall incidence proportion of <1 percent of antidoping rule violations in the Paralympic Movement is reported, mainly resulting from urine testing during in-competition periods. This led to a total of 60 antidoping rule violations (of which 37 in the sport of International Paralympic Committee powerlifting) since 2000. A critical analysis of these data allows for an assessment of risk factors by sport. An efficient transfer of knowledge indicates the need to strengthen educational awareness, preferably imbedded in a multidisciplinary approach toward athletes’ health. The particular case of
autonomic dysreflexia is addressed as a separate theme [12037].

Gym users

The use of performance- and image-enhancing drugs/substances (PIED) outside elite sports appears to be increasing, although the current knowledge of the nature of PIED use among recreational athletes is scarce. The present study analyzed enquiries that were submitted to the Danish Anti Doping Agency (ADD) over an 18-month period, to gain knowledge of PIED use among individuals who exercise recreationally in Denmark. One thousand three hundred ninety eight queries were examined with respect to the age and gender of the enquirer, affiliation to sport or exercise and substance in question. The key findings were that the ADD information service is generally used by males in their mid-20s who exercise in gyms and are not engaged in competitive sports. Approximately 15 percent of the enquirers were users of anabolic androgenic steroids (AAS) or other substances banned within elite sports by the World Anti Doping Agency, and an additional 15 percent considered using such substances. The present results suggest that there is a pronounced interest in the use of AAS and other PIEDs among Danish gym members [09027].

State-based sports institute

The purpose of one investigation was to examine the nutritional supplement intake of athletes from a state-based sports institute. Athletes (n=72) from seven sports (kayaking, field hockey, rowing, waterpolo, swimming, athletics and netball) completed a questionnaire detailing their daily usage and rationale therefore. The large majority (63/72; 88 %) of surveyed athletes reported using nutritional supplements, with no difference between female and male athletes. Kayakers (6.0) consumed a higher number of nutritional supplements than swimmers (4.0), field hockey (1.5), rowing (2.4), waterpolo (2.3), athletics (2.5) and netball (1.7) athletes. The athletes believed that nutritional supplements are related to performance enhancements (65 %), positive doping results (63 %), and that heavy training increases supplement requirements (65 %). The cohort was equivocal as to their health risks (56 %) or their need with a balanced diet (53 %). The most popular supplements were minerals (46 %), vitamins (43 %), other (32 %), iron (31 %), caffeine (22 %), protein (17 %), protein-carbohydrate mix (14 %), creatine (13 %) and glucosamine (4 %). The majority of supplementing athletes (n=63) did not know their supplements active ingredient (62 %), side effects (57 %), or mechanism of action (54 %) and admitted to wanting additional information (57 %). Only half of the athletes knew the recommended supplement dosages (52 %). The performance enhancing perception may explain the large proportion of athletes that reported using nutritional supplements, despite over half of the athletes believing that supplements are not required with a balanced diet and can cause positive doping violations [10021].

Pharmaco-epidemiology of anabolic steroids

The first report of AAS abuse dates from 1954 when members from the Soviet Union’s world champion’s weight lifting team were found to abuse these substances inadvertently. As late as 1975, AAS abuse was classified as doping. According to the world anti-doping agency report in 2008, AAS were the most commonly identified prohibited drugs among all, comprising 59 percent of all reported findings. Unfortunately, AAS abuse occurs frequently not only amongst professional athletes, but also in the general population, particularly high school students. Also, hypogonadism is considered to affect 2-4 million men in the United
States. In a recent Endocrine Society clinical practice guideline, AAS replacement therapy was indicated to treat men suffering from hypogonadism correlated with low testosterone blood levels. Next to relevant clinical indications of AAS in physiological doses (28-56 mg/week), illegal abuse of high doses of AAS as a muscle strengthening agent in eugonadal men is reported in high rates, which results in blood levels of androgenic compounds 10 to 100 times above the physiologic and therapeutic range [12125].

Comparison with a prison population

Use of anabolic androgenic steroids (AAS) has been associated with adverse psychiatric effect, violent behavior, and criminality. The aim of one study was to further investigate the motives for and consequences of AAS use, with focus on violent and antisocial behavior. Fifty-nine prisoners were interviewed on their use of AAS, and their history was mapped with Addiction Severity Index interviews. Of these prisoners, 56 percent admitted previous use of AAS, of whom 24 percent declared to have committed violent crimes in connection with use of AAS. However, the only significant difference between users and nonusers with regard to criminal history when measured with the Addiction Severity Index was that the AAS users more often stated that they had been prosecuted for crimes labeled as “other crimes,” which did not include violent crimes. The reported side effects of AAS corresponded well to those previously reported. These results indicate that use of AAS is common among Swedish prisoners and that the motives and consequences of such use are similar to what has been observed in other AAS-using populations. Furthermore, the study supports earlier notions that misuse of AAS might cause violent behavior, but only in certain individuals and mainly in combination with other substances [10025].

Drug Information Database

To analyse enquiries made in the Drug Information Database (DID) to develop a better understanding of athletes’ interests and concerns regarding the prohibited status of available substances a retrospective analyses of anonymous enquiries recorded in the DID in 2006 and 2007 of athletes and supporting personnel was performed. The DID recorded 223 717 enquiries with 200 of the >6000 UK licensed pharmaceutical products receiving over 100 enquiries each. The majority (79 %) of these enquiries were in the pharmaceutical product category, followed by recreational drugs (10 %). A variety of common medications were subject to enquiry, with anti-inflammatory agents, decongestants and bronchodilators being most common; a trend in keeping with reported medication use by athletes. Of all enquiries, 42 percent were not found owing to misspelled words or enquiries about unregulated substances. The proportion of enquiries about substances not listed in the database is relatively high and has increased over the 24 month observation period. The DID is a well-used information resource with some 10 000 enquiries being made each month. Of the about 60 percent of successful enquiries, the major focus was on pharmaceutical products. With some 73 percent of enquiries being made by the athletes themselves, further investigations are warranted to explore enquiry patterns in relation to specific sports. Of the unsuccessful enquiries, a large number were related to nutritional supplements, which warrants further investigation. The DID database appears to be a valid mirror of athletes’ chemically assisted practices and may be successfully used to inform health professionals as well as antidoping prevention programmes [09028].

The widespread use of chemically assisted performance enhancements in sport is a growing concern, with the emphasis on the need for harm reduction policies and intervention,
underpinned by empirical evidence from clinical trials. Considerable advances have been, and continue to be, made in the development and application of the analytical sciences that underlie the detection of prohibited performance-enhancing substances (PES) both in and out of competition. Practices of chemically assisted performance enhancements reach beyond using prohibited drugs and methods. Recent studies show that a noteworthy proportion of athletes take nutritional supplements daily and the majority of users of supplements in sports fail to take appropriate supplements to achieve their desired health-maintenance or performance-related outcomes. This mismatch between rationale underlying supplement use and the outcomes of the chosen supplements could form part of an educational programme to eradicate misplaced supplement use in sports. However, these literature reports may also be useful in designing new trials and testing programmes to evaluate the side effects of supplements. In addition to supplements, athletes competing at international sport events reported an alarmingly high use of a number and combination of nutritional supplements, over-the-counter (OTC) and prescription-only medications, a pattern that is mirrored in sub-elite athlete populations. Among Belgian athletes, the reported use of OTC medication has increased from 20 percent to 25 percent in 3 years (2002-2005), with the proportion of users above 35 percent in certain sports (such as corticosteroids in cycling). Whilst antidoping prevention programmes target high-performing athletes, the use of performance-enhancing substances has spread beyond elite sports. The complexities of ranges of prescription and over-the-counter medicines, social drugs and supplements, along with the broad range of products which contain them, necessitate an ever-watchful eye from athletes and coaching teams so that inadvertent doping does not occur. The risk to athletes is twofold: in addition to the scenario of inadvertently failing a doping test, several prescription and OTC medicines have known side effects that may hinder an athlete’s performance. This concern is exemplified by the well-known gastric irritation caused by some non-steroidal anti-inflammatory drugs (NSAIDs). Owing to the enormous number and variety of supplements, prescription and OTC medicines available, along with a lack of clear information regarding doping, further research is required for information on which studies should be undertaken in terms of drug types in order to inform WADA testing and antidoping prevention programmes. One approach to this conundrum is to utilise the drug information databases to study patterns of athlete enquiries, assuming that enquiries are true reflections of interest and behaviour or behavioural intention. While enquiries do not necessarily equate to uses, it is reasonable to assume that athletes make enquiries about the prohibited status of the drugs or substances they are taking or considering for medical or performance-enhancing reasons [09028].

Specifically, the most frequent enquiries were on variants of salbutamol (1882), caffeine (1702) and ingredients of pain/fever relievers (ibuprofen and paracetamol, 1412 and 1349, respectively) and cold medications (ephedrine, 1151). Both ephedrine and salbutamol are bronchodilators and their in-competition use is prohibited. However, salbutamol may be used under the therapeutic use exemption (TUE) scheme. The high frequency of enquiries about NSAIDs and bronchodilators is in keeping with the literature precedents. One possible explanation for the relatively high prevalence of decongestants and asthma medications among the enquiries is the exercise-induced asthma that has been documented among winter endurance athletes. It is equally possible that these substances have performance-enhancing effects but are allowed if prescribed with evidence of medical need under the TUE scheme. Therefore, further investigation is warranted into sport-specific enquiries about potentially performance-enhancing substances (i.e. salbutamol, corticosteroids, etc). The most frequent “unlisted” enquiry was creatine (24 %), followed by various commercial products for muscle building (HMB, Maximuscle, Methoxyisoflavone) and some form of sugar (dextrose, glucosamine) at 9 percent and 8 percent, respectively. In this survey among UK athletes, respondents believed that unintentional doping offences are mainly caused by inadequate labelling, changes in composition of supplements and lack of information, and felt
that increased awareness of the UK Sport website and regularly updated list of acceptable supplements would help to prevent inadvertent doping. However, nutritional supplements, herbal remedies and other non-herb non-mineral substances are not covered in the DID [09028].

Different countries

The most common steroids involved with doping are testosterone and nandrolone based on WADA data and retrospective autopsy data. In 2006, 34 WADA-accredited laboratories analyzed almost 200,000 urine samples with positive findings in approximately 2 percent. Of the positive samples, AASs accounted for 45 percent of the adverse findings with the most common AASs being testosterone, nandrolone, stanozolol, and methandienone [13003].

Sweden

A recent doping report performed by the Swedish National Institute of Public Health estimated that at least 10,000 people in Sweden, among 9 million people, have used AAS in 2008. However, higher estimations of 50,000–100,000 users have also been made. Different questionnaires among gym customers showed a lifetime prevalence between 2.7 and 4.8 percent. Among the males 3.8-6.0 percent had tested AAS/doping agents at some time and 0-4 percent of the females. In an investigation the prevalence of abuse among young adolescents, 16 and 17 years old, in one Swedish county, by an anonymous multiple-choice questionnaire, indicating a misuse of 2.9 percent among the male population. The Swedish Customs and the National Criminal Police in 2010 reported an increasing illegal import of AAS into Sweden. In particularly, the import of pure substances, used in local production of ampoules and tablets for the black market, has increased markedly over the last years [12025].

Forensic study in Sweden

Anabolic Androgenic Steroids (AAS) are controlled substances in Sweden. The law was passed in 1992 and concerns synthetic anabolic steroids, testosterone and its derivatives, growth hormones and chemical substances that increase the production or release of testosterone and its derivatives or of growth hormones. Even the use of AAS is prohibited in Sweden since 1999, which is quite unique compared to other countries in Scandinavia and also worldwide. Traditionally AAS have been used by elite athletes to enhance performance, but in recent years it has become an increasing problem outside elite sport among athletes, bodybuilders and criminals. Use of AAS is associated with psychiatric side effects such as aggression, depression and violent behavior. Supraphysiological doses and long term use can cause serious physical harm such as cardiovascular toxicity and even premature death. It was investigated and evaluated the drug analytical findings in forensic cases from suspected perpetrators in cases from the police where a screening for AAS was requested to get information about the prevalence of AAS use and the occurrence of poly-drug abuse. The study was based on samples submitted from the police authorities to the Department of Forensic Toxicology in Sweden during the period 1999–2009. Urines were analyzed by methods based on GC–MS and LC–MS–MS. It was also analyzed the prevalence of AAS use at the prison and probation services. A total number of 12,141 urine samples (6362 police cases and 5779 inmates) were analyzed and 34 percent of the cases from the police and 12 percent of the inmates were tested positive for AAS. Nandrolone was the most frequently detected AAS, found in 1249 (62 %) of the positive cases followed by testosterone found in 719 (36 %) cases. Methandienone, stanozolol, boldenone, trenbolone and drostanolone are also commonly misused. Thirteen different AAS substances were detected
In 2009, an addition of eight new substances since 1999 when only five different types of AAS were detected. Including oxymesterone, which only has been identified once in 2003, gives a total number of fourteen different AAS identified during the study period. Nandrolone, testosterone, methandienone and stanozolol have overall been the most frequently used AAS and are currently still in lead. 1120 (60 %) of the positive cases were found to have used more than one type of AAS. The number of AAS found simultaneously has increased from 1 (48%) or 2 (52 %) in 1999 up to eight different AAS in year 2009. High concentration levels, more than 30,000 ng/mL urine, were measured for some of the metabolites and even unchanged steroids were detected at several thousand ng/mL. The most commonly illegal drugs found were cannabis and amphetamines (including methamphetamine and MDMA), both of which were detected in 440 (37 %) cases each. Benzodiazepines were detected in 339 (28 %) cases, cocaine in 218 (18 %) cases, opiates (morphine and codeine) in 77 (6 %) cases with 6- acetylmorphine present in 9 of these cases indicating intake of heroin, ephedrine in 68 (6 %) and GHB in 61 (6 %) cases. It was also investigated the drug abuse pattern of the AAS positives (n=921) compared to the 148,585 cases of petty drug offences, analyzed 1999–2009, where AAS were not measured. The drug abuse pattern for the confirmed AAS users corresponds to the pattern for other drug addicts with some minor differences. Amphetamine and cannabis were most frequently used by both groups, but to a wider extent noted for the non-AAS group. Also opiates were most commonly used within the non-AAS group. Cocaine and benzodiazepines were on the other hand used more broadly by the AAS-users. Thus, the illegal use of AAS in Sweden has increased over the last eleven years. Of the individuals suspected of doping offence, more than 30 percent were tested positive for AAS. At the correctional institutions, 11 percent of the inmates tested, were using AAS. The AAS users in Sweden are primarily young men (99 %) with a median age of 25 years. The high concentrations of AAS and their corresponding metabolites measured in urine, reveals that supraphysiological doses of AAS are administered. The incidence of poly-drug abuse of 60 percent unequivocally demonstrates that AAS are commonly used together with other drugs of abuse, which is in accordance with the drug abuse pattern of the average drug addict. AAS have to be considered as an equally serious social problem as narcotics in Sweden [12026].

**In Swedish prisons**

Anabolic Androgenic Steroids (AAS) are considered drugs of abuse and are controlled substances in Sweden since 1999. Traditionally AAS have been used by elite athletes to enhance performance, but in recent years it has become an increasing problem outside elite sport among athletes, bodybuilders and criminals. Use of AAS is associated with psychiatric side effects such as aggression, depression and violent behavior. Supraphysiological doses and long term use can cause serious physical harm such as cardiovascular toxicity and even premature death. It was investigated and evaluated the drug analytical findings in forensic cases from suspected perpetrators in cases from the police where a screening for AAS was requested to get information about the prevalence of AAS use and the occurrence of poly-drug abuse. The study was based on samples submitted from the police authorities to the Department of Forensic Toxicology in Sweden during the period 1999-2009. Urines were analyzed by methods based on GC-MS and LC-MS-MS. We also analyzed the prevalence of AAS use at the prison and probation services. A total number of 12,141 urine samples (6362 police cases and 5779 inmates) were analyzed and 33.5% of the cases from the police and 12 percent of the inmates were tested positive for AAS. The users of AAS were mainly in 99 percent men with a mean age of 26 years whereas the women were 30 years old. The most frequently used AAS was nandrolone followed by testosterone and methandienone. Other illicit and licit drugs were detected in 60 percent of the cases from the police, strongly indicating a frequent poly-drug abuse among users of AAS [12118].

**Denmark**
From 2003 to 2009, the number of cases testing positive in Denmark for use of doping increased from 11 to 181. The cases were observed exclusively among individuals exercising in fitness centers. Consequently Anti Doping Danmark initiated a population based survey about individual knowledge, attitudes and use of muscle enhancing drugs. The survey focused in particular on young males aged 15 to 25 years old exercising in fitness centers. 5,010 individuals aged 15-60 years were selected at random and asked to respond to a postal or web-based questionnaire. 1,703 individuals (34 %) responded to the questionnaire. The most important results from the survey included:

- 1.5% reports that they currently use or have been using muscle enhancing drugs. The proportion amounts to 44,000 individuals aged 15-60 years in the general population. The prevalence of use among individuals that exercises in a fitness center was 3.3 %, which amounts to approximately 16,500 individuals
- 6% have considered using muscle enhancing drugs. This proportion amounts to 150,000 individuals
- more than half of those that have considered using muscle enhancing drugs knows of other people in their social network, that uses the drugs
- a substantial proportion of the population opposes the use of muscle enhancing drugs
- attitudes to muscle enhancing drugs among individuals exercising in fitness centers are no different from others
- 19 % of the population knows where to acquire muscle enhancing drugs. Among those that have considered using the drugs, 49 % report that they know where to get the drugs
- the majority of those using anabolic steroids do not discuss their abuse with their own doctor.

In addition, results showed a more relaxed attitude to muscle enhancing drugs and a higher level of knowledge about the effect of the drugs among the 6 percent of the respondents that at some point have considered using the drugs. Users of muscle enhancing drugs are found more frequently in fitness centers than other sport facilities. Muscle enhancing drugs are more frequently a topic of discussion among respondents exercising in fitness centers, and several report about supervision in use of muscle enhancing drugs being available in the fitness center. At the same time, significant more individuals in the fitness environment report knowing about someone in their social network that use muscle enhancing drugs, compared to other respondents. A positive results is the rarity of offers of muscle enhancing drugs among individuals exercising in fitness centers, which occurs equally seldom as among other respondents exercising elsewhere. Also positive is the opposing attitude to muscle enhancing drugs among respondents exercising in fitness centers, as among others. The rarity of offers and the opposing attitudes among respondents exercising in fitness centers points to a good social environment. In sum, the positive results observed should be included in the preventive activities [10429].

Individuals exercising to for a more muscular and athletic body or to gain more self confidence, report that use of muscle enhancing drugs is acceptable if use of drugs was not associated with health hazards. Individuals that exercise to increase their muscle volume are more frequently observed in fitness centers and other areas where excessive weight training is a supplement to the main sport. The positive attitude to muscle enhancing drugs among individuals exercising for a more muscular and athletic body is contrasting the attitude among individuals for whom such motives for exercising are of no importance. For this reason,
information and education about the health hazards associated with use of muscle enhancing drugs should be continued and increased in strength – both within and outside commercial fitness centers. As argued above, information about short- and long term health hazards associated with use of muscle enhancing drugs should be included as an integrated part of the preventive initiatives. In contrast, information on legal consequences should be included to a lower degree – if at all. Narratives that illustrate the health and social risks associated with use of muscle enhancing drugs could form the core of the information and education parts of the preventive work. The prevalence of attitudes to and use of muscle enhancing drugs is documented in the present survey. Results indicate a possible higher prevalence of use in some environments – including fitness centers. Since the latest survey on use of muscle enhancing drugs in Denmark published in 1999, other surveys have been conducted. Any results and conclusions that are based on self-reported behavior that is perceived a criminal act and social unacceptable will necessarily face major methodological challenges. The results of the now presented survey are no exception. Notwithstanding these caveats, the overall conclusion of the surveys conducted within the past ten years is that the abuse of muscle enhancing drugs at best remains stable or worse is increasing. Nothing points to a decrease in use of the drugs [10429].

In general practice
The goal of one study was to investigate the use and side effects of anabolic androgenic steroids (AASs), growth hormone (GH), erythropoietin (EPO) and other enhancing drugs by patients in general practice. In a questionnaire, 702 general practitioners (GPs) in Denmark were asked to estimate the number of their patients who within the preceding year had admitted to using or were highly suspected of having used AASs, GH, EPO or other enhancing drugs. In addition, they were asked to describe the possible side effects of their use. Of 571 eligible GPs, 119 had within the preceding year treated patients who had admitted to or were highly suspected of having used AASs, GH, EPO or other enhancing drugs. 182 users were reported by the GPs during that period; 180 (99 %) were males, and 156 (86 %) were between 20 and 40 years of age. 125 of the patients (69 %) had admitted the use to the GP; AASs had been used by 123 patients (98 %). EPO was not reported in any case, but GH had been used by 9 patients (7 %). 127 (70 %) of the patients had experienced side effects, and 87 (49%) had contacted the GP due to these side effects. The use and side effects of AAS are commonly reported in general practice, whereas the use and side effects of GH and EPO seem to be uncommon. Their use is mainly by men under 40 years of age. The use of AAS is often connected with dermatological and musculoskeletal side effects. It is recommended also to consider possible use of AASs when consulted by a patient with unexplained symptoms of cardiovascular disease, psychological or sexual dysfunction, gynaecomastia or liver dysfunction [06026].

Norway

Adolescents
To prospectively study the stability of anabolic androgenic steroid (AAS) use and predictors of AAS use, and to investigate whether AAS use alters the risk of later emotional and behavioral problems a survey of a national sample of Norwegian high school students (age 15-19) in 1994 was followed up in 1999 (n=2924). Measures of frequent alcohol intoxication (50+ times per 12 months), cannabis use (12 months), hard drug use (12 months), being offered cannabis, eating problems, conduct problems, sexual debut before age 15, BMI, involvement in power sports, perceived physical appearance, and satisfaction with body parts were obtained. Life-time prevalence of AAS use were 1.9 and 0.8 percent in the follow-up period. Multivariate logistic regression revealed that future AAS use was predicted by young age, male gender, previous AAS use, involvement in power sports, and frequent
alcohol intoxication. AAS use did not predict future emotional or behavioral problems other than reducing the risk of future frequent alcohol intoxication. It was concluded that frequent alcohol intoxication and involvement in power sports appear to predict future AAS use. At the population level there was little stability in individual AAS use from adolescence to early adulthood. No detrimental effects of AAS use could be detected in this study, but low statistical power limits this conclusion.

A total of 1351 high school students (52 % males, 48 % females) with mean age 18 years from randomized school classes in Hordaland County, Norway, participated in an Internet survey conducted in 2004 about the lifetime use of anabolic steroids and personal acquaintance with at least one user of anabolic steroids. In addition to questions about anabolic steroids the participants completed the Hospital Anxiety and Depression Scale and the Alcohol Use Disorders Identification Test. They also answered questions about demography, smoking, and narcotic use. The lifetime prevalence for use of anabolic steroids was 3.6 percent for males and 0.6 percent for females. In all, 28 percent of the respondents reported having at least one acquaintance that used or had used anabolic steroids. Use of anabolic steroids and having acquaintances using such drugs were strongly related to use of other drugs such as alcohol, nicotine, and narcotics. Implications for prevention are discussed and the study's limitations are noted.

Finland

The aim of one study was to describe the lifetime occurrence and associated factors of anabolic-androgenic steroids (AAS) among young Finnish males. Of the 10 829 male conscripts (median age 19), 10 396 (96 %) answered a questionnaire during the first days of their conscription in the years 2001-2007. The main outcome was lifetime AAS use. It was also studied associations between 13 socioeconomic, health, and health behavioral background variables and AAS use by logistic regression. Eighty-nine (0.9 %) respondents reported having used AAS. In addition, 26 (0.3 %) respondents reported that they would use AAS if they could obtain them. In multivariate analysis, which included all significant variables and age, the strongest associated factors were weight training at fitness centers more than three times a week (odds ratio 11.8; 95 % confidence interval 7.1 to 19.6), low educational status (odds ratio 3.7; 95 % confidence interval 2.0 to 7.0), and weekly drunkenness as drinking style (odds ratio 2.4; 95 % confidence interval 1.4 to 4.5). Sports other than weight training were not associated with AAS in the sample. The use of AAS is relatively uncommon among Finnish males. It is strongly associated with weight training at fitness centers but also with lower educational status and a drunkenness-oriented lifestyle. Prevention should be targeted at those males participating in weight training.

UK

In an English report the House of Commons Science and Technology Committee says that more needs to be done on every level to combat the use of illegal substances by athletes. The cross party group of MPs says that athletes caught cheating by using chemicals or biological agents should be banned from sport for four years and ordered to repay any financial gains they have made since their last clean test. Athletes should also have to state where they obtained the banned substances before they are allowed to return to competitive sport. The committee concluded that official figures on the incidence of illegal doping may not accurately reflect the problem, and it called for more research into the true scale of the problem. Figures from the World Anti-Doping Agency show that 2.1 percent of tests for banned substances resulted in "adverse analytical findings" in 2005; in the UK 1.3 percent of 7968 tests proved positive in 2005-6. To make it easier to detect performances improved by
illegal substances all UK athletes should be made to compete on the international circuit during the 12 months before the Olympics, says the report. And a new agency that is independent of UK Sport and other national sporting bodies should be set up to test athletes for drug use. The agency should also monitor and evaluate potential new illegal substances and methods as they are developed. The report also recommends a pilot project to examine the feasibility of a physiological or doping passport to be carried by all athletes. This would record the results of doping tests and natural concentrations of hormones such as erythropoietin during their careers, which would make it easier to detect any substance abuse, the committee says. The committee also expressed concern at the ease in which banned and potentially dangerous substances can be obtained for use by athletes. It recommended that the government review regulation in this area [07035].

Figures from the Department of Health in the United Kingdom showed that 0.2 percent of young people had tried anabolic steroids in 2001-4 and 0.5 percent in 2006. A questionnaire study of 3403 12th grade students (final year of secondary school) in the United States found that 6.6 percent admitted to taking anabolic steroids. Worryingly, two thirds of those who started using anabolic steroids when they were aged 16 or younger. A study of homosexual men who regularly attended gyms in London in 2000 found that 15 percent of the 792 men surveyed had used anabolic steroids in the preceding year, with 12 percent of them having injected the drugs. Two thirds of the respondents used more than one agent (so called "stacking"). The high prevalence of use of injectable anabolic steroids correlates with a local experience, where 43 percent of new registrations for needle exchanges were users of anabolic steroids. This figure might be an underestimate as many users of anabolic steroids will collect needles and syringes for friends and other users as well [12025].

**Greece**

Doping use is an ongoing problem in contemporary sports. Despite efforts to detect and control doping, research on its etiology is limited, especially among elite-level athletes. One study used an integrated social cognition model to examine the predictors of doping intentions. Structured anonymous questionnaires were completed by 1075 Greek adult elite-level athletes (medium age = 25 years, 36 % females) from both team and individual sports. Multiple regression and mediation analyses showed that attitudes, normative beliefs, situational temptation, and behavioral control significantly predicted doping intentions. A normative process was identified whereby situational temptation mediated the effects of normative beliefs on intentions. The findings provide the basis for future social cognition research in doping use, and set the framework for the development of evidence-based preventive interventions [10436].

One article concerns the analysis of the adverse analytical findings (AAFs) and the appropriate alterations made during the period 2005-2011, so that the Doping Control Laboratory of Athens (DCLA) obeys the updated World Anti-Doping Agency (WADA) List of Prohibited Substances. The percentage AAFs of the DCLA was compared with those of WADA-Accredited Laboratories. In 2008, the term Atypical Finding was introduced by the WADA representing a reported but inconclusive result. A characteristic example is when a testosterone-to-epitestosterone ratio is >4 followed by a negative gas chromatography/combustion/isotope ratio mass spectrometry result. In a total of about 30,000 athlete samples, 136 athletes were found with an increased testosterone/epitestosterone ratio and 43 with tetrahydrocannabinol metabolite (THCCOOH) of 427 reported AAFs. Twenty-one athletes in total were found positive with methylhexaneamine, the 11 found after a batch of 1000 samples was reprocessed. Besides, there were AAFs below their Minimum Required Performance Level (MRPL). The increasing need for higher detectability imposed new
apparatus, e.g., liquid chromatography/quadrupole/time-of-flight mass spectrometry, whereas that for lowering the capital costs and reporting times led to the unification of the screening method which includes stimulants, diuretics, anabolics and other substances [0125].

**Italy**

The objective of one study was to assess the prevalence of illicit drugs use among young adults, in particular elite athletes. The study considers the data obtained from anti-doping analyses performed on nearly 100,000 urine samples from 2000 to 2009 by the World Anti-Doping Agency accredited Italian Anti-Doping Laboratory. The percentage of adverse analytical findings varies on a yearly basis, but it is in the range 1.0-1.8 percent (not considering atypical findings, such as an altered endogenous steroid profile). Among positive results, there is a high prevalence of stimulants and drugs of abuse. The drug of abuse found most frequently is the tetrahydrocannabinol (cannabis) metabolite, accounting for 0.2-0.4 percent of the total samples analysed (18 % of the positive results). The second most frequently encountered drug is cocaine, as detected from cocaine metabolites, accounting for 0.1 percent of the total samples analysed (7 % of positive results). Other stimulants found included amphetamines, ephedrines, carphedon, modafinil, and anorexic compounds. No amphetamine-like designer drugs were detected. These data are indicative of the widespread prevalence of cocaine and cannabis use among the young adult population. However, due to the particular population studied, it must be considered an underestimation of the phenomenon among elite athletes with respect to the general population [11016].

**France**

To describe the prevalence of doping and its progression in a cohort of preadolescent athletes during a 4-year follow-up a prospective cohort study was performed. It was a self-questionnaire survey where all of the pupils entering the first year of secondary school (sixth grade) in the Vosges Département (east France) and followed for 4 years was asked about drug use (prohibited substances, tobacco, alcohol, cannabis), intention to use, reported health hazards, perceived drug effectiveness, self-esteem, trait anxiety. At the beginning of the study, 1.2 percent (95 % confidence interval 0.8 to 1.6) stated that they had taken doping agents at least once in the preceding 6 months, and this had risen to 3.0 percent four years later, which was a statistically significant difference. Of those who had used doping agents, 4 percent reported that they had experienced a health problem related to doping, and 44 percent reported that they had won at least one sports event as a result of using the drug.

Use of doping agents is linked to the number of hours of practice per week, intention to use, use of other drugs, self-esteem and trait anxiety. The results show that doping does exist in preadolescent athletes who train every day [07034].

The French report of the National Academy of Medicine named "Sport and Health" underlines the medical, social and educational dimensions of sporting activities. Various kinds of sporting practices are described: they concern the approximately 7,000 high level athletes, around 8,000 professional (licensed) sportsmen, and sporting club members (approximately 15 millions people). A large number of amateurs do not practice in any structure and therefore are neither managed in their activities nor medically followed. Some characteristics of sporting practice at various stages of life have been documented. Around 50 percent of the teenagers from 12 to 17 years have a sporting practice out-of-school besides the weekly three hours applied at school or college; however, the withdrawal of sporting practice by a high number of teenagers results in a sedentary lifestyle with overweight and obesity, major risks factors for health. Elderly people take a profit from a regular and medically controlled physical activity. Functional capacities are thus improved,
cardiovascular risks factors among other, which results in better quality of life of the aged and delays their dependence. The benefit upon public health of sporting practice has been pointed out in the primary prevention of cardiovascular and respiratory diseases, osteoporosis, obesity, diabetes, breast and colon cancer, and mood disturbances. It is currently well acknowledged that sporting practice is an important component of public health in both primary and secondary prevention of many diseases. Deleterious effects of which the most serious is the sudden death related to a cardiovascular anomaly, which generally occurs during an important physical effort. An important sport drift is the practice of doping to improve performances through the use of hormones, anabolics, EPO, transfusions, ... When a person exceeds his/her capacities of adaptation, because of a badly adapted or a too intense drive, this overtraining results in a reduction in physical capabilities, stress, behavioral issues and sleep-wake disorders. All of those issues often lead sportsmen to doping with the aim to improve their capabilities, rapidly installing an overtiredness state resulting in a fall of performances. A major aim from the view point of public health is to reinforce the fight against doping since it concerns a large number of people, sportsmen and amateurs, with teenagers among them. Lastly, the report underlines that sport medicine is practically not taught in the initial training of medical doctors [09029].

The purpose of one investigation was to determine the substances used, and the attitudes towards doping of high school athletes. A four-page, self-completed questionnaire was designed to determine the drugs used (licit, illicit and doping substances) along with beliefs about doping and the psychosociological factors associated with their consumption. The questionnaire was distributed to all the high school students enrolled in a school sports association in the Lorraine region in Eastern France. The completed forms were received from 1459 athletes: 4 percent stated that they had used doping agents at least once in their life (their main source of supply being peers and health professionals). Thirty-four percent of the sample smoked some tobacco, 66 percent used alcohol, 19 percent cannabis, 4 percent ecstasy, 10 percent tranquilizers, 9 percent hypnotics, 4 percent creatine and 41 percent used vitamins against fatigue. Beliefs about doping did not differ among doping agent users and non-users, except for the associated health risks which were minimized by users. Users of doping agents stated that the quality of the relations that they maintain with their parents is sharply degraded, and they reported that they are susceptible to influence and difficult to live with. More often than non-doping agent users, these adolescents are neither happy, nor healthy, while paradoxically, they seem less anxious and they are more self-confident. The findings suggest that doping prevention among young athletes cannot be limited uniquely to the list of banned drugs [10441].

Germany

Goal-directed measures to prevent doping and drug abuse in sports requires empirical data. In this connection, a cross-sectional analysis was carried out in 2004. The purpose of the study, on the one hand, was to register reliable data of the current situation in Thuringia, and, on the other hand it was to give information on possible interventional steps with scientific support. Within three months, 2319 adolescents from 16 Thuringian schools (5 regular schools, 4 secondary schools, 3 sport schools and 4 vocational schools) were surveyed. Three hundred and forty-six (15 %) students out of 2287 students (26 students without a statement) indicated use of prohibited substances from the WADA list in the previous year: 16 (0.7 %) anabolic-androgenic steroids (AAS), 10 (0.4 %) growth hormones, 56 (2.4 %) stimulants, 305 (13.2 %) cannabis, 2 (0.1 %) diuretics, 52 (2.2 %) cocaine/heroin and 6 (0.3 %) erythropoietin. Moreover, nonathletes (n=490) reported a substance use that was approximately 5 percent higher than that of recreational athletes (n=1254) and nearly three times higher than that of competitive athletes (n=497). All three groups (nonathletes, recreational athletes and competitive athletes) performed poorly on a knowledge test
regarding doping in general with an average below 60 percent in each case. Another main aspect of the study was to determine factors influencing substance use in sports. Besides the doping specific knowledge, age contributed as well as anti-doping attitude, to the resulting variance. Gender, however, played no role. The findings of the study point towards the need for improvement of specific knowledge of doping among students and that their attitude towards doping must be altered. The goal in this case is to test the effectiveness of appropriate scientific intervention [07033].

Doping controls are key factors for fair and clean sports. The developments of German activities in the national antidoping fight were evaluated over a period of 18 years (1989-2006) with regard to in-competition and out-of-competition testing. The quantity of respective controls conducted by federations and antidoping organizations, the ratio of in- and out-of-competition controls, the number of athletes per squad (and thus per-capita tests) as well as adverse analytical findings were summarized in a review. The available data demonstrated a constantly increasing effort, particularly regarding the amount of out-of-competition controls, but also discrepancies in per-capita analyses between different federations. In light of recent doping scandals and confessions in 2007, a critical review of national antidoping actions is considered necessary [08031].

In the context of house searches in Germany, numerous drugs were confiscated and subjected to chemical analysis, including anabolic agents such as various anabolic-androgenic steroids (stanozolol, testosterone derivatives, trenbolone esters, etc.) and clenbuterol, as well as agents with anti-estrogenic activity (tamoxifen, clomiphene), drugs stimulating virility (sildenafil, tadalafil), and unlabeled plastic bags. Liquid chromatography-tandem mass spectrometry, gas chromatography-mass spectrometry with nitrogen-phosphorus specific detection, gel electrophoresis, and immunological tests were employed to test for the effective content of 70 products. In 18 cases (26 %), the declared ingredients differed from the actual content, in particular concerning anabolic-androgenic steroids. Nandrolone and trenbolone esters, for instance, were frequently substituted or complemented by various testosterone derivatives, and several testosterone depot formulations originally composed of four different esters were found to contain fewer or wrong components. Except for those drugs supposedly originating from so-called underground labs, fake packings were hardly or not distinguishable from original boxes by visual inspection [08032].

**Adolescents**

Goal-directed measures to prevent doping and drug abuse in sports requires empirical data. In this connection, a cross-sectional analysis was carried out in 2004. The purpose of the study, on the one hand, was to register reliable data of the current situation in Thuringia, and, on the other hand it was to give information on possible interventional steps with scientific support. Within three months, 2319 adolescents from 16 Thuringian schools (5 regular schools, 4 secondary schools, 3 sport schools and 4 vocational schools) were surveyed. Three hundred and forty-six (15 %) students out of 2287 students (26 students without a statement) indicated use of prohibited substances from the WADA list in the previous year: 16 (0.7 %) anabolic-androgenic steroids (AAS), 10 (0.4 %) growth hormones, 56 (2.4 %) stimulants, 305 (13.2 %) cannabis, 2 (0.1 %) diuretics, 52 (2.2 %) cocaine/heroin and 6 (0.3 %) erythropoietin. Moreover, nonathletes (n=490) reported a substance use that was approximately 5 percent higher than that of recreational athletes (n=1254) and nearly three times higher than that of competitive athletes (n=497). All three groups (nonathletes, recreational athletes and competitive athletes) performed poorly on a knowledge test regarding doping in general with an average below 60 percent in each case. Another main aspect of the study was to determine factors influencing substance use in sports. Besides the doping specific knowledge, age contributed as well as anti-doping attitude, to the resulting
variance. Gender, however, played no role. The findings of the study point towards the need for improvement of specific knowledge of doping among students and that their attitude towards doping must be altered. The goal in this case is to test the effectiveness of appropriate scientific intervention [06023].

**Serbia**

Socio-economic changes that occurred in the wake of dismemberment of former Yugoslavia resulted in the appearance of social pathology, one of which was the increase in the use of psychoactive substances. A study was carried out among 1011 elementary school children (seventh and eighth grades) and secondary school children (all four grades) in the area of Belgrade from 2003 to 2004. Out of the total number 457 (45 %) were elementary school pupils and 554 (55 %) secondary school pupils. There were 524 (52 %) boys and 487 (48 %) girls, aged from 12 to 18 years (the average age being 15 years). The method used was the European School Survey Project on Alcohol and Other Drugs Questionaire. Totally 14 percent examinees tried psychoactive substances. The most frequent drug used at the first contact was marijuana (10.8 %) at the age of 15 tried by 13 percent examinees, inhalants (4.4 %), amphetamines (4.1 %), sedatives (3.7 %), alcohol combined with marijuana (3.9 %), then cocaine (2.8 %), heroin (2.3 %), alcohol combined with sedatives (2.2 %), and ecstasy (1.6 %), followed by anabolic steroids, heroin, diethylamid lisergic acid (LSD) and magic mushrooms. It was determined that going out in the evening, smoking and binge form drinking were directly connected with the use of psychoactive substances [08030].

**Croatia**

Substance use and misuse (SUM) and the relation to physical activity/exercise/athletic participation (sport factors) and scholastic achievement are rarely studied in Croatia. The aim of this study was to investigate the SUM habits in Croatian adolescents (17-18 years of age, 254 males, and 218 females), and to study potential gender-specific interrelationships between scholastic and sport factors in relation to SUM. The testing was done using an extensive, anonymous, self-administered questionnaire that consisted of scholastic variables, sport factors, and SUM data. Descriptive statistics, counts, and proportions were calculated. Gender differences were established using the Kruskal-Wallis test. Gender-specific correlations within and between studied variables were established using the Spearman's correlation. The incidence of smoking habits and alcohol consumption among Croatian adolescents was alarming, and a serious intervention program should be developed to address this issue. Educational achievement was negatively related to SUM, with no gender-specific relationships. The data indicated some "protective" effects of the sport factors against SUM in boys, but a significant positive correlation between alcohol drinking and sport participation in girls was also noted [11019].

**Poland**

To estimate the prevalence of anabolic-androgenic steroids (AAS) abuse among adolescent and young adults in Poland 3,687 men (48 %) and women (52 %), median age 23 (interquartile range 19-30 years) participated in a survey via a "pop-up window" which appeared on two popular Polish internet portals during one month. Questions concerning their body image, exercise behaviour, education level and use of anabolic-androgenic steroids were asked. The prevalence of anabolic-androgenic steroids use was 6.2 percent among males and 2.9 percent among females. Male AAS users, compared to non-users, were more often concerned about their physical appearance, were less educated and often engaged in some sport activity. Among female AAS users, no significant differences
concerning self-body image satisfaction or participation in sports were found. However, compared to non-users, female AAS users were less educated. It was concluded that the abuse of AAS is a reality in Poland and may become a serious health concern among adolescents and young adults [06027].

**Europe, combined countries**

Data on doping among young non-professional athletes are scarce. In order to estimate the prevalence and predictors of doping use, a standardized, anonymous questionnaire was self-administered by 2650 tertiary education students from five European Union countries (Finland, France, Germany, Greece, Italy) and Israel. The reported usage rate of a doping agent (at least once) was 2.6%, with no significant variation in the frequency of doping reporting among the participating countries. Doping was, however, less common among students of biomedical schools (OR: 0.49) and was higher among males (OR: 2.16). Students, who use to drink coffee or recall frequent occasions of involvement in drunkenness episodes, were more likely (twice and three times, respectively) to report doping, and students using nutritional supplements or having participated in a major athletic event were more likely (four times and twice, respectively) to report doping in comparison with students who do not. Of note is the high odds ratio for reporting individual doping when having a friend who uses doping (OR: 8.61). Given the large size of the physically active young individuals in the population and the small number of professional athletes, doping in the general population may be, in absolute terms, as sizeable problem as it is among the professional athletes. There was evidence that high-risk behaviour and supplement use increased the risk of doping [06028].

**Jordan**

One study was conducted to measure the extent of androgenic steroids abuse among two targeted groups in Jordan, college students and athletes, and the risk factors associated with this abuse. Five hundred and three Jordanian collegiate students and 154 bodybuilding athletes completed a three section questionnaire that investigated demographic information, prevalence of anabolic-androgenic steroids and attitude towards steroids abuse. Of the investigated collegiate students, 4.2 percent were current users, while the percentage rose to 26 percent among the athletes; the mean age of users in the two groups was 20 and 28 years, respectively. Almost one-third of the students started abusing anabolic steroids before the age of 15 years while more than half of the athletes started between the ages of 15 and 18 years. Knowing where and how to get the drugs has not been a problem for either the students or the athletes as their friends and coaches were the major sources. The main reasons for using anabolic steroids have been found to help improving athletic performance and physical appearances [08029].

**Iraq**

The majority of men's sports need high levels of strength and power. The effects of any given type of performance-enhancing substance are mostly directly related to its ergogenic effects (enhanced strength, higher energy production, and better recovery), anabolic potential (increased protein synthesis, especially in muscles), and/or stimulating properties (increased attention and loss of fear), which give a competitive advantage to athletes. A descriptive correlational study was conducted to identify bodybuilders' and athletes' perception toward substance use and to identify the relationship between substance use and those athletes' sociodemographic characteristics of age, level of education, social status, and monthly income. A purposive "nonprobability" sample of 172 bodybuilding athletes were recruited.
from gym users of Baghdad city. The study found that two fifths of those who used anabolic-androgenic steroids (AAS) were 19 years old or younger, less than one half were overweight (body mass index 25-30), two fifths of participants enjoyed exercise/training to an extreme level, two fifths of study participants highly perceived the improvement of athletic performance, two fifths of the study participants highly perceived the importance of improving athletic performance, less than half of the study participants used AAS, one quarter of the study participants who used AAS had been influenced by their coaches to use such substances, and more than one third of the study participants who used AAS were using such substances in the form of oral tablets and intramuscular injection together [12027].

Korea

Athletes report frequent use of various dietary supplements (DSs). The objectives of one study were to obtain information about Korean Olympians' DS use during the training period for the Beijing 2008 Summer Olympic Games and immediately before their Olympic events, to obtain DS-intake reasons and DS providers, and to obtain information on athletes' doping education, knowledge, and educators. Korean Olympians completed 2 questionnaires 1 week before the opening and within 1 week after the closing of the Beijing 2008 Summer Olympic Games. Results showed that 79 percent of male and 82 percent of female Olympians take more than 1 dietary supplements during the training period and that vitamins and Oriental supplements are the 2 top-ranked DSs. Reasons for dietary supplements use were to improve recovery ability (66 %) and muscle performance (22 %), and sources of obtaining dietary supplements were parents (36 %) and coaches (35 %). Furthermore, 79 percent of Korean Olympians reported receiving regular education on antidoping regulations from Olympic-sponsored education classes (64 %) and coaches (15 %) [11021].

USA

Although various surveys have tracked the prevalence of anabolic-androgenic steroid (AAS) use in American teenagers and young adults, no recent surveys have assessed the lifetime prevalence of AAS use in Americans overall. It was therefore analyzed serial youth-survey data to derive estimates of the lifetime prevalence of AAS use in the current American general population. It was first determined the distribution of age of onset of AAS use, based on pooled data from nine studies. Using this distribution, we then developed equations to project the eventual lifetime prevalence of AAS use among young survey respondents, once they aged and completed the period of risk for initiating AAS. It was similarly calculated the denominator of lifetimes of risk for AAS use in the total American population. It was next applied these equations to four independent national youth datasets to derive current American general-population estimates for lifetime AAS use. Finally, using data from 10 pooled studies, it was estimated the lifetime prevalence of AAS dependence among AAS users. Age-of-onset studies consistently showed that AAS use begins later than most drugs, with only 22 percent of users (95 % confidence interval 19 to 25 %) starting before age 20. Applying the age-of-onset findings to national youth datasets, it was estimated that among Americans currently age 13-50 years, 2.9-4.0 million have used AAS. Within this group, roughly 1 million may have experienced AAS dependence. Although subject to various limitations, the estimation techniques suggest a surprisingly high prevalence of AAS use and dependence among Americans [13030].

Because 57 percent of all high school students play on formal sports teams, the use of both illicit and legal ergogenic drugs to enhance performance in amateur athletics is of significant concern today. Furthermore, up to one third of high school students who use anabolic steroids are in the population of nonathletes who use steroids to improve their appearance.
Drug and supplement use is not uncommon today. It is estimated today that 1 to 3 million US athletes are taking steroids, and 2500 tons of creatine were consumed in 1999. Many substances are being used by today’s youths, commonly without recognizing any risks of such drugs. Even as this problem increases, there are concerns that pediatric residents are receiving minimal education in the field of sports medicine during both medical school and residency. Although the focus of pediatric sports medicine is typically proper training and managing common injuries, an emerging issue is learning about the drugs that are chosen by young athletes to improve athletic performance [06003].

The US National Institute on Drug Abuse has called for increased research into the use of physical activity in substance abuse prevention, specifically research into physical activity type and context. One paper examined the relationships between secondary school student substance use and exercise in general and school athletic team participation, and examines such relationships over time. Nationally representative cross-sectional samples of 8th-, 10th-, and 12th-grade students were surveyed each year from 1991 to 2009. Substance use measures included past 2-week binge drinking and past 30-day alcohol, cigarette, smokeless tobacco, marijuana, and steroid use. Analyses were conducted during 2009-2010. Across grades, higher levels of exercise were associated with lower levels of alcohol, cigarette, and marijuana use. Higher levels of athletic team participation were associated with higher levels of smokeless tobacco use and lower levels of cigarette and marijuana use across grades and to higher levels of high school alcohol and steroid use. Exercise helped suppress the undesired relationship between team participation and alcohol use; exercise and athletic team participation worked synergistically in lowering cigarette and marijuana use. Observed relationships were generally stable across time. There appear to be substantive differences between exercise and team sport participation in relation to adolescent substance use. These findings from cross-sectional data suggest that interventions to improve levels of general physical activity should be evaluated to determine if they help delay or reduce substance use among youth in general as well as among student athletes [11020].

Data on the actual prevalence of AAS use are limited by recall and reporting biases associated with illicit drug use. Many studies of AAS use focus on adolescents. In a nationwide study of 3403 12th-grade male students in 46 private and public US high schools during the 1980s, 6.6 percent of the respondents admitted to ever using AASs based on their response to questionnaires. The individual participation rate was low (50%). Almost 40 percent of the respondents admitted to the administration of 5 or more cycles of AASs. Further studies performed at local and statewide levels have confirmed similar findings indicating that 3-12 percent of high school male adolescents use AASs at some time in their lives. These studies indicate that about one-third of the high school students use AASs for appearance rather than athletic performance. In 1999, the National Institute on Drug Abuse Monitoring the Future study indicated that approximately 2.7 percent of US 8th and 10th graders and 2.9 percent of 12th graders admitted to the use of AASs at least once. For 10th graders, the prevalence of AAS use increased to 2.7 percent in 1999 from 2.0 percent in 1998. For all 3 grades, the 1999 levels represented a significant increase from 1991, when 1.9 percent of 8th graders, 1.8 percent of 10th graders, and 2.1 percent of 12th graders admitted AAS use at least once. The data on adolescent use of AAS in 2004 and 1999 were similar with 2.5 percent of 12th graders reporting the use of AASs at least once. Risk factors for the use of AAS among adolescents include male gender, participation in strength-related sports, and use of other illicit drugs. In college and professional athletics, the prevalence of AAS abuse is less defined because of the ramification of AAS use. However, the prevalence of AAS use among these groups is probably substantially higher than in high school students, particularly in football players and male track-and-field-athletes. Between 1972 and 2000, there were 29 athletes disciplined for positive AAS drug tests. However, the abuse of AASs is probably more widespread among these athletes because of the difficulty detecting
all AAS use and the small number of doping charges compared with the number of positive drug tests. Current trends suggest that most AAS abusers are non-athletes using these drugs for cosmetic purposes [13003].

**Origin of AAS in the United States**

AASs are DEA schedule III drugs of the Controlled Substances Act. The primary sources for illicit AASs in the United States are manufacturing facilities in Mexico. Traffickers from the United States enter Mexico and purchase AASs at pharmacies in Baja, California, where AASs are available by prescription. They subsequently smuggle the AASs back in to the United States. Other sources of illicit AAS in the United States include eRussia, Poland, Hungary, Spain, Italy, Greece, Canada, and the Netherlands as well as some clandestine labs in the United States. The diversion of legitimate pharmaceutical preparations provides a much smaller portion (i.e. 10-15%) of illicit AASs compared with other illicit sources. Information on the administration and procurement of AASs is widely available on the Internet [13003].

**Australia**

There is evidence to suggest that the prevalence of anabolic-androgenic steroids (AAS) is higher among young people than the general population. The purpose of one study was to examine the proportion of students who reported lifetime and past-year AAS use, explore other drug use among those who reported AAS use, and investigate demographic correlates of AAS use. Data was taken from a cross-sectional survey of a representative sample of Australian secondary students. A stratified two-stage probability sampling methodology was employed and schools were randomly sampled from each Australian State and Territory. A total of 376 schools participated in the survey. Lifetime AAS use was reported by 2 percent of 12-17-year-old students; use was more common among 12-15-year olds then 16-17-year olds. Regardless of age, being male, speaking a language other than English at home, not be at school on the previous school day, and rating own scholastic ability as below average were all associated with a greater likelihood of using AAS in their lifetime and in the past year. Those who reported AAS use also reported the use of a range of other substances, suggesting that AAS use may be part of a broader experimentation with substances. Interventions towards these groups regarding AAS may best be placed within a larger substance use intervention rather than being AAS-specific. In light of the low levels of AAS use among this group, more detailed research into AAS use among adolescent sporting groups may be warranted [11017].

One study aimed to investigate the prevalence of illicit drug use among elite Australian athletes with a focus upon cannabis, ecstasy, meth/amphetamine, cocaine, GHB and ketamine; explore perceptions concerning the extent of drug use among this group; ascertain opinions regarding specific drugs of concern; and investigate predictors of recent drug use. Data were taken from surveys with 974 elite athletes. One-third of the sample had been offered or had the opportunity to use illicit drugs in the past year; despite this, the self-reported prevalence of all six drugs under investigation was lower than that reported by the general population. Sixteen percent of athletes believed that there was a drug of concern in their sport, with ecstasy, cocaine and alcohol being nominated. Knowing other athletes who use illicit drugs, being offered or having the opportunity to use drugs and identifying as a “full-time athlete” were significant predictors of recent drug use. The study found that one-third of the athlete sample had been offered or had the opportunity to use illicit drugs in the past year; despite this, there was low self-reported drug use. Despite media discussion regarding alcohol use in sport, alcohol was nominated as a drug of concern only by a small proportion of athletes, and further research investigating this issue may be warranted [11018].
One study aimed to determine through a questionnaire applied to interviewers, the current or past use of anabolic androgenic steroids (AAS), as well as other hormones, and other medicines, food supplement and illicit drugs among strength training apprentices in the city of Porto Alegre, RS. It was interviewed 288 subjects draw from a sample of 13 gyms. The prevalence of current and past use of AAS was about 11 percent (32/288), other hormones 5 percent (16/288) and other medicine 4 percent (12/288). The most used AAS were nandrolone and stanozolol; the other hormones were gonadotropin, triiodothyronine (T3). The most frequent side-effects were behavioral such as humor oscillation, irritability and hostility, and endocrine disturbances such as acne and increased or decreased libido. When analyzed together with other hormones in a variable named "hormonal agents" (AH), AAS presented a statistical difference among genders considering that the most frequent use of hormones occurred among men and those who consume food supplements. The comparison of these findings to other national and international results is difficult due to the epidemiological design. Even if it is considered, the observed prevalence suggests that preventive attitudes as well as special care in the orientation and education of this population must be taken [07036].

Different sports

Prevalence of use depending on type of sports

Prior research shows that college athletes have higher rates of substance use, especially alcohol, than do college students who are not involved in athletics. To augment the literature, the author sought to determine which sports/teams are at the greatest risk for substance use. The author used data from the 1999 Harvard School of Public Health College Alcohol Study, a national survey of college and university students in the United States. Findings indicated that male hockey and female soccer athletes were the most likely to report substance use and that male basketball and cross-country/track athletes reported lower levels of substance use. There is variation in substance use on the basis of sport/team affiliation, and future researchers should examine why certain groups of athletes have higher rates of substance use [07037].

Correlation to selected socio-demographic, health-related, and sports-related predictors

Conducted researches recognize various risk factors, as well as protective factors against doping behaviour in different sports i.e. sports disciplines or activities. The main goal of one research was to identify the correlation between selected socio-demographic, health-related, and sports-related predictors with doping factors in three different types of sports, which are (1) highly energetic demanding sports (weightlifting), (2) highly technical demanding sports (racquet sports), and (3) highly tactical demanding sports (sailing). The research consisted of three separate studies, each one of them researching one of the sports. The sample of subjects included altogether 293 athletes, senior level competitors (older than 18 years of age). In total, the sample comprised three homogenous sub-samples, as follows: athletes in highly energetic demanding sports (weightlifters and power lifters; n=27), athletes in highly technical demanding sports (table tennis, tennis and badminton players; n=188), and athletes in highly tactical demanding sports (sailing; n=78). The first study involved weightlifters where it should be pointed out the existence of high doping behaviour In this study, religiousness was interpreted as the most significant protective factor against doping behaviour, while
sports factors are not found to be significantly related to doping. The study involving racquet
sport athletes suggests a high risk of doping behaviour among those athletes who observe
doping behaviour in their sport. It was noticed low levels of athletes' trust in their coaches'
and physicians' opinions on doping issues. This is an issue which should be researched in
the future, because the underlying cause has not been studied as yet. Briefly, it seems that
either the athletes are not convinced of their coaches'/physicians' expertise regarding doping
issues, and/or they do not believe in their good intentions. It is particularly important, as the
previous research has shown that with the increased trust in coaches and physicians, the
chance that an athlete will use doping decreases. As expected, it is characteristic for sailing
that it has a low likelihood of potential doping behaviour, although the consumption of dietary
supplements is high. Substance abuse in sports spreads beyond those that enhance athletic
performance. All of these issues should be studied in more detail in the future and, if
appropriately validated, incorporated into anti-doping intervention programs [13031].

Professional ballet dancers

One study investigated substance use and misuse among 16 female and 9 male Croatian
ballet professionals in 2008 using an original questionnaire. It was analyzed social, personal,
activity- and training-related, and educational factors, and criteria such as: binge alcohol
drinking, cigarette smoking, appetite suppressant consumption, analgesic use, and actual
and potential "doping" habits. Frequency tables and rank-order correlation were calculated.
More than one third of the male dancers reported binge drinking, while 20 percent of the
females smoked more than a box of cigarettes per day. Almost 25 percent of these dancers
would use "doping" if it will ensure successful ballet performance, regardless of negative
health consequences. In males, the risk of potential "doping" behavior increased with age. In
females, education level was negatively related to cigarette smoking, but positively correlated
to potential "doping" habits and behavior. In both genders, religiousness was the factor
negatively related to potential "doping" behavior and belief that "doping" exists in
professional ballet. Results suggest that there is evident need for more specific medical
and/or psychological services in professional ballet [10318].

Track and field

To document the use of prescribed medication and nutritional supplements in female and
male junior, youth, and adult track and field athletes depending on their sports discipline
analysis of 3,887 doping control forms undertaken during 12 International Association of
Athletics Federations World Championships and 1 out-of-competitions season in track and
field was performed. There were 6,523 nutritional supplements (1.7 per athlete) and 3,237
medications (0.8 per athlete) reported. Nonsteroidal anti-inflammatory drugs (NSAIDs; 0.27
per athlete, n=884), respiratory drugs (0.21 per athlete, n=682), and alternative analgesics
(0.13, n=423) were used most frequently. Medication use increased with age (0.33 to 0.87
per athlete) and decreased with increasing duration of the event (from sprints to endurance
events; 1.0 to 0.63 per athlete). African and Asian track and field athletes reported using
significantly fewer supplements (0.85 vs 1.93 per athlete) and medications (0.41 vs 0.96 per
athlete) than athletes from other continents. The final ranking in the championships was
unrelated to the quantity of reported medications or supplements taken. Compared with
middle-distance and long-distance runners, athletes in power and sprint disciplines reported
using more NSAIDs, creatine, and amino acids, and fewer antimicrobial agents. It was
concluded that the use of NSAIDs in track and field is less than that reported for team-sport
events. However, nutritional supplements are used more than twice as often as they are in
soccer and other multi-sport events; this inadvertently increases the risk of positive results of
doping tests [10018].
Football

Big sports events like the 2008 European Football Championship are a challenge for anti-doping activities, particularly when the sports event is hosted by two different countries and there are two laboratories accredited by the World Anti-Doping Agency. This challenges the logistics of sample collection as well as the chemical analyses, which must be carried out timeously. In the paper it was discussed the handling of whereabouts information for each athlete and the therapeutic use exemption system, experiences in sample collection and transportation of blood and urine samples, and the results of the chemical analysis in two different accredited laboratories. An overview of the analytical results of blood profiling and growth hormone testing in comparison with the distribution of the normal population was also presented [09033].

Tennis

The sport of tennis has had its own experiences regarding nutritional supplements and doping. Bohdan Ulihrach and Greg Rusedski are rare examples of athletes who tested positive in a doping case, but were exonerated because they might have used contaminated supplements. The complexity in these cases lies in the fact that the source of their positive tests might have been supplied by the testing authority itself: the Association of Tennis Professionals (ATP). The tribunals, special enquiries, and task forces that studied these cases all named the nutritional supplements provided by the ATP organisation as the most likely source of the nandrolone metabolite. However, many minerals and vitamins that were available on the ATP tour have actually been tested, and the true source has never been confirmed. Because there were more (anonymous) cases within the ATP that were all linked, as demonstrated by an analytical anomaly noticeable in the mass spectrogram of the urine analysis, all of these tennis players have been cleared. Such exoneration by an anti-doping tribunal is extremely rare [07025].

Table tennis

Substance use and misuse was studied in athletes competing at the Slovenian Nationals 2008-2009 (responding rate was 100 percent; 50 males and 29 females; aged 18 years or older). The anonymous questionnaire for studying the use and corresponding educational, socio-demographic, and sport factors was used. More than 90 percent of all the athletes included in our study do not rely on coaches’ and/or physicians’ opinion regarding nutritional supplements and doping. Chi-square test revealed higher prevalence of binge drinking, cigarette smoking, and potential doping behavior in males. In both genders, with the advancement of the sport status, the probability for potential doping behavior increases [10022].

Combined racket sports

Furthermore, it is apparent from annual lab statistics that the doping-testing programmes concentrate the analyses on Olympic rather than in Non-Olympic sports, and on sports which are already associated with doping (e.g. physically demanding sports). For example, in 2009, 26,593 urine and blood samples from track and field athletes yielded 398 total findings of suspicious substances. At the same time, 467 tests of curling athletes resulted in only 14 total findings. The higher absolute number of adverse or atypical analytical findings in “highly physically demanding” track and field athletics than in “less-demanding” curling seems unsurprising (398 vs 14). But, the surprising pattern is evident for aquatics (13,995 total
samples: 156 total findings, or 0.65 \% of samples) in comparison to shooting (24/2,630; 0.91 \% of samples) or archery (14/976; 1.44 \% of samples). Doping in Olympic racket sports was found to range from 0.17 to 0.94 percent in the following order: badminton: 2/1,175, tennis: 17/3,945 and table tennis: 10/1,066. Racket sport games are characterised by a handheld racket that is used to propel a missile between two (or four) players with the purpose of placing the missile in such a position that one player is unable to return it successfully. These sports are also characterised by an area of play that has a specified size, within which the missile must be contained, and by the presence of a net that the missile must pass above on each play. The unique sizes and shapes of the area of play, the height of the net and the type of missile and racket used give character to each variant of the game. Racket sports are unique due to the fact that players can modify the physiological demands of the game by controlling the rest intervals between rallies, games and sets. Average oxygen consumption for single-match duration badminton is reported to be 39.6 ± 5.7 ml/kg/min (73 \% VO_{2\text{max}}); oxygen consumption for table tennis is 26 ± 4 ml/kg/min (47 \% of VO_{2\text{max}}), and consumption for tennis is 29 ± 6 ml/kg/min (51 \% of VO_{2\text{max}}). Of course, average match duration must also be considered. In the 2006 badminton World Championship in Madrid, the average match duration was 33:35 minutes. At the Olympic Games in Beijing, the average table tennis match lasted for 27:31 minutes. The average duration of tennis matches depends on the type of court but typically ranges from 120 to 180 minutes. For example, at Wimbledon in 2005, the average duration of tennis matches was 137 minutes, whereas the average match in the Australian Open that same year lasted for 154 minutes. A major determinant of the outcome of a game is an individual's physical fitness, which can be influenced by SUM. Although SUM is regularly investigated in sports as a whole, SUM is rarely studied in racket sports. Apart from studies dealing with sports and physical activity in youth and related SUM issues in which racket sports (tennis mostly) were not studied systematically, there are only a few papers addressing SUM in Olympic racket sports. Briefly, Kondric it was reported on SUM habits in Slovenian table tennis players. Also, Maquirriain it was analysed offences to the Doping Code committed by tennis players between 2003 and 2009. When studying SUM problems in sports, previous investigations noted that SUM is gender-, sociodemographic-, culture-, and sport-specific and, therefore should be studied accordingly. Apart from the fact that SUM is rarely investigated among racket sports, we determined that these sports would be particularly suitable for our study based on several factors. First, table tennis, tennis and badminton are Olympic Sports that fall directly under WADA jurisdiction and anti-doping legislation. Second, all three sports share similar competitive characteristics as they are all individual sports with no physical contact between opponents. However, these sports are also diverse in terms of physiological demands [11557].

It was studied a total of 188 participants divided into three groups: table tennis players (n=78), badminton players (n=83), and tennis players (n=27). All players were 18 years of age or older and had participated in at least one of the two most recent competitions at the highest national level for their sport (e.g. Slovenian Nationals). The number of tennis players is almost half the size of the other two groups because mature tennis players (+18) are typically professionals and rarely compete in the Slovenian Nationals. SUM and its corresponding educational, sociodemographic, and sport-specific factors were investigated using a previously developed and validated questionnaire for studying SUM. Substance use and misuse data consisted of questions on binge drinking (7-point scale from "I do not drink alcohol" to "I binge a few times a week"), cigarette smoking (7-point scale from "not smoking" to "2+packs daily"), consumption of drugs and opiates (use of different drugs and opiates were inquired after but subjects reported only marihuana and hashish use). Doping factors were evaluated with questions concerning the athlete's opinions on doping practice in their sport (4-point scale from "I do not think doping is used" to "Doping is often"), potential doping habits (4-point scale from "I do not intend to use doping" to "I'll use it if assured it will help me"), and trust in their coach regarding doping and trust in their physician regarding doping
Nutritional supplements were reported separately and included the consumption of isotonics, proteins, carbohydrates, and recovery supplements. Additionally, we asked athletes to indicate who advised them to use NS with the coach, physician, friend, and self-decided as choices. Badminton players reported the highest level of binge drinking. Statistically significant differences were found in cigarette use, but this was mostly because of the high proportion of smoking cessation among badminton and tennis players. No significant differences were found for doping factors, although 1 in 10 badminton players said they would use doping if they were assured that it will improve their performance without any negative health consequences. Data revealed that most female athletes do not trust their own coaches regarding doping issues (mistrust in coaches ranges from 61% in badminton to 83% in tennis), whereas their trust in their physicians' opinions on the same issue was somewhat higher. Approximately 50% of females declared no use of nutritional supplementation. Female racket sport athletes reported using vitamins, minerals and isotonics almost exclusively. The reported use of other substances was very low among tennis players who were mostly advised by coaches or medical professional to consume nutritional supplements, whereas athletes in table tennis and badminton were not. In male athletes, there was no statistically significant difference between players of different racket sports in their perception of doping behaviours. One-third of the studied athletes thought that doping is used in their sport. Sixty to 90% of the male athletes reported that they do not trust coaches' or medics' opinions regarding doping issues and problems. A minority of athletes (10% in badminton, 15% in table tennis and 24% in tennis) indicated that they would use doping if assured that it would help them achieve competitive results without any negative health consequences. However, 5 to 10% of the studied male athletes declared that they might potentially dope regardless of the possible health hazard. Nutritional supplement use was mostly frequently reported by tennis players, followed by badminton and table tennis. More than half of the tennis and badminton players were formally advised by a coach or medical professional to use nutritional. Players in this sample reported varied levels of substance use with binge drinking and cannabinoids use reaching a concerning level with 40 and 30% binge drinking and 16 and 21% using cannabinoids, form males and females respectively. This level of use is comparable with the national statistics as detailed below. Tobacco use, in contrast, appears to be a male phenomenon. It was revealed an overall trend among racket sport athletes showing that the most significant overlap between self-reported use of these substances exist between binge drinking and opioid use, reaching 11 percent (males) and 7% percent (females). More precisely athletes who reported either binge drinking or opioid use were more likely to also use the other. Although these activities take place outside of the controlled sporting arena, the extent to which athletes reported these activities is concerning. Almost half of the athletes in the sample reported NS use. Interestingly, there was very little overlap between current NS use and willingness to use prohibited substances. The majority of those who indicated that they would be willing to use doping did not report current supplement use. Even more disturbing is the fact that more than 80% of the tennis and table tennis players and 60% of the badminton players report not trusting physicians' opinions on doping issues. Additionally, sports physicians are mostly focused on orthopaedic and locomotor injuries in sports and are rarely systematically educated regarding nutritional supplementation and doping. Consequently, athletes do not consider them to be reliable, leading to low levels of trust regarding the information they provide on doping issues. These problems must not be overlooked because those who trust physicians' and coaches' opinions on doping are less prone to doping behaviour in the future.

**Biking**

The human physiological system is stressed to its limits during endurance sports competition events. It was described a whole body computational model for energy conversion during...
bicycle racing. About 23 percent of the metabolic energy is used for muscle work, the rest is converted to heat. It was calculated heat transfer by conduction and blood flow inside the body, and heat transfer from the skin by radiation, convection and sweat evaporation, resulting in temperature changes in 25 body compartments. It was simulated a mountain time trial to Alpe d'Huez during the Tour de France. To approach the time realized by Lance Armstrong in 2004, very high oxygen uptake must be sustained by the simulated cyclist. Temperature was predicted to reach 39°C in the brain, and 39.7°C in leg muscle. In addition to the macroscopic simulation, it was analysed the buffering of bursts of high adenosine triphosphate hydrolysis by creatine kinase during cyclical muscle activity at the biochemical pathway level. To investigate the low oxygen to carbohydrate ratio for the brain, which takes up lactate during exercise, it was calculated the flux distribution in cerebral energy metabolism. Computational modelling of the human body, describing heat exchange and energy metabolism, makes simulation of endurance sports events feasible [11561].

Imagine a medicine that is expected to have very limited effects based upon knowledge of its pharmacology and (patho)physiology and that is studied in the wrong population, with low-quality studies that use a surrogate end-point that relates to the clinical end-point in a partial manner at most. Such a medicine would surely not be recommended. The use of recombinant human erythropoietin (rHuEPO) to enhance performance in cycling is very common. A qualitative systematic review of the available literature was performed to examine the evidence for the ergogenic properties of this drug, which is normally used to treat anaemia in chronic renal failure patients. The results of this literature search show that there is no scientific basis from which to conclude that rHuEPO has performance-enhancing properties in elite cyclists. The reported studies have many shortcomings regarding translation of the results to professional cycling endurance performance. Additionally, the possibly harmful side-effects have not been adequately researched for this population but appear to be worrying, at least. The use of rHuEPO in cycling is rife but scientifically unsupported by evidence, and its use in sports is medical malpractice. What its use would have been, if the involved team physicians had been trained in clinical pharmacology and had investigated this properly, remains a matter of speculation. A single well-controlled trial in athletes in real-life circumstances would give a better indication of the real advantages and risk factors of rHuEPO use, but it would be an oversimplification to suggest that this would eradicate its use [13063].

The 1990-2010 period in professional cycling is labeled by some as the epo epidemic. Surprisingly, performance enhancement by epo and blood doping is not that clear-cut for endurance athletes, leading to the question whether doping indeed strongly influenced cyclists' performances from the 1990s onwards. It was examined the records (1947-2008) of the Tour de France, Giro d'Italia, and Vuelta a España (n=181) and assessed the time it took riders to win the race. The findings revealed normally distributed performances and linear and quartic relationships in victors' performances over time that correspond with Brewer's (2002) sociohistorical analysis of professional cycling suggesting that effects of the epo epidemic on professional cyclists' achievements may be overestimated [11562].

Professional cycling has suffered from a number of doping scandals. The sport's governing bodies have responded by implementing an aggressive new antidoping program known as the biological passport. Cycling's biological passport marks a departure from traditional antidoping efforts, which have focused on directly detecting prohibited substances in a cyclist's system. Instead, the biological passport tracks biological variables in a cyclist's blood and urine over time, monitoring for fluctuations that are thought to indirectly reveal the effects of doping. Although this method of indirect detection is promising, it also raises serious legal and scientific concerns. Since its introduction, the cycling community has debated the reliability of indirect biological-passport evidence and the clarity, consistency, and
transparency of its use in proving doping violations. Such uncertainty undermines the legitimacy of finding cyclists guilty of doping based on this indirect evidence alone. Antidoping authorities should address these important concerns before continuing to pursue doping sanctions against cyclists solely on the basis of their biological passports [11563].

To understand why pharmacological enhancements should never be allowed in cycling, you need to understand that all spectator sports thrive by selling simple stories to their fans. The cycling story is that, with great talent and after years of training, the best riders ride faster than the others at the very limits of natural human endurance. In the Tour de France, this story has been told and retold for 100 years – over stages, tours and careers. It describes the overall winner, the best hill climber and even the failed solo breakaway. How could cycling’s story survive if pharmacological enhancements were allowed? Even if the time comes when botulinum toxin injections are available from vending machines, doping should never be allowed in cycling [07038].

Using a psychosociological approach, the purpose of one study was to identify and understand the use of doping substances by young elite cyclists. Semi-structured interviews were conducted with young cyclists who were hoping to find a professional team and cyclists who had recently become professional. All of the young cyclists interviewed took nutritional supplements and believed that they improved their performance, which has been shown by other scholars to be a risk factor for doping. These cyclists believed that doping at the professional level in cycling was acceptable but did not approve of it at the amateur level. They were attracted to doping; they were open to using doping substances themselves if it was the key to continuing their cycling career, but only after they became professional. Team staff, doctors, parents and friends helped to create a “clean” environment that prevented the young cyclists from doping before becoming professional. The more experienced cyclists, who doped or used to dope, transmitted the culture of doping to the young cyclists, teaching them doping methods and which substances to use. This study could help to improve prevention and help to detect doping, as it is clear that doping behaviors begin at the amateur level [10019].

After recent scandals in cycling involving doping, it has been asserted that top-level cycling is impossible without pharmacological support. An important prerequisite for successfully completing the Tour de France is maintaining energy balance. To compensate for the daily caloric expenditure of 23-25 MJ, conventional food must be supplemented with liquid food. Quick administration of liquid carbohydrates is essential for optimal recovery of glycogen stores in the liver and skeletal muscle. Androgenic anabolic steroids are a frequently used form of doping. In endurance sports, these drugs have not been shown to affect endurance performance, and there is little evidence to suggest that they enhance recovery. Although epoetin use can increase maximal oxygen uptake, its effects on maximal power output are less pronounced than what is generally assumed. A relationship between haemoglobin concentration and sport performance has not been proved. It has been found that growth hormone rather has a negative than a positive influence on the sport performance. The doping problem is due in part to superstition, hearsay and insufficient knowledge among the athlete's support personnel, which frequently leads to medical malpractice in sport. Education and quality control for sport professionals, including sports physicians, may help to control the doping problem [06029].

In 2006, a couple of professional cycling teams initiated their own testing programs. The objective of one study was to describe fluctuations in commonly measured blood parameters among top-level riders. From 2006 to 2007, a total of 374 blood samples and 287 urine samples were obtained from 28 elite, male cyclists. Blood was analyzed for hematocrit (Hct), hemoglobin concentration ([Hb]) and % reticulocytes. Seventy-six percent of all samples
were collected out-of-competition (OOC). From December 2006 to September 2007, the average Hct and [Hb] decreased by 4.3 percent point and 1.3 g/dL, respectively. After the end of the competitive season, the values increased back to baseline levels. During the Tour de France, the [Hb] decreased by 11.5 percent, with individual decreases ranging from 7.0 to 20.6 percent. Hct and [Hb] values were lower in-competition (40.9 % and 14.1 g/dL) compared to out-of-competition (43.2 % and 15.0 g/dL) and pre-competition (43.5 % and 14.9 g/dL). The results suggest that when interpreting blood sample results in an anti-doping context, the sample timing (OOC, pre- or in-competition) and time of year should be kept in mind [08033].

The protection of the health of athletes is one of the three criteria taken into account when registering a substance in the World Anti-Doping Agency prohibited list. Nevertheless, in elite-level cycling, banned substance use is widespread. The present research adopted a psychological approach to examine how or whether perceived health risks influence elite-level cyclists' decisions to use banned substances. Sixteen semi-structured interviews were conducted with cyclists hoping to join a professional team (n=6), neo-professional cyclists (n=2), and former professional cyclists (n=8). Although an evolution was observed in the organization of doping and perceptions of doping over the last decade, the perceived health hazards did not influence, most of the time, decisions to use banned substances among the sample of cyclists. There was a systematization of exogenous substance use in the cycling environment and a trivialization of the side effects of the banned substances. Finally, younger cyclists were not concerned about the long-term health consequences of banned substances; they were more focused on the short-term performance-enhancing benefits. There is a need to implement more effective preventive programs to change athletes' attitudes toward doping and its health risks [11015].

In 1998, the Festina scandal at the Tour de France provided the first proof of widespread doping in professional cycling. This doping scandal marked the end of team-organized doping in professional cycling and ushered in a new period marked by the increasing implementation of anti-doping measures. One article evaluates the impact of the anti-doping rules and tests instituted since the Festina scandal. It was adopted a psychosocial approach to analyze the organization of doping and the development of doping attitudes and practices in high-level cycling. Sixteen cyclists were interviewed, of which eight were young, current cyclists and eight were former cyclists who became professionals before the Festina scandal. The results show that although the fight against doping in the last decade has reduced doping use in high-level cycling, anti-doping measures have also had unexpected effects. The fight against doping in cycling is not over [13064].

**Indirect evidence of effects**

Since doping improves athletic performance, anti-doping policies should have the opposite effect. One analysis examined whether changes in the speed of major cycling races reflect recent anti-doping efforts. Average speeds of 5th place finishers of the Tour de France, Giro d'Italia, and Vuelta a España cycling races were obtained for the period 1990-2009. Between 1990 and 2004, the average speed had been significantly increasing by 0.16 km/h per year. In a downturn, since 2004, the average speed has significantly decreased by 0.22 km/h per year. The slowing down of professional cycling races is compatible with the hypothesis that recent anti-doping efforts in professional cycling have curbed the use of performance-enhancing substances [10020].

**Tour de France 2006**

The saga of the 2006 Tour de France is disappointing. Cycling fans have always thought that the greatest cycling competition in the world, next in terms of audience and media involvement to the Olympics and the football World Cup, was an endurance race in which
cycling performance and racing ability would have been the main requisites for wearing the yellow jersey in Paris. However, recent developments have profoundly altered this scenario, transforming the Tour into an elimination race. Just 24 h ahead of the prologue start in Strasbourg, nine riders from five teams were ruled out of the race, suspected of doping by an international probe based on blood transfusions involving more than 200 athletes from different sporting disciplines. This huge doping scandal, conventionally known as the “affair Fuentes”, began in an ordinary apartment in Madrid, where the Spanish police discovered the covert structure of an international performance-enhancement business; they seized more than 200 blood bags, along with doping records and several other doping substances. The investigators were able to match code names of athletes with their highly detailed doping records. In the prosecution, the American rider Floyd Landis, who wore the 2006 yellow jersey in Paris, tested positive for abnormal concentrations of testosterone after winning stage 17 and is now set to lose his title. If this were not enough, the runner-up Oscar Pereiro of Spain, who would probably have been awarded the yellow jersey, is under investigation for testing positive for the banned substance salbutamol! Metabolites of this drug, often prescribed for asthma, were discovered by the French antidoping body, AFLD, in Pereiro's urine sample after stages 14 and 16. Although the authority of the AFLD is limited to French soil only, Pereiro may not be allowed to take part in the 2007 Tour and could be stripped of second place in the 2006 race until he has been definitely cleared of this allegation. These disappointing events warrant further consideration. Firstly, the unexpectedly high number of cyclists still involved in doping cases clearly indicates that the strict control strategies adopted by sports federations and antidoping organisations will probably not modify this trend. It must be assumed that the athlete's desire to win, along with the vision of glory and money, will always overcome the risk of being found guilty. Different and multifaceted strategies are needed, which should be based on preventing rather than identifying or criminalising doping. Once the young athlete becomes familiar with unfair practices, it is difficult to modify this attitude. It is clear that controls, suspensions and civil and penal sanctions are not reliable deterrents [07030].

Floyd Landis

Another question is: are antidoping controls absolutely reliable? This is probably the foremost question that should be answered. In the specific case of the 2006 Tour de France, former winner Floyd Landis has denied ever taking performance-enhancing drugs. His key defence is the contention that the National Laboratory for Doping Detection in Paris made technical and analytical errors. In testosterone cases, the first level of testing is to measure the ratio of testosterone to epitestosterone (T/E ratio). A ratio higher than 4:1 triggers a further test based on the measurement of trace isotopes of carbon in the urine sample. The documents Landis has posted show that the laboratory measured the T/E ratio in his urine sample at least three times, producing three different results: 4.9:1, 5.1:1 and 11.4:1. A variety of additional reasons were offered for the failed test: one was that he drank whisky and beer on the night before the incriminating stage. Additional explanations were dehydration, anti-inflammatory injections for hip pain, and natural metabolism. The third crucial issue is the hullabaloo when an athlete tests positive. Doping cases are not supposed to be made public until they are resolved, but most become public through the media once a positive “A” test is confirmed. There is a tendency for there to be access to confidential information on previous tests of athletes before a definitive result, either positive or negative, is released by the competent sport authority and antidoping organisation. Enormous emphasis was given to the exclusion of the nine riders before the official start of the competition in Strasbourg. On some occasions, these athletes have been judged by the media in advance of the sport authorities and declared guilty on the basis of contradictory evidence, causing enormous human and financial problems and ultimately jeopardising their careers. None of these athletes has yet been charged. On the contrary, some have been completely cleared and are free to race. Landis criticised officials from the UCI and WADA for announcing the results of
his test without analysing the second sample, as normally takes place in the anti-doping procedure. He also claimed that the test was not conducted anonymously, saying he had evidence to prove that laboratory staff had access to the names of the cyclists whose samples were being tested. In the Pereiro case, it appears that the UCI had allowed him to use salbutamol under the therapeutic use exemptions scheme. However, AFLD claim that Pereiro's team did not complete the relevant medical forms. Regardless of the definitive conclusion of the cases, all these riders have been designated as doping athletes by the media, with potential detrimental economic and moral consequences. This is unacceptable, considering that a definitive test result may be unavailable for several months after the opening of the case [07030].

**Germany**

Doctors and politicians in Germany are demanding stricter laws for sports medicine after three doctors were discovered to have given performance enhancing drugs to professional cyclists. Two of the three doctors, from Freiburg University Hospital, were suspended in 2007 by the university when they admitted doping professional cyclists. In separate statements, Lothar Heinrich and Andreas Schmid said that they gave the blood cell stimulating hormone erythropoietin to the cycling team of the German telephone company Deutsche Telekom, now T-Mobile. The confessions were made after several cyclists had recently publicly admitted to taking drugs for performance and accused the doctors of involvement. The incident had spread to amateur ranks a few days later when another doctor from the Freiburg sports medicine department who had worked several times for German Olympic teams (not only cyclists) admitted giving performance boosting testosterone to riders as far back as 1980. The third doctor, Georg Huber, was suspended by both German cycling authorities and the University of Freiburg. Two former cyclists had triggered his resignation, naming him in a newspaper story and claiming that doping in amateur German cycling was widespread long before team Telekom. The German Sports Medicine Association decided that all its members who look after athletes, professional and lay, must sign a statement distancing themselves from any doping. In Germany 11,000 doctors are qualified in sports medicine [07039].

**Bodybuilding**

Bodybuilding is a sport in which competitors are judged on muscular appearance. One case study tracked a drug-free male bodybuilder (age 26-27 years) for the 6 months before and after a competition. The aim of one study was to provide the most comprehensive physiological profile of bodybuilding competition preparation and recovery ever compiled. Cardiovascular parameters, body composition, strength, aerobic capacity, critical power, mood state, resting energy expenditure, and hormonal and other blood parameters were evaluated. Heart rate decreased from 53 to 27 beats/min during preparation and increased to 46 beats/min within 1 month after competition. Brachial blood pressure dropped from 132/69 to 104/56 mmHg during preparation and returned to 116/64 mmHg at 6 months after competition. Percent body fat declined from 15 to 5 percent during preparation and returned to 15 months during recovery. Strength decreased during preparation and did not fully recover during 6 months of recovery. Testosterone declined from 9.22 to 2.27 ng/mL during preparation and returned back to the baseline level, 9.91 ng/mL, after competition. Total mood disturbance increased from 6 to 43 units during preparation and recovered to 4 units 6 mo after competition. The case study provides a thorough documentation of the physiological changes that occurred during natural bodybuilding competition and recovery [13062].

**Dancesport**
DanceSport is the competitive form of ballroom dancing, and even though it has more participants worldwide than ballet and modern dance, there is less peer-reviewed research. A review was conducted to identify all relevant literature to help researchers and clinicians gain an enhanced understanding of dancesport. Eight databases were searched, with 34 articles found in topics including participation motives, psychology, exercise physiology, fitness training, injuries and injury prevention, biomechanics, menstrual dysfunction, and substance use. The results indicate that researchers have been inconsistently recording and reporting anthropometric and dancesport data; for example, 31 studies separated participants by gender, 21 included the competition classification of dancers, 19 reported which style of dancesport participants competed in, and 13 described the participants as a dance couple. Common injuries affected the neck, shoulder, spine, knee, lower leg, and foot. Dancesport is in the very heavy to extremely heavy category in energy expenditure (mean heart rate: male 175.2 ± 10.7, female 178.6 ± 8.6 bpm) and utilizes both aerobic and anaerobic energy systems. Alpha-beta and heart rate variability intervention techniques are reported to successfully enhance performance in dancers. Dancesport participants also appear less likely to smoke cigarettes, but have little knowledge about anti-doping rules. During events, professionals danced farther (30 m) and faster (0.3 m/sec) than junior dancers. Female competitors were more likely to be eumenorrheic. Dancesport is a physically and mentally demanding competitive sport, but there is a need to standardize measurements in future studies to allow comparison [13065].

Recreational sports

Substance abuse has become increasingly widespread among athletes at sub competitive and recreational level, due in part to the lack of controls in form of doping tests. Hypertension and the many other side effects related to the illicit use of prescription drugs pose a substantial but often underestimated threat to public health. The symptoms are recognized late and are then mostly repressed or misjudged. Since the abuse is concealed to the doctor when help is finally sought, it results in extensive and expensive tests that can seldom lead to an effective treatment. Two case reports were presented to elaborate on this issue [10023].

Prevalence of use by fitness centre members

Studies on the use of performance enhancing drugs (PED) in fitness centres rely predominately on conventional survey methods using direct questioning. However, research indicates that direct questioning of sensitive information is characterized by under-reporting. The aim of one study was to contrast direct questioning of different types of PED use by Dutch fitness centre members with results obtained with the Randomized Response Technique (RRT). Questionnaires were conducted among members of fitness centres. PED were classified into the following categories: anabolic steroids, prohormones, substances to counteract side-effects, growth hormone and/or insulin, stimulants (to reduce weight), and miscellaneous substances. A total of 718 athletes from 92 fitness centres completed the questionnaire. The conventional method resulted in prevalences varying between 0 and 0.4 percent for the different types of PED with an overall prevalence of 0.4 percent. RRT resulted in prevalences varying between 0.8 and 4.8 percent for the different types of PED with an overall prevalence of 8.2 percent. The overall prevalence of the two survey methods differed significantly. The current study showed that the conventional survey method using direct questioning led to an underestimation of the prevalence. Based on the RRT results, the percentage of users of PED among members of fitness centres is approximately 8.2 percent. Stimulants to lose weight had the highest prevalence, even higher than anabolic steroids. The key task for future preventive health work is to not only focus on anabolic steroid use,
but also include interventions focusing on the use of stimulants to lose weight [13032].
THEORETICAL ASPECTS ON DOPING-TESTING

Overview

Testing results show that cheating athletes alter their drug abuse behaviors to avoid detection. For example, when a urinary test was developed for recombinant EPO, athletes changed doses and routes of administration to shorten the detection window. This is confirmed by information obtained from athlete blogs and government investigations. Thus, continued research into innovative test methods and strategies is necessary to deter drug abuse. Perhaps more importantly, the scientific contributions from antidoping research go beyond the field itself to affect other scientific disciplines, such as analytical chemistry, endocrinology, genetics, laboratory medicine, pharmacology, physiology, and sports medicine. More collaborative research with experts in these fields should enhance the rate of discovery of innovative approaches to solve doping problems. It is critical to recognize that new tests and methods must be fit for purpose. The tests and methods developed must make the transition into routine testing use. Thus, antidoping research is yet another field where translational research is a key component to applying new technology to solve problems [12006].

Doping in competitive sport is a peculiar phenomenon. The need for performance enhancement is emerging from the desire to maximise or even expand human capacities, and by doping to gain competitive edge in a situation where athletes’ performances are judged on two levels simultaneously: athletes compete against the opponents in situations where typically only one can win and are also automatically entered into a quest for breaking records which opens up the competitive arena including all from the past. From the array of substances with performance enhancing properties, a wide range represents fully acceptable means, whilst a defined set is prohibited by some authorities. In general terms, and for the purpose of this paper, the term “doping” refers to the latter category. From the system’s point of view, the current detection-based anti-doping policy does not automatically eradicate the use of prohibited substances, but rather presents a barrier with a quantifiable risk of being caught. It is easy to see that such a system leads to two primary strategies employed by the athletes [13016]:

- compliance, driven by respect for the rules, desire to compete clean or fear of being caught
- circumvention, i.e. outwitting the system by using not-yet-known or undetectable substances, masking or simply betting on chances of not being selected for testing

In order to design effective anti-doping measures, gaining insight into the driving forces behind doping behaviour is vital. Whilst the doping decision is very complex involving moral, economical and health considerations, theoretically this complexity can be distilled into a simple decision situation where pros and cons are weighed against each other in the context of unknown but assumed choices of the opponents. Based on the assumption that eradicating doping from sport requires a significant change in this decisional balance; by formulating and formally solving multi-player doping games, we aim to make a contribution to developing a better understanding of doping decisions [13016].

Theories on laboratory testing

A well-planned testing strategy for anti-doping organizations is a key element in order to
obtain representative samples and a correct biomatrix for efficient doping control, but the contribution of anti-doping laboratories is also fundamental to the overall success. Analytical methods may be needed to reveal potential masking attempts and fraud which could take place outside the sample collection session (e.g. haemodilution) to complement carefully supervised sample collection procedures. As pre-analytical processes, laboratories verify the authorized origin, evaluate the transport time and conditions, and also verify the identity and integrity of the biological samples at the time of receipt. In the actual analytical processes, fit-for-purpose methods and instrumentation are used for the detection of prohibited substances which are specified by WADA. The majority of the prohibited substances are exogenous, i.e. they are not naturally present in the body. In these cases, qualitative identification of the substance and/or its metabolite is sufficient for establishing an anti-doping rule violation. In the prohibited list, however, there are substances such as testosterone, erythropoietin (EPO), growth hormone (GH), and insulin-like growth factor 1 (IGF-1), which are available as pharmaceutical products for clinical purposes, but which are also produced endogenously. In these cases the analytical methods and result interpretation should be capable of discriminating between exogenous source and clinical or pathological conditions. Implementation of gas chromatography-combustion-isotope ration mass spectrometry (GC-C-IRMS) has enabled the analysis of endogenous anabolic steroids and their misuse, whereas methods based on electrophoretic techniques (IEF-PAGE and SDS-PAGE) and immunoassays have provided tools to detect large biomolecules, the concentration of which is still often below the sensitivity limits of mass spectrometric approaches. Research projects within these special topics require active and devoted scientists, and also provide significant improvements for routine analysis in the form of enhanced detection times and by facilitating the result evaluation [13078].

In general terms, technical improvements, for example enhanced chromatographic and mass spectrometric resolution, higher sensitivity, scan-to-scan polarity switching, and more powerful data analysis allow for faster, more sensitive, and more reliable screening strategies. According to the prevailing International Standard for Laboratories (ISL), the doping control samples can be re-analyzed within a time period of up to eight years following the reporting of the original result. This is particularly interesting when new instrument technologies are introduced in the analysis routine for the purpose of monitoring new drug-derivatives or new chemical entities emerging onto market, and also when new long-term excreted metabolites are reported for already known prohibited substances. Although the flexibility of the ISL increases the risk of an adverse analytical finding, it also requires adequate sample storage condition and knowledge on the long-term effects on various analytes. The list of prohibited substances is updated annually; active research and up-to-date analytical processes are mandatory in order to reveal the high-risk emerging compounds and to target the appropriate sample matrix. The laboratories’ assignment is to search for and to adapt the applicable parts of modern methodologies to the anti-doping context. In the success of these research projects and with efficient implementation of new techniques, international and interdisciplinary co-operation plays a major role. Similar to any branch of applied sciences, in doping control the science is not for science’s sake only. With respect to routine analysis and service to the customers, these improvements should be also practical, prompt, flexible, and cost-effective [13078].

Homo economicus: pay-offs and sanctions

Lay explanation for doping rests on the assumption that for those who engage in doping practices “winning is everything”, hence they use prohibited methods to ensure this outcome. This approach assumes that the choice is purely rational-economic and responds to externally imposed incentives and deterrents. As long as the perceived advantages from using doping constitute a far better scenario than any scenario with no doping, factoring in
the risk of being detected and its consequences, the only logical action is to dope. Contrary to the detection-sanction based deterrence methods, economical models recognise the importance of the prize structure, considering both benefits and costs. Prize structures can also be manipulated so the monitoring cost is kept low. These models suggest that eradicating doping would require changes in the external factors, such as increased dis-utility (including the chance of being detected and its consequences), decreased utility (reduced pay-off) or some combination of the two. In reality, it is unlikely that such change will be effectively implemented. Based on a review of economical models of doping, posit that rank order contests such as sport competitions with highly skewed prize structures inevitably lead to undesirable practices (i.e. doping) players may employ in order to enhance their chances to finish in positions with high pay-off. A follow-up study with empirical data from thirteen different athletic events reinforced the assumption that increase in competition increases doping, and consequently lead to equitable sanctions. The nature of doping makes policing difficult and leads to an imperfect but costly monitoring system, where externally imposed sanctions may inadvertently motivate doping use by indicating that doping is widespread, hence the need for harsh sanctions [13016].

**Aim of anti-doping**

The aims of the World Anti-Doping Programme and the Code are to care for the athlete’s fundamental right to participate in doping-free sport and thus promote health, fairness and equality for athletes worldwide, and to guarantee harmonized, coordinated and effective anti-doping programmes at the international and national level relating to the detection, deterrence and prevention of doping [13017].

**The Goldman dilemma**

Discussions of doping often report Goldman’s sensational results that half of the elite athletes asked would take a drug that guaranteed sporting success which would also result in their death in 5 years’ time. There has never been any effort to assess the properties of the “Goldman dilemma” or replicate the results in the post World Anti-Doping Agency context. This research evaluated the dilemma with contemporary elite athletes. Participants at an elite-level track and field meet in North America were segregated into an interview or online response. After basic demographics, participants were presented with three variant “Goldman dilemmas” counter-balanced for presentation order. Only 2 out of 212 samples (119 men, 93 women, mean age 20.89) reported that they would take the Faustian bargain offered by the original Goldman dilemma. However, if there were no consequences to the (illegal) drug use, then 25/212 indicated that they would take the substance (no death condition). Legality also changes the acceptance rate to 13/212 even with death as a consequence. Regression modelling showed that no other variable was significant (gender, competitive level, type of sport) and there was no statistical difference between the interview and online collection method. It was concluded that Goldman’s results did not match this sample. A subset of athletes is willing to dope and another subset is willing to sacrifice their life to achieve success, although to a much lesser degree than that observed by Goldman. A larger scale online survey is now viable to answer important questions such as variation across sports [13018].

**Forensic intelligence in anti-doping**
Today's approach to anti-doping is mostly centered on the judicial process, despite pursuing a further goal in the detection, reduction, solving and/or prevention of doping. Similarly to decision-making in the area of law enforcement feeding on Forensic Intelligence, anti-doping might significantly benefit from a more extensive gathering of knowledge. Forensic Intelligence might bring a broader logical dimension to the interpretation of data on doping activities for a more future-oriented and comprehensive approach instead of the traditional case-based and reactive process. Information coming from a variety of sources related to doping, whether directly or potentially, would feed an organized memory to provide real time intelligence on the size, seriousness and evolution of the phenomenon. Due to the complexity of doping, integrating analytical chemical results and longitudinal monitoring of biomarkers with physiological, epidemiological, sociological or circumstantial information might provide a logical framework enabling fit for purpose decision-making. Therefore, Anti-Doping Intelligence might prove efficient at providing a more proactive response to any potential or emerging doping phenomenon or to address existing problems with innovative actions or/and policies. This approach might prove useful to detect, neutralize, disrupt and/or prevent organized doping or the trafficking of doping agents, as well as helping to refine the targeting of athletes or teams. In addition, such an intelligence-led methodology would serve to address doping offenses in the absence of adverse analytical chemical evidence [13079].

Colored illicite tablets

The necessity of specific, confirmatory tests in the identification of seized illicit products was highlighted by the analysis of eighteen heart shaped, blue tablets confiscated by Police at a street control in the North East of Italy. The tablets responded as amphetamines to a preliminary color test (Marquis); a subsequent, confirmatory assay by gas chromatography-mass spectrometry revealed the presence of two anabolic androgen steroids (AAS), methandienone and methyltestosterone, in concentration of 1.7 and 1.5 mg respectively per tablet; no trace of amphetamine-like or nitrogen containing compounds was found. The observed orange coloration was due to the reaction of concentrated sulphuric acid, contained in the Marquis reagent, with the delta(4) C-3 keto group of steroids. The two AAS, banned under the world antidoping code, are not considered as psychoactive drugs of abuse in most countries, although their trafficking may entangle severe public health concerns [13083].

Theories on doping in sports

Human behavior occurs within a system, and as such, so do behaviors in performance-related domains (e.g. athletics, academics). Doping is a performance enhancement behavior that can be problematic because of the negative physical and psychological effects associated with the use of some substances and the common argument that doping is unfair. However, doping continues and may be increasing. Because a firm theoretical or empirical understanding of doping does not exist, one article proposed a conceptual, comprehensive, and innovative systemic model of doping behavior. The model is built from relevant empiricism supporting the idea that contemporary doping behavior is a function of systemic transactions between historical doping practices, the present environment, current antidoping interventions, one's genetic makeup, developmental milestones, social factors, and epigenetics [11424].

The fight against doping is a challenging task. Owing to the complexity of the doping phenomenon, simultaneous consideration of physiological, medical, pharmacological, psychological, ethical and systemic factors is required in order to be successful in this endeavor. The need for effective deterrence policy is underscored by the fact that the
The problem of performance enhancements has spread beyond the elite athlete population. It is well documented that groups other than competitive athletes are at risk of using doping agents, especially steroids. Furthermore, medical enhancement of non-sport performance (i.e., quality of life, appearance) appears to be widely acceptable among non-athlete population. For effective deterrence methods, individual, systemic and situational factors that make an athlete or athlete group more susceptible to doping than others should be fully investigated. Traditional behavioral models assume that the behavior in question is the ultimate end. However, growing evidence suggests that in doping situations, the doping behavior is not the end but a means to an end, which is gaining competitive advantage. Therefore, models of doping should include and anti-doping policies should consider attitudes or orientations toward the specific target end, in addition to the attitude toward the tool itself. Data were collected by questionnaires containing a battery of psychological tests among competitive US male college athletes (n=199). Of the 199 athletes, 15 (8%) reported having personal experience with doping and an additional 9 (5%) claimed to have used substances classified as doping for medical reasons. The same figures for current use of performance enhancing substances were lower: 5 (3%) and 1 (1%), respectively. Outcome measures included sport orientation (win and goal orientation and competitiveness), doping attitude, beliefs and self-reported past or current use of doping. A structural equation model was developed based on the strength of relationships between these outcome measures. Whilst the doping model showed satisfactory fit, the results suggested that athletes’ win and goal orientation and competitiveness do not play a statistically significant role in doping behavior, but win orientation has an effect on doping attitude. The structural equation modeling (SEM) analysis provided empirical evidence that sport orientation and doping behavior is not directly related. It was concluded that the considerable proportion of doping behavior unexplained by the model suggests that other factors play an influential role in athletes' decisions regarding prohibited methods. Future research, followed by policy development, should incorporate these factors to capture the complexity of the doping phenomenon and to identify points for effective anti-doping interventions. Sport governing bodies and anti-doping organisations need to recognize that using performance enhancements may be more of a rational, outcome optimizing behavior than deviance and consider offering acceptable alternative performance-enhancing methods to doping.

Despite the increased anti-doping effort, the relative number of adverse analytical findings has not decreased considerably in the past four years (written 2007). The appropriateness of education as a deterrent is questionable as it has been shown that doping specific knowledge is higher among doping users than among their non-user counterparts. While prevention, complemented with detection, will be likely to be the main approach to the doping problem, the ultimate goal for sport governing bodies should be creating policies for a truly effective deterrence. Setting detection aside, there is still a fundamental distinction between prevention and deterrence. It is suggested that prevention (and detection) create an environment where the chances of detection and punishment for using doping are uncomfortably high, hence keep athletes away from employing such means, regardless of their motives. On the other hand, value-based deterrence in its true, perhaps Utopian sense, is associated with the creation of an environment where athletes never feel motivated to use illegal means for performance enhancement.

### Doping Detection

Historically, the anti-doping movement has been based on detection and prevention, with the initial emphasis on detection. Organisational structures and standard operating procedures have been in place to ensure compliance with the anti-doping regulations. Detection relies on testing, which has been increasingly problematic in high performance sport. It has been argued persuasively that making testing effective as a deterrence method, either the volume
of tests conducted or the sanctions imposed have to be increased significantly, potentially to the level that is practically not feasible. The new technologies in both the development of undetectable methods and the detection of the new methods have led to rapidly escalating costs, bearing in mind that tests are currently not even available for all banned substances and methods. If the trend continues, costs of effective testing will soon became a prohibiting factor. Athletes, as they progress in their sports career, are gradually drawn into the vicious circle of the constant desire to enhance performance. In this process, some athletes may become more susceptible to doping than others, depending on the combination of their personality and the situation. Therefore, both the individual and systemic factors contributing to doping behavior should be fully investigated in order to underpin effective, targeted anti-doping intervention. In support of the argument against detection from a psychological perspective, it was provided empirical evidence for the failure of detection based deterrence showing that in a hypothetical situation, athletes first consider their moral beliefs, followed by the fear of negative health consequences and legal sanctions associated with the use performance-enhancing drugs. The effect of the threat of legal sanctions practically diminished when moral beliefs and health concerns were added to the behavioral model, directing policy makers to alternative deterrence methods. Additionally, many speculate that with gene doping on the horizon of competitive sport, detection based regulation will soon be seriously undermined [07004].

Doping prevention

The WADA and national sport governing bodies have added preventive measures to their detection programs. Examples for anti-doping prevention include: WADA’s Athlete Outreach Program (launched in 2001) targeting top performing athletes at major sporting events, the Anti-Doping Development Program (started in 2004), which aims to help countries and organizations to set up quality doping control, and the Educational Programme, which is a major tool of the WADA in an attempt to create a doping free culture by providing education to all stakeholders about the dangers of doping and its consequences. Congruently, the 100 percent me programme of UK Sport aims to promote positive attitudes and values of those who successfully competed drug-free and to provide accurate and relevant information on anti-doping. The 100 percent me is an educational program with three distinct but related strands. Outreach programme provides a framework for delivering accurate information and giving advice on anti-doping issues to athletes, athlete support personnel, and parents across the UK via sports events, workshops, training sessions and conferences. The accreditation programme allows interested individuals to gain knowledge in anti-doping and became a “100 % me” tutor. The 100 percent me is also a brand promoting the image of the “clean athlete” based on values of personal responsibility, choices, fairness and honesty. This image is linked to the Ambassador programme where successful drug-free athletes committed to anti-doping use the 100 percent me platform to promote drug-free sport among their fellow athlete. The Education Model Guidelines (EMG) are in place to help National Governing Bodies (NGBs) develop their own programmes using the 100 percent me framework. The UK model is one of the existing anti-doping national programmes. In the US, the U.S. Anti-Doping Agency (USADA) is responsible for similar testing and education programmes, and in place to eliminate conflict of interest of NGBs testing and sanctioning their own athletes. The Australian Sports Anti-Doping Authority (ASADA) has also launched a comprehensive the ASADA Education Service Charter in 2007. The Charter places an emphasis on developing athletes’ and support personnel’s understanding of the physical and psychological risks of doping to ensure that athletes and support personnel are aware of their rights and responsibilities [07004].

Explaining the doping behavior
Whether it is a realistic goal or not, effective deterrence is hindered as long as doping behavior is poorly understood. Before any serious consideration is given to deterrence methods, factors that make an athlete or athlete group more inclined to doping than others must be fully investigated. The WADA has only just started to channel funds to social science doping research to develop better understanding and consequently, more effective deterrence programs. Aiming to add to the body of knowledge on one possible cause of doping behavior (i.e. individual dispositions and attitudes) is congruent with the current priorities of the WADA Social Science Research Programme [07004].

Both the eminent literature and the official global sport organisational stance suggest that athletes’ attitudes are responsible for the deviant behavior of doping. Being overly competitive or exceedingly win-orientated is often used as a lay explanation for doping. Although gender, cultural and competitive level differences among athletes have been scrutinized since the late '80s the relationship between these factors and doping behavior has not been empirically tested, except in one project. In one study the classic “theory of planned behavior” (TPB) model provided a theoretical framework for a study among Italian adolescents, where attitude was found to be the strongest predictor for behavioral intention. The TPB model held across different levels of sport involvement and gender. Alternative theoretical models of doping have been developed attempting to explain the complex nature of doping. The models are based on existing general models from either health science or criminology but their application to the doping situation has not been empirically validated. The first among the few used the “Health Belief Model” to develop a theoretical drug control model. Although it was not explicitly stated, the model also incorporates some kind of economic rationality when it considers the balance between deterrence and incentives and availability and affordability of performance enhancing substances. According to the model, athletes' doping behavior is the ultimate function of this cost/benefit ratio, personality and morality, legitimacy of sanctioning organisation, social context (reference group) and attitude toward doping. The “Drugs in Sport Deterrence Model” also considered costs and benefits but used these concepts in a broader sense. Their model is based on “Deterrence Theory” used in criminology and costs and benefits include material and social consequences, as well as individual effects, such as health concerns, guilt or even satisfaction from sport achievement. Situational factors (i.e. prevalence perception, professional status, type of drug, experience with testing, etc.) were also thought to have an effect on the final decision regarding doping use. The common element of all three models is that subjective norms play a seemingly important role in doping behavior. As it is evidenced in a recent, WADA Social Science research funded extensive literature review, published research into athletes' motivation and reasons for doping use reveal an important factor that has been prominent in game theory models but overlooked in the existing doping behavior models: that doping behavior is not the ultimate end but rather a means to an end. It can be argued whether the ultimate end is winning or achieving a specific sport related goal (i.e. breaking a record); and it may vary from athlete to athlete. Nevertheless, if doping is a tool to achieve an end-goal, then models of doping should include attitudes or orientations toward the specific target end,
In consideration of the structural model of doping, the existing literature, more specifically the Theory of Reasoned Action (TRA), the Theory of Planned Behaviour (TPB), previous structural equation models of attitude and behavior and previous doping models were consulted. The Theory of Reasoned Action established a linear sequence of cognition (beliefs), affects (attitude), conation (behavioural intention) and behaviour. Later, the model has been criticized for the underlying and unrealistic assumption of absolute behavioural control, hence perceived behavioural control was added and the model expanded into the TPB. Models have been empirically tested and refined by showing interaction between the predictors and by questioning the generality of the model. An earlier model suggests an important notion, namely multiple factors influencing the behaviour. The notion of multiple factors is, of course, not new. In 1977, it was already mentioned multiple-act criterion, where attitudes toward a target (i.e. doping in general) is linked with observed heterogeneous behaviors (i.e. supporting the anti-doping movement but using doping at the same time). Influencing factors can be learned experiences (past behavior), perceived control, personality, cost/benefit ratio and most importantly: goals. Also, it was focused on past behavior (in general) whereas new doping models consider personality, availability, free choice of actions and situational factors as well as perceived control over behavior and free choice. Curiously, a situation where multiple attitudes are influencing a single behavior has not been considered in doping attitude-behavior modeling. If doping behavior is considered as a means to an end, attitude toward the end point should be taken into account. Support for this assumption can be found in the literature for at least two decades.

Others have suggested that doping may be used to achieve one or more of many goals, including reaching unattainable goals, breaking off the plateau, or even to signal group membership; or mark transition from being recreational to professional athlete. Contrary to the argument that the crucial element of doping is the intent to gain unfair advantage at the expense of other competitors, athletes do not necessarily see using doping as unfair or advantageous. Doping may be employed as a useful tool to improve performance to the level that is, or perceived to be necessary to have a reasonable chance for winning. When athletes assume that their competitors follow the same logic, the motivation for doping use is often reduced to the desire to level the playing field and ensure equal chances. These rational decisions regarding doping behavior could easily be against the general attitude toward doping, which is suppressed by other, stronger driving forces such as the desire to win, goal orientation or competitiveness.

One of the most important features of the present study was the finding that sport orientation is not strongly related to doping behavior, or to doping attitude. The only exception was win orientation, which showed a significant relationship with doping attitude. Thus the importance of winning may have influenced what athletes think about doping, but it does not necessarily manifest in their behavior. From the path coefficients, it was clear that athletes' desire to win, to achieve their personal goals or their competitive nature is not necessarily related to their decision regarding use of prohibited performance enhancements. None of the measures, except expressed belief, had a significant path to behavior. Apparently, athletes using prohibited means of performance enhancements do not have to be overly competitive or win-orientated. They do not have to endorse such pharmaceutical agents, or agree with the use of such substances in order to actually use them. Many athletes claimed that they would prefer not to use drugs and would not do it if they were certain that the competition was drug-free. The paranoia about other competitors using performance enhancement is a reappearing theme in these papers. In addition, it has been noted that athletes often feel an external pressure to win, most often in the form of warning about exceptionally good opponents. Hence, using doping agents may be more of a rational, outcome optimizing
behavior than deviance. If this is the case, sport governing bodies may do well if in addition to placing a ban on certain performance enhancing substances and methods, they provide athletes with acceptable alternatives. The small negative (but not significant) relationship between goal orientation and doping behavior was a logical connection because among the three sport orientation measures, goal orientation reflects an orientation to personal standards, regardless of the situation. The other two measures, desire to win and competitiveness reflect a tendency to enter and strive for success in a sport situation. Using banned performance enhancements in most athletes' view was expected to be against their standards as sportsmen. However, at the same time doping is often viewed as a means to an end; a 'tool' that is bad but necessary to ensure success in competition. Therefore, a positive relationship was expected. Of the two measures studied, competitiveness had a small but insignificant, positive path to doping behavior, whilst winning practically showed no relationship at all. On the other hand, the only statistically significant relationship with sport orientation measures and other factors was between win orientation and doping attitude. Sport orientation and attitude appear to be similar constructs and distinctly different from behavior. Athletes may think that doping is needed or not needed for winning but when it comes to actual behavior, it might be influenced by other factors more than attitude or orientation. This is not to say that personality, attitude, values should be discarded in order to make room for other factors. As probably no two individuals would react identically to the same combination of environmental factors, it is fair to assume that contextual contingencies are mediated through the combination of individual factors. Adherence to norms is a particularly difficult question. Decisions regarding doping use are influenced by at least two possibly competing norms:

- the general social norms, such as fair play, condemnation of cheating
- the special norms held by the athletes' immediate subcultures

One possible explanation for the strong path between belief and behavior is justification. Those athletes who use doping or wish to use such performance enhancements would prefer to do so without social stigmatization. Such a view is in keeping with previous research where athletes expressed their view of doping as a necessary means to a desired end and whilst they acknowledge rule breaking behavior, they do not consider themselves cheaters or more cheating than any other [07004].

The results of this research have both theoretical and practical implications. At the theoretical level, the findings of the paper are a step toward a comprehensive doping model. It highlights the need for the inclusion of other influencing factors and makes suggestions for future model testing. At the practical level, understanding the driving forces behind doping and how athletes wish to deal with these factors must be at the center of informed deterrence policies. Athletes are, by nature, highly motivated and achievement oriented individuals and have grown to appreciate methods for performance enhancement (training, nutrition, physiotherapy, equipment, etc.). The distinction between acceptable and prohibited methods must be made clear and convincing. To be effective, authorities must be able to

- justify the doping ban in general
- use evidence-based selection of substances and methods included into the prohibited list
- use the same criteria for all substances and methods
- communicate such decisions to all stakeholders

Suggesting anti-doping education and perhaps changes in attitudes to doping is a rather futile approach if the other influencing factors are kept constant. A value-based deterrence requires changes at all levels and in all stakeholders. Large scale research aiming to
understanding the driving forces behind doping behavior and gaining knowledge of effective deterrent factors is much needed and should be extended beyond the athlete population to include coaches, managers and officials. Sport governing bodies and anti-doping organisations are in the unique position to endorse and foster such research. International and national anti-doping organisations should make targeted funding opportunities for doping-related research aiming at increasing knowledge regarding both the doping behavior and alternative acceptable means of performance enhancement. Constant improvement of performance is, after all, the core characteristic of competitive sport [07004].

Multiple drug use

Because the use of anabolic steroids remains illicit, detailed knowledge of their side effects is unknown. Reported side effects emanate from case reports, retrospective studies, and comparisons drawn from prospective studies of steroid therapy in patients with a variety of wasting syndromes. Further confusing the specific side effects of a given anabolic steroid is the common practice that many athletes take multiple drugs simultaneously and in multiple administration routes. Additionally, physiologic differences between patients with wasting syndromes and athletes limit our ability to extrapolate the results of controlled studies to anabolic steroid use in sports. One other compounding factor in determining which side effects arise from anabolic steroid use is that users also ingest other illicit drugs including cocaine, marijuana, alcohol, and tobacco. Doctors and training staff must be aware of the potential harms in order to both recognize and more importantly educate patients about these possibly life-threatening adverse effects [06031].

Athletes often alternate or combine multiple forms of AAS in an effort to maximize benefits while minimizing side effects. Users often take an average of five different drugs to achieve supraphysiologic anabolic levels exceeding 40 to 100 times the normal physiologic hormonal effects. This use of a combination of products is commonly referred to as stacking, and it is this stacking that makes it difficult to pinpoint the direct effect of different agents. The effects of AAS tend to follow a linear doseresponse curve for both anabolic and androgenic actions, although at high doses there appears to be a plateau to their physiologic effects. The supraphysiologic doses used by athletes far exceed the saturation point of the androgenic receptors. Therefore, there must be additional mechanisms to explain why supraphysiologic doses of steroids seem to enhance strength. There are three different physiologic mechanisms through which AAS may exert their effects [06031]:

- First, AAS improve the body's utilization of ingested protein, which favorably alters nitrogen balance. They mainly stimulate protein synthesis by turning on gene transcription after binding to androgenic receptors at the cellular level. Androgens exert their effects on a number of varied tissues including bone, adipose tissue, skeletal muscle, brain, prostate, liver, and kidney, as well as reproductive tissues. Therefore, a more complex understanding at the cellular level is needed to explain the variety of effects, knowing that their actions are mediated by only one androgen receptor. These receptors appear to be identical in muscle and various other organs, but their absolute number and affinity for various types of AAS potentially explain the variety of different effects in multiple organ systems and from various AAS products. Some effects of testosterone are mediated through conversion to other bioactive compounds including dihydrotestosterone and estradiol.
- A second effect of steroids is to displace glucocorticoids from binding to their receptors, thus exerting an anticatabolic effect. Because glucocorticoids usually depress protein synthesis, this antagonistic effect explains muscle mass gain and also the utility of these drugs in wasting syndromes.
- A third postulated effect of steroids is that they confer a psychologic benefit to athletes wishing to gain strength. AAS users describe a euphoria or high following ingestion that allows them to work harder during workouts and recover more rapidly, which allows them both to intensify their training and become more aggressive in competition.

Co-operation in drug testing

There are many areas of common interest between anti-doping laboratories and those working in the clinical, legal and forensic fields. In addition to methodological similarities, there are aspects of the findings in sport drug testing that overlap with other fields in such a way that sport drug testing and clinical, legal or forensic work may benefit from mutual interaction. Three recent examples are presented from the author’s experience. Case report 1 concerns the clinical relevance of hCG findings in sport drug testing as potential indicators of the presence of a (testicular) tumour in athletes. Case report 2 refers to difficulties that accredited laboratories can encounter due to differences between national legal systems and the administrative regulation systems of sport authorities. The example involves a network of blood collection for further autologous transfusion. Case report 3 relates to additional forensic-type investigations needed to interpret a situation where intoxication of a whole delegation was responsible for apparent doping cases. Clinical, legal and forensic fields must recognize the added value that some results and developments coming from anti-doping laboratories may have. At the same time anti-doping analysts should be aware of new issues, methodologies and problems appearing in related fields [10438].

Methodology for investigation of doping in the society

To date, there are estimates for the percentage of unknown cases of doping and illicit drug use in fitness sports, but not for elite sports. This can be attributed to the problem of implementing questionnaires and surveys to get reliable epidemiological estimates of deviant or illicit behaviour. All athletes questioned were subject to doping controls as members or junior members of the national teams. In order to estimate the prevalence of doping and illicit drug abuse, the athletes were either issued an anonymous standardized questionnaire (SQ; n=1394) or were interviewed using randomized response technique (RRT; n=480). It was used a two-sided z-test to compare the standardized questionnaire and RRT results with the respective official German NADA data on the prevalence of doping. Official doping tests only reveal 0.81 percent (n=25,437; 95 % confidence interval 0.70 to 0.92 %) of positive test results, while according to RRT 6.8 percent (n=480; 95 % confidence interval 2.7 to 10.9 %) of our athletes confessed to having practiced doping. Standardized questionnaire and randomized response technique both revealed a prevalence of about 7 percent for illicit drug use, but SQ failed to indicate a realistic prevalence of doping (0.20 %; 95 % confidence interval 0.02-0.74 %). It was thus demonstrate for the first time that data from official doping tests underestimate the true prevalence of doping in elite sports by more than a factor of eight. The results indicate that implementing randomized response technique before and after anti-doping measures could be a promising method for evaluating the effectiveness of anti-doping programs [09017].

Understanding athletes’ attitudes and behavioural intentions towards performance enhancement is critical to informing anti-doping intervention strategies. Capturing the complexity of these attitudes beyond verbal declarations requires indirect methods. One pilot study was aimed at developing and validating a method to assess implicit doping attitudes.
using an Implicit Associations Test (IAT) approach. The conventional IAT evaluation task (categorising "good" and "bad" words) was combined with a novel "doping" versus "nutrition supplements" category pair to create a performance-enhancement related IAT protocol (PE-IAT). The difference between average response times to "good-doping" and "bad-doping" combinations represents an estimate of implicit attitude towards doping in relation to nutritional supplements. 111 sports and exercise science undergraduates completed the PE-IAT, the Performance Enhancement Attitude Scale (PEAS) and answered questions regarding their beliefs about doping. Longer response times were observed in the mixed category discrimination trials where categories "good" and "doping" shared the same response key (compared to "bad-doping" combination on the same key) indicating a less favourable evaluation of doping substances. The PE-IAT measure did not correlate significantly with the declared doping attitudes, indicating a predictable partial dissociation. Action-oriented self-report expressed stronger associations with PE-IAT; participants who declared they would consider using doping showed significantly less implicit negativity towards banned substances. Similarly, those who reported more lenient explicit attitudes towards doping or expressly supported legalizing it, showed less implicit negativity towards doping in the sample, although neither observed differences reached statistical significance. Known-group validation strategy yielded mixed results: while competitive sport participants scored significantly lower than non-competitive ones on the PEAS, the two groups did not differ on PE-IAT. It was concluded that the results suggest a potential of the PE-IAT method to capture undeclared attitudes to doping and predict behaviour, which can support targeted anti-doping intervention and related research [08019].

To date, there are estimates for the percentage of unknown cases of doping and illicit drug use in fitness sports, but not for elite sports. This can be attributed to the problem of implementing questionnaires and surveys to get reliable epidemiological estimates of deviant or illicit behaviour. All athletes questioned were subject to doping controls as members or junior members of the national teams. In order to estimate the prevalence of doping and illicit drug abuse, the athletes were either issued an anonymous standardized questionnaire (SQ; n=1394) or were interviewed using randomized response technique (RRT; n=480). It was used a two-sided z-test to compare the standardized questionnaire and RRT results with the respective official German NADA data on the prevalence of doping. Official doping tests only reveal 0.81 percent (n=25,437; 95 % confidence interval 0.70 to 0.92 %) of positive test results, while according to RRT 6.8 percent (n=480; 95 % confidence interval 2.7 to 10.9 %) of our athletes confessed to having practiced doping. Standardized questionnaire and randomized response technique both revealed a prevalence of about 7 percent for illicit drug use, but SQ failed to indicate a realistic prevalence of doping (0.20 %; 95 % confidence interval 0.02-0.74 %). It was thus demonstrate for the first time that data from official doping tests underestimate the true prevalence of doping in elite sports by more than a factor of eight. The results indicate that implementing randomized response technique before and after anti-doping measures could be a promising method for evaluating the effectiveness of anti-doping programs [09401].

Current antidoping policy, essentially a costly repressive zero-tolerance approach in elite sport, will continue to be hampered by the limits of technology. False negatives and false positives are inherent possibilities with testing technology and current protocols do not adequately address the problem of biological and pre-analytical variability, which both may lead to unreliable test results. This uncertainty is acceptable in the field of therapeutic medicine but problematic in sport because athletes can never be considered truly clean, whereas false accusations should be avoided at all cost. Pragmatically, the introduction of additional analyses to the already huge armamentarium of antidoping tests is questionable, both in ethical and economical terms, especially when the diagnostic efficiency of the new tests is not proven [08045].
Enforcement of the antidoping-code is performed by doping controls. For this purpose, blood and urine samples of athletes are collected and analysed. In 2006 approximately 200,000 samples were analysed worldwide, with 1.96 percent being tested positive [08046].

Drug-testing practices are based on separation of a sample's constituents by chromatography and detection of target compounds by mass spectrometry, one of the workhorses in anti-doping research. Identification is reported as positive when the test and reference sample signals agree within a particular tolerance window. However, the size of this window is not constructed with an acceptable risk of false positives in mind. Rather, fixed decision criteria hold, regardless of the quality of the laboratory or the signal properties of the target compound. However, a laboratory that produces relatively precise results should deploy stricter criteria. Likewise, target compounds should be differentiated so that information in their signals can be respected [08047].

Always deploying the same rigid criteria leads to a probability of false positives that depends on the particular laboratory and target compound in an undefined way. This situation is frustrating because the statistical solution - flexible criteria that account for various complications - was already published and thoroughly tested five years before these rigid criteria were introduced. So, is it ignorance of the literature or failure to understand the analytical problem at hand that underlies the ongoing usage of these arbitrary decision rules? Laboratories, as well as their clients and (re-)accrediting organizations, should start reflecting on their accountability with regard to this avoidable malpractice [08047].

Already, in the run-up to the Olympic Games, vast amounts of time, money and media coverage have been spent on sports doping. Several doping experts have contended that tests aren't sensitive enough and let dozens of cheaters slip through the cracks, but only some athletes are facing sanctions. For example upon testing positive for clenbuterol, US swimmer Jessica Hardy was held back from the 2008 Olympic team and faces a two-year ban from the sport. China has already banned several athletes, some of them for life, on doping charges. Indeed, many world-class athletes will find their life's accomplishments and ambitions, their integrity and their reputations hinging on urine or blood tests [08048].

One factor at play in many cases that involve statistical reasoning, is what's known as the prosecutor's fallacy. At its simplest level, it concludes guilt on the basis of an observation that would be extremely rare if the person were innocent. Consider a blood test that perfectly matches a suspect to the perpetrator of a crime. Say, for example, the matching profile occurs in just 1 out of every 1,000 people. A naive prosecutor might try to convince a jury that the odds of guilt are 999:1, that is, the probability of guilt is 0.999. The correct way to determine odds comes from Bayes rule and is equal to 999 times P/(1-P) where P is the "prior probability" of guilt. Prior probability can be difficult to assess, but could range from very small to very large based on corroborating evidence implicating the suspect. The prosecutor's claim that the odds are 999:1 implies a prior probability of guilt equal to 0.5 (in which case P and 1-P cancel). Such a high value of P is possible, but it would require substantial evidence. Suppose there is no evidence against the suspect other than the blood test: he was implicated only because he was from the city where the crime occurred. If the city's population is one million then P is 1/1,000,000 and the odds of his guilt are 1001:1 against, which corresponds to a probability of guilt of less than 0.001 [08048].

Therefore it must be asked if, when an athlete tests positive, he or she without doubts is guilty of doping? The international Court of Arbitration for Sport upheld doping charges against cyclist Floyd Landis, stripping him of his title as winner of the 2006 Tour de France and suspending him from competition for two years. The court agreed with the majority
opinion of a divided three-member American Arbitration Association (AAA) panel and essentially placed a stamp of approval on a laboratory test indicating that Landis had taken synthetic testosterone. Despite that there might be inherent flaws in the testing practices of doping laboratories. Close scrutiny of quantitative evidence used in Landis’s case show for example it to be non-informative. This says nothing about Landis's guilt or innocence. It rather reveals that the evidence and inferential procedures used to judge guilt in such cases don't address the question correctly [08048].

The prosecutor's fallacy is at play in doping cases. For example, Landis's positive test result seemed to be a rare event, but just how rare? In doping cases the odds are dictated by the relative likelihood of a positive test assuming the subject was doping (“sensitivity”) against a positive result assuming no doping (which is one minus “specificity”). Sensitivity and specificity are crucial measures that must be estimated with reasonable accuracy before any conclusion of doping can be made. The studies necessary to obtain good estimates are not easy to do. They require known samples, both positive and negative for doping, tested by blinded technicians who use the same procedures under the same conditions present in actual sporting events. Most often in doping testing, such studies have not been adequately done, leaving the criterion for calling a test positive unvalidated [08048].

Urine samples from cyclists competing in the 2006 Tour de France were analysed at the French national anti-doping laboratory in Châtenay-Malabry. This is one of 34 laboratories accredited by the World Anti-Doping Agency to receive and analyse test samples from athletes. The laboratory flagged Landis's urine sample following race stage 17, which he won, because it showed a high ratio of testosterone to epitestosterone. Based on the initial screening test, the laboratory conducted gas chromatography with mass spectrometry, and isotope ratio mass spectrometry on androgen metabolites in Landis's sample. Such laboratory tests involve a series of highly sophisticated processes that are used to identify the likelihood of abnormal levels of plant-based androgen metabolites (from dietary or pharmaceutical sources) in a urine sample. The goal is to differentiate from endogenous androgen metabolites normally found in urine. Mass spectrometry requires careful sample handling, advanced technician training and precise instrument calibration. The process is unlikely to be error-free. Each of the various steps in handling, labelling and storing an athlete's sample represents opportunity for error. The criteria used to discriminate a positive from a negative result are set by the World Anti-Doping Agency. However, there is no way of knowing which cases are truly positive and which are truly negative. It is proper to establish threshold values such as these, but only to define a hypothesis; a positive test criterion requires further investigation on known samples. However, the method used to establish the criterion for discriminating one group from another has rarely been published, and tests have not been performed to establish sensitivity and specificity. Without further validation in independent experiments, testing is subject to extreme biases [08048].

Landis seemed to have an unusual test result. Because he was among the leaders he provided 8 pairs of urine samples (of the total of approximately 126 sample-pairs in the 2006 Tour de France). So there were 8 opportunities for a true positive - and 8 opportunities for a false positive. If he never doped and assuming a specificity of 95 percent, the probability of all 8 samples being labelled “negative” is the eighth power of 0.95, or 0.66. Therefore, Landis's false-positive rate for the race as a whole would be about 34 percent. Even a very high specificity of 99 percent would mean a false-positive rate of about 8 percent. The single-test specificity would have to be increased to much greater than 99 percent to have an acceptable false-positive rate [08048].

More important than the number of samples from one individual is the total number of samples tested. With 126 samples, assuming 99 percent specificity, the false-positive rate is
72 percent. So, an apparently unusual test result may not be unusual at all when viewed from the perspective of multiple tests. This is well understood by statisticians, who routinely adjust for multiple testing. It is believe that test results much more unusual than the 99th percentile among non-dopers should be required before they can be labelled “positive” [08048].

Other doping tests are subject to the same weak science as testosterone, including tests for naturally occurring substances, and some that claim to detect the presence of a foreign substance. Detecting a banned foreign substance in an athlete's blood or urine would seem to be clear evidence of guilt. But as with testing for synthetic testosterone, such tests may actually be measuring metabolites of the drug that are naturally occurring at variable levels. Whether a substance can be measured directly or not, sports doping laboratories must prospectively define and publicize a standard testing procedure, including unambiguous criteria for concluding positivity, and they must validate that procedure in blinded experiments. Moreover, these experiments should address factors such as substance used (banned and not), dose of the substance, methods of delivery, timing of use relative to testing, and heterogeneity of metabolism among individuals. To various degrees, these same deficiencies exist elsewhere - including in some forensic laboratories. It was stated that all scientists share responsibility for this [08048].

Against this discussion representatives of the World Anti-Doping Agency (WADA) argued that all WADA’s accredited laboratories, including the French national laboratory must meet standards set by the International Standard for Laboratories (ISL) in validation methods, staff competency and chain of custody, for example. Compliance is assessed independently by bodies of the International Laboratory Accreditation Cooperation. It should also be mentioned that the majority of the substances reported by the anti-doping laboratories are exogenous substances not naturally present in human beings. The development of testing procedures for endogenous substances includes samples from normal reference populations and from subjects administered with the substance under investigation, so that test-sample status and positivity criteria can be established. To determine cut-offs for the ratio of testosterone to epitestosterone (T/E), tens of thousands of athlete samples were analysed to establish reference values. To detect exogenous administration of endogenous substances (such as pharmaceutical testosterone) by isotope-ratio mass spectrometry (iRMS), validation is based on a combination of hundreds of known positive and negative samples analysed by many WADA anti-doping laboratories operating under the scrutiny of the ISL and of the International Organization for Standardization (such as ISO 17025) [08049].

Each sample test includes positive and negative quality-control samples to assess the possibility of a false result. If these samples fail, the test must be repeated. An adverse analytical finding is not reported unless the quality criteria are met. All the laboratories participate in at least four rounds of blind and one double-blind proficiency test per year; the results of each round determine the accreditation status of the laboratory. False positives mean immediate revocation of accreditation [08049].

Also, mass-spectrometry identification of exogenous substances relies on at least three diagnostic ions to avoid any interference or misidentification. For immunoassays, antibodies in the initial testing and confirmation procedures must have different antigen-epitope specificity. For analytes that are too small to have two independent antigenic epitopes, two different purification methods or two different analytical methods are used [08049].

Testosterone abuse is conventionally assessed by the urinary testosterone/epitestosterone (T/E) ratio, levels above 4.0 being considered suspicious. A deletion polymorphism in the gene coding for UGT2B17 is strongly associated with reduced testosterone glucuronide (TG)
levels in urine. Many of the individuals devoid of the gene would not reach a T/E ratio of 4.0 after testosterone intake. Future test programs will most likely shift from population based- to individual-based T/E cut-off ratios using Bayesian inference. A longitudinal analysis is dependent on an individual's true negative baseline T/E ratio. The aim of one study was to investigate whether it is possible to increase the sensitivity and specificity of the T/E test by addition of UGT2B17 genotype information in a Bayesian framework. A single intramuscular dose of 500 mg testosterone enanthate was given to 55 healthy male volunteers with either two, one or no allele (ins/ins, ins/del or del/del) of the UGT2B17 gene. Urinary excretion of TG and the T/E ratio was measured during 15 days. The Bayesian analysis was conducted to calculate the individual T/E cut-off ratio. When adding the genotype information, the program returned lower individual cut-off ratios in all del/del subjects increasing the sensitivity of the test considerably. It will be difficult, if not impossible, to discriminate between a true negative baseline T/E value and a false negative one without knowledge of the UGT2B17 genotype. UGT2B17 genotype information is crucial, both to decide which initial cut-off ratio to use for an individual, and for increasing the sensitivity of the Bayesian analysis [08050].

A support vector machine

Due to their performance enhancing properties, use of anabolic steroids (e.g. testosterone, nandrolone, etc.) is banned in elite sports. Therefore, doping control laboratories accredited by the World Anti-Doping Agency (WADA) screen among others for these prohibited substances in urine. It is particularly challenging to detect misuse with naturally occurring anabolic steroids such as testosterone (T), which is a popular ergogenic agent in sports and society. To screen for misuse with these compounds, drug testing laboratories monitor the urinary concentrations of endogenous steroid metabolites and their ratios, which constitute the steroid profile and compare them with reference ranges to detect unnaturally high values. However, the interpretation of the steroid profile is difficult due to large inter-individual variances, various confounding factors and different endogenous steroids marketed that influence the steroid profile in various ways. A support vector machine (SVM) algorithm was developed to statistically evaluate urinary steroid profiles composed of an extended range of steroid profile metabolites. This model makes the interpretation of the analytical data in the quest for deviating steroid profiles feasible and shows its versatility towards different kinds of misused endogenous steroids. The SVM model outperforms the current biomarkers with respect to detection sensitivity and accuracy, particularly when it is coupled to individual data as stored in the Athlete Biological Passport [13019].

Performance profiling

In recent years, antidoping strategies underwent a significant development, from purely biochemical analyses and the detection of substances in urine samples to a biological approach, using blood samples, longitudinal monitoring, and probabilistic techniques. Nowadays, the appropriate timing of testing and the targeting of the athletes to be tested with antidoping tests is a major issue. A new strategy to improve the targeting of suspicious athletes might be the longitudinal monitoring of individual performances. By these means, suspect athletes might be identified, as doping will not only alter their blood or steroid profiles, but ultimately boost their performance, as well. Through the proposed approach, the effectiveness in the fight against doping might be improved considerably [09002].

Controls at random

Substance abuse, particularly among young people, does not seem to have the tendency to
decrease. The knowledges on this phenomenon are manifold and they validly compete to address the actions of contrast. Nevertheless, it would seem profit to be able to have further informations, to place side by side to those already existing, with the aim to improve the surveillance of the phenomenon. For this purpose, in one paper it was proposed a monitoring model based on the results of random controls on road, carried out by the Police (or by the Hospital) in relationship to the road safety. The representativeness of the data that we could get this way appears elevated as a high percentage of the population own the driver's licence. As it is shown, these controls could be both individual and related to drivers' pools of biological samples. This last approach would seem to be more practicable since problems relating to the drivers' privacy would be avoided [09003].

Errors in drug testing

To date, there are estimates for the percentage of unknown cases of doping and illicit drug use in fitness sports, but not for elite sports. This can be attributed to the problem of implementing questionnaires and surveys to get reliable epidemiological estimates of deviant or illicit behaviour. All athletes questioned were subject to doping controls as members or junior members of the national teams. In order to estimate the prevalence of doping and illicit drug abuse, the athletes were either issued an anonymous standardized questionnaire (SQ; n=1394) or were interviewed using randomized response technique (RRT; n=480). Official doping tests only reveal 0.81 percent (n=25,437; 95 % confidence interval 0.70 to 0.92 %) of positive test results, while according to RRT 6.8 percent (n=480; 95 % confidence interval 2.7-10.9 %) of our athletes confessed to having practiced doping. SQ and RRT both revealed a prevalence of about 7 percent for illicit drug use, but SQ failed to indicate a realistic prevalence of doping. It was demonstrate for the first time that data from official doping tests underestimate the true prevalence of doping in elite sports by more than a factor of eight [10011].

Incongruity of data

Antidoping testing is currently exclusively based on hematochemical analysis performed in specialized laboratories accredited by WADA (World Anti-Doping Agency). Many of the analytical methods used for the determination of the parameters considered, such as hematological parameters (hemoglobin, hematocrit and reticulocytes), proteins (soluble transferrin receptor and hepcidin) and hormones (erythropoietin and growth hormone) are often affected by lack of clear standardization and harmonization. The observed incongruity of the data deriving from different laboratories often results in the risk of false positive results in athletes [10012].

Theoretical testing

Currently a large range of pure substance reference materials are available for calibration of doping-control methods. These materials enable traceability to the International System of Units (SI) for the results generated by World Anti-Doping Agency (WADA)-accredited laboratories. Only a small number of prohibited substances have threshold limits for which quantification is highly important. For these analytes only the highest quality reference materials that are available should be used. Many prohibited substances have no threshold limits and reference materials provide essential identity confirmation. For these reference materials the correct identity is critical and the methods used to assess identity in these cases should be critically evaluated. There is still a lack of certified matrix reference materials
to support many aspects of doping analysis. However, in key areas a range of urine matrix materials have been produced for substances with threshold limits, for example 19-norandrosterone and testosterone/epitestosterone (T/E) ratio. These matrix-certified reference materials (CRMs) are an excellent independent means of checking method recovery and bias and will typically be used in method validation and then regularly as quality-control checks. They can be particularly important in the analysis of samples close to threshold limits, in which measurement accuracy becomes critical. Some reference materials for isotope ratio mass spectrometry (IRMS) analysis are available and a matrix material certified for steroid delta values is currently under production. In other new areas, for example the Athlete Biological Passport, peptide hormone testing, designer steroids, and gene doping, reference material needs still need to be thoroughly assessed and prioritized [11029].

Efforts for drug free sport include developing a better understanding of the behavioural determinants that underline doping with an increased interest in developing anti-doping prevention and intervention programmes. Empirical testing of both is dominated by self-report questionnaires, which is the most widely used method in psychological assessments and sociology polls. Disturbingly, the potential distorting effect of socially desirable responding (SD) is seldom considered in doping research, or dismissed based on weak correlation between some SD measure and the variables of interest. The aim of one report was to draw attention to the potential distorting effect of SD and to the limitation of using correlation analysis between a SD measure and the individual measures. Models of doping opinion as a potentially contentious issue was tested using structural equation modeling technique (SEM) with and without the SD variable, on a dataset of 278 athletes, assessing the SD effect both at the indicator and construct levels, as well as testing SD as an independent variable affecting expressed doping opinion. Participants were categorised by their SD score into high- and low SD groups. Based on low correlation coefficients observed in the overall sample, SD effect on the indicator variables could be disregarded. Regression weights between predictors and the outcome variable varied between groups with high and low SD but despite the practically non-existing relationship between SD and predictors in the low SD group, both groups showed improved model fit with SD, independently. The results of this study clearly demonstrate the presence of SD effect and the inadequacy of the commonly used pairwise correlation to assess social desirability at model level. In the absence of direct observation of the target behaviour (i.e. doping use), evaluation of the effectiveness of future anti-doping campaign, along with empirical testing of refined doping behavioural models, will likely to continue to rely on self-reported information. Over and above controlling the effect of socially desirable responding in research that makes inferences based on self-reported information on social cognitive and behavioural measures, it is recommended that SD effect is appropriately assessed during data analysis [11030].

Self-reporting

Social psychology research on doping and outcome based evaluation of primary anti-doping prevention and intervention programmes have been dominated by self-reports. Having confidence in the validity and reliability of such data is vital. Epidemiological and social science research assessing social cognitions linked to doping behaviour has been constrained by the almost exclusive use of self-report methodology. Anti-doping prevention programmes are also evaluated via self-reported changes in attitudes and willingness to use doping substances, anabolic steroids in particular. However, recent research has drawn attention to a potential distorting effect of social desirability observed in self-reported social cognitive measures related to doping. It has been shown, albeit on a small sample, that taking self-reports at face value could lead to misleading conclusions about the social cognitive processes that underlie doping behaviour. Whilst differences in explicit (self-
reported) social cognitive measures between user and non-user groups were observed in the expected direction when groups were created from self-report, generally the reverse was evidenced when the user status was based on hair analysis results (i.e. based on the presence of at least one prohibited performance enhancing drug in hair). Implicit measures were consistent with the grouping based on hair analysis. The outcome of this project suggested that respondents may consistently manipulate their answers on all related measures in order to maintain the image they wish to project, although the possibility that this response bias might stem, at least partially, from self-deception (as opposed to strategic responding for impression management) cannot be ruled out. The strikingly different patterns in self-reports and implicit associations in the context of behavioural data inevitably lead to the question of: Which data should we trust? The self-report methodology has endured a mix of support and criticism in the past. Whilst a plethora of literature suggests that self-report can yield a valid assessment of substance use behaviour, it has also drawn equally strong criticism. Whilst these tests have provided adequate evidence of validity and reliability, other studies using various biomarkers to validate self-reported behaviour data have put convincing evidence forward for a considerable under-reporting of substance use. A systematic review revealed that this bias is not limited to socially undesirable behaviours; it also extends to simple measures such as height and weight with a tendency towards over- and under-reporting, respectively. The effect of gender, race, age and contextual contingencies such as drug type and seriousness of the offence on over- and under-reporting substance use has also been investigated with race as the only factor so far demonstrating an effect on admitting drug taking behaviour. One study utilised a mixed method design to afford triangulation between explicit measures through self-reported questionnaire, implicit associations using a computerised test for latency measures, and bioanalysis via hair specimens. The sample of 82 athletes from 30 sports (52 % female, mean age: 21 years) was split into quasi-experimental groups based on self-admitted previous experience with prohibited performance enhancing drugs (PED) and the presence of at least one prohibited PED in hair covering up to 6 months prior to data collection. Approximately 100 mg untreated head hair, cut at scalp, was screened using ELISA kits for the presence of the most commonly used anabolic steroids (stanozolol, nandrolone and boldenone). Positive samples for anabolic steroids were confirmed and quantified using liquid chromatography-tandem mass spectrometry (LC-MS/MS) methods. Erythropoietin (EPO) was detected using quantifiable ELISA. Hair digestion and analytical methods using LC-MS/MS were developed in house to increase sensitivity and to reduce the amount of hair required. Participants responded to questionnaires assessing a range of social cognitive determinants of doping via self-reports; and completed a modified version of the Brief Implicit Association Test (BIAT) assessing implicit attitudes to doping relative to the acceptable nutritional supplements (NS). Social projection regarding NS was used as control. PEDs were detected in hair samples from 10 athletes (12 % prevalence), none of whom admitted doping use. Nutritional supplement use was reported by 60 percent, whereas those having personal experience with doping constituted 13 percent of the athletes. Admitted doping appears to be independent of self-reports on nutritional supplements or social drug use. Eight hair samples were positive for stanozolol and two for EPO, giving a 12 percent prevalence rate for prohibited performance enhancing substance use in the sample. EPO levels were 13 picog/mg and 12.53 picog/mg for the two positives. Interestingly, more males admitted having experience with doping than females (21 % vs 7 %, respectively) with a reversed pattern for positive hair analysis (5 % vs 19 %, respectively). None of the athletes who returned positive hair samples admitted doping use. Conversely, no self-admitted doping was confirmed by current hair sample tests. Social projections for nutritional supplements, doping and social drug use showed a positive, statistically significant but relatively weak relationship between fellow athletes using prohibited performance enhancing drugs and nutritional supplements and social drugs by the general population. Based on self-declared doping behavior, an interaction effect between user group and gender was only found for social projection of
doping and nutritional supplements use by fellow athletes. No gender difference was evidenced for any of the outcome variables except the pressure to use banned substances. A statistically significant difference was found between admitted doping users and non-users in explicit attitude and social projection of doping use, with a borderline significance for pressure to use doping. As expected, those who admitted having personal experience with doping exhibited more of a lenient attitude (shown by higher PEAS score) towards doping and gave higher estimated proportions of doping users among athletes and reported higher perceived pressure to use doping. Athletes who denied doping contrary to the evidence in their hair samples exhibited less lenient attitudes toward doping. These results support the previous observation that athletes who deny their doping use behaviour gave answers on social cognitive measures that are consistent with a typical non-user. In other word, they are “faking good” in a consistent manner. These results are not surprising, considering that the outcome measures were exclusively based on self-declarations. The picture, however, has changed for the implicit associations. Albeit the differences in latency or D-scores did not reach statistical significance, the sample means suggest that performance on the BIAT was revealing for deniers. That is, latency measures and D-scores set deniers apart from clean and self-admitted users, but did not differentiate between the latter two groups. The majority of the athletes (89 %) indicated that they would prefer to compete in a doping free environment. The remaining 11 percent opted for a scenario in which both players use doping. The fact that no athletes opted for a unilateral use of doping suggests that there is a proportion of athletes who might be more motivated about enhancing performance in general (including using prohibited means) than gaining competitive advantage against opponents. Interestingly, 62 percent of all respondents believed that athletes use performance enhancing substances in training and competition. Overall, discrepancies in the relationship between declared doping-related opinion and implicit doping attitudes were observed between the groups, with control measures remaining unaffected. The results suggest, with considerable confidence, that the “denier” group is characterised by a pattern of dissociation between explicit and implicit responding. This dissociation is, in fact, likely to be a cognitive marker for this group, which may lead to a promising application of the combined explicit-implicit cognitive protocol used in this study as a proxy for the less readily available biochemical detection methods for large scale social science research on doping. Athletes’ views on doping were first and foremost influenced by the “legality” of the substance, then on performance. In this, athletes interviewed considered prohibited performance enhancing substances as cheating but acceptable enhancers as essential. The most important contribution that the results can add to drug use research is the observed distinct patterns of explicit and implicit responding among self-declared doping users and deniers which may lead to significant advances in both detection and treatment interventions for these groups. The findings question the validity of self-reports which may have significant implications in interpreting previous and future doping research. A combination of self-report and implicit cognitive measures seems to hold the strongest promise for future doping research. It is this combination that is likely to produce, with attendant methodology refinements, robust cognitive markers of denial. Objective verification using biomarkers or chemical analysis may not be a feasible approach in all social science research. However, our results suggest that triangulating results obtained on the same or related constructs but using different methodologies could be a cost-effective avenue. Hence, further research into the methods of combining self-report methodology, with indirect, implicit methods is warranted. Assuming that social desirability has a root in contextual contingencies, research among different user groups could be beneficial. Doping social science research, particularly quantitative research, is seriously lacking in studies using samples drawn from athletes banned from competition owing to doping offences and longitudinal research. Research in this field would benefit from looking beyond doping and having a greater use of direct and indirect methods from social psychology, particularly those used successfully in substance use and addiction research. Incorporating implicit social cognition is one promising avenue for doping social
Although it is still debated whether implicit social cognitions reveals something about the individual or the individual's environment, implicit social cognition research is among the thriving areas in social psychology. Doping research, owing to the unique nature of doping (i.e. being positioned between illicit behaviour and functional use of ergogenic aids) provides an excellent testing field for developing a better understanding of the explicit and implicit social cognition and the environment. Questionnaire responses thus showed a pattern consistent with self-reported doping use. Following this preliminary work, the study provides further evidence that both self-reports on behaviour and social cognitive measures could be affected by some form of response bias. This can question the validity of self-reports, with reliability remaining unaffected. Triangulation of various assessment methods is recommended [11031].

**Testing as a way of decreasing intent for doping**

To assess the effects of random drug and alcohol testing (DAT) among high school athletes a 2-year prospective randomized controlled study was performed. It was a study of a single cohort among five intervention high schools with a DAT policy and six schools with a deferred policy, serially assessed by voluntary, confidential questionnaires. DAT school athletes were at risk for random testing during the full academic year. Positive test results were reported to parents or guardians, with mandatory counseling. Indices of illicit drug use, with and without alcohol use, were assessed at the beginning and end of each school year for the past month and prior year. Potential mediating variables were evaluated. Student-athletes from intervention and control schools did not differ in past 1-month use of illicit drug or a combination of drug and alcohol use at any of the four follow-up periods. At the end of the initial school year and after 2 full school years, student-athletes at DAT schools reported less drug use during the past year compared to athletes at the deferred policy schools. Combining past year drug and alcohol use together, student-athletes at DAT schools reported less use at the second and third follow-up assessments. Paradoxically, DAT athletes across all assessments reported less athletic competence, less belief authorities were opposed to drug use, and indicated greater risk-taking. At the final assessment, DAT athletes believed less in testing benefits and less that testing was a reason not to use drugs. It was concluded that DAT deterrent effects were evident for past month use during any of the four follow-up periods. Prior-year drug use was reduced in two of four follow-up self-reports, and a combination of drug and alcohol use was reduced at two assessments as well. Overall, drug testing was accompanied by an increase in some risk factors for future substance use. More research is needed before DAT is considered an effective deterrent for school-based athletes [07018].

**Fatigue as a limit for test performance**

Muscle physiologists often describe fatigue simply as a decline of muscle force and infer this causes an athlete to slow down. In contrast, exercise scientists describe fatigue during sport competition more holistically as an exercise-induced impairment of performance. The aim of one review was to reconcile the different views by evaluating the many performance symptoms/measures and mechanisms of fatigue. It was describe how fatigue is assessed with muscle, exercise or competition performance measures. Muscle performance (single muscle test measures) declines due to peripheral fatigue (reduced muscle cell force) and/or central fatigue (reduced motor drive from the CNS). Peak muscle force seldom falls by >30 percent during sport but is often exacerbated during electrical stimulation and laboratory exercise tasks. Exercise performance (whole-body exercise test measures) reveals impaired physical/technical abilities and subjective fatigue sensations. Exercise intensity is initially sustained by recruitment of new motor units and help from synergistic muscles before it
declines. Technique/motor skill execution deviates as exercise proceeds to maintain outcomes before they deteriorate, e.g. reduced accuracy or velocity. The sensation of fatigue incorporates an elevated rating of perceived exertion (RPE) during submaximal tasks, due to a combination of peripheral and higher CNS inputs. Competition performance (sport symptoms) is affected more by decision-making and psychological aspects, since there are opponents and a greater importance on the result. Laboratory based decision making is generally faster or unimpaired. Motivation, self-efficacy and anxiety can change during exercise to modify RPE and, hence, alter physical performance. Symptoms of fatigue during racing, team-game or racquet sports are largely anecdotal, but sometimes assessed with time-motion analysis. Fatigue during brief all-out racing is described biomechanically as a decline of peak velocity, along with altered kinematic components. Longer sport events involve pacing strategies, central and peripheral fatigue contributions and elevated RPE. During match play, the work rate can decline late in a match (or tournament) and/or transiently after intense exercise bursts. Repeated sprint ability, agility and leg strength become slightly impaired. Technique outcomes, such as velocity and accuracy for throwing, passing, hitting and kicking, can deteriorate. Physical and subjective changes are both less severe in real rather than simulated sport activities. Little objective evidence exists to support exercise-induced mental lapses during sport. A model depicting mind-body interactions during sport competition shows that the RPE centre-motor cortex-working muscle sequence drives overall performance levels and, hence, fatigue symptoms. The sporting outputs from this sequence can be modulated by interactions with muscle afferent and circulatory feedback, psychological and decision-making inputs. Importantly, compensatory processes exist at many levels to protect against performance decrements. Small changes of putative fatigue factors can also be protective. We show that individual fatigue factors including diminished carbohydrate availability, elevated serotonin, hypoxia, acidosis, hyperkalaemia, hyperthermia, dehydration and reactive oxygen species, each contribute to several fatigue symptoms. Thus, multiple symptoms of fatigue can occur simultaneously and the underlying mechanisms overlap and interact. Based on this understanding, it was reinforce the proposal that fatigue is best described globally as an exercise-induced decline of performance as this is inclusive of all viewpoints [11032].

Economical aspects

According to the framework legislation promulgated as part of the reform of finance laws in France, quality is a mandatory feature of all governmental actions. In this context, this work was conducted to assess the construction cost of a national health program designed to promote physical and sports activities and prevent doping behaviors. This program was considered to have the characteristic features of a successful governmental health intervention. Four cost categories were evaluated: cost of the activity itself, transportation costs, communication costs and promotion costs. It was found that the program costs for 2002-2007 were 100,000 euros, with 15 percent of the costs in the communication category. This means that economic elements could be associated with factors of successful health service interventions in order to help decision makers responsible for the public interest and the consistency of public health actions [09012].

The overall economic costs of the fight against a doping allegation deserve consideration. WADA is the international independent organisation created in 1999 to promote, coordinate and monitor the fight against doping in sport in all its forms. Composed of and funded equally by the sports movement and governments of the world, WADA received its first 2 years of funding (USD18.3 million) from the Olympic Movement. Since 2002, according to its statutes, WADA's funding is sourced equally from the Olympic Movement and the governments of the world. The total budget for the year 2006 has been estimated at nearly USD 24 million, 60
percent for research, 15 percent for out of competition testing, 15 percent for education and 10 percent for contingencies. The budget of the Australian Sports Anti-Doping Authority (ASADA) for the period 1 July 2005 to 30 June 2006 was 13.681 million Australian dollars. The total revenue from grants and other financial support of the US Anti-Doping Agency (USADA) reached USD 10.9 million in the year 2005. These are only part of the huge economic resources currently devoted to the fight against doping worldwide, which are predicted to reach or exceed USD 10 billion. Therefore, in practice, healthcare systems and national governments worldwide are expected to devote to the fight against doping the same resources that the US government dedicates to prevention and treatment of diseases that cause great morbidity, mortality and economic burden for individuals, families and the entire population. Is this really necessary and morally acceptable? [07030].

Chemoinformatics-based classification of prohibited substances

Representative molecules from 10 classes of prohibited substances were taken from the World Anti-Doping Agency (WADA) list, augmented by molecules from corresponding activity classes found in the MDDR database. Together with some explicitly allowed compounds, these formed a set of 5245 molecules. Five types of fingerprints were calculated for these substances. The random forest classification method was used to predict membership of each prohibited class on the basis of each type of fingerprint, using 5-fold cross-validation. It was also used a k-nearest neighbors (kNN) approach, which worked well for the smallest values of k. The most successful classifiers are based on Unity 2D fingerprints and give very similar Matthews correlation coefficients of 0.836 (kNN) and 0.829 (random forest). The kNN classifiers tend to give a higher recall of positives at the expense of lower precision. A naïve Bayesian classifier, however, lies much further toward the extreme of high recall and low precision. The results suggest that it will be possible to produce a reliable and quantitative assignment of membership or otherwise of each class of prohibited substances. This should aid the fight against the use of bioactive novel compounds as doping agents, while also protecting athletes against unjust disqualification [06034].

Need of excretion studies

The list of prohibited anabolic steroids in sports has grown due to the addition of numerous steroids that have been introduced on the market by non-pharmaceutical companies. Moreover, several designer steroids, specifically developed to circumvent doping control, have also been detected. Because anabolic steroids are most often intensively subjected to phase I metabolism and seldom excreted unchanged, excretion studies need to be performed in order to detect their misuse [06004].

Preanalytical variability

The use of illicit substances and methods contravenes the ethics of sports and may be associated with side effects. Antidoping testing is an essential tool for preventing or limiting the consequences of cheating in sports. As for conventional laboratory testing, major emphasis has been placed on analytical quality, overlooking the inherent risks that may arise from analysis of unsuitable doping samples. The adherence to scrupulous criteria for collection, handling, transportation and storage of samples, especially blood and urine samples, is essential. The leading preanalytical variables that influence doping sample quality include biological variability, sample collection, venous stasis, spurious hemolysis and
presence of other interfering substances, sample manipulation and degradation, and inappropriate conditions for transportation and storage. One article provided a personal overview about the current challenges in preanalytical management of doping samples, as well as potential solutions for preventing the negative impact of preanalytical variables on sample quality and test results [13080].

Chemical and physical manipulations of doping tests

Detection and proof of doping control sample manipulation is a challenging task, and one of the most efficient tools to identifyurine substitution is careful steroid profile evaluation. In 2009/2010, identical steroid profiles of supposedly eight different athletes (from different teams and collection sites) were found and DNA analyses requested, demonstrating that all eight urine specimens were provided from a single donor. This donor was eventually identified as the doping control officer and none of the athletes was actively involved in the sample manipulation. In another case of urine substitution, no natural endogenous steroid was observed in steroid profile analyses, triggering further investigations into the composition of the specimen. Based on findings of hordenine, trace amounts of alcohol, various saccharides and intact proteins including Serpin-Z4, the liquid was identified as non-alcoholic beer. This manipulation however entitled the suspension of the athlete [12017].

Manipulation of urine specimens provided by elite athletes for doping control purposes has been reported several times in the past, and in most of these cases urine substitution was eventually proven. Recent findings of suspected and substantiated manipulation have outlined the complexity and diversity of tampering options, sample appearance alterations resulting from non-manipulative influence, and the analytical challenges arising from these scenarios. Using state-of-the-art mass spectrometric and immunological doping control and forensic chemistry methodologies, four unusual findings were observed. One sports drug testing specimen was found to contain an unusually high content of saccharides accompanied by hordenine and Serpine-Z4, while no endogenous steroid (e.g. testosterone, epitestosterone, androsterone and etiocholanolone) was detected. This specimen was identified as non-alcoholic beer filled into the doping control sample container, constituting an undisputed doping offense. A doping control sample of bright green color was received and found to contain residues of methylene blue, which is not considered relevant for doping controls as no masking or manipulative effect is known. In addition, the number of urine samples of raspberry to crimson red coloration received at doping control laboratories has constantly increased during the last years, attributed to the presence of hemoglobin or betanin/isobetanin. Also here, no doping rule violation was given and an impact on routine analytical results was not observed. Finally, a total of 8 sports drug testing samples collected at different competition sites was shown to contain identical urine specimens as indicated by steroid profile analysis and conclusively proven by DNA-STR (short tandem repeat) analysis. Here, the athletes in question were not involved in the urine substitution act but the doping control officer was convicted of sample manipulation [12088].

The case of seven urine samples collected for anti-doping purposes during a cycling stage race with moderately elevated testosterone and epitestosterone ratio (T/E) is reported. The very low probability of having all seven urine samples with such similar elevated T/E ratio (from 3.2 to 4.7) was very suspicious. Different pattern classification tools were tested to categorize the most similar steroid profiles, but none of the models enabled a clear classification of the different urine samples. Subsequently, genetic profiling of all urine samples was performed and demonstrated that three of the seven samples were collected from the same cyclist. Finally, the International Federation confirmed DNA profiling results.
This suggests that urinary steroid data using several methodologies are not appropriate for identification purposes and to an extent not unique to individuals [06033].

**Designer drugs in Japan**

In recent years, many analogs of narcotics have been widely distributed as easily available psychotropic substances and have become a serious problem in Japan. To counter the spread of these non-controlled substances, the Pharmaceutical Affairs Law in Japan was amended in 2006 to establish a new category; Designated Substances in order to more strictly control these substances. In April 2007, 31 compounds and 1 plant were first controlled as Designated Substances. Before 2007, the major compounds distributed in the Japanese illegal drug market were tryptamines, phenethylamines and piperazines. Alkyl nitrates, such as isobutyl nitrite and isopentyl nitrite, were also widely distributed. After they were listed as Narcotics or Designated Substances in 2007, these compounds, especially the tryptamines, quickly disappeared from the market. In their place, cathinone derivatives have been widely distributed, as well as different phenethylamines and piperazines. Additionally, in recent years, new herbal products containing synthetic cannabinoids have appeared globally. As at July 2012, 78 substances (including 1 plant; Salvia divinorum) were listed in the category of Designated Substances. They were 13 tryptamines, 17 phenethylamines, 11 cathinones, 4 piperazines, 23 synthetic cannabinoids, 6 alkyl nitrates, 3 other compounds and 1 plant. In this review, we show our survey of the spread of new designer drugs in Japan, focusing especially on synthetic cannabinoids and cathinone derivatives. Also, the prevalence and legal status of these substances in other countries will be presented [13057].

**Testing efficiency**

In the early 2000s, United States track and field athlete Kelly White passed 17 drug tests while on steroids (tetrahydrogestrinone, THG, testosterone), stimulants (modafinil), and EPO before she was caught on modafinil, then confessed to having used the whole regimen. THG was not found in her samples because laboratories were still blind to this designer steroid (used only to beat the test). Testosterone use was not detected because she masked it by taking epitestosterone as well; because her T/E never exceeded the cut-off, it never triggered IRMS analysis, which would have detected exogenous testosterone. Modafinil was first targeted and found by the French WADA-accredited laboratory; her EPO use was not detected because sprinters’ samples were not tested for EPO yet [07011].

**Anti-doping research opportunities**

The key areas of antidoping research include detection of compounds and methods for increasing the absorption, transportation, and delivery of oxygen from the lung to the muscle; detection of compounds or methods that increase the efficiency of conversion of oxygen to intracellular energy; detection of compounds and methods that enhance muscle growth and recovery; detection of genetic modifications applied to sport performance; identification of additional matrices (oral fluid, dried blood spots, etc) to detect doping; and identification and detection of masking techniques. The challenge of developing and validating methods for the long list of prohibited substances and methods is daunting, requiring analytical skills, a thorough understanding of drug metabolism and pharmacokinetics, and an appreciation of human physiology and endocrinology. Antidoping science would benefit from the expertise of scientists working on proteomics collaborating with scientists interested in changes in the red
blood cell during storage – hopefully resulting in a test for autologous blood transfusions. Other key areas of research in the future will involve recombinant protein and glycoprotein characterization and quantification using mass spectrometry and other techniques. The potential for genetic modification for performance enhancement is of great concern, and methods will need to be developed to detect gene doping. New methods of drug administration may impact detection methods. Alternative testing matrices, such as oral fluid, dried blood spots, and hair, may become more important [12006].

**Economy**

According to the WADA website, they have distributed over USD 50 million in research funding since 2001. Between 2002 and 2010, USADA distributed an additional USD 9 million in research funding. In 2008, the USADA, the U.S. Olympic Committee, the National Football League, and Major League Baseball joined forces to create the Partnership for Clean Competition (PCC) to support research in antidoping science. PCC has now funded 28 proposals totaling USD 6 million. In addition to research proposals, PCC will continue to establish collaborative working groups to focus the efforts of the best researchers on the science of antidoping. While significant advances have been made in improving detection strategies and methods, increased collaboration with the basic research community should enhance the progress of drug abuse deterrence. Translation of those findings to routine testing will also require funding and effort [12006].

**Placebo**

In the perpetual quest for better performance, athletes are using an increasingly diverse range of ergogenic aids. Some are permitted; however, this “drug” use is often seen as an ethically questionable behavior. A variety of research suggests that much of the impact of such aids may be due to expectancy—the belief that the substance will aid performance. It would be useful to demonstrate this to athletes considering such usage, especially as a pillar of antidrug education. Accordingly, this investigation used sodium bicarbonate and placebo additives in a double dissociation design, with athletes completing a series of 1,000-m time trials. Results showed that believing one had taken the substance resulted in times almost as fast as those associated with consuming the drug itself. In contrast, taking the drug without knowledge yielded no significant performance increment. Results are discussed against the backdrop of applying expectancy effects in high-performance sport, including dissuading athletes from using illegal aids [07026].

One article described a study examining placebo effects associated with the administration of a hypothetical ergogenic aid in sport. Forty-two team-sport athletes were randomly assigned to 2 groups. All subjects completed 3 x 30-m baseline sprint trials after which they were administered what was described to them as an ergogenic aid but was in fact 200 mg of cornstarch in a gelatin capsule. Group 1 was provided with positive information about the likely effects on performance of the substance, whereas Group 2 was provided with negative information about the same substance. The sprint protocol was repeated 20 min later. Although for Group 1 mean speed did not differ significantly between baseline and experimental trials, a significant linear trend of greater speed with successive experimental trials suggested that positive belief exerted a positive effect on performance. Group 2 ran 1.6 percent slower than at baseline (95 % confidence intervals 0.32 to 2.82 %), suggesting that negative belief exerted a negative effect on performance. Collectively, data suggest that subjects’ belief in the efficacy or otherwise of a placebo treatment might significantly influence findings in experimental research [07027].
The recent advances in the neurobiology of the placebo effect have shown that the administration of a placebo (inert substance), along with verbal suggestions of clinical benefit, activates different neurotransmitters in the brain, like endogenous opioids and dopamine and is associated to neural changes at both the cortical and subcortical level. Powerful placebo responses can be obtained after pharmacological preconditioning, whereby the repeated administration of a drug is replaced with an inert substance. For example, the morphine-like effects of placebos after morphine preconditioning have been shown in the context of pain management. Although these drug-like effects of placebos represent an interesting phenomenon in the clinical setting, they also have implications that have been ignored so far. One of these has to do with the use of drugs in sport competitions to boost physical performance. Among performance-boosting drugs, morphine is known to be a powerful analgesic that increases tolerance to pain, thereby improving physical performance. The importance of opioid-mediated placebo responses consists in the fact that they can be exploited when one wants morphine-like effects without giving morphine. For example, in the context of pain management, it has been shown that morphine administration for 2 days in a row may induce robust placebo analgesic responses when morphine is replaced with a placebo on the third day. This raises the important question whether two morphine administrations separated several days or weeks from each other have similar powerful effects on subsequent placebo responses. The neurobiological investigation of the placebo effect has thus shown that placebos can activate the endogenous opioid systems in some conditions. So far, the impact of this finding has been within the context of the clinical setting. Here it was present an experiment that simulates a sport competition, a situation in which opioids are considered to be illegal drugs. The subjects were healthy males who agreed to participate in one of the experimental groups after they signed an informed consent form in which the details of the experiment, including the drugs to be administered, were explained. In particular, the subjects were told that either morphine or naloxone would be administered at a given time, depending on the experimental group. None of them were training as a competitive athlete, but all the subjects engaged in recreational fitness training. After repeated administrations of morphine in the precompetition training phase, its replacement with a placebo on the day of competition induced an opioid-mediated increase of pain endurance and physical performance, although no illegal drug was administered. The placebo analgesic responses were obtained after two morphine administrations that were separated as long as 1 week from each other. These long time intervals indicate that the pharmacological conditioning procedure has long-lasting effects and that opioid-mediated placebo responses may have practical implications and applications. For example, in the context of the present sport simulation, athletes can be preconditioned with morphine and then a placebo can be given just before competition, thus avoiding administration of the illegal drug on the competition day. However, these morphine-like effects of placebos raise the important question whether opioid-mediated placebo responses are ethically acceptable in sport competitions or whether they have to be considered a doping procedure in all respects. The present study demonstrates that a pharmacological preconditioning, with morphine given twice at intervals as long as 1 week, can induce robust placebo analgesic responses when morphine is replaced with a placebo. It should also be noted that placebo administration without previous morphine conditioning induced a small but significant increase in pain endurance, which indicates smaller effects when a placebo is given for the first time compared with its administration after pharmacological conditioning. The study shows that long time lags between two consecutive administrations of morphine and the administration of the placebo are not very different from short time lags, at least in the range of days/weeks. This indicates that the pharmacological conditioning procedure has long-lasting effects. In addition to the mechanisms of placebo responsiveness and the preconditioning effects of morphine, this study raises important ethical questions: do opioid-mediated placebo effects during competitions have to be considered a doping procedure?
Should we consider morphine conditioning in the training phase ethical and legal? This issue is not easy to be resolved and will need both an ethical and legal discussion. Although one must be aware that the experimental conditions of the present study do not represent a real competitive event, but a pain challenge paradigm, the increase in pain endurance after the placebo is real and robust and has key attributes relevant to situations encountered in sport competitions. For example, our model of tonic ischemic arm pain represents a long-lasting painful stimulation that is likely to be encountered in real long-lasting sport activities. Therefore, if the conditioned subjects of this study engaged in a real sport activity, they would tolerate pain for a longer time [07202].

**Medical history of placebo**

Over the last 200 years, the placebo effect has cast a large and persuasive shadow over the medical field. In that time it has been by turn; harmless charade, charlatan's ruse, therapeutic device, methodological tool, ethical dilemma, research theme and source of controversy. Despite popular recognition, pervasive problems underlie conceptualisation of placebos and placebo effects. With medicine now firmly entrenched in the age of evidence based practice, there is a question as to whether it is time to leave the old placebo behind us. The idea of a magical black box from which unexplained therapeutic effects spring up is archaic and also unhelpful from a scientific point of view. If there really is an effect, surely we are best served by directly investigating what is responsible for it. This knowledge can be used in the clinic to improve treatment effectiveness and in research to inform study design. The view and role of placebos have developed over time. Modern medical understanding of placebos dates back to the late 1700s, and since then, placebo interventions appear to have been used fairly commonly in medical practice alongside other treatments. Up until midway through the 20th century, the prevailing opinion appears to have been that placebo interventions had no effect on pathophysiology. Placebos were used only to bring comfort to the patient, “a camouflage behind which to watch nature takes its course.” From the 1950s onwards, there was a shift towards regarding placebos as having genuine effects of their own. This period also saw the start of rapid growth in the use of placebos as a control intervention for testing the efficacy of other treatments. Thus, as research generally, and randomised controlled trials (RCTs) in particular, grew in stature and volume, placebo interventions also gained a more prominent face in the medical literature [13029].

**Powerless placebo**

The view that placebos have a powerful therapeutic effect remained largely unchallenged until the 1990s. Around this time, authors began to question the scientific basis upon which the claims of large therapeutic placebo effects were made. Critically, it was pointed out that longitudinal changes in a group of patients who have received a placebo intervention are not only due to placebo effects. From the point of onset (or clinical contact), many conditions improve with the passage of time independent of clinical management, due to the natural history of the condition. Improvements over time are likely to be further enhanced by regression to the mean which is a statistical artifact whereby scores that are high at one point in time, i.e. at study entry, are always more likely to be lower at a later time. Thus, when a group of patients receive a placebo intervention the changes afterwards may be due to placebo effects plus changes due to natural history plus the effects of regression to the mean. Experimental pain researchers pointed out the apparent discrepancy between the very small placebo effect sizes reported in clinical studies and the much larger effects in studies investigating placebo mechanisms [13029].

**Lack of effect of flavor**
One study investigated whether a change in beverage flavor during endurance cycling improves subsequent performance. Eight trained male athletes (age 24 years) undertook 3 trials, with training and diet being controlled. Trials consisted of 120 min of steady-state (SS) cycling at approximately 70 percent VO$_2$peak, immediately followed by a 7-kJ/kg time trial (TT). During exercise subjects were provided with fluids every 20 min. After 80 min of SS cycling subjects either continued drinking the same-flavor sports drink or changed to an alternate flavor—in either a alternate-flavor sports drink (AFSD) or cola. All beverages were carbohydrate and volume matched. Changing drink flavor caused no significant change in TT time. The various flavors produced no treatment effects on heart rate, blood glucose, or rating of perceived exertion throughout the SS exercise protocol. The influence of other taste variables such as palatability, bitterness, or timing of flavor change on endurance-exercise performance requires more rigorous investigation [07028].

**Ethical issues**

Along with the developing view of the role of placebos, the last half century has seen a shift towards acceptance of the evidence-based medicine paradigm. These two factors have led to increasing recognition of ethical and legal concerns associated with the administration of placebos in practice. The issues are difficult and consensus as to the appropriateness of placebos in clinical practice has not been achieved. At the heart of the matter lies the question of whether deliberate deception of the patient is acceptable in the course of their treatment. Implicit in the definition of placebo effects is that they are psychologically mediated. Whether the placebo is an ingested agent such as a sugar or vitamin pill, or a procedural intervention such as non-penetrating acupuncture, sham electrotherapy or an inert topical formulation, it must be physically inert. However, there follows the issue of disentangling inert from non-inert psychological interventions. The problem is, if there is a (psychological) mechanism, can the psychotherapeutic part of the intervention still be said to be inert? Along a similar line, researchers have proposed the term “nocebo” to describe undesirable effects of placebos. For example, studies have described immunosuppressive effects of placebo interventions which may be undesirable (a nocebo) for one patient group, for example general surgery patients but desirable (a placebo) for another group, for example, organ transplant recipients. Further, an intervention assumed to have an effect at one point in time could subsequently be shown to have no physiological effect and be used as a placebo. In some ways, it is therefore not surprising a definition for the placebo effect has proven so elusive. Conceivably, the same agent might be a placebo, a nocebo or an active intervention depending on who gives it, who gets it or when it is given [13029].

**Concluding remarks on placebo**

The conception of placebos and placebo effects has developed significantly over the past 200 years in concert with changes in the nature and practice of healthcare as a whole. In the past 20 years, questions have arisen as to the clinical significance of placebo effects and perhaps more importantly, the logical basis of the concept itself. As things stand, enquiry into placebo effects faces the nonsensical situation of attempting to explain an effect that has no mechanism. Abandoning the placebo black box in favour of theory-directed research that specifically targets and investigates the cause of therapeutic effects offers several advantages. Effective techniques can be manipulated and incorporated in clinical practice to produce better outcomes for patients, and better control interventions can be designed too [13029].
Measurement uncertainty in anti-doping quantitative analysis

The standards of laboratory performance of the World Anti-Doping Agency (WADA)-accredited laboratories are defined in the WADA International Standard for Laboratories and its associated Technical Documents. These sets of rules aim to harmonize the production of valid laboratory test results and evidentiary data as well as the reporting of laboratory analytical findings. The determination of anti-doping rule violations in sport made on the basis of analytical quantitative confirmatory analyses for the presence of prohibited threshold substances, in particular, requires the application of specific compliance decision rules, which are established in the WADA Technical Document on Decision Limits. In one article, the use of measurement uncertainty information in the establishment of compliance Decision Limits and in evaluating the performance of a laboratory's quantitative analytical procedures over time and in relation to other laboratories through WADA's External Quality Assessment Scheme program is reviewed and discussed. Furthermore, a perspective is provided on the emerging challenges associated with the harmonization of the quantitative measurement of large-molecular weight biomolecules [12053].

Statistical aspects

The detection of growth hormone (GH) abuse by athletes raises statistical problems as well as biochemical ones. It was outlined the statistical approaches to the various issues which have arisen; in particular, it considers the need to develop a test which detects GH abuse in any elite athlete “beyond reasonable doubt”. The test needs to be robust enough to withstand legal challenge, while minimising the risk of false accusation. Since GH is a naturally occurring hormone whose concentration varies substantially, its abuse cannot be detected by direct measurement. The methodology considered here made use of markers whose levels are more stable but are influenced by GH. The statistical methods employed aimed to make the best use of these markers, taking account of all factors contributing to errors in measurement. There were two key steps in the statistical investigation undertaken to develop the GH detection algorithm. The first was the requirement to identify GH-dependent biomarkers which would identify GH doping reliably and robustly for a significant length of time. The second was to calibrate the GH detection method in the elite athlete population, so that the method would be applicable to all athletes, regardless of age, sex and ethnicity, and regardless of whether they had recently sustained an injury. In practice, further work was needed to ensure that the methodology met the WADA testing protocol rules, but also that the proposed method can be used by any WADA accredited lab without placing any athlete at an unfair disadvantage and ensuring a high level of confidence in any result produced [09004].

The comparison among different modelling techniques, such as multiple linear regression, partial least squares and artificial neural networks, has been performed in order to construct and evaluate models for prediction of gas chromatographic relative retention times of trimethylsilylated anabolic androgenic steroids. The performance of the quantitative structure-retention relationship study, using the multiple linear regression and partial least squares techniques, has been previously conducted. In the present study, artificial neural networks models were constructed and used for the prediction of relative retention times of anabolic androgenic steroids, while their efficiency is compared with that of the models derived from the multiple linear regression and partial least squares techniques. For overall ranking of the models, a novel procedure [Trends Anal Chem 2010; 29: 101-9] based on sum of ranking differences was applied, which permits the best model to be selected. The
suggested models are considered useful for the estimation of relative retention times of designer steroids for which no analytical data are available [12052].

**Wald test**

One article derived the power curves for a Wald test that can be applied to randomized response models when small prevalence rates must be assessed (e.g., detecting doping behavior among elite athletes). These curves enable the assessment of the statistical power that is associated with each model (e.g., Warner's model, crosswise model, unrelated question model, forced-choice models, item count model, cheater detection model). This power analysis can help in choosing the optimal model and sample size and in setting model parameters in survey studies. The general framework can be applied to all existing randomized response model versions. The Appendix of the article contains worked-out numerical examples to demonstrate the power analysis for each specific model. (PsycINFO Database Record) [12051].

**Bayesian statistics**

Research on biological markers is a fast-growing field for assessing evidence in biomedical toxicology. In forensic toxicology in particular, major goals are to develop and validate measurements of endogenous substances that may reveal the presence of toxic substances, drugs of abuse, and/or doping agents. The development and validation of biomarkers of response are either based on the statistical description of endogenous substances measured on a population or on a longitudinal evaluation of a series of repeated tests performed on the same individual. Longitudinal studies are particularly interesting in forensic toxicology when the biomarker has a significantly smaller intraindividual variability than interindividual variability. This is the case for several biomarkers currently used in antidoping investigations, such as indirect markers of blood doping and the testosterone over epitestosterone (T/E) ratio for the detection of the abuse of testosterone and its precursors. These biomarkers are all characterized by a small ratio of intra- to interindivdual variability. In contrast to the abundant number of statistical models that analyze serial biomarkers of disease, the development of reliable methods for the detection of abnormal variations of a longitudinal biomarker has remained astonishingly limited in forensic toxicology. Current methods employ either population-derived limits – to detect “absolute” abnormal values of the biomarker – or individual-based thresholds – to detect abnormal deviations relative to an individual baseline. There is no reason why a test cannot combine formally population-based information with individual-based data for better decision making. Failure to combine these two types of information may lead to a low sensitivity/specificity relation of the biomarker. For example, when a biological product such as the carbohydrate-deficient transferrine or a transaminase (alanine transaminase (ALAT) and/or aspartate transaminase (ASAT)) is used as an indirect marker of chronic alcohol abuse no effective method integrates previous readings for better decision making. In the antidoping world, at least four readings are currently required by the World Anti Doping Agency (WADA) for the detection of abnormal variations of the T/E ratio, with no knowledge of the rate of false positives. Note that a precise valuation of the specificity is important in forensic toxicology, because a very low false-positive rate is demanded in order to prevent the accusation of an innocent individual. Finally, with biomarkers of blood doping, there is currently no procedure that has a specificity that does not depend on the number of test results. It is believed that “at least six samples for the baseline reading and possibly considerably more” are needed to derive cutoff thresholds that take into account the intraindividual variability of the biomarker. It was developed a test that compares sequential measurements of a biomarker against previous readings performed on the same individual.
A probability mass function expresses prior information on interindividual variations of intraindividual parameters. Then, the model progressively integrates new readings to more accurately quantify the characteristics of the individual. The idea is to use prior knowledge on interindividual variations of intraindividual parameters, and to progressively integrate previous readings to more accurately quantify the characteristics of the individual. Each new measurement of the biomarker is compared to a critical range. Before the first measurement on the individual, the critical range is derived from the population only. Then, this range progressively adapts itself as the number of readings performed on the same subject increases to finally characterize a particular individual only as the number of readings becomes very large. The rate of false positives does not vary with the number of previous test results. The specificity is independent of the number n of previous test results, with a model that gradually evolves from population-derived limits when n = 0 to individual-based cutoff thresholds when n is large. We applied this model to detect abnormal values in an athlete's steroid profile characterized by the testosterone over epitestosterone (T/E) marker. A cross-validation procedure was used for the estimation of prior densities as well as model validation. The heightened sensitivity/specificity relation obtained on a large data set shows that longitudinal monitoring of an athlete's steroid profile may be used efficiently to detect the abuse of testosterone and its precursors in sports. Mild assumptions make the model interesting for other areas of forensic toxicology [06032].

**Decision limit (CCalpha) and detection capability (CCbeta)**

Initially in the Decision 2002/657/EC the criteria for the calculation of the decision limit (CCalpha) and the detection capability (CCbeta) have been estimated as purely quantitative (alpha-error is 1 % and beta-error is 5 %). In 2004, the European Commission has issued a document to provide guidance for the interpretation of the 2002/657/EC. In this document it is mentioned that also qualitative criteria should be fulfilled. Therefore, the calculated CCalpha and CCbeta must be verified by using fortified samples. The method should be able to detect/identify the target component in 50 percent of the cases at CCalpha and in 95 percent of the cases at CCbeta. Analytical methods for the analysis of nitroimidazoles, nitrofurans and corticosteroids with LC-MS/MS have been validated by fortifying blank samples below and above the MRPL. CCalpha and CCbeta were calculated using the ISO 11843 approach. In addition, the frequency of methodical compliance for the qualitative criteria was determined at each concentration level. It was observed that at the calculated CCalpha and CCbeta levels the qualitative criteria were not fulfilled. It was concluded that the detection capability of the analytical method should be calculated by using decreasing fortification levels at and below the MRPL. A protocol validating methods for banned substances by limiting the number of samples is presented and the qualitative criteria for the assessment of CCalpha and CCbeta were verified based on the same set of data without the need of performing additional validation experiments [06035].

**Prediction of future doping**

The World Anti-Doping Agency (WADA) publishes the Prohibited List, a manually compiled international standard of substances and methods prohibited in-competition, out-of-competition and in particular sports. It would be ideal to be able to identify all substances that have one or more performance-enhancing pharmacological actions in an automated, fast and cost effective way. Here, it was used experimental data derived from the ChEMBL database (7,000,000 activity records for 1,300,000 compounds) to build a database model that takes into account both structure and experimental information, and use this database to predict both on-target and off-target interactions between these molecules and targets.
relevant to doping in sport. The ChEMBL database was screened and eight well populated categories of activities (Ki, Kd, EC50, ED50, activity, potency, inhibition and IC50) were used for a rule-based filtering process to define the labels "active" or "inactive". The "active" compounds for each of the ChEMBL families were thereby defined and these populated our bioactivity-based filtered families. A structure-based clustering step was subsequently performed in order to split families with more than one distinct chemical scaffold. This produced refined families, whose members share both a common chemical scaffold and bioactivity against a common target in ChEMBL. It was thus used the Parzen-Rosenblatt machine learning approach to test whether compounds in ChEMBL can be correctly predicted to belong to their appropriate refined families. Validation tests using the refined families gave a significant increase in predictivity compared with the filtered or with the original families. Out of 61,660 queries in an Monte Carlo cross-validation, belonging to 19,639 refined families, 41,300 (67 %) had the parent family as the top prediction and 53,797 (87 %) had the parent family in the top four hits. Having thus validated our approach, we used it to identify the protein targets associated with the WADA prohibited classes. For compounds where we do not have experimental data, we use their computed patterns of interaction with protein targets to make predictions of bioactivity. It was hoped that other groups will test these predictions experimentally in the future [13081].
ATHLETE BIOLOGICAL PASSPORT (ABP)

Overviews and background

The illicit routes to enhanced oxygen transfer capacities in athletes are manifold and the provision of evidence has been a considerable challenge for doping control laboratories. Comprehensive reviews on accomplishments as well as unsolved issues were reviewed in several recent articles. A central aspect of contemporary efforts towards the determination of autologous blood doping in particular is the Athlete Biological Passport (ABP), which has been employed as an anti-doping tool since 2009 and enabled various convictions of doped athletes during the last three years. The ABP’s principle relies on the intra-individual stability of selected blood parameters such as % reticulocytes (%Ret) and hemoglobin concentration ([Hb]), the long-term variation of which was tested over 4 consecutive competition seasons in elite triathletes. Both parameters were found stable and thus suitable for sports drug testing purposes, although significant variations among female athletes were detected concerning %Ret. Since ABP results must allow for comparison of data with other doping control laboratories, harmonized protocols are important. In that context, the influence of pre-analytical mixing strategies (manual, mechanical mixing, and automated mixing in the analyzer autosampler) on full blood counts was assessed, demonstrating that no significant difference was observed and that 15 min of mechanical shaking as commonly conducted are more than sufficient [13072].

In the last few years, the increasing number of published studies on variations in hematological parameters in elite athletes reflects the growing interest in the athlete’s physiological response to strenuous metabolic effort, especially in the context of the current debate on blood doping and the ABP. Current knowledge of sports physiology and doping biomarkers is formalized in the Athlete Biological Passport (ABP) program: an algorithm tracking the longitudinal record of hematological parameters as a means to define an individual’s hematological profile and thereby identify potential deviations. The central concept of the ABP is that a better appreciation of the physiological changes in the hematological profile related to training, competition, and altitude will allow discrimination of variations induced by illicit practices from those due to homeostatic response to physical activity [13072].

During the last four decades, the main instrument at the disposal of anti-doping authorities has been the detection of prohibited substances in biological samples collected from athletes. However, the availability of substances identical to those produced by the human body, such as EPO, testosterone and GH, necessitated a new drug-testing paradigm. From the early 2000’s, the Athlete Biological Passport (ABP) was proposed as an alternative means to drug testing. Doping leaves a characteristic fingerprint on the biology of the athlete and the ABP is used to prove the act of doping from the detection of that fingerprint. Once a biomarker of doping is implemented in the ABP, it will continue to remain valid and should be able to detect the physiological changes brought on by performance-enhancing drugs that have not yet been invented. However, the sensitivity of the ABP to detect doping is limited if the physiological result of a low level of doping remains within the individual's own reference range. Recent advances in proteomics and metabolomics show the huge potential of the ABP [12040].

Expert evaluation of biological data is a key component of the Athlete Biological Passport approach in the fight against doping. The evaluation consists of a longitudinal assessment of biological variables to determine the probability of the data being physiological on the basis
of the athlete’s on own previous values (performed by an automated software system using a Bayesian model) and a subjective evaluation of the results in view of possible causes (performed by experts). The role of the expert is therefore a key component in the process. Experts should be qualified to evaluate the data regarding possible explanations related to the influence of doping products and methods, analytical issues, and the influence of exercise or pathological conditions. The evaluation provides a scientific basis for the decision taken by a disciplinary panel. This evaluation should therefore encompass and balance all possible causes for a given blood profile and provide a likelihood for potential scenarios (pathology, normal variation, doping) that might have caused the pattern. It should comply with the standards for the evaluation of scientific evidence in forensics. On the basis of their evaluation of profiles, experts might provide assistance in planning appropriate target testing schemes [12041].

The increase of the body’s capacity to transport oxygen is a prime target for doping athletes in all endurance sports. For this purpose, blood transfusions or erythropoiesis stimulating agents (ESA), such as erythropoietin, NESP, and CERA are used. As direct detection of such manipulations is difficult, biomarkers that are connected to the haematopoietic system (haemoglobin concentration, reticulocytes) are monitored over time (Athlete Biological Passport, ABP) and analyzed using mathematical models to identify patterns suspicious of doping. With this information, athletes can either be sanctioned directly based on their profile or targeted with conventional doping tests. Key issues for the appropriate use of the ABP are correct targeting and use of all available information (e.g. whereabouts, cross sectional population data) in a forensic manner. Future developments of the passport include the correction of all concentration-based variables for shifts in plasma volume, which might considerably increase sensitivity. New passport markers from the genomic, proteomic, and metabolomic level might add further information, but need to be validated before integration into the passport procedure. A first assessment of blood data of federations that have implemented the passport show encouraging signs of a decreased blood-doping prevalence in their athletes, which adds scientific credibility to this innovative concept in the fight against ESA- and blood doping [12042].

Steroid profile analyses represent an important resource of information concerning both the administration of natural (endogenous) steroids as well as those of xenobiotic origin. Steroid profiling has been utilized in sports drug testing for more than three decades and still much effort is invested in elaborating and improving this valuable tool, particularly to increase its screening efficiency and to allow for consideration of more recently clarified (genetically or pharmacologically induced) variations influencing the steroid profile interpretation. A central aspect of contemporary efforts towards the determination of autologous blood doping in particular is the Athlete Biological Passport (ABP), which has been employed as an anti-doping tool since 2009 and enabled various convictions of doped athletes during the last three years. The ABP’s principle relies on the intra-individual stability of selected blood parameters such as %reticulocytes (%Ret) and hemoglobin concentration ([Hb]), the long-term variation of which was tested over 4 consecutive competition seasons in elite triathletes. Both parameters were found stable and thus suitable for sports drug testing purposes, although significant variations among female athletes were detected concerning %Ret. Since ABP results must allow for comparison of data with other doping control laboratories, harmonized protocols are important. In that context, the influence of pre-analytical mixing strategies (manual, mechanical mixing, and automated mixing in the analyzer autosampler) on full blood counts was assessed, demonstrating that no significant difference was observed and that 15 min of mechanical shaking as commonly conducted are more than sufficient [12017].

The Athlete Biological Passport (ABP), is a new testing paradigm with immense potential
value in the current climate of rapid advancement in biomarker discovery. It offers the enormous advantage of being independent of this endless pharmaceutical race. In addition to its original aim of providing proof of a doping offense, the ABP can also serve as a platform for a Rule of Sport, with the presentation before competition of the ABP to objectively demonstrate that the athlete will participate in a healthy physiological condition that is unaltered by performance-enhancing drugs. Finally, the decision-support system used today for the biological monitoring of world top-level athletes can also be advantageously transferred to other areas of clinical practice to reach the goal of personalized medicine. The promotion of ethical values and the protection of health in and throughout sports are the primary objectives of the sport movement. In that context, the abuse of substance doping represents the most serious threat to the integrity of modern sports. The World Anti-Doping Code, the reference document that provides the framework for harmonized antidoping rules within sports organizations, has been written to preserve the core values of natural performance, protection of health, and the spirit of the sport. Accordingly, a substance or method is considered for prohibition if it violates at least 2 of these 3 values. Doping triggers physiological changes that provide physiological enhancements. In the same way that disease-related biomarkers are invaluable tools that assist physicians in the diagnosis of pathology, specifically selected biomarkers can be used to detect doping. The primary tool used by sports authorities to ensure a doping-free sport has been the detection of prohibited substances in the biological fluids of athletes, specifically urine and blood. This drug-testing paradigm was introduced in the 1960s and has since been remarkably successful in the detection of substances that are not naturally produced by the body, such as stimulants, narcotics, beta2-agonists, and diuretics. This success is largely attributed to the use of chromatography coupled to mass spectrometry techniques that have revolutionized the detection of a large number of compounds. As a result of advances in biotechnology, the pharmaceutical industry continues to market new drugs at a remarkable pace. A substantial number of these new substances are recombinant proteins or peptides that are strikingly similar in structure, and in some instances absolutely identical, to those naturally produced by the human body. The identification of these substances in biological fluids can be difficult or virtually impossible in some cases. In modern sports, doped athletes are in a constant race with antidoping researchers, who must employ great ingenuity to develop toxicology tests capable of distinguishing exogenous substances from their endogenous counterparts. In addition, detection is further complicated by the medical supervision and increased sophistication of doping protocols. Contemporary protocols are shifting towards long cycles of small microdoses taken repeatedly that are difficult to detect by using conventional drug tests. Worse, designer drugs are currently being produced by black-market laboratories to get around existing drug tests. Consequently, the drug-testing paradigm established in the 1960s cannot prevent elite athletes from doping with impunity when using many potent doping substances such as designer recombinant erythropoietin (rEPO) and designer testosterone. For these reasons, alternative strategies that are independent of this endless pharmaceutical race must be developed to maintain fairness in elite sports [11426]. Biological fluids, such as blood and urine, contain a treasure trove of potential doping markers that can be discovered by today’s omics techniques, such as proteomics and metabolomics. The usefulness of this gold mine for diagnostic purposes has been recognized, and the same is true for doping biomarkers. By definition, any deviation in a biomarker from what is expected in a healthy physiological condition according to well-defined protocols can be attributable only to doping or a medical condition. Interestingly, these two possible causes are the exact targets of any antidoping program; hence, the criteria that are used to introduce new biomarkers into the ABP are the same as those that are used to define a banned substance, more specifically, the criteria of performance and health. In addition, an eligibility rule becomes a logical consequence of this assumption, wherein athletes present their passports at the beginning of a competition and individuals are
allowed to participate only if their passport indicates that they are in a healthy and unaltered physiological condition. Therefore, in addition to proving a doping offense under the World Anti-Doping Code, the ABP can be a platform for a Rule of Sport enforced by the sport authorities to prevent athletes from manipulating their physiology to an extent that would significantly impact their performance and health. It may be foreseen the implementation of a Rule of Sport in which the athletes who have demonstrated unnatural deviations in physiology would be temporarily withdrawn from competition to allow a period for return to normal physiological levels or initiation of appropriate medical controls or treatments. This short period of debarment could also be used by a panel of experts to determine the cause of the abnormality and may lead to sanctioning the athlete for a longer period if doping is the cause [11426].

Although drug tests have been remarkably successful in the detection of synthetic doping substances, the recent availability of doping substances identical to those naturally produced by the human body demonstrates the limits of this testing paradigm to ensure fairness and health protection in elite sports. In that context, the ABP represents the new paradigm in detection of doping-triggered physiological changes in elite sports. Doping biomarkers provide a means to deter the athlete from using performance-enhancing drugs that will lead to deviation from natural baseline values. In contrast to a drug test that returns a result for a precise moment in time and does not have any memory or perspective, the presentation at the beginning of competitions of an ABP that demonstrates normal longitudinal profiles will allow athletes to objectively demonstrate that they will participate in an unaltered physiological condition clear of any doping suspicion. Scientists are developing methods that provide an unequalled opportunity to ensure fairness and the protection of health in elite sports; worldwide ABP implementation is now at the discretion of antidoping organizations. The same paradigm can be used in the clinics so that personalized medicine will not only be centered on the deeper molecular makeup of each patient, but also on an interpretation of existing biomarkers tailored to each individual [11426].

The gatekeepers of fair sport have a whole new way to identify doping: the “athlete biological passport.” An approach that has evolved over the last several years, it is an electronic record of test results of the lingering effects of banned substances in the body, rather than the substances themselves. Like a valid passport required for entry into foreign countries, a valid (clean) biological passport is now required for many athletes to gain entry into elite competitions. Hopes are high among sports federations and antidoping agencies that the biological passport will close some of the biggest loopholes that have let cheaters slip into the Olympics, the Tour de France, and other major events [10008].

One gaping loophole in such tests is that some drugs, like erythropoietin, can only be detected in the body for a few days. But the effects of the drugs last for a week or more, increasing the odds that users will get caught. Another loophole is that banned substances, for a variety of reasons, are sometimes impossible to detect: they can be designed to elude specific tests, new substances can be made for which there are no tests, and a genetic trait—missing copies of a gene called UGT2B17, which makes testosterone soluble in urine—renders testosterone doping invisible to conventional urine tests (the absence of this gene is strongly related to ethnicity: 81 percent of Asians, 22 percent of Africans, and 10 percent of Caucasians are missing both copies). Looking for the physiological footprints left by such drugs, rather than the particular culprits, should reduce these problems [10008].

Few reliable estimates of the prevalence of doping in elite sports have been published. Since 2001, the international governing body for athletics has implemented a blood-testing program to detect altered hematological profiles in the world's top-level athletes. A total of 7289 blood samples were collected from 2737 athletes out of and during international athletic
competitions. Data were collected in parallel on each sample, including the age, gender, nationality, and birth date of the athlete; testing date; sport; venue; and instrument technology. Period prevalence of blood-doping in samples was estimated by comparing empirical cumulative distribution functions of the abnormal blood profile score computed for subpopulations with stratified reference cumulative distribution functions. In addition to an expected difference between endurance and nonendurance athletes, it was found nationality to be the major factor of heterogeneity. Estimates of the prevalence of blood doping ranged from 1 to 48 percent for subpopulations of samples and a mean of 14 percent for the entire study population. Extreme cases of secondary polycythemia highlighted the health risks associated with blood manipulations. It was concluded that when applied at a population level, in this case the population of samples, hematological data can be used to estimate period prevalence of blood doping in elite sports. It was found that the world’s top-level athletes are not only heterogeneous in physiological and anthropometric factors but also in their doping behavior, with contrasting attitudes toward doping between countries. When applied at the individual level, the same biomarkers, as formalized in the Athlete Biological Passport paradigm, can be used in analysis of the observed different physiological characteristics and behavioral heterogeneities [11130].

In 1996 several sports federations introduced an upper limit for hemoglobin and hematocrit. Violation did not lead to a doping conviction, but a temporary suspension for health reasons. By recording the hematological parameters over time and analyzing the data with a scoring system based on Bayesian probability theory it is possible to determine whether or not the changes are physiological. This model is called the Athlete's Biological Passport (ABP). Thus, the Athlete Biological Passport (ABP) is principally founded on monitoring an athlete's biological variables over time, to identify abnormal biases on a longitudinal basis. Several factors are known to influence the results of these markers. However, the manner in which the altitude factor is taken into account still needs to be standardized. Causal relationships between haematological variables should be correctly integrated into ABP software. In particular, modifications of haematological parameters during and after exposure to different altitudes/hypoxic protocols need to be properly included within detection models [13072].

Individualized statistics

The relevance of indirect biomarkers persisted even after the introduction of a direct test for rhEPO abuse because the time frame of direct rhEPO detection was short and other forms of blood doping such as transfusions are believed to have been revived by fraudulent athletes in that time. Even with the availability of a direct test for homologous transfusions biomarkers may be used to reveal manipulations induced by blood transfusions regardless of the origin. It is clear now that the biomarker approach bears another advantage. These markers are already sensitive to any future compound that elicits a similar physiological response, such as the increase of the oxygen carrying capacity. Therefore, the concept of a hematologic passport was developed further and is presented in detail in this section. Early subject-specific reference ranges were defined for Hb and Hct to encourage the hematologic passport in a global strategy to deter blood doping. The main theory behind this concept is that each athlete provides individual reference values that allow a longitudinal analysis by applying various algorithms [13006].

Owing to high individuality, the use of absolute reference ranges for hematological parameters is not really useful for monitoring athletes. However, as the analytical and intra-individual biological variability of most hematological parameters are both contained, the definition of a type of “hematological passport” would allow a longitudinal comparison of data
for individual patients, accomplished with major transferability among clinical and antidoping laboratories. So far, this appears suitable for detecting a variety of blood doping practices, and would also be acceptable in practice, considering that the individuality index of most hematological parameters (ratio between intra- and inter-individual biological variability) is always -0.6. The current availability of fully automated hematological systems can easily provide the traditional parameters of the hematological profile, along with a wide range of additional parameters for reticulocytes and erythrocytes, increasing the potential use of laboratory testing in clinical and sports medicine. Repeated evaluation over a period of time of several of these parameters, including hemoglobin, hematocrit, reticulocyte count and indexes, would define a highly specific hematological profile, which is supposed to remain relatively stable over time. At least five sequential determinations should be obtained to define a reliable subject-specific reference range; substantial variations from the baseline, or any value exceeding the allowable variation, could highlight either pathologies or unfair practices, in both cases providing a good reason for an athlete’s withdrawal from competition. Same major drawbacks of this approach, including collecting samples at altitude, sample manipulation or the use of plasma expanders, and the type of instrument used to measure reticulocytes, can be prevented by implementation of standardized analytical protocols, exclusion of values obtained from samples collected at altitude, specific instrument calibration, etc. A basic problem is that competitive athletes display significant differences in hemoglobin, erythrocytes, hematocrit and mean corpuscular volume compared to the sedentary population, whereas other erythrocyte indexes, reticulocyte counts and reticulocyte parameters appear to be less influenced by lifestyle [06005].

Personalized monitoring of biomarkers for doping

The Athlete Biological Passport (ABP) is an individual electronic document that collects data regarding a specific athlete that is useful in differentiating between natural physiologic variations of selected biomarkers and deviations caused by artificial manipulations. A subsidiary of the endocrine module of the ABP that which here is called Athlete Steroidal Passport (ASP), collects data on markers of an altered metabolism of endogenous steroidal hormones measured in urine samples. The ASP aims to identify not only doping with anabolic-androgenic steroids, but also most indirect steroid doping strategies such as doping with estrogen receptor antagonists and aromatase inhibitors. Development of specific markers of steroid doping, use of the athlete’s previous measurements to define individual limits, with the athlete becoming his or her own reference, the inclusion of heterogeneous factors such as the UDPglucuronosyltransferase B17 genotype of the athlete, the knowledge of potentially confounding effects such as heavy alcohol consumption, the development of an external quality control system to control analytical uncertainty, and finally the use of Bayesian inferential methods to evaluate the value of indirect evidence have made the ASP a valuable alternative to deter steroid doping in elite sports. The ASP can be used to target athletes for gas chromatography/combustion/ isotope ratio mass spectrometry (GC/C/IRMS) testing, to withdraw temporarily the athlete from competing when an abnormality has been detected, and ultimately to lead to an antidoping infraction if that abnormality cannot be explained by a medical condition. Although the ASP has been developed primarily to ensure fairness in elite sports, its application in endocrinology for clinical purposes is straightforward in an evidence-based medicine paradigm [10007].

In elite sports, the growing availability of doping substances identical to those naturally produced by the human body seriously limits the ability of drug-testing regimes to ensure fairness and protection of health. The Athlete Biological Passport (ABP), the new paradigm in testing based on the personalized monitoring of biomarkers of doping, offers the enormous
advantage of being independent of this endless pharmaceutical race. Doping triggers physiological changes that provide physiological enhancements. In the same way that disease-related biomarkers are invaluable tools that assist physicians in the diagnosis of pathology, specifically selected biomarkers can be used to detect doping. The ABP is a new testing paradigm with immense potential value in the current climate of rapid advancement in biomarker discovery. In addition to its original aim of providing proof of a doping offense, the ABP can also serve as a platform for a Rule of Sport, with the presentation before competition of the ABP to objectively demonstrate that the athlete will participate in a healthy physiological condition that is unaltered by performance-enhancing drugs. Finally, the decision-support system used today for the biological monitoring of world top-level athletes can also be advantageously transferred to other areas of clinical practice to reach the goal of personalized medicine [11126].

**Technical specifications necessary**

The prerequisite of valid biomarker data for objective interpretation and legal use is a strict process for sample collection, transport, and analysis that has been put into place for the ABP. For instance, sample collection must not occur within 2 h after training or competition and must be carried out after the athlete has remained in a seated upright position for 10 min with feet on the floor in order to allow the vascular volumes to equilibrate. In addition, important minimum information should be included on the ABP control form to review blood data in an individual context such as and among others blood loss in the 3 months preceding each sample collection, use of simulated hypoxic conditions (e.g. altitude house, tents), or exposure to altitude above 1,000 m above sea level. Furthermore, technical documents of the ABP guideline define the transport and storage conditions, e.g., the type of storage device, the necessity of a storage temperature data logger, and the rapid transport so that analysis can ideally be performed within 36 h of sample collection, although there is growing evidence that this time frame might be extended. Samples should only be analyzed in WADA-accredited or WADA-approved laboratories or their satellite facilities which must all be subject to strict regular internal and external quality control procedures and follow the WADA international standard of laboratories [13006].

Current ABP guidelines describe the particular importance of an athlete passport management unit (APMU) that is responsible for the administrative management of the ABP. This includes advising anti-doping organizations about intelligent, targeted testing, liaising with the expert panel, compiling an ABP documentation package, and reporting adverse analytical findings to anti-doping organizations and WADA. It seems essential that APMU personnel has profound knowledge of the ABP concept and indirect doping detection methods to ensure the intelligent, targeted approach that helps to avoid a waste of organizational and financial resources. It can be postulated that a main goal is to avoid parallel passport data collected by different stakeholders such as national anti-doping organizations (NADO) or governing bodies of each sport. Therefore, harmonization of data storage with mutual sharing of results that were analyzed with strict adherence to the WADA protocol is important to use the ABP in its full capacities. The ADAMS (anti-doping administration and management system) platform could provide a system for all stakeholders for the planning, collection, and evaluation of all ABP data although the exact responsibility of each stakeholder remains to be defined. For instance, NADOs could emphasize the testing of a young and/or nationally active athlete but as the athlete moves on to a regular international competition setting, testing could be taken over by the international sporting federation [13006].

*Still an interpretation*
Furthermore, it is prudent to consider that blood values may always be subject to biological variability (e.g. gender, age) – heterogeneous factors – and confounding factors such as physical activity (e.g. type of sport, competition vs training, or exposure to altitude). Some of these factors may change over time, such as altitude or the type of instrument used, and then influence longitudinal monitoring. Yet, time-independent or fixed factors such as ethnic origin or gender are specific for a given athlete. It has also been considered heterogenous factors and proposed a model based on a global Bayesian inference approach for the detection of abnormal blood values over time. In such a Bayesian network, the causal relationship between a doping activity and the induced alterations of blood markers is represented as probabilities where every causal relationship is itself a model represented by a conditional probability density function. WADA and other sports federations observed the growing scientific knowledge of longitudinal subject-specific monitoring of blood values until, in 2008, UCI was the first sports organization to introduce the hematological module of the ABP to detect blood doping. WADA followed in December 2009 and approved the first version of the WADA ABP operating guidelines which have since been revised. Nowadays, the hematological module of the ABP includes the longitudinal monitoring of eight hematological markers (Hct, Hb, RBC, reticulocyte count (#retics), %retics, MCV, MCH, and MCHC) to identify abnormal patterns with a subject becoming her or his own reference. From some of the hematological markers additional models are calculated: OFF-hr and ABPS (containing 7 markers). According to the WADA ABP guidelines the application of the “adaptive model” predicts an expected range for an individual within which a series of marker values falls assuming a normal physiological condition. Outliers correspond to values out of the 99.9 percent range (0.05-99.95 percentiles) and warrant further attention and review. Anti-doping organizations may select a value lower than 99.9 percent to identify atypical samples and/or profiles that warrant further investigation. An expert chosen by the responsible anti-doping organization shall initially review atypical values or an atypical longitudinal profile. This expert shall evaluate the anonymous passport data and respond on the basis of four hypotheses that will trigger the indicted further action:

- the measured values can be considered natural variation and thus normal: normal testing pattern is continued
- the measured values are suspicious: further data are required and target tests shall be performed
- the measured values may be the result of the use of a prohibited substance or prohibited method: two further experts review the passport
- the measured values are indicative of a pathological condition: information of the athlete or involvement of two further experts.

As the role of scientific experts in doping cases based on indirect evidence will considerably gain in importance, an emphasis should be made in regular scientific exchange and continuous education of the experts [13006].

**An international tool**

The ABP introduces a new form of doping evidence and, as such, paves the way for a more global and integrated fight against doping. In particular, we foresee a global forensic approach in which multiple pieces of evidence, not restricted to those in the current testing paradigm, are used to demonstrate the culpability of a suspect. For example, the drug enforcement agencies and customs departments of many countries seize large quantities of doping substances with investigations that target illicit drugs, manufacturing companies, and
trafficking networks. Until recently, the lack of collaboration between governmental, public, and sports authorities has hindered the combination of analytical and nonanalytical evidence in many countries. In the current fight against doping, a customs agency can learn that a top-level athlete has received some rEPO by mail before an important competition, but this information is not shared with sports authorities, so that the athlete is still permitted to participate in that competition. Interestingly, the methodology developed for the ABP provides the necessary framework to combine evidence gathered by sports-testing organizations with nonanalytical evidence gathered by public law enforcement agencies. For example, knowledge that an athlete received some rEPO by mail can be combined with the information stored in the ABP to evaluate whether the athlete used that substance before competition. As such, we do not foresee any scientific limitation for a global fight against doping that is based on various sources of evidence [11426].

A handful of sports federations have used the biological passport on a trial basis, but it is becoming more widespread because the World Anti-Doping Agency, which leads the international effort against banned sports enhancement, just released guidelines on its use. The U.S. Anti-Doping Agency and similar groups in the United Kingdom and Norway have adopted the passport for elite athletes in those countries. To prevent false positives, information is collected about legitimate activities that can affect the readings, such as blood donation during the previous six months, medications or supplements taken, and training [10008].

Three complementary items of ABP

Three distinct modules can be distinguished in the ABP: the hematological, steroidal, and endocrinological modules. The hematological module of the ABP aims to detect any form of blood doping. As part of a full blood count, 8 hematological variables are considered today in this module. In 2008, the Union Cycliste Internationale was the first sports organization to implement the hematological module of the ABP to deter blood doping in elite cycling, and subsequently, several riders have been prosecuted and sanctioned on the sole basis of their abnormal hematological profiles. Currently, hematological tracing is performed by several antidoping organizations for several thousand athletes worldwide. The steroidal module of the ABP, which aims to detect direct and indirect forms of doping with anabolic agents, is presently being finalized for implementation in the near future. The endocrinological module of the ABP aims to detect doping with growth factors, such as growth hormone and insulin growth factor-1. Despite abundant scientific publications on growth hormone-dependent markers, the implementation of the endocrinological module in the ABP in the network of WADA-accredited laboratories requires further validation to fulfill forensic standards [11426].

Aiming for three complementary items, the ABP will consist of a hematological, a steroidal, and an endocrinological module with the hematological module aiming to detect any form of blood manipulation. The fact that the ABP relies on indirect evidence for an anti-doping rule violation, i.e. changes in parameters that are not consistent with natural variations as determined in extensive validation studies rather than the detection of a prohibited substance, raised concerns about the validity of the approach and led to several (scientific) retorts and discussions [12016].

Hematological parameters
The longitudinal tracking and recording of eight hematological parameters should provide a fingerprint for both the doped and the non-doped athletes, thus representing an approach that anti-doping organizations have supported in its pioneering endeavour to demonstrate the use (rather than the presence) of a prohibited substance or method of doping. Limitations were reported concerning the sensitivity of the ABP analytical approach in case of EPO microdosing, where a 12-week intravenous EPO injection intervention remained undetected in ten subjects. The necessity to improve the current approaches was stressed (particularly in light of the required logistics and costs concerning the ABP) and anecdotal evidence that athletes might have adapted to the “new situation” was presented. Complementary to the existing algorithms employing predominantly the blood parameters hemoglobin concentration ([Hb], g/l), hematocrit (Hct), and %reticulocytes (e.g. in the OFF-hr score model) the utility of haemoglobin mass particularly in combination with %reticulocytes was evaluated in an original mathematical model. In addition to the subject-based interpretation of blood parameters collected in the course of ABP programs between 2001 and 2009, the utility of the available data concerning the estimation of the blood doping prevalence among elite track and field athletes has been described. Evaluating the empirical cumulative distribution functions of the abnormal blood profile scores in comparison to stratified reference cumulative distribution functions differences in blood doping prevalence were observed to be connected to the type of sports (endurance vs. non-endurance) and, to the athletes' nationality. That study revealed that the average prevalence of blood doping in the investigated population is to be estimated at 14 percent [12016].

Regarding blood doping, the traditional analyses based on the detection of a substance in biologic fluids have major limitations. Presently, only the misuse of allogeneic blood can be directly detected, whereas retransfused autologous blood is not detectable. There is a plethora of novel ESAs that are difficult to uncover. To overcome the detection problems, the “Athletes Biologic Passport” has been developed, which is based on the monitoring of selected RBC parameters. Blood doping may be suspected, when these parameters change in a nonphysiologic way. There are methodologic problems because of the lack of clear standardization and harmonization in antidoping testing. The longitudinal evaluation of several hematologic variables needs high comparability among various analytical technologies used by the different accredited laboratories. Although some parameters (i.e. concentration of hemoglobin and hematocrit) are comparable when measured on different instrumentations, others (i.e. percentage of macrocytes or reticulocytes parameters) are peculiar. This bears the risk of false-positive results in athletes. On the other hand, when 400 blood samples obtained from 24 subjects receiving rhEpo injections were screened by the passport parameters, 42 percent of the subjects were not identified as rhEpo doped. The statistical approach for evaluating the passport data are focused on the biologic variation of hematologic values. Critical experts in the analysis of laboratory data have argued that antidoping tests are based on fraud statistics. Traditional antidoping analyses are based on the detection of a substance in biologic fluids (“Adverse analytical finding”). This approach has major limitations in regard to blood doping. As outlined in the previous section, autologous blood cannot be detected, there is a plethora of ESAs, the detection window is limited, and there is urine manipulation. Some sports federations earlier introduced upper concentration of hemoglobin and Hct limits to escape from this dilemma. Athletes tested above the limits were declared unfit for competition (“No-start rule”). However, concentration of hemoglobin and hematocrit are influenced by external factors, such as body posture, exercise, or residence at altitude. In addition, “clean” athletes can have naturally high hemoglobin and hematocrit values. A large retrospective study on male blood donors in Denmark revealed that 3.9 percent of nonathletes and 10.4 percent of elite rowers had hematocrit values more than 0.51 (i.e. above the recommended limits for athletic competition). Hematologic parameters depend on ethnicity, age, and gender. Some blood parameters, such as the concentration of Epo and reticulocytes (Ret), increase on
administration of ESAs (ON-score), whereas they decrease after RBC transfusion or after the cessation of ESA administration (OFF-score). The “Abnormal Blood Profile Score” (not presently used for the assessment of abnormal blood profiles based on the passport data) regards additional red cell parameters, including the mean corpuscular hemoglobin concentration (MCHC), mean corpuscular volume (MCV), mean corpuscular hemoglobin mass (MCH), Ret counts, serum Epo, and soluble transferrin receptor (sTfR).95 Algorithms have been used that are sensitive during one of the two phases, with ON-score being sensitive during ESA treatment and OFF-score during the cessation phase. Having become effective in December 2009, the “Athlete Biologic Passport Operating Guidelines” equip Anti-Doping Organizations with a framework in which to pursue antidoping rule violations in accordance with Article 2.2. of the World Anti-Doping (WAD) Code (“Use or At tempted Use by an Athlete of a Prohibited Substance or a Prohibited Method”). The guidelines include mandatory requirements for collection, transportation, analysis of blood samples, and results management. The following markers are considered in the Athlete Biologic Passport hematologic module: Hct, Hb, RBC count, reticulocyte percentage, reticulocyte number, MCV, MCH, MCHC, and OFF-hr score (Index of stimulation derived from a formula. In addition, parameters of interest can be the mean Ret cell volume (MCVr), Ret Hb concentration (MCHCr) and Ret Hb content (MCHr), as measured by flow cytometry as in clinical routine. The results reported to the WADA are processed by an “Adaptive Model” that identifies abnormal blood parameter changes related to the athlete’s individual profile. In particular, concentration of hemoglobin or OFF-hr score abnormalities with a 99.9 percentage probability or more will be reviewed by experts [11428].

The development and validation of blood-doping biomarkers have also greatly evolved since the introduction of hematological variables by some international sports federations in the mid-1990s. With the advent of automated blood analyzers, blood variables can be quantitatively measured to yield a complete hemogram, either in an accredited laboratory or directly at the location of the competition, in less than a minute after blood collection. Several approaches have contributed in recent years to make the use of biomarkers of altered erythropoiesis an efficient approach to deterring any form of blood doping in sports:

- the introduction of multiparametric blood-doping markers
- the inclusion of heterogeneous factors, such as sex and age, as recommended by the WHO in the diagnosis of anemia as well as other factors specific to sports
- the add-on of potentially confounding factors, such as the athlete’s exposure to altitude
- the record of the athlete’s own previous measurements, with the underlying concept being the use the athlete as his or her own reference
- the adoption of standardized protocols for sample collection and analysis, in addition to the extensive use of external QC systems to control analytical uncertainty
- the development and validation of probabilistic inference techniques to evaluate the value of doping evidence

All of the knowledge that has been acquired in recent decades concerning doping biomarkers has been formalized in the athlete biological passport (ABP) program. The term passport was first proposed in the early 2000s when the preservation and tracking of a longitudinal record of hematological variable measurements were planned to be used as a means to define an individual’s hematological profile. Large disparities between an athlete’s historical values and the values obtained in a recent test indicate that either doping has taken place or that the athlete has a potential medical condition that requires closer examination. The concept of the ABP has been discussed and then further elaborated for antidoping application by the World Anti Doping Agency (WADA) beginning in 2002. Since the 2006 Torino Winter Olympic Games, several international sports federations have agreed that the WADA should
harmonize the development and validation of the ABP program. As a result, in 2009, the WADA published the Athlete Biological Passport Operating Guidelines, which can be used as a reference for any antidoping organizations that are interested in developing a concordant biological monitoring program [11426].

The World Anti-Doping Agency has implemented the Blood Passport in attempt to detect blood doping in athletes. The Blood Passport looks for uncommon changes overtime in reticulocytes percentage (Ret %), as a variable of the OFF-hr score, and hemoglobin concentration reflecting potential doping violations. Few studies, however, have actually investigated the concurrent stability of Ret % and hemoglobin concentration in athletes over extended periods of time, none of which were measured in athletes who undergo strenuous and prolonged physical exercise. Measurements of Ret % and hemoglobin were assessed over the course of four competitive seasons in elite triathletes (10 males and seven female). Blood was obtained at the start of the season, precompetitive period, competitive period and at the end of the competitive period. Significant differences were observed in both hemoglobin concentration and Ret % between genders and there was a high variability between subjects. Neither males nor females exhibited differences in hemoglobin across all periods within one season. Within gender, analysis revealed that Ret % varied significantly between periods only in female athletes. It was thus concluded that Ret % and hemoglobin concentration remain stable over four consecutive seasons in elite triathletes, confirming that both parameters are valid for antidoping purposes based on the Blood Passport. In addition, Ret % fluctuations within one season require further investigation in females [11127].

The Athlete’s Biological Passport (ABP) is an evaluation of hematological parameters, hemoglobin (Hb), reticulocytes (Ret), and their combination in the OFF-score. Recently, the Court of Arbitration for Sport accepted it as a suitable indirect method for detecting blood doping. There are various topics which are not defined and scientifically completely explained in ABP, limiting its effectiveness as evidence and as suspect of blood manipulation. The data source the ABP used for designing a profile is unclear. The variance used for cyclists is not correct. The covariables which should be calculated together with the measures of Hb and Ret are not always considered in the statistical program. The pre-analytical warnings for correct and valid collection, transport, and storage of the specimens are not assured. Quality control of the instruments is not completely assured. Analytical variability is not appropriately considered in the program. The seasonal changes of the hematological parameters, due to training and competitions, are not calculated. Statistical analysis, based on a Bayesian-like program, not available to the scientific community, does not follow the classical decision-making approach of medicine and science. Therefore, the ABP needs of additional evidences and of scientific debate [11128].

The Athlete Blood Passport is the most recent tool adopted by anti-doping authorities to detect athletes using performance-enhancing drugs such as recombinant human erythropoietin (rhEPO). This strategy relies on detecting abnormal variations in haematological variables caused by doping, against a background of biological and analytical variability. Ten subjects were given twice weekly intravenous injections of rhEPO for up to 12 weeks. Full blood counts were measured using a Sysmex XE-2100 automated hematology analyser, and total hemoglobin mass via a carbon monoxide rebreathing test. The sensitivity of the passport to flag abnormal deviations in blood values was evaluated using dedicated Athlete Blood Passport software. Our treatment regimen elicited a 10% increase in total haemoglobin mass equivalent to approximately two bags of reinfused blood. The passport software did not flag any subjects as being suspicious of doping whilst they were receiving rhEPO. It was conclude that it is possible for athletes to use rhEPO without eliciting abnormal changes in the blood variables currently monitored by the Athlete Blood Passport [11131].
Manipulation of the blood's oxygen carrying capacity (CaO$_2$) through reinfusion of red blood cells, injections of recombinant erythropoietin or by other means results in an increased maximal oxygen uptake and concomitantly enhanced endurance performance. Therefore, there is a need to establish a system – "A Blood Pass" – through which such illegal and unethical methods can be detected. Venous blood samples were taken under standardized conditions from 47 male and female Swedish national and international elite endurance athletes four times during the athletic year of the individual sport (beginning and end of the preparation period and at the beginning and during peak performance in the competition period). In these samples, different hematological values were determined. ON(hes) and OFF(hre) values were calculated according to the formula of Gore et al. A questionnaire regarding training at altitude, alcohol use and other important factors for hematological status was answered by the athletes. There were some individual variations comparing hematological values obtained at different times of the athletic year or at the same time in the athletic year but in different years. However, the median values of all individual hematological, ON(hes) and OFF(hre), values taken at the beginning and the end of the preparation or at the beginning and the end of the competition period, respectively, as well as median values for the preparation and competition periods in the respective sport, were all within the 95% confidence limit (CI) of each comparison. It must be mentioned that there was no gender difference in this respect. This study shows that even if there are some individual variations in different hematological values between different sampling times in the athletic year, median values of important hematological factors are stable over time. It must be emphasized that for each blood sample, the 95% CI in each athlete will be increasingly narrower. The conclusion is that there is a physiological basis for establishing an individual-based "Blood Pass" system, mainly for athletes competing at the international level. On indications of manipulations of hemoglobin concentration and red cell mass by deviations from established "Blood Pass" data, more specific methods can be applied [07023].

Indirect markers of altered erythropoiesis can provide enough evidence to differentiate between natural variations and blood doping. Forensic techniques for the evaluation of the evidence, and more particularly Bayesian networks, allow antidoping authorities to take into account firstly the natural variations of indirect markers – through a mathematical formalism based on probabilities – and secondly the complexity due to the multiplicity of causes and confounding effects, through a distributed and flexible graphical representation. The information stored in an athlete's biological passport may be then sufficient to launch a disciplinary procedure against the athlete. The strength of the passport is that it relies on a statistical approach based on sound empirical testing on large populations and justifiable protocols. Interestingly, its introduction coincides with the paradigm shift that is materializing today in forensic identification science, from archaic assumptions of absolute certainty and perfection to a more defensible empirical and probabilistic foundation [10010].

Following the doping scandals at the World Championships in cross-country skiing in 2001, the International Ski Federation decided to generate individual blood profiles. From 2001 to 2007, 7081 blood samples from 1074 male and female elite cross-country skiers were collected and analyzed for hemoglobin concentration and % reticulocytes. Data were applied to blood algorithms wherefrom blood model scores were calculated. From 1997-1999 to 2001-2002, the mean hemoglobin concentration was reduced by 0.9 g/dL to 15.3 g/dL in male skiers and by 0.4 g/dL to 13.8 in female skiers. From 2002-2003 to 2006-2007, the combination of increases in hemoglobin concentration and decreases in % reticulocytes led to pronounced increases in mean OFF-model scores. Hemoglobin concentration was 0.2 g/dL higher at Olympic Games/World Championships (WOCs) than at World Cups competitions <4 weeks before and after WOCs. Hemoglobin concentration and % reticulocytes increased with altitude in both genders. Since the introduction of an enlarged
blood testing program, the mean hemoglobin concentration values were lowered to close to normal levels, but over the last 2-3 years there has been a small elevation and an increase in OFF-model scores, which may indicate a change in the manipulations used to elevate the hemoglobin concentration [08211].

The aim of one study was to investigate an indirect method based on a determination of absolute norms of variation in biological markers that could be used to identify autologous blood transfusion within the framework of the fight against doping. The selection of markers was made from experimental variations obtained during different phases including an increase in training volume at sea level, high altitude training, blood withdrawal and autologous blood reinfusion. The global statistical method was then developed in order to fix absolute norms of variation for each selected marker. The markers selected were haematocrit (Hct), haemoglobin concentration (Hb), stimulation index (Off-hr) and the absolute norms of variation (normDelta) established for a maximal 15 days period were normDeltaHct(0-15) >6%, normDeltaHb(0-15) >4% and normDeltaOff-hr(0-15) >20 percent. From analyses between two blood samples spaced at an interval of maximum 15 days, this method allows to show "abnormal" variation when a variation for one of the selected markers is strictly superior to the absolute norms of variation established. The legal framework for an immediate application of this method could be that of the internal regulations implemented by each international federation in accordance with the health policy in vigour [08212].

An efficient antidoping test designed to obtain direct proof of allogeneic blood transfusion was developed and validated. This test, based on flow cytometry analysis of red blood cell (RBCs) phenotypes, was used to determine the absence or the presence of numerous RBCs populations in a blood sample. A such, it may constitute a direct proof of an abnormal blood population resulting from homologous transfusion. Single-blind and single-site studies were carried out to validate this method as a forensic quality standard analysis and to allow objective interpretation of real cases. The analysis of 140 blood samples containing different percentages (0-5 %) of a minor RBCs population were carried on by four independent analysts. Robustness, sensitivity, specificity, precision and stability were assessed. ISO-accredited controls samples were used to demonstrate that the method was robust, stable and precise. No false positive results were observed, resulting in a 100 percent specificity of the method. Most samples containing a 1.5 percent minor RBCs population were unambiguously detected, yielding a 78 percent sensitivity. These samples mimicked blood collected from an athlete 3 months after a homologous blood transfusion event where 10 percent of the total RBCs present in the recipient originated in the donor. The observed false negative results could be explained by differences in antigen expression between the donor and the recipient. False negatives were more numerous with smaller minor RBCs populations. The method described here fulfils the ISO-17025 accreditation and validation requirements. The controls and the methodology are solid enough to determine with certainty whether a sample contains one or more RBCs populations. This variable is currently the best indicator for homologous blood transfusion doping [08213].

The aim of one study was to evaluate physical performance loss and underlying mechanisms following voluntary blood donation. Eleven voluntary subjects (four female) completed a symptom-limiting cardio-pulmonary exercise test before and after blood donation (500 mL blood). The haemoglobin value significantly decreased by 1.2 mg/dL (9 %), maximal oxygen uptake by 9 percent, maximal work rate by 13 percent and duration of exercise fell from 663 down to 607 seconds. Anaerobic transition occurred at 81 percent and 72 percent of maximal oxygen uptake before and after blood donation, respectively, which was a significant difference. Subjects who practise recreational endurance sports appear to be more effected by endurance loss. The haemoglobin value was the only significant predictor of maximal oxygen uptake in regression analysis. It was concluded that maximal physical performance is
impaired after blood donation. Haemoglobin decline accounts for the decreased oxygen uptake. As a consequence thereof the anaerobic transition occurs earlier. Subjects not engaged in regular sports activity did not experience a decline in their capacity [08214].

Allogeneic transfusions are normally mismatched at one or more minor blood group antigens. The most sensitive and accurate method known to detect this form of blood doping is flow cytometry. Low percentages of antigen-positive and antigen-negative red blood cells (RBCs) can be quantitated using suitable specific alloantibodies and careful analysis. By testing blood samples taken at various times, a reduction in the percentage of a minor population of RBCs will indicate transfusion has occurred [08215].

Hemoglobin (Hb) and hematocrit (Hct) are measured as indirect markers of doping in athletes. We studied the effect of posture on these parameters in a typical antidoping setting. Venous blood samples were obtained from nine endurance athletes (six males, three females) and nine control subjects (six males, three females) immediately and after 5, 10, 15, 20 and 30 min after having adopted a seated position from normal daily activity. Hb (CV 0.72 %) and Hct (CV 0.87%) were determined using an automated cell counter, plasma volume changes were calculated. Differences between the time points, gender and groups were calculated using a mixed-model procedure. Significant changes were observed in the first 10 min after sitting down but no further changes were noted between 10 and 30 min. Mean directional change for Hb and Hct between 0 min and the average of the period from 10 to 30 min was -2.4% (-0.35 g/dL) for Hb and -2.7% (-1.2%) for Hct. Plasma volume increased accordingly. Neither group nor gender had significant effects. Under typical conditions encountered during blood testing in doping control, a period of 10 min in a seated position is sufficient for the vascular volumes to re-equilibrate and to adapt to the new posture [10465].

Hemoglobin mass

Coinciding with the agreement on the ABP, it was evaluated three passport approaches for their sensitivity and specificity for the detection of autologous blood transfusion. The best possible marker for lower dosages of transfused blood (e.g. one bag) was OFF-hr. Interestingly, a new score (Hbmr) was introduced and showed the best performance for larger amounts (e.g. three bags), but requires the determination of total hemoglobin mass (Hb mass) as a further measure. Hb mass determined by the optimized CO rebreathing method was first suggested as a potential biomarker in the context of blood doping in 2007 mainly because it is independent of plasma volume fluctuations. The usefulness and applicability in several circumstances were evaluated in several studies thereafter. Hb mass was also evaluated as a marker in the adaptive model of the ABP in a longitudinal blinded study, in which a new score (OFFmass including %retics) was likewise published and yielded a sensitivity of 73 percent without false-positives at the 99.9 percent specificity level. Hb mass was also evaluated for the potential to detect rhEPO misuse. Various efforts have been made to improve the problems associated with the CO rebreathing method such as the administration of a potentially toxic substance and lack of a quality control system. Nevertheless, it seems that these problems limit the applicability of the method in antidoping. Therefore, the search is on for an alternative to Hb mass determination which is compatible with today's standards of testing because of its potential to improve the detection rate of autologous blood transfusion. On such approach could be the indirect modeling of Hb mass from indirect markers [13006].

Animal studies

The extent to which hematocrit is regulated and the impact of altered hematocrit on blood
oxygen transport in avian embryos are largely unknown. Consequently, it was investigated how acute blood removal or Ringer solution injection modified hematocrit in day 15 embryos, and how “blood doping” with erythrocyte-enriched whole blood influenced O\textsubscript{2} consumption in day 15-17 chicken embryos. Mean hematocrit (± s.e.m.) at day 15, 16 and 17 was 27 ± 1 percent, 28 ± 0 percent, and 31 ± 1 percent, respectively. Blood withdrawal (19 increments of 125 ml each, separated by 30 min) caused a progressive fall in hematocrit to approximately 12 percent at day 15. Hematocrit decline was strictly proportional to the extent of blood withdrawal. Incremental Ringer solution injection over an 8 h period, transiently increasing blood volume up to 85 percent over initial values, did not decrease hematocrit, indicating that injected Ringer solution rapidly left the circulating blood compartment. Blood doping with erythrocyte-enriched whole blood artificially elevated hematocrit from 27 percent to 38 percent, but caused no significant change in routine O\textsubscript{2} consumption (0.35-0.39 ml O\textsubscript{2} per min per egg) at any point over the subsequent 6 h period in day 15-17 embryos. It was conclude that hematocrit is not protected acutely in day 15 chicken embryos, with no evidence of erythrocyte sequestration or release. Additionally, at day 15-17, hematocrit increases of approximately 10 percent do not enhance embryonic oxygen consumption, suggesting that blood oxygen carrying capacity per se is not limiting to oxygen consumption [08216].

**Biking**

During the Tour de France 2007, 7 riders were randomly tested on 3 different occasions; the day before the prologue, and 12 and 19 days after the prologue. Blood was drawn into 3 mL EDTA covered tubes and kept at 4 degrees Celsius. They were analyzed within 24 hours. The concentration of hemoglobin and hematocrit were significantly lower on day 12 and day 19 compared to baseline. All 7 riders had lower hemoglobin and hematocrit on day 19 compared to baseline, while this was the case in 6 out of 7 riders already on day 12. The concentration of hemoglobin and hematocrit were 11.5 percent and 12.1 percent lower on day 19 compared to baseline. Whether or not this low value is due to decrease in hemoglobin mass or hemodilution, or the latter solely, increases in hemoglobin and hematocrit during prolonged stage racing seem unphysiological and should therefore lead to further examination of the rider [08217].

**Possible variables**

Blood passport has been suggested as an indirect tool to detect various kinds of blood manipulations. Autologous blood transfusions are currently undetectable, and the objective of this study was to examine the sensitivities of different blood markers and blood passport approaches in order to determine the best approach to detect autologous blood transfusions. Twenty-nine subjects were transfused with either one (n=8) or three (n=21) bags of autologous blood. Hemoglobin concentration ([Hb]), percentage of reticulocytes (%ret) and hemoglobin mass (Hb\textsubscript{mass}) were measured 1 day before and 6 times after reinfusion. The sensitivity and specificity of a novel marker, Hb\textsub{nr} (based on Hb\textsub{mass} and %ret), was evaluated together with [Hb], Hb\textsub{mass} and OFF-hr by different passport methods. The novel Hb\textsub{nr} marker showed superior sensitivity in detecting the highest dosage of transfused blood, with OFF-hr showing equal or superior sensitivities at lower dosages. Hb\textsub{nr} and OFF-hr showed superior but equal sensitivities from 1 to 4 weeks after transfusion compared with [Hb] and Hb\textsub{mass}, with Hb\textsub{mass} being the only tenable prospect to detect acute transfusions. Because autologous blood transfusions can be an acute practice with blood withdrawal and reinfusion within a few days, Hb\textsub{mass} seems to be the only option for revealing this practice [11132].
Erythropoietin

The so-called third-generation tests or the z-score were introduced to distinguish the effect of rhEPO abuse from natural biological fluctuations with longitudinal observations of Hb or OFF-hr. Assuming a universal within-subject variation only two values from one athlete could be used for the calculation of the z-score. In a new approach, it was concluded that longitudinal data might not only be used to ban participation in competition but also to establish target testing of suspicious athletes. This was important as only positive direct test results could be used for sanctioning of manipulating athletes. Progress of the passport concept prevailed as Sottas et al. combined all data contained in a single blood profile of an athlete in a universal multiparametric score (abnormal blood profile score, ABPS) that was initially presented in various versions using between three and 12 different biomarkers responding to either rhEPO administration or blood transfusion. In the current version of the WADA ABP operating guidelines, ABPS calculated from Hct, Hb, RBC count, reticulocyte percentage (RET%), mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC) is recommended as a marker in addition to OFF-hr. In a universal marker such as ABPS various doped states might equally lead to a high score, e.g., the donation and reinfusion of autologous blood both will elevate the score, whereas this will lead to a one-directional change only from a low to a high value for the non-universal marker OFF-hr [13006].

Steroid profile for athlete biological passport

The athlete's steroid profile analysis represents a powerful tool to identify the administration of AAS (including those of endogenous as well as xenobiotic nature). This is achievable by monitoring urinary concentrations of selected steroids and comparing their levels and specific steroid ratios to inter-individual and intra-individual reference ranges. Traditionally, population-based reference ranges are applied as defined in respective technical documents issued by WADA. The five-year data review from a single laboratory demonstrated a rather limited gain in sensitivity for identifying testosterone abuse along with a de facto considerably increased workload concerning the confirmatory analyses required in cases of T/EpiT ratios > 4. Alternatively, subject-based reference ranges were favoured and the consideration of additional hormone concentrations (e.g. of luteinizing hormone, LH) was recommended. In another study, the threshold values for testosterone (200 ng/mL), epitestosterone (200 ng/mL), androsterone (10,000 ng/mL) etiocholanolone (10,000 ng/mL), dehydroepiandrosterone (DHEA, 100 ng/mL), 5alpha-androstane-3alpha,17beta-diol (200 ng/mL) and 5beta-androstane-3alpha,17beta-diol (200 ng/mL) were evaluated. The consideration of subject-based (intra-individual) reference ranges in particular has gained much attention and several initiatives pursuing this route for complementing modern anti-doping efforts have been initiated. In a recent pilot study, new potential biomarkers to support the identification of testosterone misuse in sports were described. Besides the established testosterone/epitestosterone ratio (T/EpiT), other additional steroid ratios have been found to possess the potential to support the detection of testosterone abuse, namely 6alpha-OH-androstenedione/16alpha-OH-dehydroepiandrosterone, 4-OH-androstenedione/16alpha-OH-androstenedione, 7alpha-OH-testosterone/7beta-OH-dehydroepiandrosterone, and dihydrotestosterone/5beta-androstane-3alpha,17beta-diol. Since these findings represent results of a pilot study, the variability and susceptibility of the identified marker ratios will require follow-up studies under different conditions to demonstrate their long-term stability and influences caused for example by acute ethanol consumption or bacterial activity. The same approach was also used to screen for additional biomarker ratios supporting the identification of
dihydrotestosterone (DHT) or DHEA misuse in sports. Besides the detection of steroid abuse, steroid profiles have also been shown to provide valuable information concerning possible degradation processes occurring in urine specimens due to the non-sterile collection conditions. The measurement of free testosterone and/or epitestosterone (the percentage of which should be below 5 % of the glucuronic acid-bound counterpart) and free 5alpha- and 5beta-androstane-3,17-dione (elevated concentrations of which are considered as indicative for urine degradation) is used to test for the validity of doping control samples regarding the steroid profile interpretation [12016].

The Athlete Biological Passport (ABP) is an individual electronic document that collects data regarding a specific athlete that is useful in differentiating between natural physiologic variations of selected biomarkers and deviations caused by artificial manipulations. A subsidiary of the endocrine module of the ABP that which here is called Athlete Steroidal Passport (ASP), collects data on markers of an altered metabolism of endogenous steroidal hormones measured in urine samples. The ASP aims to identify not only doping with anabolic-androgenic steroids, but also most indirect steroid doping strategies such as doping with estrogen receptor antagonists and aromatase inhibitors. Development of specific markers of steroid doping, use of the athlete’s previous measurements to define individual limits, with the athlete becoming his or her own reference, the inclusion of heterogeneous factors such as the UDPglucuronosyltransferase B17 genotype of the athlete, the knowledge of potentially confounding effects such as heavy alcohol consumption, the development of an external quality control system to control analytical uncertainty, and finally the use of Bayesian inferential methods to evaluate the value of indirect evidence have made the ASP a valuable alternative to deter steroid doping in elite sports. The ASP can be used to target athletes for gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS) testing, to withdraw temporarily the athlete from competing when an abnormality has been detected, and ultimately to lead to an antidoping infraction if that abnormality cannot be explained by a medical condition. Although the ASP has been developed primarily to ensure fairness in elite sports, its application in endocrinology for clinical purposes is straightforward in an evidence-based medicine paradigm [10009].

Confounding factors

Physical exertion, training periodization, time of year, dehydration and altitude may all affect different hematological parameters and lead to false positives. Even though the ABP protocol is designed to account for these factors, the addition of an expert panel minimizes this risk [13006].

Although the ABP had the initial exclusive intent of biological monitoring, today, the ABP contains more than a simple series of individual biomarker values. Heterogeneous factors, such as age, gender, and genotype; confounding factors, such as exposure to higher altitudes for the hematological module; and some information regarding the conditions of sample collection, transport, and analysis are also stored in the passport for improved decision making. As such, the ABP becomes a platform for the evaluation of multiple pieces of scientific evidence, which is similar to a forensic approach. Similarly to forensic identification science, the strength of the ABP is that it relies on sound empirical testing in large populations by use of justifiable protocols. The decision support system that is used routinely to interpret the biomarker data stored in an ABP heavily relies on Bayesian inference techniques. Every element of information that constitutes doping evidence can be incorporated into other elements and/or corroborated by additional evidence. For example, the result of traditional drug tests, such as the detection of rEPO in urine; some
characteristics of athletes, such as a particular genotype; and the longitudinal monitoring of individual performance are evidentiary values that can be incorporated into the ABP decision support system for improved detection of doping [11426].

**Plasma osmolality**

One investigation quantified the effect of changes in plasma osmolality on the measurement of hematocrit (Hct) and the implications for the subsequent use of these data to calculate changes in plasma volume and application to the WADA Athlete Biological Passport. Two groups of eight male volunteers visited the laboratory after an overnight fast. In study 1, a 20 mL blood sample was collected and aliquoted into collection tubes containing saline of varying concentrations to alter the sample osmolality. In study 2, plasma osmolality was manipulated in vivo through prolonged exercise. Samples were analysed for hemoglobin concentration and Hct using manual methods and using an automated hematology analyser (AHA). Changes in blood, plasma and red cell volumes were calculated. While AHA Hct values did not change spun plasma volume changes (PCV) fell progressively as the osmolality of the sample increased. Consequently, there was a significant increase in apparent plasma volume as osmolality increased: regression analysis revealed that a 10 mOsmol/kg change in plasma osmolality produced a difference of 0.8 Hct units and a 1.6 percent change in plasma volume. In study 2, exercise produced a 12 ± 3 mOsmol/kg increase in plasma osmolality. No difference in Hct was observed at rest, but spun PCV was 1.0 ± 0.9 Hct units lower during exercise compared to AHA data. There was a difference in the degree of plasma volume change calculated, with a reduction of 8.7 ± 3.4 percent and 11.3 ± 3.5 percent reported with the manual and AHA methods respectively. It was concluded that conditions or interventions which result in a marked change to plasma osmolality produce a discrepancy in Hct measured using an AHA, consequently introducing errors into any calculation of changes in plasma volume using these data. These findings may also have implications for the measurement of Hct by WADA-accredited laboratories [13074].

**Stability of athlete blood passport parameters during air freight**

Fluctuations in ambient temperature and pressure, as well as physical jostling, may affect the stability of whole blood samples transported by air freight. The aim of one study was to characterize the stability of key blood variables during air freight and to investigate whether vibration or reduced pressure alone affected results. Over a 72-h interval, it was evaluated the stability of full blood count indices (plus reticulocytes) in tubes that were air-freighted a total of 2, 10 and 28 h. It was also examined the impact of 24 h of reduced atmospheric pressure (750 hpa or approximately 2500 m.a.s.l) and vibration (5 Hz). Samples were measured on a Sysmex XT-2000i instrument. The two key variables in the context of antidoping (haemoglobin concentration, reticulocytes) remained stable over a 72-h period regardless of the duration of air freight. Atmospheric pressure and vibration had no discernible effect. It was concluded that whole blood samples stored in NanoCool devices can be relied upon to remain stable for at least 72 h despite interim air freight [13075].

**Gastroenteritis**

The hematological module of the "Athletes Biological Passport" (ABP) is used to detect blood doping through the longitudinal variation of blood variables, such as hemoglobin concentration (Hb). Sporting federations have opened disciplinary procedures against athletes based on ABP results. Suspicious athletes try to explain the variations in their blood values with dehydration caused by gastrointestinal (GI) problems. The aim of one report was to describe hemoglobin concentration, a key variable of the ABP, during acute gastroenteritis
in athletes. 5 athletes with severe gastroenteritis were studied in retrospective. Blood test results (Hb, white blood cell count (WBC) and differential, CRP) obtained on hospital admission for GI problems were compared to data obtained from the same athletes in states of good health on previous occasions. During GI problems, athletes displayed marked inflammatory constellations with increased CRP and typical WBC shifts. Hb was not affected and remained mostly unchanged. This is in line with basic physiologic fluid regulation, where plasma volume is kept constant, even under conditions of severe dehydration. It is therefore unlikely that fluid loss associated with gastroenteritis will cause athletes blood data to reach levels of abnormality that will be suspicious of blood doping [11133].

Also for research

Marion Jones, who were tested for years and were never found to be cheating, admitted in 2007 to using “the clear,” a steroid formulated by the Bay Area Laboratory Cooperative, known as BALCO, to elude steroid testing. It is probable that the passport approach will identify athletes like Jones. If the athletes consented to have their test samples used for research, it would improve scientific understanding of the range of readings that are normal. But support for a voluntary program has not caught on. But culture change takes time, and the need to secure the borders of fair sport is urgent [10008].

Law issues

The Athletes Biological Passport (ABP) has received both criticisms and support during this year. In an issue of The Lancet, Michael Wozny considered that the use of the ABP makes it more difficult to take banned substances and that it was successfully used against the Italian elite cyclist Franco Pellizotti. After that, Italy's anti-doping tribunal considered that there was not enough evidence to prove manipulation of his own blood profile in Pellizotti's case. However, the UCI appealed to the Court of Arbitration for Sport (CAS) that sanctioned Pellizotti with a suspension of 2 years. Since its implementation, some problems have emerged. From 2010 to date, a large number of reports regarding the stability of the blood variables used to determine the ABP have been published, showing mixed results. One study considered that there is a risk of misinterpreting the physiological variations of the hematological parameters determined by the anti-doping authorities in the ABP. The analytical variability due to exercise training and competitions and/or to different metabolic energy demands, hypoxia treatments, etc. could lead to an increase in false-positives when using the ABP with the dramatic consequences that they might cause in major sports events like the forthcoming London Olympic Games. Moreover, the ABP characteristics, procedures, thresholds, or individual determination of reference ranges, abnormal out-comes, strikes, "how the profile differs from what is expected in clean athletes" should be clearly stated and explained in a new public technical document to avoid misunderstandings and to promote transparency [11129].

Software

Substances and methods used to increase oxygen blood transport and physical performance can be detected in the blood, but the screening of the athletes to be tested remains a critical issue for the International Federations. One project, AR.I.E.T.T.A., aimed to develop a software capable of analysing athletes’ hematological and performance profiles to detect abnormal patterns. One-hundred eighty athletes belonging to the International Biathlon Union
gave written informed consent to have their hematological data, previously collected according to anti-doping rules, used to develop the AR.I.E.T.T.A. software. Software was developed with the included sections: 1) log-in; 2) data-entry: where data are loaded, stored and grouped; 3) analysis: where data are analysed, validated scores are calculated, and parameters are simultaneously displayed as statistics, tables and graphs, and individual or subpopulation profiles; 4) screening: where an immediate evaluation of the risk score of the present sample and/or the athlete under study is obtained. The sample risk score or AR.I.E.T.T.A. score is calculated by a simple computational system combining different parameters (absolute values and intra-individual variations) considered concurrently. The AR.I.E.T.T.A. score is obtained by the sum of the deviation units derived from each parameter, considering the shift of the present value from the reference values, based on the number of standard deviations. Future studies aiming to validate the AR.I.E.T.T.A. score and improve the diagnostic accuracy will improve the system [11134].

Passports in practice

The 2011 International Association of Athletics Federation (IAAF) World Championships took place in Daegu, Korea. For the first time, all athletes were blood tested prior to the competition in order to give a clear signal to the world athletic community of the wish to enter into the era of the Athlete Biological Passport and fight against doping in their sport. The hematological parameters were measured on site. Thus, a mobile-accredited laboratory for blood testing was created in Daegu. Two serum tubes were collected for clinical chemistry and hormonal analyses in order to build the bases of the endocrine and the androgen (steroid) modules of the Athlete Biological Passport in blood. One paper described some of the main challenges the project faced with regard to the large number of athletes, competing in different disciplines, and the logistic problems that had to be solved for smart implementation of one of the most complex operations organized in the last decade in the fight against doping [12043].

The most promising attempt to reveal otherwise undetectable autologous blood doping is the Athlete Biological Passport enabling a longitudinal monitoring of hematological measures. Recently, the determination of hemoglobin mass (tHb) was suggested to be incorporated in the adaptive model of the Athlete Biological Passport. The purpose therefore was to evaluate the performance of tHb as part of the adaptive model for the detection of autologous blood transfusions in a longitudinal blinded study. Twenty-one subjects were divided into a doped group (n=11) and a control group (n=10). During the time course of a simulated cycling season (42 weeks) including three major competitions (Classics, Grand Tour, World Championships), multiple autologous transfusions of erythrocyte concentrates were assigned in the doped group. A blinded investigator ordered up to 10 tHb measurements (carbon monoxide rebreathing) per subject, mimicking an intelligent doping testing approach in obtaining hematological data (tHb, OFFmass (novel marker including reticulocytes), and respective sequences) for the adaptive model. The final analysis included 199 of 206 overall tHb measurements. The use of tHb, OFFmass, and their sequences as markers of the adaptive model at the 99 percent specificity level allowed identification of 10 of 11 doped subjects (91 % sensitivity) including one false positive in the control group. At the 99.9 percent specificity level, 8 of 11 subjects were identified without false positives (73 % sensitivity). It seems that the problems of tHb determination by carbon monoxide rebreathing limit the application of this method in antidoping. Because of its potential to detect individual abnormalities associated with autologous blood transfusions shown in this study, a method for tHb determination that is compatible with today's standards of testing should be the focus of future research [12044].
Erythropoiesis stimulating agents

Blood doping, through the increase of red cells, induces changes of hematological parameters. The aim of the Biological Passport is first to analyse individual longitudinal profiles in order to identify, through variations of the specific parameters, doping manipulations. Additionally, on the basis of abnormal values or profiles, athletes can be targeted for traditional anti-doping tests in order to detect forbidden substances or methods. We report the experience of the International Cycling Union in applying the Biological Passport to target athletes for the presence of erythropoiesis stimulating agents. All positive results which have been reported between 2008 and 2010 concerning athletes enrolled in the Biological Passport program are presented. Four cases are discussed more in details. To conclude, it was propose possible ways of using the Biological Passport in order to better understand athletes' doping modalities, so that testing programs efficiency can be improved [12045].

Testing during cycle tournament

Cycling stage races are among the most strenuous of endurance events. The exercise-induced variations observed in hematological parameters appear to be consistent with the rider's physiological response to maintain and improve highly demanding performances day-after-day. During training and competition, an essential part of evaluating the health and performance of professional and recreational athletes is periodic assessment of the hematological profile. Together with evaluation of iron metabolism, serial blood chemistry analysis can point to whether an out-of-range shift in blood parameters may be attributable to the response to physical effort or to an index of abnormal response. A starting point for determining irregular and suspect behavior in athletes is a better appreciation of the hematological response to vigorous physical activity. This is of particular interest in the context of the Athlete's Biological Passport (ABP), which was devised to detect abnormal variation(s), even at a single time-point, versus a subject-specific physiological range deduced from the athlete's own previous data. Because the variations during a competitive season affect the behavior of hematological parameters over a season, knowing their variability could help to define the physiological ranges in an athlete. The GiroBio, held in mid-June every year in northern Italy, is the "under-27s amateur Giro d'Italia", a surrogate for the Giro d'Italia and other international road races (Tour de France, Vuelta a Espana) for young cyclists. It attracts more than 150 professional cyclists from all over the world annually. Since 2005 it has been included in the Union Cycliste Internationale (UCI) Europe Tour circuit, category 2.2. About half the duration of its major counterpart, the GiroBio format is 10 stages over 11 days. The GiroBio race represents the entry step to a fully professional career for most cyclists. The race aims to promote the values of sport and fair play in healthy competition, counteracting the doping culture, through the adoption of innovative organizational aspects, as discussed below. The aims of one study were to determine the hematological response to middle-term strenuous endurance and to determine whether a relationship exists between the athlete-specific hematological profile and final placement in a cycling stage race. The study population was male professional cyclists (n=253) competing in the 2010 (n=144) and 2012 (n=109) GiroBio 10-day stage races. Blood draws taken before the start of the race, at mid-race, and at end-race were performed in strict compliance with academic and anti-doping pre-analytical warnings. Blood chemistry included white blood cell, red blood cell, hemoglobin concentration, hematocrit, mean corpuscular volume (MCV), mean hemoglobin content (MCH), mean corpuscular hemoglobin content (MCHC), platelets, and reticulocyte relative and absolute counts. Compared to baseline values, erythrocyte, hemoglobin, hematocrit, MCHC, platelet and reticulocyte counts were all consistently lower.
at mid-race, but returned to normal by race-end, while leukocytes were increased in the final phase. MCV increased during both events. MCH increased in the first part to then return to baseline in the 2012 race. The calculated OFF-score consistently decreased in the first half of the race before increasing, but remained lower than the baseline value. The trends of variation in hematological parameters were substantially similar in both events. There was an inverse, albeit weak, relationship between placement and erythrocyte, platelet, hemoglobin, hematocrit and OFF-score values in the 2010, but not in the 2012 race. In conclusion, the data confirm that, in this large series of elite road cyclists, the strenuous effort a rider sustains during a stage race induces appreciable changes in the hematological profile.

Positive cases in biking

Blood doping, through the increase of red cells, induces changes of hematological parameters. The aim of the Biological Passport is first to analyse individual longitudinal profiles in order to identify, through variations of the specific parameters, doping manipulations. Additionally, on the basis of abnormal values or profiles, athletes can be targeted for traditional anti-doping tests in order to detect forbidden substances or methods. We report the experience of the International Cycling Union in applying the Biological Passport to target athletes for the presence of erythropoiesis stimulating agents. All positive results which have been reported between 2008 and 2010 concerning athletes enrolled in the Biological Passport program are presented. Four cases were discussed more in details. To conclude, it was proposed possible ways of using the Biological Passport in order to better understand athletes’ doping modalities, so that testing programs efficiency can be improved.

Continuous evaluation of the ABP

Further studies evaluated the strength and possible limitations of the ABP after introduction of the hematological module by UCI and WADA which will be presented in the subsequent paragraph. As the ABP depends on analytically flawless data, the pre-analytical conditions and the laboratory testing were put into question. Thus, it seemed of great importance whether the adherence to the ABP guidelines will allow high quality results respecting forensic standards and thus assure their applicability in a juridical context. It was confirmed that the rigorous adherence to WADA’s guidelines yields excellent results required in the anti-doping context. According to previous studies on the topic, the limit of 36 h from blood collection to analysis is reasonable to guarantee analytical quality, when the samples are transported at 4 °C which seemed to improve the stability of hematological parameters independently from the analytical methodology. Further studies on the stability of blood parameters used within an anti-doping setting were available before the ABP was officially introduced. In addition, pursuing the goal to provide a sound foundation for the interpretation of blood profiles in athletes, more data were published on various confounding factors and analytical aspects which may help to refine existing guidelines. For instance, from a practical point of view, it was reported that long-haul air travel leads to normal diurnal variations of Hb without any indication that travel will affect the hematological measures in a way that might be interpreted as blood doping. Despite the general appreciation of the concept, it also became clear that the ABP has some limitations. It has also been discussed that “the sensitivity of the ABP to detect doping is limited if the physiological result of a low level of doping remains within the individual’s own reference range”. It fits in this context that microdosing of rhEPO does not lead to abnormal changes in the current ABP markers during rhEPO administration. Nevertheless, for example, blood counts were measured only during
the titration and following maintenance phase, but not longitudinally after rhEPO was discontinued for which OFF-hr was originally described [13006].

In order to evaluate the best possible realistic performance of the ABP adaptive model for a blood doping technique (autologous blood doping), a longitudinal blinded study design included 21 subjects that were divided into two groups of which one was transfused with 1-2 bags of blood at 2-3 time points during a simulated time course of a professional cycling season. A blinded investigator who was well trained in the use of the ABP was requested to apply an intelligent testing approach which allowed a sensitivity of 82 percent at the 99 percent threshold of the adaptive model as 9 of 11 subjects in the doped group had at least one value outside of the individual limits for Hb and OFF-hr or a sequence (Hb and OFF-hr) above the 99.9 percent probability threshold. The specificity was 90 percent for Hb (one false-positive value in 1 of 11 athletes) and 100 % for OFF-hr, sequence Hb as well as sequence OFF-hr [13006].

Several aspects allude to the effectiveness of the ABP hematological module. First, individual non-physiological data from the ABP have been used to sanction athletes and were recognized by the Court of Arbitration in Sport (CAS) in a final hearing. Second, these precedents might have had a deterrent effect on future behavior of athletes as the value of %retics has significantly changed and normalized since the introduction of the ABP in 2008, which may reflect a decreased prevalence of blood manipulations in the professional cycling peloton. From a practical and more measurable perspective, the introduction of the ABP hematological module and dedicated target testing based on the ABP data led to a 250 percent increase in the number of positive rhEPO cases in 2008 and 2009. In 2011 the number of cases was still about 300 percent higher than it was before the introduction of the ABP (data available from www.wada-ama.org) [13006].
SOCIO-MEDICAL ASPECTS ON DOPING

Doping in sport has been a focus of medical, physiology and social science research in recent years. Whereas medical and physiology researchers focus on improving methods (e.g. blood, urine and gene tests) for detecting the use of prohibited substances and to deter athletes from their use, social science researchers strive to better understand the psychosocial factors (e.g. attitudes, environment and beliefs) that may offer targets for educational programs aimed at preventing this behaviour [13017].

Costs of antidoping programs are high, and programs are increasingly complex and difficult to manage. As the bureaucratic burden imposed on athletes, physicians and sport organizations grows, concerns about sustainability abound. But the resolve of athletes and sport organizations to maintain integrity and eradicate cheating is strong [014]. However, taken together it is obvious that the fight against doping not only is played on a morality ground but also have economical implications.

Although difficult to document, it has been postulated that more steroid use takes place outside organized sport, within body-building and other subcultures, where no attempt is made to address drug-taking behaviour. Adolescent athletes, often eager to gain weight and muscle mass, are ripe targets for those who offer easy approaches that promise startling results in just a few weeks. To some, performance and size are paramount; they are seen to be the keys to success and stardom. And therein lies a special challenge for physicians interested and involved in sport: one must ensure that those athletes and, perhaps more importantly those who coach them, develop approaches to sporting success that emphasize excellence in every domain. Pharmacologic approaches to enhanced performance represent a witches' brew of distorted values and maligned perspectives with potentially devastating health risks [08014]. This means that doping is not a problem only for the athletic movements.

Semantics in doping

Several studies have looked at the unsupervised drug habits of AAS users, but these are clearly subject to different types of bias. Nevertheless, these field studies should not be overlooked. According to the studies, drug regimens follow typical patterns. Different oral and injectable compounds are generally combined (“stacked”), creating large dose regimens usually self-administered during periods (“cycles”) lasting 4-12 weeks. “Stacking” is based on the idea that smaller dosages of multiple drugs might reduce the chance of complications than larger dosages of a single drug. This may also facilitate the administration of multiple AASs (necessary to achieve supraphysiologrphical doses) for longer periods, and so minimizing the plateauing effect. The aim of “stacking” is to rationally combine different characteristics, avoiding overlap of benefits or side effects. Combinations of testosterone and nandrolone (or similar drugs) are the basis of the “massbuilding stacks” used to maximize muscular and strength gains. Combinations containing potent androgens are preferred for dieting and body definition, because of their lack of estrogenic activity (less water, salt and fat retention). These are the “cutting stacks”. Heavy users may combine a “mass-building cycle” with a subsequent “cutting cycle”, finishing with a ‘post-cycle therapy’, with anti-estrogens or hCG, in an attempt to restart androgen production. Frequent users may also combine AASs with other “performance drugs”, such as painkillers (including opioids), diuretics, insulin, growth hormone, stimulants, aromatase inhibitors and thyroxine [11028].
Political and economical aspects of anti-doping

One article examines the processes by which the Anabolic Steroid Control Act of 2004, an act that added steroid precursors such as androstenedione to the list of Schedule III Controlled Substances in the United States, came to pass in both the House of Representatives and the Senate. Grounded theoretically in political economy, the article addressed how the interplay of political pressures and economic influences stands to affect the actions of public officials, and how "tougher" drug policies-those touted to be more substantive and efficacious than existing regulations-often fail to effect change. The article concludes with implications for those involved in the regulation of anabolic steroids and steroid precursors [06011].

Social and socio-medical issues

Social psychological determinants

The aim of one study was to identify the social psychological determinants of the use of performance-enhancing drugs by gym users who practice bodybuilding, fitness, powerlifting or combat sports. In this questionnaire-based study, 144 respondents answered questions on their actual use and intention to use such drugs and also on their background characteristics and beliefs, such as their attitudes, social influences and self-efficacy. While all social psychological determinants correlated with intention to use these drugs, the most important predictors were personal norms, beliefs about performance outcomes and the perceived behavior of others. Non-users held more restrictive norms about using performance-enhancing drugs, were less optimistic about the performance-enhancing outcomes and believed that fewer significant others used performance-enhancing drugs than users and ex-users. The results of this study indicate that users attribute advantages to performance-enhancing drugs and are inclined to overlook the risks of using them. Preventive interventions should focus on influencing personal norms and social processes [07019].

Risk-taking individuals, such as those who abuse alcohol or drugs, engage in criminality or have eating disorders, have been shown to have an increased predisposition for doping use. Despite this evidence, questions remain about the relationship between risk behaviours such as abuse of alcohol and narcotics and doping. For example, in a study on 15,000 sports active high school students in the US, there was no correlation between doping use and risk behaviour [Dodge & Jaccard, 2006]. Coakley and Pike [2009] argue that such results reflect young people’s use of alcohol and drugs to escape from reality being a completely different phenomenon to athletes doping to improve athletic performance. Coakley and Pike argue doping is not about violating social and legal norms, typically seen when abusing alcohol and drugs, but rather a manifestation of an “over conformity” in relation to basic norms in sport – the “sport ethic” (which not should be confused with norms of fair play). The “sport ethic” is characterised as how the athlete should prioritise sport and their team before everything else in life, continually striving to improve sporting performances, struggle for victories. Doping becomes a tool in this endeavour. One article investigated doping use in relation to substance abuse, health risks, risks of being caught in a doping control, and other risk behaviours, in a qualitative interview study of 11 Swedish elite athletes sanctioned for using anabolic androgenic steroids (AAS) during their sports careers. Most respondents grew up in secure, intact families with siblings. Virtually all respondents were from working class homes.
where the father typically worked in industry and the mother a housewife who worked part time in retail when the children become older. The majority of respondents were also workers, including business owners, clerks and managers. Most attended a vocational program at high school, although some have no secondary education. No respondent had a university degree. Respondents reported a positive school experience, with good friends and mediocre or good school performances. Most respondents had excellent results in junior and/or senior national championships. Several respondents had a good international record, participating in national teams, with some winning national and international championships. Ten of the respondents were convicted 1990–1996 and one in the mid-2000s. AAS was the only doping agent used by the athletes in this study. None of the respondents reported using other doping agents; some reported amphetamine and cocaine use for social rather than sporting reasons. Respondents in this study were not using AAS in cycles, and were instead using preparations on a daily basis. However, respondents did interrupt use before competitions to avoid being caught in a doping control. Some respondents mentioned that they stopped using AAS when they were injured and unable to carry out their training sessions. Taking AAS without training was typically described as a complete waste of time, effort and drugs. The “gateway effect” seen in other substance use behaviour (where abusing one substance is a risk factor for developing other forms of more harmful drug behaviours) has also been established in doping. Patterns of other substance abuse were investigated in this study. Overall the respondents were very restricted in their use of alcohol and drugs. Substance abuse was unusual among the respondents, and in that sense they could not be regarded as typical risk takers. Their AAS use could characterise them as risk-takers with regards to doping control and health. Overall, the respondents perceived the health risks as very limited. Even though respondents did not perceive any serious health risks due to their use of AAS, they would arguably have been better off if they refrained entirely. However, this depends on what benefits the AAS provide. If athletes have a lot to gain in terms of medals, money, less pain or making exercise easier, and the risks are moderate or small – then doping could be considered a rational choice of action instead of an irrational risk behavior. Only two respondents were uncertain about the positive effects of the steroids. Comparing the positive and negative effects of AAS use, most respondents perceived distinct positive effects from using. It was easier to work-out and they achieved better results. The negative effects of doping were, except for one respondent, very small. Another characteristic of risk-taking behaviour, in addition to the lack rationality, is the failure to analyse the consequences of different opportunities before action. This was also investigated among the respondents by probing how they reasoned in relation to the risk of being caught in doping control, and in connection with possible health risks. Almost all respondents said that they were cautious and used moderate doses. Respondents were asked to self-assess their propensity to take different risks in life using a broad understanding of the concept of risk-taking. To do this, respondents were asked how they see themselves in relation to risk-taking using examples like drug use, crime, gambling, speeding, driving without seat belt, skydiving and bungee jumping. Not one of the respondents describes themselves as risk-takers. It is clear that results focusing on risk behaviour to explain doping use are not relevant to explain AAS use among most of the respondents in this study. The respondent who was the heaviest user went on regular medical surveillance to insure against health risks. Finally, none of the respondents in the study assessed themselves as risk-takers; they described themselves as cautious, calculating, planning and cowardly. The findings around risk and doping may also be a result of the methodological approach taken by the study. Most studies on this topic have a quantitative design. Evaluating different methodological approaches is an important but complex question for doping related research [13034].

Psychological background
Drugs and methods to improve physical performance among athletes have been used since the beginning of sport history, but the use of performance enhancing drugs has not always been regarded as cheating. In short, the motives for doping are improving and maintaining physical functioning, coping with the social/psychological pressures and striving for social and psychological goals, including economic benefits. Factors such as, "doping dilemma", "win at all costs", cost versus benefit, and the specificity of some specific doping agents, also play major roles. It seems that action on the athletes' attitude about the achievement of physical improvement and creating effective methods to reveal the drug abuse, are two main ways in winning the struggle against doping [09005].

One of the major justifications for the ban on the use of performance-enhancing drugs in sport has been that relating to the protection of the health of athletes. One paper subjected this argument to critical analysis by putting it in the context of the broader relationship between sport and health. More particularly, the paper sought to unravel some of the complexities of this relationship by an examination of some aspects of sports sponsorship, particularly with alcohol and tobacco companies; (the health risks associated with elite level sport; and the widespread and legal use within the sporting context of drugs that can have dangerous side effects. The paper concluded with an examination of some aspects of anti-doping policies within sport and it is suggested that a more imaginative approach to athlete education is needed to prevent the misuse of drugs [09006].

A total of 40 talented male and female athletes (mean average age 20 years) from 13 different sports attended 12 focus groups held over the UK intended to investigate athletes' attitudes toward doping. Athletes in general did not report a significant national doping problem in their sport, but exhibited sporting xenophobia with regard to both doping practices and the stringency of testing procedures outside of the UK. Athletes often viewed doping as "unnatural" and considered the shame associated with doping to be a significant deterrent. Athletes perceived no external pressure to use performance enhancing drugs. In response to hypothetical questions, however, various factors were acknowledged as potential pressure points: most notably injury recovery and the economic pressures of elite sport. Finally, a significant minority of athletes entertained the possibility of taking a banned hypothetical performance enhancing drug under conditions of guaranteed success and undetectability. It was concluded that the athletes in this study generally embraced those values promoted in anti-doping educational programmes, although there were some notable exceptions. That the social emotion of shame was considered a significant deterrent suggests anti-doping efforts that cultivate a shared sense of responsibility to remain "clean" and emphasise the social sanctions associated with being deemed a 'drugs cheat', resonate with this atypical social group [10013].

**Athletes' interpersonal antisocial behaviour**

The link between fear of failure and students' antisocial behaviour has received scant research attention despite associations between fear of failure, hostility, and aggression. Also, the effect of sport experience on antisocial behaviour has not been considered outside of the sport context in adult populations. Further, to date, gender differences have not been considered in fear of failure research. To examine whether fear of failure and sport experience predict antisocial behaviour in the university and sport contexts in student athletes, and whether this prediction is the same in males and females; and gender differences exist in antisocial behaviour and fear of failure. British university student athletes (n=176 male; n=155 female; median age 20 year) completed questionnaires assessing fear of failure, sport experience, and antisocial behaviour in both contexts. Fear of failure and sport experience positively predicted antisocial behaviour in university and sport and the strength of these predictions did not differ between males and females; females reported higher levels of fear of devaluing one's self-estimate than males whereas males reported
higher levels of fear of important others losing interest than females. Males engaged more frequently than females in antisocial behaviour in both contexts. It was concluded that fear of failure and sport experience may be important considerations when trying to understand antisocial behaviour in student athletes in education and sport; moreover, the potential effect of overall fear of failure and of sport experience on this frequency does not differ by sex. The findings make an important contribution to the fear of failure and morality literatures [11421].

Subjective effects

The use of anabolic androgenic steroids (AAS) to increase muscle size and strength is widespread. Information regarding self-administered AAS used nonmedically to enhance athletic performance or improve physical appearance is sparse and poorly documented. The purpose of one study was to identify current trends in the drug-taking habits of AAS users. An anonymous self-administered questionnaire was posted on the message boards of Internet Web sites popular among AAS users. Of the 500 AAS users who participated in the survey, 78 percent (392/500) were noncompetitive bodybuilders and nonathletes; 60 percent (298/500) of the respondents reported using at least 1000 mg of testosterone or its equivalent per week. The majority (99%) of AAS users (496/500) self-administer injectable AAS formulations, and up to 13 percent (65/500) report unsafe injection practices such as reusing needles, sharing needles, and sharing multidose vials. In addition to using AAS, 25% of users admitted to the adjuvant use of growth hormone and insulin for anabolic effect, and 99 percent (496/500) of users reported subjective side effects from AAS use. The survey reveals several trends in the nonmedical use of AAS. Nearly four out of five AAS users are nonathletes who take these drugs for cosmetic reasons. AAS users in this sample are taking larger doses than previously recorded, with more than half of the respondents using a weekly AAS dose in excess of 1000 mg. The majority of steroid users self-administer AAS by intramuscular injection, and approximately 1 in 10 users report hazardous injection techniques. Polypharmacy is practiced by more than 95 percent of AAS users, with one in four users taking growth hormone and insulin. Nearly 100% of AAS users reported subjective side effects [06020].

Expectation of the doped

Long-term use of anabolic-androgenic steroids (AASs) is associated with both positive and negative effects. The authors examined possible mechanisms by which these effects contribute to AAS satisfaction and predict intentions for future AAS use. Five hundred male AAS users completed an interactive Web-based instrument assessing the psychological and physical effects of AAS use. Covariance structure modeling was used to evaluate both direct and indirect effects of AAS consequences on satisfaction with AASs and intentions for future AAS use. Results suggest that gain in muscle mass and psychological benefits from AAS use uniquely contributed to both AAS satisfaction and intentions for future use. Side effects from AAS use also uniquely contributed to AAS satisfaction, but ancillary drug use was found to partially mediate this relationship, suggesting that the satisfaction of experienced AAS users is enhanced by their mastery of side effects through the use of ancillary drugs. The final model explained 29 percent of the variance in intentions for future AAS use. Mechanisms for sustained AAS use and implications for intervention and prevention strategies are discussed [06013].

Muscle dissatisfaction in young adult men

Appearance concerns are of increasing importance in young men’s lives. It was investigated whether muscle dissatisfaction is associated with psychological symptoms, dietary supplement or anabolic steroid use, or physical activity in young men. As a part of a
questionnaire assessment of health-related behaviors in the population-based FinnTwin16 study, we assessed factors associated with muscle dissatisfaction in 1245 men aged 22-27 using logistic regression models. Of men, 30 percent experienced high muscle dissatisfaction, while 12 percent used supplements/steroids. Of highly muscle-dissatisfied men, 22 percent used supplements/steroids. Mean body mass index, waist circumference, or leisure aerobic activity index did not differ between individuals with high/low muscle dissatisfaction. Muscle dissatisfaction was significantly associated with a psychological and psychosomatic problems, alcohol and drug use, lower height satisfaction, sedentary lifestyle, poor subjective physical fitness, and lower life satisfaction. It was concluded that muscle dissatisfaction and supplement/steroid use are relatively common, and are associated with psychological distress and markers of sedentary lifestyle [06014].

Beliefs about the causes of success in sports and susceptibility for doping
One study set out to assess the impact of attributional beliefs about success on the susceptibility for doping use in adolescent athletes. The sample consisted of 309 adolescent athletes participating in both team and individual sports. Participants completed a battery of questionnaires including Beliefs about the Causes of Success in Sport Questionnaire (BACSSQ), current and past doping use, and measures of attitudes, norms, situational temptation and social desirability. Variance reduction rate analysis revealed that social desirability did not act as a confounder in the relationship between doping susceptibility and its predictors. With regard to beliefs about the causes of success dimensions, only deception emerged as a significant predictor of doping use susceptibility over and above the effects of well-established social-cognitive predictors of doping intentions and use. These findings imply that beliefs about the causes of success in youth sports may comprise another dimension of risk factors for doping susceptibility and use [13051].

Rejuvenation
A search for a hormonal fountain of youth has been hotly pursued over the last century, predominately by those who wish to market hormones to a gullible public. There is little or no benefit of hormone replacement in persons who do not have a hormone deficiency. Overall, the present state of the art suggests that the findings have been disappointing. In persons who fail to get adequate sunlight, and therefore have low vitamin D levels, vitamin D replacement appears to have positive effects, including decreasing mortality. Testosterone in hypogonadal males has a number of positive effects such as improving libido and erectile capacity, increasing strength and bone mineral density, and perhaps having a small effect on cognition. These effects need to be balanced against long-term side effects, the evidence for which studies are lacking. There is little evidence to recommend DHEA, pregnenolone, growth hormone, ghrelin, or melatonin to older persons. Overall, exercise, adequate exposure to sunlight, and adequate dietary protein appear to have at least as positive an effect as any of the hormones being used to rejuvenate older persons [13052].

Interaction between athletes and coaches
The sport nutrition and doping are known to be important issues in sports, but there is evident lack of studies which investigated those issues in swimming, especially with regard to parallel analysis of coaches and athletes. The first aim of one study was to compare knowledge of swimming coaches and their athletes about nutrition and doping. Also, it was identified interrelationships between studied sociodemographic-, sport-; nutrition- and doping-related-factors. The sample of subjects comprised 55 athletes (20 years of age; 24
females) and 22 coaches (mean age 37 years; 4 females) from Croatia (98% of respondents). In the first phase of the investigation we have validated specific questionnaires to determine the knowledge of sport nutrition (KSN), and knowledge on doping (KD). The test-retest correlation and percentage of equally responded queries revealed both questionnaires as reliable. The discriminative validity was proven also since coaches scored better than their athletes on both questionnaires. Athletes declared their coaches as the primary sources of knowledge about nutrition and doping. Among coaches, formal and self-education are equally important sources of information about doping and nutrition. The age is negatively, while the formal education is positively correlated to KD and KSN scores among coaches. Consequently, permanent educational programs about nutrition and doping are emphasized, especially among older coaches and younger athletes [13053].

Athlete support personnel (ASP) failing to meet responsibilities under the World Anti-Doping Code risk sanction. It is unclear whether the poor knowledge of responsibilities seen in sports physicians and coaches applies to other ASP (e.g. administrators, chiropractors, family, nutritionists, physiotherapists, psychologists, and trainers). A purposive sample of Australian ASP (n=292) responded to a survey on knowledge of anti-doping rules (35 true/false questions), ethical beliefs and practice, and attitudes toward performance enhancement. Some ASP declined to participate, claiming doping was irrelevant to their practice. Physicians were most knowledgeable (31/35), with family and trainers the least (26/35). ASP reported that improvements were needed to support anti-doping education (e.g., basis for anti-doping) and practice (e.g. rules). ASP also had a slightly negative attitude toward performance enhancement. Linear regression showed that being a sports physician, providing support at the elite level, and 15 years of experience influenced knowledge. The results confirm gaps in knowledge, suggesting that stronger engagement with ASP anti-doping education and practice is needed. Applying the principles of andragogy could help foster active engagement through emphasis on active inquiry, rather than passive reception of content [13054].

The purpose of one study was to examine whether the relationships between contextual factors (i.e. autonomy-supportive vs. controlling coaching style) and person factors (i.e. autonomous vs. controlled motivation) outlined in self-determination theory (SDT) were related to prosocial and antisocial behaviors in sport. We also investigated moral disengagement as a mediator of these relationships. Athletes’ (n=292, median 19 years) responses largely supported our SDT-derived hypotheses. Results indicated that an autonomy-supportive coaching style was associated with prosocial behavior toward teammates; this relationship was mediated by autonomous motivation. Controlled motivation was associated with antisocial behavior toward teammates and antisocial behavior toward opponents, and these two relationships were mediated by moral disengagement. The results provide support for research investigating the effect of autonomy-supportive coaching interventions on athletes' prosocial and antisocial behavior [11419].

Sports addiction

Socially valorised, sport like other forms of behaviour, can take on an addictive aspect. A review of the English and French literatures from 1979 to 2012 was conducted, using PubMed, Google Scholar, EMBASE, and PsycInfo, using the following key words alone or combined: sport, dependence, exercise, addiction. Exercise dependence is defined as a craving for physical activity that leads to extreme exercise intensity and generates physiological and psychological symptoms. Measurement scales have been proposed to make the diagnosis. No epidemiological studies have examined the prevalence of exercise dependence in the general population, although some studies suggest a frequency ranging
from 10 to 80 percent. Disorders begin with a search for pleasure in physical effort, which then gives way to an obsession for sport resulting in a need to practice a sport more and more frequently and intensely. This addiction is more common among alcohol and illicit drug addicts than among the general population, while the rate of eating disorders can reach 40 percent. Personality traits most often associated are perfectionism, extraversion, and sensation seeking, while possible links between sporting activity and intensive doping will be discussed [13039].

**Motivational and social cognitive predictors of doping**

Doping use is an important issue in both competitive and non-competitive sports, and poses potentially irreversible health consequences to users. Scholars increasingly call for theory-driven studies on the psychosocial processes underlying doping use that will inform subsequent policy-making and prevention interventions. The aim of the study was to implement an integrative theoretical model to assess the direct and indirect effects of motivational variables, moral orientations, and social cognitions on doping intentions. A randomly selected and representative sample of 750 elite athletes anonymously completed a battery of questionnaires on motivational and moral constructs, and social cognitions related to doping. Hierarchical linear regression analysis and multiple mediation modeling were used. The effects of achievement goals and moral orientations were significantly mediated by attitudinal, normative, and self-efficacy beliefs, in both lifetime ever and never doping users. Moral orientations indirectly predicted the doping intentions of never users, but did not predict ever users’ doping intentions. Achievement goals and sportspersonship orientations influence doping intentions indirectly, through the effects of attitudes and self-efficacy beliefs. Sportspersonship (moral) orientations were relevant to doping intentions among athletes with no prior experiences with doping, while achievement goals and situational temptation were relevant to both lifetime never and ever dopers [13040].

**Motives for use**

Several factors that are unique to our current society may contribute to young people’s using drugs to succeed in sports. First is the message that is being sent by many sports idols today. The steroid investigations in baseball and books by former players make it clear that steroids and other drugs have played a part in many record-breaking performances. However, the fame and the respect that still is garnered by these athletes sends the message that ergogenic drugs are accepted, if not necessary, to reach such success. As young athletes begin to model themselves after sport icons, heartbreaking stories are beginning to unfold. One young athlete in a tear-filled confrontation with his father only months before committing a now highly publicized suicide linked to his steroid use confessed, “I'm on steroids, what do you think? Who do you think I am? I'm a baseball player, baseball players take steroids. How do you think Bonds hits all his home runs? How do you think all these guys do all this stuff? You think they do it from just working out normal?” Second, society today places a huge emphasis on sports with collegiate football stadiums seating nearly 100000 people and countless events featured on national television. From high school basketball all-star games to the Little League World Series, our youths are placed under the national spotlight at exceedingly young ages. With professional scouts now following high school sports and collegiate coaches eyeing even younger talent, the pressure to succeed is placed now on younger, more impressionable shoulders than ever before. Finally, several economic factors encourage drug use to gain an edge in sports. One is the resultant money and social stature that accompany athletic success when worthy of garnering professional contracts. Another more subtle but increasingly wide-reaching monetary influence is the rising cost of collegiate education. This has been shown to be a
self-reported factor for high school girls to use performance-enhancing drugs while competing for prestigious and now very valuable athletic scholarships to college. Whether they turn to ergogenic drugs for the competitive edge or as a means of keeping up with fellow students who are already using these substances, it is clear that the pressure to do so is significant today [06003].

The use of anabolic androgenic steroids (AAS) has been associated with the use of illegal drugs. Earlier observations suggested that users of illegal drugs may use AAS for reasons other than increasing muscle strength or size. The aim of one study was to investigate the motives for AAS use among outpatients at a substance abuse center in Stockholm, Sweden. All male patients under the age of 50 were asked whether they had used AAS during a 2-month period. An AAS survey was administered to those who reported AAS experiences in the admittance interview. Twenty of the 175 respondents (11%) reported using AAS. The most frequently reported motives were related to anabolic effects (i.e. for a good-looking body, to become stronger, or to perform better in sports). However, some users reported other motives; for example, to conceal concomitant drug use, to alleviate insecurity or low self-esteem, to become brave, or in preparation of committing a crime. Furthermore, many respondents reported side effects that were associated with AAS; most notably, irritability and depression/suicidal ideation. It was concluded that some users of illicit drugs also use AAS for reasons other than the anabolic properties of these compounds. Therefore, considering that AAS may cause or contribute to diverse morbidity, it is important to ask users of illicit drugs about AAS use, even when obvious external signs of AAS use are lacking [10014].

One study presents an opportunistic examination of the theoretical tenets outlined in the Australian Sport Drug Control Model using questionnaire items from a survey of 643 elite Australian athletes. Items in the questionnaire that related to the concepts in the model were identified and structural equation modelling was employed to test the hypothesised model. Morality (cheating), benefit appraisal (performance), and threat appraisal (enforcement) evidenced the strongest relationships with attitude to doping, which in turn was positively associated with doping susceptibility. Self-esteem, perceptions of legitimacy and reference group opinions showed small non-significant associations with attitude to doping. The hypothesised model accounted for 30 percent and 11 percent of the variance in attitudes to doping and doping susceptibility, respectively. These present findings provide support for the model even though the questionnaire items were not constructed to specifically measure concepts contained in it. Thus, the model appears useful for understanding influences on doping. Nevertheless, there is a need to further explore individual and social factors that may influence athletes' use of performance enhancing drugs [11003].

One study aimed to construct a hierarchy of motives linked to doping behaviors. Between 2000 and 2005, calls to a national antidoping phone-help service by 115 cyclists, 203 bodybuilders, and 40 footballers were analyzed. The results showed that the main motives were preserving health for cyclists, increasing muscular strength for bodybuilders, and personal recreation for footballers. However, in contrast to the literature, group influence was low and health preoccupations were high for cyclists; the influence of body image was relatively low for bodybuilders; and footballers cited muscular strength enhancement as a motive. The study's limitations are noted. The prevention campaigns therefore need to be specific [11004].

Anti-ageing and body building substances became widely accepted in the 21st century due to modified social and economical attitudes. Such requirements are characteristic of a visually oriented consumer society. The body is considered to be a marker of social prestige and in the striving for a nicer appearance is becoming a part of šperaon's identity. Medical
and pseudo-medical approaches have been developed to fulfill these desires. In the general perception of a modern society such efforts are considered as positive, but some of such procedures are potentially risky, while others seem to be not efficient [07013].

One paper addressed a gap in the literature of empirically derived models of performance enhancing supplement use by developing a demographic and psychosocially based model of athlete supplement use. Selected questions were used from a larger survey conducted by UK Sport into British athletes’ experiences, knowledge, attitudes and opinions in relation to anti-doping activities. Forward conditional step wise logistic regression was employed on data from 757 athletes to develop a model that discriminated supplement non-users from users. The model identified that British athletes most likely to use supplements were younger (under 23) males who were more likely to see doping as a problem in their sport and were more knowledgeable about testing procedures than their non-user counterparts. Post hoc analysis reinforced that non-users saw doping as less of a problem in their sport and were less knowledgeable about drug testing procedures relative to those using supplements. The pattern of results indicated gender-specific interventions on supplement use for young male athletes may yield significant benefits. The relationship between supplement use and perception of a doping problem suggested more work is needed to understand supplement use culture within sports. The relationship between knowledge of testing procedures and supplement use suggested further research is needed to see whether this is a positive or negative effect of detection-based doping deterrence activity [07014].

The objective of this study was to use self-determination theory to analyze the relationships of several motivational variables with exercise dependence. The study involved 531 exercisers, ranging in age from 16 to 60 years old, who responded to different questionnaires assessing perception of motivational climate, satisfaction of basic psychological needs, motivation types, and exercise dependence. The results of multiple mediation analysis revealed that ego-involving climate and perceived competence positively predicted exercise dependence in a directed and mediated manner through introjected and external regulation. Gender and age did not moderate the analyzed relationships. These results allow us to better understand the motivational process explaining exercise dependence, demonstrating the negative influence of the ego-involving climate in the context of exercise [12020].

**Specificity of motives for doping**

Most of the data to rank doping motives have been gathered from epidemiological with the use of questionnaires. However, questionnaires are known to systematically underestimate the reality (regarding the nature and relative proportion of motives) of addictive behaviors because of common social representations of doping. Qualitative studies based on retrospective interviews or information from champions’ confessions tend to emphasize extrinsic reasons for doping and thereby limit personal responsibility and protect self-esteem. Moreover, the “true story” may be modified to limit the risks of sanction. Whatever the protocol design, researchers are confronted with the approach to doping in sport, in which it is never admitted to any substance abuse. Furthermore, the motives for using prohibited substances seem to concern a minority of athletes: generally those of a high level and those who have tested positive in doping controls. The motives offered by these athletes, such as enhancing performance, increasing financial gain, and making a sporting name for one-self, are associated with common social representations. The studies to determine and rank the motives for secretive doping behaviors have met with methodological difficulties. Few sporting figures have a personal interest in breaking the secrecy of doping, not individual athletes or teammates, staff or federation members, journalists, or sponsors. Deliberately damaging the popular myth of athletic perfection is anathema to virtually all members of the world sporting community. Thus, the power of common social representations limits access to the real thoughts and behaviors concerning doping.
Researchers can obtain cold cognitions, with memory biases (deliberate or not), reconstructions to protect self-esteem, and external causal attributions. But classical interviews with athletes who have tested positive cannot deliver “the whole story.” These athletes are under intense social pressure and at risk of condemnation; media scrutiny has a powerful impact, and any inquiry is retrospective, with responses subject to deformation and omission. Doping thus remains a taboo, and the biases inherent to standard retrospective studies are too great to obtain a model with quantitative ranking of doping motives in athletes. Moreover, many studies have focused their investigations on adolescents, sportspersons of a low level (local, regional), or retired elite athletes. Nevertheless, the evidence shows that the risk of doping is highest among men, young adults (20-25 years old), and high-level practitioners [10303].

One study aimed to construct a hierarchy of motives linked to doping behaviors. Between 2000 and 2005, calls to a national antidoping phone-help service by 115 cyclists, 203 bodybuilders, and 40 footballers were analyzed. The results showed that the main motives were preserving health for cyclists, increasing muscular strength for bodybuilders, and personal recreation for footballers. The cyclists first cited health concerns to justify the use of several illicit substances (rank 1). They reported trying to reduce health problems associated with their sport. Other motives in the same vein were limiting pain during effort (rank 6), reducing fatigue (rank 7), reducing pain in general (rank 10), treating acute injury (rank 14), and enhancing fatigue recovery (rank 14). It was thus logical that glucocorticosteroids were the most cited substance (35%). Therefore, the priority of the cyclists appeared to be a strategy to preserve fitness and prevent injuries and symptoms due to intensive training. Their health concerns were due to the training intensity and sensitivity to pain and fatigue. Associated with this motive, it was also observed that sport doctors were a real support in justifying consumption (rank 4). Cyclists have been shown to be predisposed to collaborate with team sport doctors to treat and medicate for any health concerns that may affect their performance. It is also interesting to note that concern for health was the argument put forth by the east Germans to defend their use of illegal substances: They argued that these substances were used not as performance enhancers but as performance enablers. From their viewpoint, these substances were required to maintain homeostasis during heavy and prolonged training. This conception (i.e. medical use of substances to maintain health) is also a current topic in American horse racing, another example that emphasizes the complexity of understanding the “doping” activity. The second motive was performance enhancement (rank 2). The third motive was the social norms associated with the sport. The cycling subculture has a powerful impact on its members. Cycling is ruled by implicit principles that create high team cohesion. Doping is one of the principles of this cohesion, but no one refers to it. The risks are minimized, considered as banal, so that they become normal. The first motive for the bodybuilders was strength enhancement. Thus, the frequent phone discussions about steroids were unsurprising (78%), as noted by several researchers and as it has been shown that 38 percent of amateur bodybuilders used anabolic steroids, but body image disturbance was not the main reason. First of all, these athletes hoped to increase their muscular strength and seemed to be in good shape. The doping substance might not be considered by the bodybuilders to be dangerous. The substance is perceived as a “natural” addition of exercise to rapidly increase muscular volume. The second motive was the sport's norms. Bodybuilders justify doping as a natural means to increase muscular volume, improve attractiveness, and decrease fatigue. Because nearly all bodybuilders consume these substances, their use is legitimized. Moreover, the bodybuilders reported receiving considerable advice from proximal circles such as other athletes (rank 7), family (rank 11), dealers (rank 12), others (rank 13), and friends (rank 15). This finding supports the observation that bodybuilders have higher scores of social dependence than other athletes. They easily follow the lead of others in denying any inappropriate behavior and controlling their use of anabolic substances. They underestimate their own consumption compared with
other athletes who use steroids dangerously in intensive sessions, such as cyclists. The third motive was body image. The high value that society gives to physical attractiveness encourages bodybuilders to try to conform to an ideal image. They are fascinated by their own image, and the walls of mirrors in fitness centers reinforce this feeling. This motive was associated with the need to affirm masculine identity. The bodybuilders wanted to become more “male” and attractive. They hoped to dominate and use their bodies as a power vehicle. However, in this particular sport culture, a pervasive belief is that power must be acquired by pain and effort, enhancing virility and courage, with bodybuilders seen as modern gladiators. The first motive of the footballers was conformity to the social norms of their general culture and not their sport. This motive was associated with the influence of friends (rank 4) and suggests that football exerts a pressure on players to do as others do. The substances massively cited were cannabinoids (52 %) as well as stimulants (13 %). Creating and maintaining a festive atmosphere thus emerged as a predominant motivation are widely used at social events among friends and are characterized by relaxation and a decrease in inhibition. They are found in all social classes. Although the players reported using cannabis for reasons other than performance enhancement, the substance is still prohibited by football governing bodies and the WADA. The group enhances a collective dynamic to use this substance. The second motive was the control of anxiety, probably due to the uncertainty of the game results. The game of football is highly unpredictable because it is a team sport that depends on the performances of many players, the performances of opponents, the weather, the partiality/impartiality of referees, coaches’ choices, and injuries, among other. The high number of factors that footballers cannot control generates considerable anxiety. The efficiency of cannabis to decrease anxiety has been well demonstrated. Use of this substance can also be a self-handicapping strategy to limit the impact of poor sporting results and explain defeat. The third motive was strength enhancement. Football requires leg speed, and anabolic steroid substances can enhance individual performance during matches. The results showed that doping motives differed between cyclists, bodybuilders, and footballers. The main motives for doping were specific: preserving health for cyclists, increasing muscular strength for bodybuilders, and enjoyment for footballers. The callers all knew the best substances to obtain the desired effect. Compared with the literature, the surprising results of this study were the weak group influence and the impact of health preoccupations for the cyclists, the relatively low influence of body image for the bodybuilders, and the motivation to increase muscular strength in the footballers. Thus, prevention campaigns need to be specific. Comparing motives for prohibited substance use can lead to confusion if the individual sport is not taken into consideration. The first motive cited by cyclists indicates the paradoxical strategy of current antidoping campaigns. The campaigns focus on the dangers of illicit substances to athletes’ health. Yet these athletes were using appropriate and efficient substances to preserve their health. Thus, a prevention message targeting health maintenance misses the point because their main doping motive is to combat the very real (and subjective) risk of falling ill. The real risk instead seems to be self-medication, and a more effective message to cyclists should thus emphasize means to maintain a good balance between high performance and optimal health. Issues of domination and male identity need to be addressed in campaigns for bodybuilders via better health education. Prevention should be more focused on body self-acceptance. The footballers hoped to strengthen their team relationships. Prevention campaigns must insist on limiting use of recreational drugs and supplements [10303].

The use of anabolic androgenic steroids (AAS) has been associated with the use of illegal drugs. Earlier observations suggested that users of illegal drugs may use AAS for reasons other than increasing muscle strength or size. The aim of the present study was to investigate the motives for AAS use among outpatients at a substance abuse center in Stockholm, Sweden. All male patients under the age of 50 were asked whether they had used AAS during a 2-month period. An AAS survey was administered to those who reported
AAS experiences in the admittance interview. Twenty of the 175 respondents (11%) reported using AAS. The most frequently reported motives were related to anabolic effects (i.e. for a good-looking body, to become stronger, or to perform better in sports). However, some users reported other motives; for example, to conceal concomitant drug use, to alleviate insecurity or low self-esteem, to become brave, or in preparation of committing a crime. Furthermore, many respondents reported side effects that were associated with AAS; most notably, irritability and depression/suicidal ideation. It was thus concluded that some users of illicit drugs also use AAS for reasons other than the anabolic properties of these compounds. Therefore, considering that AAS may cause or contribute to diverse morbidity, it is important to ask users of illicit drugs about AAS use, even when obvious external signs of AAS use are lacking [10316].

Population heterogeneity
Appearance- and performance-enhancing drugs (APEDs) constitute a wide range of substances, including anabolic-androgenic steroids, nonsteroidal anabolics, and licit and illicit ergo/thermogenics. A great deal of heterogeneity exists in APED use patterns among weight-lifting men, and, consequently, little is known about how these patterns are related to side effect profiles or risk potential. In the current study, a sample of 400 adult men who were regular APED users completed an interactive Web-based instrument detailing information about APED use, side effects, and related indicators of risk. To explore the heterogeneity of APED use patterns, the authors subjected data on use patterns to latent class analysis (LCA), latent trait analysis (LTA), and factor mixture analysis to determine the best model of APED use. Results indicated that a 4-class factor mixture model provided a better fit than LCA and LTA models. The authors also found that severity and latent class were uniquely associated with negative outcomes. Each of the 4 classes was associated with unique side effects, motivations, and participant use patterns. Implications for identifying pathological forms of APED use are discussed [07016].

An age factor
It was attempted to qualitatively investigate why men of two age categories have chosen not to use androgenic-anabolic steroids (AASs). Twelve men (22 years [group I] and 53 years [group II]) were selected on the basis of specific inclusion criteria, including age and fitness levels (i.e. "do you weight train?"). Subjects were classified in 1 of 2 categories-younger or older precluders-and were asked to complete two survey instruments before their participation. The Drive for Muscularity Scale (reliability 0.85) and Body Image Questionnaire were used to gain a better understanding of perceptions and motivations regarding health, fitness, and body image. A series of semistructured questions were used to enhance focus group discussion regarding attitudes. Questions were validated by a panel of experts in qualitative methods. Member checks were conducted to enhance trustworthiness of the data. Data were transcribed verbatim and analyzed with thematic open-coding techniques. Various behaviors were reported regarding body image. Emerging themes showed a clear demarcation between age categories. Younger subjects cited power, control, body image, and narcissism, whereas older subjects viewed AAS use as more of an athletic-based phenomenon, such as with performance enhancement, when asked about steroids. Groups were in agreement that media trends and perceptions of the ideal male body are becoming "superhuman" and unattainable without chemical means. Understanding attitudinal perspectives might help complement national data on AAS trends. Future investigations could help coaches and allied health professionals collaborate with each other, as well as with national groups and foundations, to devise more appropriate strategies in addressing this growing athletic and public health concern [07017].

Elite athletes’ attitudes, beliefs, and knowledge
In the absence of objective information on the use of performance-enhancing drugs (PED), attitudes are often used as a proxy for doping behaviour, assuming that those who use banned substances show greater leniency towards doping than those who stay clear of doping. Consequently, researchers have identified the need to develop more sophisticated and bespoke interventions to support the athletes with attitudes that increase their likelihood of using banned substances, and the need to develop empirically tested models. Doping has evolved greatly in recent years, and greater understanding of it is essential for developing efficient prevention programmes. In the psychosocial approach, attitudes are considered an index of doping behaviour, relating the use of banned substances to greater leniency towards doping. The aim of one review was to gather and critically analyse the most recent publications describing elite athletes' attitudes, beliefs and knowledge of doping in sport, to better understand the foundations provided by the previous work, and to help develop practical strategies to efficiently combat doping. For this purpose, we performed a literature search using combinations of the terms "doping", "sport", "elite athletes", "attitudes", "beliefs", "knowledge", "drugs", and "performance-enhancing substances" (PES). A total of 33 studies were subjected to comprehensive assessment using articles published between 2000 and 2011. All of the reports focused on elite athletes and described their attitudes, beliefs and knowledge of doping in sport. It has been emphasized that athletes who use banned substances mainly do so to improve their performance, even though most athletes acknowledge that doping is dishonest, unhealthy and risky because of the impact of sanctions. The "false consensus effect" seems to play a key role in legitimizing the use of banned substances. Anti-doping programmes are generally considered to be ineffective and inefficient, and the way tests are performed is often criticized, particularly WADA's location reporting system. Athletes consider the severity of punishment to be appropriate or not severe enough, although there are some differences between sports. In this sense, the advisors and stakeholders who can influence athletes should also be educated and punished if they are found guilty of supporting doping. In this way, all interested parties would be aware of the magnitude of the problem. The current generation of athletes is more familiar with anti-doping rules than earlier generations, but there is still a lack of knowledge that should be improved using well designed educational programmes. There is also a distinct lack of information around dietary supplements and the possible side effects of PES. There is a general belief about the inefficacy of anti-doping programmes, and athletes criticise the way tests are carried out. Most athletes consider the severity of punishment to be appropriate or not severe enough. There are some differences between sports, as team-based sports and sports requiring motor skills could be less influenced by doping practices than individual self-paced sports. However, anti-doping controls are less exhaustive in team sports. The use of banned substance also differs according to the demand of the specific sport. Coaches appear to be the main influence and source of information for athletes, whereas doctors and other specialists do not seem to act as principal advisors. Athletes are becoming increasingly familiar with anti-doping rules, but there is still a lack of knowledge that should be remedied using appropriate educational programmes. There is also a lack of information on dietary supplements and the side effects of PES. Therefore, information and prevention are necessary, and should cater to the athletes and associated stakeholders. This will allow us to establish and maintain correct attitudes towards doping. Psychosocial programmes must be carefully planned and developed, and should include middle- to long-term objectives (e.g. changing attitudes towards doping and the doping culture). Some institutions have developed or started prevention or educational programmes without the necessary resources, while the majority of the budget is spent on anti-doping testing. To minimize the phenomenon of doping, information and prevention programmes, starting with athletes at a young age, and involving other stakeholders (e.g. the athletes’ doctors, coaches or family), are necessary to establish and maintain correct attitudes and behaviours. It is also very important that the sport institutions at all levels (from WADA to regional governments) provide more resources to psychosocial projects in relation to the biomedical approach (i.e. anti-doping controls),
which have been the main priority of anti-doping programmes currently in use. Also, event organizers and federations should check that sporting rules do not favour the possible advantages of using banned substances in competitions (i.e. by reducing the distance covered in competitions, allowing longer recovery between stages and encouraging, where possible, the importance of technical/tactical aspects rather than physical aspects). The programmes targeting athletes and those around them must be carefully planned and developed as a middle- to long-term objective and, ultimately, change attitudes towards doping and the doping culture. Current research methods are weak, especially questionnaires. A combination of qualitative and quantitative measurements are recommended, using interviews, questionnaires and, ideally, biomedical tests. Studies should also examine possible geographical and cultural differences in attitudes towards doping [13017].

Reports of illicit substance use by college athletes have become commonplace in recent years, yet comparatively little effort has been put forth by the research community to understand these behaviors. Data for this study came from a large, national dataset collected by the National Collegiate Athletic Association (NCAA). This study compared substance use behaviors of male undergraduate student athletes who reported using ergogenic performance enhancing substances (e.g., anabolic steroids and peptide hormones) during college (PES users) to those who did not (PES non-users). A consistent pattern of higher substance use rates was observed among PES users compared to non-users, including heavier drinking, higher prevalence rates of cigarettes, marijuana, amphetamines, narcotics, and a variety of permissible and impermissible dietary supplements. An unexpected finding was that there were large discrepancies in reported prevalence rates between similar or overlapping survey items (e.g., past year use of "narcotics" versus "I have taken Vicodin, Oxycontin or Percocet with/without a prescription"). These findings suggest that male college athletes who use PES while in college demonstrate a general tendency to engage in alcohol and drug use behaviors, regardless of whether these behaviors improve or impede athletic performance. The results further suggest that college athletes may not fully appreciate drug categorizations that are commonly employed to gauge substance use behaviors. Changes to drug education and prevention programs may be needed to enhance understanding of drug properties and actions [13041].

It was examined whether constructs outlined in self-determination theory [Deci & Ryan, 2002], namely, autonomy-supportive and controlling motivational climates and autonomous and controlled motivation, were related to attitudes toward performance-enhancing drugs (PEDs) in sport and drug-taking susceptibility. It was also investigated moral disengagement as a potential mediator. It was surveyed a sample of 224 competitive athletes (59 % female; median age 20 years; median 10 years of experience participating in their sport), including 81 elite athletes. Using structural equation modeling analyses, the hypothesis proposing positive relationships with controlling climates, controlled motivation, and PEDs attitudes and susceptibility was largely supported, whereas our hypothesis proposing negative relationships among autonomous climate, autonomous motivation, and PEDs attitudes and susceptibility was not supported. Moral disengagement was a strong predictor of positive attitudes toward PEDs, which, in turn, was a strong predictor of PEDs susceptibility. These findings are discussed from both motivational and moral disengagement viewpoints [13797].

Although nutrition and doping are important factors in sports, neither is often investigated in synchronized swimming (Synchro). One study aimed to define and compare Synchro athletes and their coaches on their knowledge of sports nutrition (KSN) and knowledge of doping (KD); and to study factors related to KSN and KD in each of these groups. Additionally, the KSN and KD questionnaires were evaluated for their reliability and validity. Altogether, 82 athletes (17 ± 2 years of age) and 28 coaches (31 ± 5 years of age) from
Croatia and Serbia were included in the study, with a 99 percent response rate. The test and retest correlations were 0.94 and 0.90 for the KD and KSN, respectively. Subjects responded equally to 91 percent queries of the KD and 89 percent queries of the KSN. Although most of the coaches are highly educated, they declared self-education as the primary source of information about doping and sport-nutrition. Coaches scored higher than their athletes on both questionnaires which defined appropriate discriminative validity of the questionnaires. Variables such as age, sports experience and formal education are positively correlated to KSN and KD scores among athletes. The athletes who scored better on the KD are less prone to doping behavior in the future. These data reinforce the need for systematic educational programs on doping and sports nutrition in synchronized swimming. Special attention should be placed on younger athletes. Although most of the synchro coaches are highly educated, self-education is declared as the primary source of information about doping and sport-nutrition. The knowledge of doping and doping-health hazards are negatively related to potential doping behavior in the future among synchronized swimmers. The data reinforce the need for systematic educational programs on doping and sports nutrition in synchronized swimming. It was advocated improving the knowledge of sports nutrition among older coaches and the knowledge of doping among younger coaches, while among athletes, younger swimmers should be targeted [13042].

Although athletes' beliefs and values are known to influence whether or not an athlete will use banned drugs, little is known about the athletes' beliefs and attitudes in different sports. The aim of this study was to clarify the beliefs and attitudes of elite athletes towards banned substances and methods in sports. A total of 446 athletes (response rate 90 %; 446/494) financially supported by the National Finnish Olympic Committee completed a structured questionnaire during their national team camps in 2002. More than 90 percent of the athletes reported to believe that banned substances and methods have performance enhancing effects, and 30 percent reported that they personally know an athlete who uses banned substances. Of the male athletes 35 percent, and 23 percent of females reported they personally know an athlete using banned substances. A total of 15 percent of the athletes reported that they had been offered banned substances: 21 percent of the speed and power athletes, 14 percent of the team sport athletes and of the athletes in motor skills demanding events, and 10 % of the endurance athletes. Stimulants were the most often offered substance group (to 7 % of all the athletes) followed by anabolic steroids (4 %). Subjects who regarded doping as a minor health risk seemed to be more often associated with doping users than those regarding doping as a significant health risk. Athletes in different sports have a different approach to doping. Risk of doping appears to be highest in speed and power sports and lowest in motor skills demanding sports. Males are at higher risk than females. Controlling doping only by tests is not sufficient. A profound change in the attitudes is needed, which should be monitored repeatedly [06015].

One study aimed to investigate, among a sample of elite Australian athletes, the extent to which this group supports drug testing as a deterrent to drug use. Data was collected from a convenience sample of (n=974) elite Australian athletes who self-completed a questionnaire, and semi-structured telephone surveys with key experts. The athletes surveyed endorsed testing for banned substances as an effective way of deterring drug use; believed that the current punishments for being caught using a banned substance was of the appropriate severity; and indicated that there should be separate policies regarding illicit drug and performance-enhancing drug use. A large proportion of elite athletes in Australia endorse drug testing as an effective means of deterring drug use. However, they perceive a difference between being detected using a performance-enhancing drug and an illicit drug and believe that penalties should reflect this difference. Future research may wish to investigate attitudes towards newer methods employed to detection drug use [10315].
Information-seeking behaviours among elite athletes

Many sporting organisations conduct drug information seminars for their athletes; however, it is uncertain whether these programs provide athletes with pertinent drug information in formats that are conducive to information retention. The aims one study were to investigate self-reported confidence in knowledge of illicit drugs and information seeking behaviours among elite athletes. Data were collected from two sources: quantitative surveys with elite athletes; and qualitative interviews with key experts who come into contact with elite athletes. Athletes were confident in their knowledge of the effects of illicit drugs such as cannabis and meth/amphetamine, but less confident in their knowledge of the effects of illicit drugs such as GHB and ketamine. A substantial proportion felt that athletes in their sport would benefit from more information concerning illicit drugs. It was concluded that both athletes and key expert believed that information on illicit drugs should be delivered to athletes in a specific and relevant manner. There may be stigma attached to information seeking within a sports club or organisation. Accordingly, improving the accessibility to creditable information via the Internet may prove to be an effective means by which to educate athletes on the effects of illicit drugs [11417].

Attitude of elite cyclists on doping

The protection of the health of athletes is one of the three criteria taken into account when registering a substance in the World Anti-Doping Agency prohibited list. Nevertheless, in elite-level cycling, banned substance use is widespread. On study adopted a psychological approach to examine how or whether perceived health risks influence elite-level cyclists' decisions to use banned substances. Sixteen semi-structured interviews were conducted with cyclists hoping to join a professional team (n=6), neo-professional cyclists (n=2), and former professional cyclists (n=8). Although an evolution was observed in the organization of doping and perceptions of doping over the last decade, the perceived health hazards did not influence, most of the time, decisions to use banned substances among the sample of cyclists. There was a systematization of exogenous substance use in the cycling environment and a trivialization of the side effects of the banned substances. Finally, younger cyclists were not concerned about the long-term health consequences of banned substances; they were more focused on the short-term performance-enhancing benefits. There is a need to implement more effective preventive programs to change athletes' attitudes toward doping and its health risks [12021].

Young athletes attitudes towards doping

There is evidence of a small but significant proportion of adolescents engaging in doping practices. Young athletes face very specific pressures to achieve results as they strive for a career at an elite level. This study used an anonymized questionnaire to survey 403 (12-21 years old) talented young athletes' attitudes toward performance-enhancing substances and supplements. Two-thirds of the sample comprised males. Athletes were generally against the use of doping substances to enhance sporting performance. Within this generally unfavorable view, males tended to express a more permissive attitude toward performance-enhancing methods than females. Those convinced of the necessity of supplementation for sporting success were also more likely to express permissive attitudes. When asked whether they would take a "magic" drug that, while undetectable, would significantly enhance performance, the overwhelming majority of athletes said "no," but many thought others would take the substance. Interestingly, there was a significant association between the projected use of the hypothetical drug by competitors and the individual respondent's willingness to take the hypothetically "magic" substance. The study offers an insight into young athletes'
attitudes toward specific forms of performance enhancement, and the strength of their beliefs in the face of a tempting hypothetical scenario [12022].

**Other athletes’ attitudes regarding doping**

Review articles suggest a small but significant proportion (between 3 and 12%) of male adolescents have used anabolic-androgenic steroids (AAS) at some point. A total of 40 talented male and female athletes (mean average age 20 years) from 13 different sports attended 12 focus groups held over the UK intended to investigate athletes' attitudes toward doping. Focus group transcriptions were analysed and coded with the use of QSR NVivo 8. Athletes in general did not report a significant national doping problem in their sport, but exhibited sporting xenophobia with regard to both doping practices and the stringency of testing procedures outside of the UK. Athletes often viewed doping as "unnatural" and considered the shame associated with doping to be a significant deterrent. Athletes perceived no external pressure to use performance enhancing drugs. In response to hypothetical questions, however, various factors were acknowledged as potential "pressure" points: most notably injury recovery and the economic pressures of elite sport. Finally, a significant minority of athletes entertained the possibility of taking a banned hypothetical performance enhancing drug under conditions of guaranteed success and undetectability. It was concluded that the athletes in this study generally embraced those values promoted in anti-doping educational programmes, although there were some notable exceptions. That the social emotion of shame was considered a significant deterrent suggests anti-doping efforts that cultivate a shared sense of responsibility to remain “clean” and emphasise the social sanctions associated with being deemed a “drugs cheat”, resonate with this atypical social group [10314].

**How athletes discuss on doping**

One study investigates the discursive management of taking prohibited substances in sport. In particular, it explores how one high-profile athlete, Australian cricketer Shane Warne, accounted for his drug-taking behavior when talking to the media. Discursive psychology (DP) is used as the theoretical and methodological framework to study drug discourses in sport. Emphasis in DP is on making explicit how psychological concepts (e.g. drug explanations) are used in everyday talk to perform certain actions. The research data is Warne's first public press statement concerning his 2003 positive test for hydrochlorothiazide and amiloride. Analysis reveals that Warne constructed his drug taking as not being related to performance enhancement and substantiated this with a history of negative test results. Warne worked up his taking as the result of ignorance rather than deliberate deception. Further, he presented this as a one-off event and not reflective of systematic drug usage. It is argued in this study that to better understand drug taking in sport, sport researchers need to understand how athletes talk about drugs. For it is through talk that most sporting activities are conducted and maintained, and it is this talk that needs to be understood and analyzed [07022].

**Attitudes against dopers**

It was investigated the social image of anabolic steroids (AS) users grounding our analysis on the achievement goal theory of Nicholls. The main goal was to explore how an athlete's acceptance of AS use would impact on the way that athlete will be perceived by others. Non-AS-using participants reacted to one of two scenarios portraying a male athlete either accepting or refusing to engage in drug use behavior. The results suggested that the acceptance of anabolic steroids yielded an unfavorable social image – perceivers inferred a predominant ego orientation to characterize the AS-user's motivation as well as weaker
sportspersonship and a stronger proclivity for reactive aggression than instrumental aggression. Moreover, the analyses did not yield significant gender or interaction effects. Finally, those findings are commented in view of methodological shortcomings and of the perspectives that they may offer for future research concerning the motivational aspects of the social perceptions of drug use in sport [13050].

**Body image and attitudes toward male roles**

The authors sought to expand on previous observations suggesting that body-image pathology is associated with illicit use of anabolic-androgenic steroids (AAS). In particular, the authors compared current versus past AAS users and short-term versus long-term users in this respect. The authors assessed 89 heterosexual men who lifted weights regularly-48 AAS users and 41 nonusers-on measures of self-esteem, attitudes toward male roles, body image, eating-related attitudes and behaviors, and muscle dysmorphia ("reverse anorexia nervosa"). AAS users as a whole showed few differences from nonusers on most measures but showed greater symptoms of muscle dysmorphia (e.g. not allowing their bodies to be seen in public, giving up pleasurable activities because of body-appearance concerns). The current and past AAS users each differed only modestly from nonusers on most measures. Short-term AAS "experimenters" were also largely indistinguishable from nonusers, but the long-term AAS users showed striking and significant differences from nonusers on many measures, including marked symptoms of muscle dysmorphia and stronger endorsement of conventional male roles. It was concluded that both body-image pathology and narrow stereotypic views of masculinity appear to be prominent among men with long-term AAS use. Although our cross-sectional observations cannot confirm that these factors help to cause or perpetuate AAS use, a causal hypothesis is certainly plausible and deserving of further testing in longitudinal studies. If these factors are indeed causal, then AAS users might respond to cognitive behavior approaches that simultaneously take aim at both types of maladaptive beliefs [06016].

Men's fitness goals are influenced by the lens through which they view their bodies, which is different from the way women view their bodies. Their increased focus on a muscular, hairless body means that they exercise to enhance their physical bulk and are more likely to engage in depilatory behaviors. In addition, the drive for muscularity may be associated with an increased risk anabolic-androgenic steroids and other nutritional supplements whose utility not clearly demonstrated. In the extreme, the drive for muscularity may manifest itself as a form of body dysmorphic disorder referred to as muscle dysmorphia. However, not all men focus on their muscularity. Gay men are more likely than heterosexual men to experience a desire to be thin and are at greater risk for eating and body image disorders [07015].

**Polypharmacy**

A review of the literature was conducted to examine the relationship between the use of anabolic androgenic steroid (AAS) use and the use of other drugs. Studies published between the years of 1995 and 2010 were included in the review. The use of AAS is positively associated with use of alcohol, illicit drugs and legal performance enhancing substances. In contrast, the relationship between AAS and the use of tobacco and cannabis is mixed. It was concluded that the results of the review indicate that the relationship between AAS use and other substance use depends on the type of substance studied [01108].

The aim of one study was to describe qualitatively and quantitatively dietary supplements
(DS) and medication use in elite athletes. Athletes (n=912; age 24 ± 6 years; 72 % male) reported medications and DSs taken within 3 days before doping control. It was analyzed data collected from 2006 to 2008, identified and classified substances. Total of 75 percent athletes reported use of at least one substance, 61 percent took DS (3 per user) and 41 percent took medications. Among users, 21 percent reported the use of six and more different products, and one took 17 different products at the same time. Majority of medication users took non-steroidal anti-inflammatory drugs (NSAID) (25 %), and 22 percent used more than one NSAID. It was found no gender differences in DS use. Individual sport athletes used more DS. The study showed widespread use of DS and drugs by elite athletes. Consumption of DS with no evident performance or health benefits, demonstrated the need for specific educational programs focused on DS use. Amount, quantity and combination of the reported products raised concern about the risk of potential side effects [11009].

Medical and nonmedical use of stimulant drugs
Smith and Farah (2011) presented a scholarly review of critical areas related to their intriguing title "Are Prescription Stimulants 'Smart Pills'?") It was contend that they accomplished the main goal of the article, to get the facts straight about possible cognitive enhancement via the nonmedical use of stimulant drugs by individuals without a diagnosis of attention-deficit/hyperactivity disorder (ADHD). At the same time, they justified their main conclusions that (a) individuals are seeking and engaging in nonmedical use of stimulant drugs with the expectations of cognitive enhancement despite uncertainty whether such expectations are valid and (b) on some tasks, there are small average benefits of nonmedical use, but the overall pattern is not clear (e.g., small beneficial effects across most individuals or large beneficial effects only in a few individuals, both of which result in small average effects). It was offeedr comments in 3 areas to amplify key topics mentioned but not emphasized by Smith and Farah: (a) characterization of the cognitive effects of medical use of stimulants to contrast with the cognitive effects of nonmedical use; (b) justification of medical use of stimulants by placement on a normally distributed dimension of behavior rather than categorical diagnosis of ADHD, which varies widely across countries; and (c) evaluation of the potential risks of nonmedical use to individuals and to society (e.g., the likelihood of addiction to stimulant drugs in a small minority of the population) rather than just the potential benefits of cognitive enhancement [11418].

Concomittant use of other substances
Reports of illicit substance use by college athletes have become commonplace in recent years, yet comparatively little effort has been put forth by the research community to understand these behaviors. Data for this study came from a large, national dataset collected by the National Collegiate Athletic Association (NCAA). The study compared substance use behaviors of male undergraduate student athletes who reported using ergogenic performance enhancing substances (e.g. anabolic steroids and peptide hormones) during college (PES users) to those who did not (PES non-users). A consistent pattern of higher substance use rates was observed among PES users compared to non-users, including heavier drinking, higher prevalence rates of cigarettes, marijuana, amphetamines, narcotics, and a variety of permissible and impermissible dietary supplements. An unexpected finding was that there were large discrepancies in reported prevalence rates between similar or overlapping survey items (e.g. past year use of "narcotics" versus "I have taken Vicodin, Oxycontin or Percocet with/without a prescription"). The findings suggest that male college athletes who use PES while in college demonstrate a general tendency to engage in alcohol and drug use behaviors, regardless of whether these behaviors improve or impede athletic performance. The results further suggest that college athletes may not fully appreciate drug categorizations that are commonly employed to gauge substance use behaviors. Changes to
drug education and prevention programs may be needed to enhance understanding of drug properties and actions [13037].

Neuropharmacy addiction

The use of psychoactive substances to neuroenhance cognitive performance is prevalent. Neuroenhancement (NE) in everyday life and doping in sport might rest on similar attitudinal representations, and both behaviors can be theoretically modeled by comparable means-to-end relations (substance-performance). A behavioral (not substance-based) definition of NE is proposed, with assumed functionality as its core component. It is empirically tested whether different NE variants (lifestyle drug, prescription drug, and illicit substance) can be regressed to school stressors. Participants were 519 students (26 years old, 73 % female). Logistic regressions indicate that a modified doping attitude scale can predict all three NE variants. Multiple NE substance abuse was frequent. Overwhelming demands in school were associated with lifestyle and prescription drug NE. Researchers should be sensitive for probable structural similarities between enhancement in everyday life and sport and systematically explore where findings from one domain can be adapted for the other. Policy makers should be aware that students might misperceive NE as an acceptable means of coping with stress in school, and help to form societal sensitivity for the topic of NE among our younger ones in general [13038].

Connexion to use of dietary supplement

Recently published case reports, coupled with a large observational study of 1017 deployed servicemen to Iraq (January 2009), has highlighted the issue and potential concerns regarding the unregulated use of dietary and exercise supplements within the British military. Consequently, an exploratory pilot study was undertaken to assess whether the findings of the previous Iraq study were applicable to current deployed British servicemen in Afghanistan. From 150 questionnaires handed out there were 87 completed questionnaires (58 % return). The mean age was 28 with 90 percent being male. From the total of 87 persons 46 percent were self-declared current smokers with 38 percent admitting to drinking >6 caffeinated drinks per day. Forty nine persons (56 %) admitted to a history of supplement use with 35 (40 % compared with 32 % in 2009 in Iraq) declaring current use. The average duration of supplement use among current users was 3 (2-9) months. The main sources of supplement supply were via local NAAFI purchase (57 %), internet purchase (40 %) and via their local chemist (3 %). The main types of supplement used were proteins/amino acids (86 %), creatine (34 %), chromium (31 %), stimulants (17 %), hydroxycut (6 %), and testosterone boosters (1 %) with no persons admitting to the use of ephedra or anabolic steroids. It was concluded that a significant proportion of the British servicemen employed on operations in Afghanistan who were sampled, admitted to current dietary and exercise supplement use whilst on deployment. The results of this small study suggest that their use on operations may be increasing. Smoking rates and caffeine consumption, on deployment, remain high in the British military. A larger detailed study with greater representation among soldiers deployed to forward operating bases would be helpful to fully appreciate the scale of supplement use [11423].

The aim of one study was to describe the prevalence, trends and associated factors of dietary supplements (DS) and anabolic-androgenic steroids (AAS) use among Finnish adolescents. The sample comprised 30 511 adolescents aged 12-18 years, of which 22 519 (74 %) answered a questionnaire. It was also studied associations between 14 socioeconomic, health and health behavioural variables and DS and AAS use by logistic regression. The proportion of respondents using DS was 45 percent during the past year and
it increased linearly by age. Vitamins (37 %) and herbal products (13 %) were the most common DSs. In 1991, 9 percent of the boys aged 16-18 years reported protein use, while the frequency in 2005 was 17 percent, which was a significant increase. AAS use was uncommon; only 53 boys (0.5 %) and 20 girls (0.2 %) reported AAS use. The strongest factors associated with DS use in multivariate model were physical exercise outside sports clubs (odds ratio 1.9; 95 % confidence interval 1.6 to 2.2), and in sports clubs (odds ratio 1.7; 95 % confidence interval 1.5 to 1.9). Recurrent drunkenness (odds ratio 5.8; 95 % confidence interval 1.5 to 21.6) and peer drug use in boys (odds ratio 2.1; 95 % confidence interval 1.2 to 3.7) were the risk factors for AAS use, whereas physical exercise outside sports clubs (odds ratio 0.3; 95 % confidence interval 0.1 to 0.5) was a protecting factor. It was concluded that although the overall use of DS remained at the same level during the study period, there was a slight trend towards increasing use of vitamin and protein supplements. Dietary supplements use is associated with frequent sports participation and poorer than average health, while anabolic-androgenic steroids use is associated with health-compromising behaviours [10015].

Nutritional supplement (NS) use is widespread in sport. This study applied an integrated social cognitive approach to examine doping attitudes, beliefs, and self-reported doping use behavior across NS users (n=96) and nonusers (n=116). Following ethical approval, 212 competitive athletes (age mean 21; 137 males) completed self-reported measures of doping-related social cognitions and behaviors, presented in an online format where completion implied consent. Significantly more NS users (23 %) reported doping compared with nonusers (6 %). NS users presented significantly more positive attitudes toward doping and expressed a significantly greater belief that doping is effective. When presented with the scenario that performance-enhancing substances are effective and increase the possibility of winning, NS users were significantly more in favor of competing in situations that allow doping. In sum, doping use is three-and-a-half times more prevalent in NS users compared with nonusers. This finding is accompanied by significant differences in doping attitudes, norms, and beliefs. Thus, this article offers support for the gateway hypothesis; athletes who engage in legal performance enhancement practices appear to embody an "at-risk" group for transition toward doping. Education should be appropriately targeted [13035].

Fitness supplements as a gateway substance for AAS use
Approximately 3 percent of young Americans have used anabolic-androgenic steroids (AAS). A traditional model of adolescent substance use, the gateway hypothesis, suggests that drug use follows a chronological, causal sequence, whereby initial use of a specific drug leads to an increased likelihood of future drug use. Therefore, the use of illicit appearance and performance enhancing drugs (APED), such as AASs, also follows an analogous progression, whereby legal APEDs, (e.g. nutritional supplements) precedes illicit APED use. It was examined the relationship between nutritional supplement use, beliefs about APEDs, and APED use in 201 male (n=100) and female (n=101) undergraduates. Participants completed measures of muscle dysmorphia (MDDI), body checking (BCQ, MBCQ), eating disorder symptoms (EDE-Q), perfectionism (FMPS), positive beliefs about the efficacy-safety of AAS use and APED use patterns. A series of covariance structure models (CSM) showed body image disturbance, compulsive exercise, illicit drug use, and perfectionism, independent of gender, were significant predictors of positive beliefs about AAS. Those who used both fat burning and muscle building supplements reported the strongest beliefs in AAS efficacy-safety, which was associated with higher likelihood of current illicit APED use. There was evidence of significant indirect relationships between supplement use and illicit APED use through contact with other AAS users and beliefs about AAS. The potential role for nutritional supplement use in the initiation of illegal APED use is discussed. Future prevention efforts may benefit from targeting legal APED users in youth. (PsycINFO Database Record) [12024].
**Complementary and alternative medicine (CAM)**

Athletes are high achievers who may seek creative or unconventional methods to improve performance. Western medicine as is practiced in many industrialised countries is generally regarded as conventional, or orthodox, and its use has a long-established history in these societies. Interest and use of complementary and alternative medicine (CAM) has, however, been growing in recent times in Western countries, as reflected by the increasing number of research papers in medical and scientific journals. The literature indicates that athletes are among the heaviest users of complementary and alternative medicine (CAM) and thus may pioneer population trends in CAM use. Surveys in many countries have suggested a high use of CAM: in the United States, about a third of adults aged 18 years or older use CAM. While nonathletes may use CAM for prevention, treatment or rehabilitation from illness/injuries, athletes may possibly also use CAM for performance enhancement. If links between sport motivation and doping exist, and athletes' sport motivation and CAM use are related, a connection between athletes' CAM use and doping may also occur. Despite this growing interest, the definition of what is complementary or alternative remains very subjective and is certainly not universally accepted. While individual organisations have their own definitions, the perceptions of the general population or the end users and even the practitioners of the various forms of medicine of what constitutes CAM vary tremendously. In addition, More physicians are also seeking training in CAM: there is an estimated 3,000 American physicians who integrate acupuncture into their practice and an estimated one-third of homeopaths who are physicians or osteopaths. Unlike non-athletes, athletes may use CAM not just for prevention, treatment or rehabilitation from illness or injuries, but also for performance enhancement. Assuming that athletes' creative use of anything unconventional is aimed at "legally" improving performance, CAM may be used because it is perceived as more "natural" and erroneously assumed as not potentially doping. This failure to recognise CAMs as pharmacological agents puts athletes at risk of inadvertent doping. The general position of the World Anti-Doping Authority (WADA) is one of strict liability, an application of the legal proposition that ignorance is no excuse and the ultimate responsibility is on the athlete to ensure at all times whatever is swallowed, injected or applied to the athlete is both safe and legal for use. This means that a violation occurs whether or not the athlete intentionally or unintentionally, knowingly or unknowingly, used a prohibited substance/method or was negligent or otherwise at fault. Athletes are therefore expected to understand not only what is prohibited, but also what might potentially cause an inadvertent doping violation. Yet, as will be discussed, athlete knowledge on doping is deficient and WADA itself sometimes changes its position on prohibited methods or substances. The situation is further confounded by the conflicting stance of anti-doping experts in the media. These highly published disagreements may further portray inconsistencies in anti-doping guidelines and suggest to athletes that what is considered doping is dependent on the dominant political zeitgeist. Taken together, athletes may believe that unless a specific and explicit ruling is made, guidelines are open to interpretation. Therefore doping risk-taking behaviours may occur because of the potential financial, social and performance gains and the optimistically biased interpretation (that trying alternatives is part of the "spirit of sport") and doping risk-taking behaviours may occur. This discussion paper seeks to situate the reader in a world where elite level sports and CAM intersects. It posits that an understanding of the underlying motivation for CAM use and doping is currently lacking and that anti-doping rules need to be repositioned in the context of the emerging phenomenon and prevalence of CAM use. Data from non-athlete patients suggests that ingested CAM substances are not viewed as medications because they are perceived as "natural". Thus athletes may use CAM in the belief that it is more natural and, erroneously, not potentially doping (either as a "method" or "substance" under the anti-doping Code). The lack of understanding of various forms of medicine by patients and athletes may result in their not informing doctors (or coaches)
about non-conventional treatment use because it is not viewed as important or relevant to their medical management. Patients thus risk complications from CAM drugs and their interaction with prescribed medications. The additional consequence from failure to recognise CAMs as pharmacological agents puts athletes at risk of inadvertent doping [12015].

**Connexion to eating habits**

Health professionals concerned about the risks of adolescent obesity and disordered eating practices need greater understanding of how families with adolescents manage food in today's fast paced environment. One paper sought to gain conceptual understanding of the food and eating routines of families with a female adolescent athlete from the perspectives of mothers and daughters. Ten white, non-Hispanic mothers and their daughters were purposively sampled from high school track and cross country teams in Upstate New York. Informants completed in-depth, qualitative interviews. Researchers used the constant comparative method to analyze transcripts for emergent themes and to build a conceptual framework that represented the many factors and processes involved in the construction of family food routines. Families varied in forms and patterns of family eating activities with mothers playing a pivotal role in these routines. Family members' individual needs and values were negotiated in constructing these routines. In this sample the daughters' involvement in sports influenced family eating routines, but mothers' employment, ethnicity, social support, income, and areas of residence also played a role. The model describes how individual participants' food choice processes interact to produce family food routines. The conceptual model can inform research and practice related to the family environments in which adolescents experience food and eating [10016].

**Eating disorders**

Eating disorders do occur in male athletes. They are less prominent than in female athletes, and therefore in danger of being missed. The high-risk sports fall into the same categories as with females: aesthetic sports, sports in which low body fat is advantageous, such as cross-country and marathon running, and sports in which there is a need to "make weight", including wrestling and horse racing. Athletic involvement may foster the development of an eating disorder. Some male athletes, in their preoccupation with body image, will abuse anabolic steroids. While sports participation may contribute to the aetiology of an eating disorder, the converse is also true. Exercise may be used as therapy for some cases of eating disorder. In order to adequately treat eating disorders in the male athlete, it is first essential to identify cases. Psychoeducation of athletes, their families, coaches and trainers is an important first step. Counselling an athlete to pursue a sport appropriate to his body type, or to leave his sport behind altogether (an unpopular recommendation from a coach's perspective) can be important to treatment. Treatment of co-morbid psychiatric conditions is essential. Treatment can be structured using a biopsychosocial approach, and all appropriate modalities of therapy, including individual, family and group, as well as psychopharmacotherapy, where appropriate, should be applied [06017].

**Eating disorders and anabolic steroids**

Dissatisfaction with the body is very common in the population, in females in all ages as well as among males. Studies on female and male body image show the role of the media in defining and perpetuating body ideals, e.g. a muscular ideal male body type, or a thin female ideal. A meta-analysis of the effects of the media on male body image concerns, yielded similar effect sizes as those found with women. As a result of internalization of cultural norms, females become dissatisfied with the lower part of their bodies from the waist down and try to lose weight while males primarily want to change the shape of upper part of their
bodies (stomach and chest) and are more likely to desire an increase in weight. Body dissatisfaction has been reported as a risk factor, and one of the strongest predictors for onset of an eating disorder (ED) and is also associated with low self-esteem and depression. Dissatisfaction with the body seems to be the common and prominent denominator, not only between the sexes, but also between males with ED and males using anabolic androgenic steroids (AAS). Both ED and the use of AAS may seriously affect physical health and the psychological and social wellbeing of those who suffer from those problems. Comparisons between males with ED, male bodybuilders and normal controls revealed that bodybuilders more closely resembled the ED group than normal controls regarding body dissatisfaction and loss of sexual desire. Other similarities found between males with ED and body-builders including AAS users were characteristics such as perfectionism, ineffectiveness and low self-esteem. An essential question is whether more similarities can be found between males with ED and AAS users or if these groups differ in some essential respects. It is for example unclear whether there is a distinction between males with ED and males using AAS regarding the occurrence of underlying interpersonal profiles like negative self-image and the severity of psychiatric symptoms. Based on earlier studies showing several similarities between these groups, we anticipated that negative self-image and psychiatric symptoms would be similar between males with eating disorders and males who recently used AAS. Few studies have however investigated if there are other similarities in respect to self-image or psychiatric symptoms between clinical samples of eating disordered males and males in treatment for negative effects of AAS use. The aim of one study was to compare two clinical samples, one of males with ED and one of males who used AAS, regarding self-image and psychiatric symptoms. The study compared males with eating disorders (n=13) and males who recently stopped AAS use (n=29) on self-image and psychiatric symptoms, using The Structural Analysis of Social Behavior self-questionnaire and a shortened version of The Symptom Check List. The eating disorder group reported significantly lower scores for Self-emancipation and Active self-love and higher scores for Self-blame and Self-hate. Both groups reported serious psychiatric symptoms. The common denominator between groups was serious psychiatric symptomatology rather than negative self-image. It was concluded that the negative self-image profile, especially self-hate, found among males with Eating Disorders may indicate that the studied groups differ in aetiology of the underlying problems. The serious psychiatric symptoms in both groups call staff to pay attention to any thoughts of suicide due to severe depressive symptoms where by specialized psychiatric treatment may be needed [13036].

Concomittant symptoms and signs

To determine whether adolescents who participate in a weight-related sport are at increased risk for unhealthful weight-control behaviors and steroid use a study was performed. Subjects were 4,746 adolescents (50 % males, 50 % females) from 31 public middle and high schools in the Minneapolis/St Paul area of Minnesota. More males (20 %) than females (16 %) reported participation in a weight-related sport. Males who reported participation in a weight-related sport had an increased risk of past-week vomiting (odds ratio 5.7), laxative use (OR 6.8), as well as past-year vomiting (OR 4.9), laxative use (OR 3.4), diuretic use (OR 6.0), and steroid use (OR 3.7), compared with those males who did not report participation. Females who reported participation in a weight-related sport had an increased risk of past week vomiting (OR 2.1), as well as past year vomiting (OR 2.0), laxative use (OR 2.6), and steroid use (OR 2.6), compared with those who did not report participation in a weight-related sport. The current study shows that participation in a sport that adolescents perceive as emphasizing weight is strongly associated with unhealthful weight-control behaviors and steroid use. Preventive efforts, targeting parents, coaches, and adolescents are needed to decrease this risk [07020].
Adolescents with learning difficulties
One study investigated the relationships among sleep problems, learning difficulties and substance use in adolescence. Previous research suggests that these variables share an association with executive functioning deficits, and are intertwined. The sample comprised 427 adolescents (median age 16 years) attending remedial schools and 276 adolescents (median age 15 years) attending a mainstream school. Participants completed anonymous self-report questionnaires. Results indicated that adolescents without learning difficulties were more likely to use tobacco, methamphetamine and cannabis, whereas those with learning difficulties engaged in more inhalant use. Adolescents who had more sleep problems were more likely to use tobacco, alcohol, methamphetamine, cannabis, inhalants, cocaine, ecstasy and any other illegal drug. Adolescents with learning difficulties had more sleep problems than those without learning difficulties. However, sleep problems remained independently associated with tobacco, cannabis and inhalant use when learning difficulties were taken into account [11422].

Female adolescents
During the 1990s, 3 different national surveys of US adolescents documented a 2-fold to 4-fold increase in the prevalence of anabolic steroid use among adolescent girls. Public awareness concerning escalating female anabolic steroid use further heightened in 2004 when the Centers for Disease Control and Prevention reported that more than 7 percent of ninth-grade girls indicated current or prior anabolic steroid use, a level exceeding that of some young male subgroups. National attention focused on steroid use in adolescent girls when it became a topic discussed during the 2005 congressional hearings on drug use in sports. Previous associations with female anabolic steroid use have been limited to older women, and most reports of mature women taking anabolic steroids have related the use to competitive athletics and to bodybuilding. Using the nationally representative 2003 Youth Risk Behavior Surveillance System data set, it was examined the characteristics of girls reporting anabolic steroid use. Because of the association between steroid use and sports participation among older women, we particularly explored that relationship among girls reporting prior or ongoing anabolic steroid use. Female students in grades 9 through 12 (n=7544) self-reported anabolic steroid use was compared with other health-related behaviors and with sports participation. Prior or ongoing anabolic steroid use was reported by 5.3 percent of female high school students. Those adolescent girls had a marked increase in other health-compromising behaviors, including past 30-day use of alcohol (odds ratio, 8.8; 95 % confidence interval 5.5 to 14.2), cigarettes (OR, 5.1), marijuana (OR, 7.9), cocaine (OR, 10.8), and diet pills (OR, 4.9). They were more likely to carry a weapon (OR, 7.5), have had sexual intercourse before age 13 years (OR, 2.9), and have had feelings of sadness or hopelessness almost every day for at least 2 consecutive weeks (OR, 4.1). They were less likely to play school-sponsored team sports (OR, 0.52). Those who reported anabolic steroid use were more likely to use extreme measures to lose weight, including greater 30-day use of vomiting and laxative use (OR 5.0) and diet pills, powders, or liquids taken for weight loss (OR, 4.9). Last, psychological problems were prominent among these adolescents. Anabolic steroid users were more likely to indicate having had feelings of sadness or hopelessness for 2 consecutive weeks or more (OR, 4) and were more likely to have attempted suicide (OR, 7.3). Overall, 52 percent of female students indicated participation on team sports. Team sports participants were less likely to be steroid users compared with team sports nonparticipants (OR, 0.52). In addition, being in sports did not seem to identify a unique subgroup of steroid users. Anabolic steroid users in team sports were more likely to use seatbelts (OR 3.1) and condoms or birth control pills (OR, 5.2), compared with anabolic steroid users who were not in team sports. Steroid users participating in sports shared the same problem behaviors as steroid users not participating in team athletics. It was concluded that self-reported anabolic steroid use is not confined to adolescent girls in competitive athletics and is an indicator of adolescent girls with a marked increase in a cluster of other...
health-harming behaviors. Adolescent female anabolic steroid users are characterized by polysubstance abuse and by a marked increase in other health-harming behaviors. Compared with nonusers, odds are higher that they became sexually active at a younger age and have had more sexual partners; they are more likely to carry weapons and to have experience with violence. Along with greater controlled and illicit drug use, they are more likely to resort to harmful weight loss practices. These adolescent girls' mental health is more likely to be impaired, with more than two thirds having had feelings of depression and with almost half having planned or attempted suicide [07021].

Performance versus recreational drugs

The relationships between projected use, self-reported behavior and attitudes to performance-enhancing (PED) and recreational (RD) drugs were investigated among 82 competitive Hungarian athletes, with 15 percent admitting using PED and 32 percent using RD. Both the observed doping estimations (even those made by non-users) and self-admitted use were considerably higher than the average rate of positive doping tests (2 % of all tests). The notable overestimation by PED users (35 % vs 17 %) was in keeping with the false consensus effect. A prediction model with attitude and projection to the likelihood of PED use suggested at least a 70 percent chance of self-involvement of athletes, with responses at or above the median scores (Performance Enhancement Attitude Scale ≥ 60 and estimation ≥ 50%) on the two independent measures. Users overestimated the prevalence of doping in their sport but not RD use, with the converse holding for RD users' views of doping. PED users also showed a significantly more lenient attitude toward doping. This domain-specific characteristic adds new information to the ongoing research effort in understanding drug-doping co-morbidity. The reasons for elevated in-group projection are discussed, along with the potential application of this phenomenon in doping epidemiology studies [11011].

Health promoting effects of sports

To study whether participation in organized sports during adolescence predicts increased smoking of tobacco, alcohol intoxication and cannabis use from late adolescence to adulthood when controlling for potential confounders by a survey of national sample of Norwegian high school students (aged 13-19 years) in 1992 (T1) followed-up in 1994 (T2), 1999 (T3) and 2006 (T4) (n=3251). Outcome measures included smoking of tobacco and 12-month prevalences of alcohol intoxication and cannabis use, respectively. Confounders included pubertal timing, friends' drug use, perceived social acceptance, grades and parental socio-economic status. Latent growth curve analyses showed that initial level of participation in organized sports predicted growth in alcohol intoxication. Those involved initially in team sports had greater growth in alcohol intoxication, but lower growth in tobacco use and cannabis use, during the adolescent and early adult years compared to those involved in technical or strength sports. Practising endurance sports, as opposed to technical or strength sports, predicted reduced growth in alcohol intoxication and tobacco use. Sports participation in adolescence, and participation in team sports in particular, may increase the growth in alcohol intoxication during late adolescent and early adult years, whereas participation in team sports and endurance sports may reduce later increase in tobacco and cannabis use [09007].

Lifestyle alteration

Lifestyle's alterations are hazardous for health. On one hand they produce a high rate of mortality and disease, on the other hand they cause a reduction of work outcomes and an
increase of occupational accidents with important consequences for both worker’s health and his/her financial status. The aim of one study was to review the scientific literature for possible relationships between mental health and lifestyle alterations of young workers. It was considered as lifestyle factors the attitudes towards: smoking, alcohol consumption, eating, use of medications and doping substances, physical activity and sleeping. From the study it clearly emerges the existence of correlation between lifestyle habits and mental health; in fact behavioral alterations can produce problems of mental health and vice versa. Furthermore, some work peculiarities can lead to psychic disturbances and/or to unhealthy habits which can themselves cause negative effects on working activity. It is very important for young workers to understand that unhealthy behaviors, which can be corrected, are hazardous in terms of health and safety for both the single worker and the collectivity and that those behaviors can enhances the other working risks. Because there is a close interaction between mental health and lifestyles, it would be necessary a careful promotion of mental health on workplaces and to take all the preventive measures, with particular regard for those related to the work organization, in order to reduce the onset, exacerbation and unmasking of mental disorders and psychological difficulties. In working environment, the occupational health physician and his relationship with the patient are of fundamental importance. During preventive and periodic medical examinations, the occupational health physician should take detailed information on young worker's habits regarding smoking, alcohol consumption, eating, physical activity, sleeping, pharmacological abuse and possible presence of mental disorders and furthermore he/she should actively take part in the information and education process of the worker [07012].

**Prediction of later life-style**

The aim of one study was to examine the associations between self-rated health (SRH), physical activity and other lifestyle habits among former athletes and referents in late adulthood. Male athletes (n=514) who represented Finland from 1920 through 1965 and referents (n=368) who were classified healthy at the age of 20 years participated in this population-based cohort study. The present analysis was based on a questionnaire study in 2001. SRH was assessed by a single question. Univariate binary and multivariate logistic regression analyses were used to examine the associations of health-related behaviours with SRH. The majority of former athletes (64 %) rated their health better than referents (48 %). A higher percentage of the athletes (54 %) compared to the referents (44 %) belonged to the most physically active groups (MET quintiles IV-V). A high percentage of the athletes (77 %) and referents (79 %) were occasional or moderate alcohol users. The proportion of never smokers among athletes was 59 percent and among referents 37 percent. Among current smokers there were no differences in nicotine dependence between athletes and referents. In the univariate analysis the odds of reporting good SRH was 2 times higher for athletes than for referents. In multivariate logistic regression analysis, former participation in team and power athletic groups had significantly higher SRH than the referents even after adjusting for age, level of physical activity, alcohol and smoking habit, and occupation. People, who participated in very active physical exercise in their youth, as indexed by participation in competitive sports by elite athletes, continue a physically active lifestyle, and maintained healthier lifestyle. They had significantly higher SRH than the referents in their senior years, which were not totally explained by their physically active and healthier lifestyles [10437].

**Risk factors for doping**

Grounded conceptually in social cognitive theory, this research examines how personal, behavioral, and environmental factors are associated with risk perceptions of anabolic-androgenic steroids. Ordinal logistic regression and logit log-linear models applied to data
gathered from high-school seniors (n=2,160) in the 2005 Monitoring the Future study showed significant explanatory effects for gender, race, exposure to drug spots, steroid availability, peer use of steroids, sensation-seeking, depression, and self-esteem. Females, African Americans, and those who had seen drug spots the most frequently estimated higher levels of risk associated with steroid use, while those who indicated ease in obtaining steroids and those with close friends who had used the drugs estimated lower risk. Also estimating lower levels of risk were sensation seekers, those who appeared depressed, and those with low levels of self-esteem. Analyses reveal how steroid risk determinants may differ from those related to methylenedioxy-methamphetamine (i.e., MDMA, ecstasy) and marijuana use [09008].

Illicit anabolic-androgenic steroid (AAS) abuse, though an important public health problem, remains inadequately studied. Almost all AAS abusers are male and lift weights, but the risk factors for AAS use among male weightlifters remain poorly understood. It was recruited 233 experienced male weightlifters, of whom 102 (44 %) reported lifetime AAS use, and assessed their childhood and adolescent attributes retrospectively, using structured clinical interviews and computerized questionnaires. This cross-sectional cohort approach—a design that we have formally presented in the recent methodological literature-utilizes a study cohort, not selected for outcomes of interest, and assesses exposures and outcomes retrospectively. It was hypothesized that conduct disorder and body-image concerns would be major risk factors for subsequent AAS use among male weightlifters. Within the study population, many attributes showed little association with AAS use, but conduct disorder and body-image concerns showed strong associations. For individuals with prior conduct disorder versus those without, the hazard ratio (95 % confidence interval) for subsequent AAS use was 2.2 (1.5 to 3.4). For individuals in the middle versus lowest tertile of scores on a retrospective adolescent muscle-dysmorphia scale, the hazard ratio was 1.5 (0.84 to 2.6); for the highest versus lowest tertile, the hazard ratio was 3.3 (2.0 to 5.3). It was concluded that conduct disorder and body-image concerns represent important risk factors for AAS use among male weightlifters. Thus, assessment of these attributes may help to identify individuals most likely to require interventions to discourage this form of substance abuse [12029].

Much of the literature investigating the relationship between sports participation and substance use has focused upon student populations, with little focus being given to athletes who participate at elite levels. Identifying why some athletes may be at a greater risk for substance use can help in the design and implementation of prevention initiatives. Data for one study was from 1684 self-complete surveys with elite Australian athletes. Eight percent (n=134) of the sample reported the use of at least one of the six illicit drugs under investigation (ecstasy, cannabis, cocaine, meth/amphetamine, ketamine and GHB) in the past year. Having been offered or having had the opportunity to use illicit drugs in the past year, knowing other athletes who use drugs and identifying as a 'full-time athlete' were significant predictors of past-year illicit drug use, while having completed secondary education or a post-school qualification was associated with a lower likelihood of past-year illicit drug use. Athletes are part of a sportsnet that includes family, coaches, support staff and other athletes, and these relationships may encourage the use, supply and demand for drugs. The current findings suggest that relationships with some of those in the sportsnet may play an important role when understanding illicit drug use among elite athletes. As education appears to be associated with a lower likelihood of illicit drug use among this group, initiatives should encourage athletes to engage in off-field pursuits which may also help prepare them for life after sport [12030].

*Psychiatric comorbidity diseases*
"Comorbidity phenomenon" defines the not univocal interrelation between medical illnesses and psychiatric disorders, each other negatively influencing morbidity and mortality. Most severe psychiatric disorders, such as schizophrenia, bipolar disorder and depression, show increased prevalence of cardiovascular disease, related to poverty, use of psychotropic medication, and higher rate of preventable risk factors such as smoking, addiction, poor diet and lack of exercise. Moreover, psychiatric and organic disorders can develop together in different conditions of toxic substance and prescription drug use or abuse, especially in the emergency setting population. Different combinations with mutual interaction of psychiatric disorders and substance use disorders are defined by the so called "dual diagnosis". The hypotheses that attempt to explain the psychiatric disorders and substance abuse relationship are examined as common risk factors, psychiatric disorders precipitated by substance use, psychiatric disorders precipitating substance use (self-medication hypothesis), and synergistic interaction [13033]

Diagnostic and therapeutic difficulty concerning the problem of dual diagnosis, and legal implications, are also discussed. Substance induced psychiatric and organic symptoms can occur both in the intoxication and withdrawal state. Since ancient history, humans selected indigene psychotropic plants for recreational, medicinal, doping or spiritual purpose. After the isolation of active principles or their chemical synthesis, higher blood concentrations reached predispose to substance use, abuse and dependence. Abuse substances have specific molecular targets and very different acute mechanisms of action, mainly involving dopaminergic and serotoninergic systems, but finally converging on the brain's reward pathways, increasing dopamine in nucleus accumbens. The most common substances producing an addiction status may be assembled in depressants (alcohol, benzodiazepines, opiates), stimulants (cocaine, amphetamines, nicotine, caffeine, modafinil), hallucinogens (mescaline, LSD, ecstasy) and other substances (cannabis, dissociatives, inhalants). Anxiety disorders can occur in intoxication by stimulants, as well as in withdrawal syndrome, both by stimulants and sedatives. Substance induced mood disorders and psychotic symptoms are as much frequent conditions in ED, and the recognition of associated organic symptoms may allow to achieve diagnosis. Finally, psychiatric and organic symptoms may be caused by prescription and doping medications, either as a direct effect or after withdrawal. Adverse drug reactions can be divided in type A, dose dependent and predictable, including psychotropic drugs and hormones; and type B, dose independent and unpredictable, usually including non psychotropic drugs, more commonly included being cardiovascular, antibiotics, anti-inflammatory and antineoplastic medications [13033].

**Sponsoring of sports**

Organised sport provides an important setting for health promotion. Peak sporting organisations have a role in assisting and overseeing sports clubs, including providing funding opportunities. As such, sponsorship of these organisations may influence the funding of community sport. One study aimed to describe the nature and scope of peak sporting organisations' sponsorship, and particularly food and beverage company sponsors. An analysis of national and state sporting organisations' websites for the nine most popular sports for children and from four Australian states and territories was conducted using a structured survey tool. Information collected included the number and type of sponsors and sponsorship policies. The nature of food and beverage sponsors was defined as more healthy or less healthy using criteria from a Delphi survey. 443 sponsors were identified across 55 websites. Overall, 9 percent of sponsors were food companies and 3 percent were alcohol manufacturers. The majority of food companies (63 %) and alcohol manufacturers (100 %) did not meet criteria as healthy sponsors. It was thus concluded that sponsorship of peak
sporting organisations is widespread and consists of a relatively high proportion of alcohol manufacturers and food companies, some of which produce products considered to be unhealthy. This sponsorship may influence community sport through sponsored sporting programs or by indicating sponsors’ acceptability [11005].

To examine the relationship between direct alcohol and non-alcohol sponsorship and drinking in Australian sportspeople 652 (51 % female) individuals completed questionnaires on alcohol and non-alcohol industry sponsorship (from bars, cafes etc.), drinking behaviour (Alcohol Use Disorders Identification Test (AUDIT)) and known confounders. Thirty-one percent reported sponsorship (30 % alcohol industry; 4 % both alcohol and non-alcohol industry and 2 % non-alcohol industry only.) Multivariate regression showed that receipt of alcohol industry sponsorship was predictive of higher AUDIT scores, but non-alcohol industry sponsorship and combinations of both were not. Governments should consider alternatives to alcohol industry sponsorship of sport. Hypothecated taxes on tobacco have been used successfully for replacing tobacco sponsorship of sport in some countries, and may show equal utility for the alcohol industry’s funding of sport [11006].

Determining children’s exposure to food and beverage company sponsorship, and the effect of this exposure, is important in establishing the extent to which there may be health and societal consequences. One paper aimed to provide preliminary evidence on the scope and potential effects on children of unhealthy food and beverage sponsorship. A review of published literature and media and marketing reports was conducted to determine the types of food and beverage sponsorship campaigns that children are exposed to, and the effect of corporate sponsorship (including tobacco and alcohol) on children and adolescents. A large range of food and beverage sponsorship activities, in Australia and internationally, were identified for both school and sport settings. In particular, food and beverage companies have attempted to develop a marketing presence at all levels of professional and community sport. No information was identified measuring the effect of food and beverage company sponsorship on children and adolescents. However, empirical evidence from consumer studies relating to tobacco and alcohol sponsorship has repeatedly demonstrated that sponsorship has an impact on children’s product recall and product-related attitudes and behavioural intentions. It was concluded that while there is no available research on the direct effect of food and beverage sponsorship, the demonstrated effects of tobacco and alcohol sponsorship on children’s product awareness, preferences and consumption are likely to be applicable to food companies [11420].

**Information to dopers**

One study was designed to investigate anabolic steroid users’ experiences of, and motivations for, use. Five men and six women users took part in in-depth interviews. Four themes emerged: Steroid Use vs Abuse; Side-effects; Trusted Information Sources; and Social Pressure. Many users believed that steroids used in moderation were safe. Serious side-effects (liver and kidney damage, hypertension) were not significant disincentives. Information from health professionals tended to be mistrusted because it was not based on first-hand experience of use. Social support, especially from within the body building community, was an important motivator. It is concluded that intervention programmes need the support of the body building community in order to be effective [06018].

**Medical practitioners’ knowledge, attitudes and beliefs**

Central to the work of many medical practitioners is the provision of pharmaceutical support for patients. Patients can include athletes who are subject to anti-doping rules and
regulations which prohibit the use of certain substances in and out of competition. One paper examined the evidence on medical practitioners’ knowledge, attitudes and beliefs towards doping in sport. A systematic search strategy was followed. Research questions and relevance criteria were developed a priori. Potentially relevant studies were located through electronic and hand searches limited to English language articles published between 1990 and 2010. Articles were assessed for relevance by two independent assessors and the results of selected studies were abstracted and synthesised. Outcomes of interest were knowledge, attitudes and beliefs in relation to doping in sport. Six studies met the inclusion criteria and were examined in detail. Samples reflected a range of medical practitioners drawn from the UK, France, Greece, Italy and Ireland. The investigations varied with respect to outcome focus and quality of evidence presented. It was concluded that whilst the extant empirical research posits a negative attitude towards illegal performance enhancement combined with a positive inclination towards doping prevention, it also exposes a limited knowledge of anti-doping rules and regulations. Insufficient education, leading to a lack of awareness and understanding, could render this professional group at risk of doping offences considering Article 2.8 of the World Anti-Doping Agency Code (WADC). Moreover, in light of the incongruence between professional medical codes and WADC Article 2.8, medical professionals may face doping dilemmas and therefore further discourse is required. At present, the current evidence-base makes it difficult to plan developmentally appropriate education to span the exposure spectrum. Addressing this situation appears warranted [11007].

One study examined General Practitioner's (GP) knowledge, practice and training requirements in relation to doping in sport in Ireland. All 2083 GPs on the Irish College of General Practitioners register received a postal questionnaire, yielding a 37 percent response rate (n=771, 63 % male, average age 46 years). Results revealed that 14 percent deemed their knowledge of doping agents to be good or very good, 12 percent had completed specific training modules in doping or sport, and 24 percent were connected with a specific sport as a team doctor or advisor. Over one in four (28 %) had been consulted for advice on doping in sport, 33 percent possessed the current list of prohibited substances, and 25 percent knew of the Irish Sports Council’s drug-testing procedures. The current initiatives to discourage doping in sport were felt to be ineffective, and although 92 percent indicated that GPs had a role to play in the prevention of doping in sport, only 9 percent felt adequately trained for such a role. There was overwhelming support for further training among GPs, although the most appropriate method of providing training is complex and requires strategic planning [09009].

**Contagiousness of doping**

Using a psychosociological approach, the purpose of one study was to identify and understand the use of doping substances by young elite cyclists in Swizerland. Semi-structured interviews were conducted with young cyclists who were hoping to find a professional team and cyclists who had recently become professional. All of the young cyclists interviewed took nutritional supplements and believed that they improved their performance, which has been shown by other scholars to be a risk factor for doping. These cyclists believed that doping at the professional level in cycling was acceptable but did not approve of it at the amateur level. They were attracted to doping; they were open to using doping substances themselves if it was the key to continuing their cycling career, but only after they became professional. Team staff, doctors, parents and friends helped to create a “clean” environment that prevented the young cyclists from doping before becoming professional. The more experienced cyclists, who doped or used to dope, transmitted the culture of doping to the young cyclists, teaching them doping methods and which substances to use. This study could help to improve prevention and help to detect doping, as it is clear

311
that doping behaviours begin at the amateur level [09010].

**Economical aspects**

In 1990, the illicit steroid market was estimated to be USD 400 million. Steroid cycles, typically lasting 6 to 14 weeks, can cost hundreds of dollars. A cycle consists of daily oral doses plus weekly or monthly intramuscular depot injections. Some users take multiple cycles per year [07031].

Illegal steroids entering the United States and distributed to athletic and at-risk populations has increased dramatically. It is now estimated to be an over 100 million US dollar black market for steroids in the US alone, with more than 80 percent manufactured in Mexico. Today performance-enhancing programs and drugs are not the exclusive province of elite athletes, but have spread to health clubs, high schools and other at-risk populations, creating an over $1.4 billion US dollar industry that is growing daily as new compounds are synthesized and marketed. Projecting these figures internationally suggests that the illegal steroid market alone approaches a billion US dollars annually [08006].

It is estimated that an eight weeks performance enhancement regime of pharmaceutical grade recombinant human growth hormone will cost about USD 2000, well out of the range of an adolescent and the majority of weekend athletes [08006].

**Importance of sports medicine as a medical specialty**

In Europe, participation in physical activity has been growing among people of all ages. Thus, there is an increasing demand for care relating to sports medicine and this has promoted the development of specialised sports physicians. Sports medicine involves a wide range of professionals with functions of taking care of active population, recreational and competitive athletes upon different aspects: curative, rehabilitative and preventive. In the light of an higher demand of expertise and sport-specific burden of knowledge, such as a further development of the phenomenon doping with all the related moral, legal and health implications, the sport physician has to deal with a complex picture. As a result, the need to provide prevention at all levels has become one of the most important objectives of sports medicine. One article aimed to give a brief overview of the state of the art of this specialty in Europe and to describe definitions, scopes and educational perspectives of the Sport Medicine Specialty Training Core Curriculum to be adopted in the EU [09013].

**Impact of national programs**

Physical activity and sports are considered as one of the determinants of health. The aim of the study was to review the rationale for the formulation of this public health issue and its integration in national action plans. The study shows that fourteen national programmes were drafted and implemented between 2001 and 2006 by seven institutions. The research methodology was based on crossing data obtained from semi-directed interviews and documents regarding the design, implementation and follow-up of these programmes. For the conditions of the success, the fourteen actions scored an average of 175 ± 67 out of 300 percent. Public health actors and professionals must be given more opportunities to involve themselves and engage in developing stronger relationships and linkages, in particular with the institutional and community settings. In general, the most invested parts of a programme are the structural and operational aspects of activities. Six significant points surfaced from the study; consideration of drug use as an addictive behaviour; recognition of the psychological stress of professional athletes; acknowledgment of youth as being at high risk
for doping behaviour; integration of the concept that physical activity and sports must take the benefit/risk perspective into account; and the necessity to promote health. Through the exchange of numerous local and regional experiences, an optimisation of their synergistic connections was made possible on a continuum extending from "health promotion through physical activity and sports" to "prevention of drug-use and doping behaviours". Professionals have been able to develop actions in the above-mentioned domains across this continuum that have, to date, remained isolated. Proposals are made to strengthen these dynamics. Other health determinants and public health priorities could be investigated with the same methodology [09014].

**Staffing protocols in high-performance sport**

A common feature of the current doping scandals appears to be that those organisations under scrutiny have allowed external "experts" or "gurus" to drift in and out of their organization and control supplementation practices in the organisation, without actually being a bona fide part of the organisation’s staffing structure. There is no point having antidoping policies and codes of conduct if individuals are allowed to drift into the organisation and influence the supplementation policy, without those individuals being legally bound to the anti-doping policy and code of conduct. No individual other than those on the supplementation panel should be able to influence or administer supplements. The issue of doping and the challenges for anti-doping organisations in staying ahead of scientific developments and remain [13027].

**Law issues**

The field of science and technology that proposes to apply enhanced understanding of the human genetic code to reshaping our individual and collective destinies has generated more interest among the general public, as well as in the athletic community, than the potential for physical enhancement of the human body and its performance. Genometric experiments have produced physically enhanced mice, and the production of similarly enhanced humans may not be far off. Although it is not the objective of most genometric research, the day will come when gene-based "treatments" will enable individuals to build muscle or increase endurance faster than is possible through conventional methods. One article described developments in the area of physical enhancement that may find application in the "gene doping" of athletes. For example, human performance-related genes may be delivered to athletes using tools developed for research in gene therapy; the protein products of these genes may be administered in recombinant form; and recently discovered small-molecule activators of the major genetic regulatory pathways of physical prowess may be taken orally, providing "exercise in a pill". The article also described the attempts to regulate and punish the use of prohibited techniques for performance enhancement among athletes. As science advances, defining and detecting "gene doping" becomes increasingly complex. Thus, the study of physical enhancement provides an ideal starting point for the interdisciplinary examination of the intersection between law and science [09015].

**Doping + violence**

Within the context of problem-behaviour theory, one study investigated the intra-relationship between attitudes and behaviours towards exercise, sport involvement, violence in sport-related events, eating fruits, smoking and hashish or ecstasy use in a sample of Greek adolescents. Participants were 5991 Greek school pupils who responded to questionnaires assessing behaviour and attitudes towards health-related behaviours. Positive associations were found between pupils’ reports of violence in sport-related events, smoking and hashish
or ecstasy use on the one hand, and eating fruits and participation in sport and exercise on
the other. In contrast, small positive association was observed between sport involvement
and violence in sport-related events. Attitudes towards health risk behaviours were inversely
related to attitudes towards health-promoting behaviours, and attitudes were positively
related to corresponding behaviours. Sport involvement and regular exercise decreased but
smoking and use of hashish or ecstasy increased with age. More males than females
participated in organized sport and violent acts in sport-related events. Males' involvement
in sport violence increased with age. Sport is a suitable context for the promotion of several
health-related behaviours apart from exercise. Nevertheless, the present sport structure
excludes most young people and is positively linked with sport violence. A less demanding
sport context should be provided for the majority of young people, particularly for females.
Sport programmes designed to promote health behaviours should be encouraged. More
concentrated actions to combat sport violence are required [10439].

Knowledge in different countries

Austria

Strategies for doping prevention are based on prior identification of opportunities for
intervention. There is no current research focusing on the potential role in doping prevention,
which might be played by the parents of junior elite athletes. The purpose of this study was to
evaluate the knowledge and attitudes toward doping among parents of Austrian junior
athletes and to analyze factors potentially influencing these beliefs. In one study, two
questionnaires were distributed to 1818 student athletes, each with instructions that these
surveys were to be completed by their parents (n\textsubscript{total} 3636). Parents filled in questionnaires at
home without observation. Responses from 883 parents were included in this analysis.
Compared to female parents, male parents demonstrated significantly better knowledge
about doping and its side effects and were more likely to be influenced by their own sporting
careers and amounts of sports activities per week. Parental sex did not demonstrate a
significant influence on responses reflecting attitudes toward doping. Additional research is
needed to compare these results with young athletes' knowledge and attitudes to determine
if and to what degree parental attitudes and beliefs influence the behavior and attitudes of
their children [13046].

Austrian juniors

An important factor while developing efficient doping prevention strategies is to identify
relevant target groups, to evaluate the state of knowledge about this topic as well as to
evaluate motivations behind using prohibited substances. Measures to prevent doping
substances abuse have to be supported in early stages of childhood. The aim of one
prospective study was to evaluate the knowledge of Tyrolean junior athletes about doping in
sport. Next to the knowledge, their attitudes in regard to doping practices have also been a
focus of this project. Within a prospective cross-sectional study, Tyrolean junior athletes
aged between 14 and 19 years (n=408) were anonymously questioned by distributing
questionnaires in three Tyrolean sport schools as well as two Tyrolean sport-training centers.
To collect the data, an anonymous questionnaire with close-ended questions was used. Next
to sociodemographic data, questions also evaluated the knowledge about prohibited
substances as well as attitudes and behaviors towards doping. The concept was set up
based on contents of comparable studies and publications. The knowledge about doping
among junior athletes was moderate. The consumer behavior of the young athletes on the
other hand has turned out to be satisfactory. Nevertheless, the overall knowledge especially
regarding potential negative side effects of doping agents is poor. Thus, to incorporate an
effective doping-prevention strategy, improved education, particularly in terms of side effects,
is clearly needed. To achieve sustainable doping-prevention effects, focus has to be generally set on education within the frame of junior competitive sport [13047].

**Australia**

One study presents a comprehensive examination of the Sport Drug Control Model via survey data of elite Australian athletes. A cross-sectional nationwide mail survey of 1237 elite Australian athletes was conducted. Structural equation modelling was employed to test the model. Morality (personal moral stance on performance-enhancing substances use), reference group opinion (perceived moral stance of reference group on performance-enhancing substances use) and legitimacy (perceptions of the drug testing and appeals processes) evidenced significant relationships with attitude towards performance-enhancing substances use, which in turn was positively associated with doping behaviour. The model accounted for 81 and 13 percent of the variance in attitude towards performance-enhancing substances use and doping behaviour, respectively. These findings validate the usefulness of the Sport Drug Control Model for understanding influences on performance-enhancing substances use. Nevertheless, there is a need to survey athletes representing a broader range of competition levels and cross-cultural research to test the model's applicability to other populations of athletes [13048].

**Italy**

It was explored use and attitudes toward drugs and dietary supplements (DS) and knowledge concerning doping in cycling retrospective cross-sectional study. Forty cyclists aged 19 to 23 years and practicing for 14 to 30 h/wk were interviewed. Previous use (last 3 months) of drugs or DS occurred in 33 of 40 (83 %) and 39 of 40 (98 %) cyclists, respectively. Almost all the subjects named at least 1 doping agent (range, 1-10). Within a fixed list of 18 substances (among which only 14 were doping agents), participants recognized 3 to 18 of them as doping agents. They recognized tramadol and sildenafil as doping agents, which are not doping agents, and failed to recognize probenecid and albumin, which actually are. Doping knowledge correlated with drug use. Participants deemed doping prevalence high among cyclists in general but not in their own team. It was concluded that the use of prescription drugs and DS was a common occurrence. Doping knowledge was poor and biased, and its relationship with drug use deserves consideration. Educational interventions are needed to improve knowledge and awareness about prescription drugs and DS use, as well as about doping [13049].

**Illicit drugs around an Olympic game**

It was aimed to describe presentations to emergency departments during the Sydney 2000 Olympic Games for conditions related to the use of illicit drugs; to discuss the implications of such presentations for surveillance and public health action at similar events in the future. Fifteen sentinel emergency departments in the greater Sydney metropolitan area for a 38-day period spanning the Sydney 2000 Olympic Games had 424 presentations to sentinel emergency departments with conditions related to illicit drug use. The mean daily number of presentations for adverse events due to illicit drug use was significantly higher (13.3 versus 8.8 presentations) in the 2-week Olympic Games period than in the lead-up to the Games, culminating in a large peak following the closing ceremony. There was also a significant increase (5.1 versus 1.7 presentations) in the mean daily number of presentations related to use of ecstasy or amphetamines, whereas no change was noted in presentations related to heroin use. Over half (52 %) of presentations occurred at two emergency departments in areas known as being hot-spots for illicit drug use. It was concluded that enhanced surveillance of adverse events following illicit drug use, possibly targeting known 'hot-spots', should be considered for future mass events. Advance preparation of preventive strategies,
such as 'party-safe' messages, will enable rapid response to unusual patterns of illicit drug-related harm during future mass events [10440].

**US position stand on androgen and human growth hormone use**

Perceived yet often misunderstood demands of a sport, overt benefits of anabolic drugs, and the inability to be offered any effective alternatives has fueled anabolic drug abuse despite any consequences. Motivational interactions with many situational demands including the desire for improved body image, sport performance, physical function, and body size influence and fuel such negative decisions. Positive countermeasures to deter the abuse of anabolic drugs are complex and yet unclear. Furthermore, anabolic drugs work and the optimized training and nutritional programs needed to cut into the magnitude of improvement mediated by drug abuse require more work, dedication, and preparation on the part of both athletes and coaches alike. Few shortcuts are available to the athlete who desires to train naturally. Historically, the NSCA has placed an emphasis on education to help athletes, coaches, and strength and conditioning professionals become more knowledgeable, highly skilled, and technically trained in their approach to exercise program design and implementation. Optimizing nutritional strategies are a vital interface to help cope with exercise and sport demands. In addition, research-based supplements will also have to be acknowledged as a strategic set of tools (e.g. protein supplements before and after resistance exercise workout) that can be used in conjunction with optimized nutrition to allow more effective adaptation and recovery from exercise. Resistance exercise is the most effective anabolic form of exercise, and over the past 20 years, the research base for resistance exercise has just started to develop to a significant volume of work to help in the decision-making process in program design. The interface with nutritional strategies has been less studied, yet may yield even greater benefits to the individual athlete in their attempt to train naturally. Nevertheless, these are the 2 domains that require the most attention when trying to optimize the physical adaptations to exercise training without drug use. Recent surveys indicate that the prevalence of androgen use among adolescents has decreased over the past 10-15 years. The decrease in androgen use among these students may be attributed to several factors related to education and viable alternatives (i.e. sport supplements) to substitute for illegal drug use. Although success has been achieved in using peer pressure to educate high school athletes on behaviors designed to reduce the intent to use androgens, it has not had the far-reaching effect desired. It would appear that using the people who have the greatest influence on adolescents (coaches and teachers) be the primary focus of the educational program. It becomes imperative that coaches provide realistic training goals for their athletes and understand the difference between normal physiological adaptation to training or that is pharmaceutically enhanced. Only through a stringent coaching certification program will academic institutions be ensured that coaches that they hire will have the minimal knowledge to provide support to their athletes in helping them make the correct choices regarding sport supplements and performance-enhancing drugs. The NSCA rejects the use of androgens and hGH or any performance-enhancing drugs on the basis of ethics, the ideals of fair play in competition, and concerns for the athlete’s health. The NSCA has based this position stand on a critical analysis of the scientific literature evaluating the effects of androgens and human growth hormone on human physiology and performance. The use of anabolic drugs to enhance athletic performance has become a major concern for professional sport organizations, sport governing bodies, and the federal government. It is the belief of the NSCA that through education and research we can mitigate the abuse of androgens and hGH by athletes. Due to the diversity of testosterone-related drugs and molecules, the term androgens is believed to be a more appropriate term for anabolic steroids [09016].
Influence of religion on use of doping

Strength of religious faith (SRF) is rarely studied as a protective factor against substance use and misuse in sports. Herein, we studied the potential buffering effect of the complex socio-educational, sports, and religiousness factors in the protection against substance use and misuse, including cigarettes, analgesics, appetite suppressants, potential doping behavior, and binge drinking. The sample of subjects included 40 high-class female athletes (22-26 years of age). Using a strictly anonymous questionnaire, we investigated different social, educational, and sports factors (including SRF measured by the Santa Clara Strength of Religious Faith Questionnaire) in relation to substance use and misuse. Following the calculation of simple correlations, multiple regression analysis revealed that in combination with low sports experience, SRF has a significant buffering effect against binge alcohol drinking and consumption of appetite suppressants. The data are discussed in comparison with previous findings and theoretical background. Future studies should study the topic while observing samples of recreational and competitive athletes of both genders [12023].

Religiousness is rarely studied as a protective factor against substance use and misuse in sport. Herein, it was studied the potential buffering effect of the complex socio-educational, sports, and religiousness factors in the protection against substance use and misuse, including cigarettes, analgesics, appetite suppressants, potential doping behavior, and binge drinking. The sample of subjects included 40 high-class female athletes (22-26 years of age). Using a strictly anonymous questionnaire, we investigated different social, educational, and sports factors (including strength of religious faith measured by the Santa Clara Strength of Religious Faith Questionnaire) in relation to substance use and misuse. Following the calculation of simple correlations, multiple regression analysis revealed that in combination with low sports experience, strength of religious faith has a significant buffering effect against binge alcohol drinking and consumption of appetite suppressants [10026].

Religiousness is rarely studied as protective factor against substance use and misuse in sport. Further, it was found no investigation where college-age athletes were sampled and studied accordingly. The aim of the present study was to identify gender-specific protective effects of the religiousness (measured by Santa Clara Questionnaire) and other social, educational, and sport variables as a potential factors of hesitation against doping behaviors in sport-science-students from Mostar, Bosnia, and Herzegovina (51 women and 111 men; age range, 18-26). The gender differences for the non-parametric variables were established by Kruskall-Wallis test, while for the parametric variables the t-test for independent samples was used. Multiple regression calculations revealed religiousness as the most significant predictor of the social, health, sport and legal factors of hesitation against doping behaviors in both genders. However, the differential influence of the social, educational, sport and religious factors in relation to negative consequences of the doping behaviors is found for men and women. Such differential influence must be emphasized in tailoring the anti-doping policy and interventions [11014].

Religiousness is rarely studied as protective factor against substance use and misuse in sport. Further, it was found no investigation where college-age athletes were sampled and studied accordingly. The aim of the present study was to identify gender-specific protective effects of the religiousness (measured by Santa Clara Questionnaire) and other social, educational, and sport variables as a potential factors of hesitation against doping behaviors in sport-science-students from Mostar, Bosnia, and Herzegovina (51 women and 111 men; age range, 18-26). The gender differences for the non-parametric variables were established by Kruskall-Wallis test, while for the parametric variables the t-test for independent samples was used. Multiple regression calculations revealed religiousness as the most significant
predictor of the social, health, sport and legal factors of hesitation against doping behaviors in both genders. However, the differential influence of the social, educational, sport and religious factors in relation to negative consequences of the doping behaviors is found for men and women. Such differential influence must be emphasized in tailoring the anti-doping policy and interventions [13067].

**The adolescent athlete**

The use of doping compounds is less likely in adolescent athletes, but the detection that much more difficult given that the baseline secretion of the endogenous hormone is shifting during pubertal development with the greatest rise in testosterone in boys occurring about the time of peak height velocity and maximal secretion of hGH and IGF-I. Can one grow more rapidly during childhood and early adolescence to a taller than genetically programmed adult height or to a more robust body composition given anabolic-androgenic steroids (AAS), human growth hormone (rhGH), insulin-like growth factor (rhIGF-I), insulin or erythropoietin [10001]? The more successful late childhood and early adolescent age athletes are often more physically mature than their age-peers. Early adolescent development seemingly permits them to use the strength and power in sport and performance that their average (or even slowly) developing age-peers have not yet attained. The exceptions might be those athletes in the more aesthetic sports in which flexibility and a lower center of gravity are more important than size and strength. These are virtually exclusively in females. Most boys’ sports require high levels of strength and power; however, at elite levels of competition technique is a strong measure of success; for the athlete must produce, control and efficiently use the energy in a fashion that maximizes athletic performance; for example, explosive power in some jumping sports or overall technical skill in the pole vault. Earlier developing children are taller and stronger than their age-peers. That may confer an advantage at younger ages; however, sport-specific skills are important. It is because of these that some of the "later blooming" adolescents catch-up in performance with their earlier developing peers and likely overtake them; for they have had the discipline to attain the requisite skills and are perhaps at lesser risk to "burn-out" and cease participation in that sport [10017].

The rationale for taking ergogenic "effectors", such as rhGH, rhIGF-I, anabolic steroids, insulin or erythropoietin, is that by becoming bigger and stronger the athlete will perform better. Some boys who are not athletes take anabolic steroids and perhaps other ergogenic aides to "look better". However, there are no definitive data for rhGH or insulin in young adults and none at all for any of these five agents in adolescents who are not deficient in them. In any experimental setting the study design is such that one studies the effects of a single agent with all other things being equal. For a drug one decides on a dose, or range of doses and the subjects are allocated randomly to receive or not receive a particular dose. The subjects should be selected from a common pool and all should have identical "requirements", for example, in studies of athletes, prescribed diet and exercise regimens. It is apparent that many athletes take a "cocktail" of drugs making it virtually impossible to denote any single agent as causing a specific outcome. The difficulty in adolescents is that increased secretion of testosterone (and growth hormone) is a natural part of human pubertal development. Thus it would be very difficult to ascribe any individual changes noted in strength and body composition to any pharmacological agent at this time. The ethics of human experimentation in adolescents precludes any serious objective study using anabolic steroids [10017].
Availability of illegitimate drugs in the society

A description of the illicit drug market in Denmark's second largest city was provided based upon the prevalence of narcotics and illicitly sold medicals during the years 2002 and 2003. The changes on the illicit drug market were described by comparing the results to a similar study conducted ten years earlier. The study comprised of 469 cases of seized material by Aarhus Police during 2002-2003. Additional information relating to the 341 persons charged is also included in the study. Heroine, cocaine and amphetamine were seized in 31 percent, 30 percent, and 28 percent of the cases, respectively, and comprise the most frequently encountered hard drugs on the market. The prevalence of cocaine in Aarhus Police District has increased more than tenfold during the past ten years. The purity of the three drugs decreased significantly during the same period, although large variations in the quality of drugs were observed. Medicals were found in 16 percent of the seizures (containing 32 different active substances). The most frequent group of medicals was benzodiazepines, which made up a total of 74 percent of the medicals in the study. Anabolic steroids, ecstasy and methamphetamine were each found in 4 percent of the seizures. Men with an average age of 29 years comprised 92 percent of the persons charged in the study. Persons with a foreign nationality comprised 15 percent of the charged, while 25 percent had a birthplace outside Denmark. This means that the prevalence of stimulants especially cocaine have increased significantly during the past ten years. Meanwhile the purity of the drugs has decreased. The benzodiazepines are still the most frequent group of medicals on the illicit market [08034].

Internet drug availability

Today's Internet provides extensive "underground" guidelines for obtaining and using illicit substances, including especially anabolic-androgenic steroids (AAS) and other appearance- and performance-enhancing drugs (APEDs). It was attempted to qualitatively characterize APED-related Internet sites. It was used relevant Internet search terms (e.g. "steroids bodybuilding" and "buy steroids online") to assess (i) the numbers of site visitors; (ii) offers of drugs for sale; and (iii) the quality of online medical information. We also chose the examples of (iv) "site-enhancing oils" and (v) "cattle implants" to illustrate the volume of available Internet information as compared with that in the medical literature. It was found thousands of sites involving AAS and other APEDs. Most sites presented an unashamedly pro-drug position, often openly questioning the qualifications and motivations of mainstream medical practitioners. Offers of AAS and other APEDs for sale, together with medical advice of varying legitimacy, were widespread across sites. Importantly, many sites provided detailed guidelines for exotic forms of APED use, some likely associated with serious health risks, which are probably unknown to most practicing clinicians. It seems important for practitioners to be aware of the extent of this "underground literature," which may strongly influence their patients' decisions about use and abuse of APEDs [13058].

Psychoactive drugs in the society

Analysis of urine samples collected across a city centre, for the detection of novel psychoactive substances (NPS) was performed with a cross-sectional study of anonymized urine samples used for the analysis of classical recreational drugs, NPS and metabolites. Pooled urine samples collected from portable stand-alone four-person urinals across a city centre were analysed using full-scan accurate-mass high-resolution liquid chromatography coupled to tandem mass spectrometry. Data were processed against compound databases
containing >1700 drug compounds and metabolites. Seven established recreational drugs (3,4-methylenedioxyamphetamine, cocaine, cannabis, ketamine, 3,4-methylenedioxy-N-methylamphetamine, methamphetamine and amphetamine) and six potential NPS [hordenine (all 12 urinals), cathine (11), methylhexaneamine (9), 4-methylmethcathinone (6), methiopropamine and metabolites (2) and methoxetamine and metabolites (1)] were detected. Methylhexaneamine, methiopropamine and hordenine are currently uncontrolled in the UK, whereas methoxetamine is currently subject to a Temporary Class Drug Order. Metabolites of the anabolic steroid nandrolone were found in two urinals and trenbolone metabolites and clenbuterol in one urinary. It was concluded that analysis of pooled urine samples collected anonymously from stand-alone urinals in a large inner city can detect the use of recreational drugs, NPS and anabolic steroids. Metabolite detection indicates actual drug use, metabolism and elimination rather than simply discarded drugs in the urinals. This technique by confirming the actual drug(s) used has the potential to be additive to currently used datasets/key indicators providing more robust information for healthcare authorities, legislative and law enforcement on the drugs actually being used [13059].

Organised crime and drugs in sport

A report was from the Australian Crime Commission and entitled “Organised Crime and Drugs in the Sport” had the main following conclusions:

- Australian professional athletes, facilitated by sports scientists, coaches and support staff are using prohibited substances including peptides and hormones
- This behaviour is occurring in a number of professional sporting codes in Australia
- The use of illicit drugs within some sporting codes is higher than previously recorded
- Organised crime is involved in the domestic distribution of peptides and hormones
- There are significant integrity concerns within professional sports in Australia
- The use of prohibited substances by athletes is leading to an association between professional athletes and criminal identities
- There is a culture in some professional sports of administering untested and experimental substances to athletes
- Some sports scientists and medical practitioners are involved in supplying peptides and hormones to athletes.

These revelations rocked the Australian sporting community and have caused significant soul-searching and reflection within sporting organisations, particularly at high-performance level. A number of organisations conducted or are conducting internal reviews of their processes and protocols around the administration of supplements and medications. What was initially perceived as a widespread issue across elite sport in Australia now appears to be a more focal issue, concentrated in small pockets of professional sport. There are assertions, yet to be validated, that in some professional clubs there were systemic injection programmes as part of the supplementation strategy. It is almost inconceivable that such practices did not cause alarm bells to ring for club officials. If the claims are proved to be correct, then one can only conclude that those organisations do not have robust internal governance processes or have drifted away from such processes [13027].
Legitimate use of drugs in sports

It was assessed and compared the prevalence of declared medication, such as corticosteroids, nonsteroidal anti-inflammatory drugs (NSAIDs), beta2-agonists, narcotic analgesics, anaesthetics, and antidepressant drugs, in time and between different sports among athletes tested for doping control in a 4-year period in Belgium. Data were obtained from 18,645 doping control forms gathered between 2002 and 2005 from national doping organisations in Belgium and The Netherlands, the International Cycling Union (UCI), and the Belgian Cycling Federation. All athletes were asked by doping control officers to declare the medication taken in the last three days before competition after which the doping control forms were double blinded and handed over to the laboratory. The overall declared use of medication belonging to one of the monitored categories increased from 20 percent in 2002 to 25 percent in 2005. Differences in use of medication were observed between sports with a higher prevalence of use of NSAIDs in ball sports compared to other sports and a higher use of beta-agonists and corticosteroids in cycling with percentages of declared corticosteroid use in samples from the UCI exceeding 36 percent in 2005. These results indicate that the current granting of therapeutic use exemption for corticosteroids and beta-agonists needs to be revised and that threshold levels for beta-agonists should be implemented [08035].

Enquiries made in the Drug Information Database (DID™) were retrospectively analysed to develop a better understanding of athletes’ interests and concerns regarding the prohibited status of available substances regarding anonymous enquiries recorded in the DID in 2006 and 2007. The DID recorded 223,717 enquiries with 200 of the >6000 UK Licensed Pharmaceutical products receiving over 100 enquiries each. The majority (79 %) of these enquiries were in the pharmaceutical product category, followed by recreational drugs (10 %). A variety of common medications was subject to enquiry with anti-inflammatory agents, decongestants and bronchodilators being most common; a trend in keeping with reported medication use by athletes. Of all enquiries, 42 percent were not found owing to misspelled words or enquiries about unregulated substances. The proportion of enquiries about substances not listed in the database is relatively high and has increased over the 24-month observation period. The DID is a well used information resource with some 10,000 enquiries being made each month. With some 73 percent of enquiries being made by the athletes themselves, further investigations are warranted to explore enquiry patterns in relation to specific sports. Of the unsuccessful enquiries, a large number were related to nutritional supplements which warrants further investigation. The DID database appears to be a valid mirror of athletes’ chemically assisted practices and may be successfully used to inform health professionals as well as anti-doping prevention programmes [08036].

Over-the-counter medicine

A questionnaire was administered to elite athletes from Australia, Canada, the UK, and the USA representing 10 Olympic sports in order to explore knowledge and understanding of over-the-counter (OTC) medication since the removal of many of these substances from the World Anti-Doping Agency Prohibited List, in 2004. Athletes demonstrated limited knowledge and understanding. Around half (51 %) knew the penalty incurred following a doping violation involving a banned OTC stimulant. The terms Monitoring Program and Specified Substance List were understood by 43 and 68 percent of respondents, respectively. Overall, the status of substances in relation to the Prohibited List was correctly identified in just 35 percent of cases. As a whole, athletes were of the opinion that OTC stimulants posed a risk to health, were performance enhancing and that their use was against the spirit of sport. They were undecided as to whether these drugs should be returned to the Prohibited List. Elite athletes require targeted education programmes that will enable them to make informed decisions on the potential of OTC medications for therapeutic or performance enhancing purposes.
Doping agents as medical treatment

Many performance-enhancing supplements and/or drugs are increasing in popularity among professional and amateur athletes alike. Although the uncontrolled use of these agents can pose health risks in the general population, their clearly demonstrated benefits could prove helpful to the critically ill population in whom preservation and restoration of lean body mass and neuromuscular function are crucial. Post-intensive care unit weakness not only impairs post-intensive care unit quality of life but also correlates with intensive care unit mortality. A review covered a number of the agents known to enhance athletic performance, and their possible role in preservation of muscle function and prevention/treatment of post-intensive care unit weakness in critically ill patients. These agents include testosterone analogues, growth hormone, branched chain amino acid, glutamine, arginine, creatine, and beta-hydroxy-beta-methylbutyrate. Three of the safest and most effective agents in enhancing athletic performance in this group are creatine, branched-chain amino acid, and beta-hydroxy-beta-methylbutyrate. However, these agents have received very little study in the recovering critically ill patient suffering from post-intensive care unit weakness. More placebo-controlled studies are needed in this area to determine efficacy and optimal dosing. It is very possible that, under the supervision of a physician, many of these agents may prove beneficial in the prevention and treatment of post-intensive care unit weakness [09031].

Pharmacists

When athletes consult sports outpatient or orthopedic clinics it is possible to undergo drug treatment with the medical staff having prior knowledge of that patient being an athlete. However, if athletes seek any other diagnosis and treatment as an ordinary patient, the possibility of medical staff realizing the potential for imposing a doping issue on the athlete is extremely low. As a result, if the athlete fails to provide medical staff with information regarding anti-doping regulations when receiving clinical treatment, drug treatment administered as part of medical practices could be viewed as doping, resulting in the athlete being disciplined. In order to avoid this, pharmacists should participate in training in order to be able to provide information for anti-doping purposes. There is an opinion that knowledge regarding anti-doping is something that should be shared by all pharmacists, as pharmacists are educated in the fields of pharmacology and pharmacokinetics during the pharmacy education process, and sports pharmacology is a part of this. However, in order for pharmacists to understand sports pharmacology, it is necessary to provide education not only on the benefits and adverse effects of pharmaceutical products, but also on the concept of banned substances. It can be considered one of the pharmacist's duties to protect athletes who purchase drugs at a pharmacy or consult medical institutions as patients. With this, it may be proposed considering the potential for introducing sports pharmacology to pharmaceutical education, and specialist pharmacist training in the sports spectrum [12038].

Compared to general practitioners

Information about doping awareness among medical professionals is scarce. It was evaluated the attitudes, level of knowledge and experience among general practitioners (GPs) and pharmacists (Ps) with regard to doping. In a cross-sectional national survey a 59-item self-administered questionnaire was sent to a representative random sample of 645 GPs and 330 Ps. Overall, 204/975 (133 GPs, 71 Ps) questionnaires were returned and
available for analysis. Fewer than half (39 % GPs vs 48 % Ps) of respondents were familiar with the formal definition of doping. The abbreviation WADA was correctly interpreted by 42 percent (33% vs 59 %), and 65 percent knew that the European Commission has the legislation to fight against doping. More GPs (69 % vs 31 %) agreed to have a role to play in doping prevention, similar proportions considering themselves to have sufficient knowledge of prevention initiatives (65 % vs 35 %). Overall, 12 percent of respondents (9 % GPs, 19 % Ps) reported being directly confronted with a request for prescription of doping agents in the previous 12 months (mainly stimulants, anabolic agents, hormones, corticosteroids). It was concluded that GPs and Ps are frequently exposed to questions about and requests for doping agents. They have acceptable level of general knowledge but are in need for more specific information on prohibited substances and legislature [12039].

Pharmacy students

Doping is one of the most serious problems for the sport community, and it is important that pharmacists have more interaction with athletes to ensure safer drug usage. Education is one of the most important roles of sports pharmacists, who are specialists regarding drug usage for athletes. It was investigated pharmacy students' interests and comprehension regarding drug usage, doping and supplement intake by using the form of a questionnaire, since it is important to know how they understand these subjects as part of their greater educational program. The subjects were sophomore and junior pharmacy students at three universities. It was revealed that most of the students have negative images regarding doping violation, and they answered that they are familiar with doping. However, only sixteen percent of the students had attended lectures by specialists on doping. In addition, one third of pharmacy students did not know that some over-the-counter (OTC) drugs might contain doping substances. With regard to supplement intake, approximately two thirds of the respondents had an interest in and positive image of supplement intake. However, it was revealed that only one third of them recognized supplements as food, and their information regarding supplements was obtained from uncertain media. It was suggested that it is important for pharmacy students to have more opportunities to learn about what doping is. More education and enlightenment by sports pharmacists would be effective for pharmacy students as well as athletes, and it would help us to broaden the scope of what we can do for athletes and society [13045].

A cancer risk of doping?

Anabolic steroid and peptide hormones or growth factors are utilized to increase the performance of athletes of professional or amateur sports. Despite their well-documented adverse effects, the use of some of these agents has significantly grown and has been extended also to non-athletes with the aim to improve appearance or to counteract ageing. Pre-clinical studies and epidemiological observations in patients with an excess of hormone production or in patients chronically treated with hormones/growth factors for various pathologies have warned about the potential risk of cancer development and progression which may be also associated to the use of certain doping agents. Anabolic steroids have been described to provoke liver tumors; growth hormone or high levels of its mediator insulin-like growth factor-1 (IGF-1) have been associated with colon, breast, and prostate cancers. Actually, IGF-1 promotes cell cycle progression and inhibits apoptosis either by triggering other growth factors or by interacting with pathways which have an established role in carcinogenesis and cancer promotion. More recently, the finding that erythropoietin (Epo) may promote angiogenesis and inhibit apoptosis or modulate chemosensitivity in cancer cells expressing the Epo receptor, raised the concern that the use of recombinant
Epo to increase tissue oxygenation might favor tumor survival and aggressiveness. Cancer risk associated to doping might be higher than that of patients using hormones or growth factors as replacement therapy, since enormous doses are taken by the athletes often for a long period of time. Moreover, these substances are often used in combination with other licit or illicit drugs and this renders almost unpredictable all the possible adverse effects including cancer. Anyway, athletes should be made aware that long-term treatment with doping agents might increase the risk of developing cancer [07032].

**Dependence in clinical practice**

The nonmedical use of anabolic-androgenic steroids (AAS) appeals to athletes across several sports, particularly those whose activity makes muscle size and strength advantageous, and in individuals (usually men) with body dysmorphic disorder. Patterns of nonmedical use, including supratherapeutic doses of illicitly obtained drugs, increase the risk for adverse psychiatric and other medical consequences. Although AAS users may be more likely to consult physicians for nonpsychiatric medical consequences than changes in their mental status, it is argued that the motivation for persistent use despite adverse consequences is sustained in large part by psychological variables. Therefore, all physicians who treat nonmedical AAS users will benefit from an understanding of these psychological variables, including the potential for AAS to cause dependence [09032].

**Treatment of drug addicts**

The objective of this review is to describe self-administration procedures for modeling addiction to cocaine, cannabis and heroin in the human laboratory, the benefits and pitfalls of the approach, and the methodological issues unique to each drug. In addition, the predictive validity of the model for testing treatment medications will be addressed. The results show that all three drugs of abuse are reliably and robustly self-administered by non-treatment-seeking research volunteers. In terms of pharmacotherapies, cocaine use is extraordinarily difficult to disrupt either in the laboratory or in the clinic. A range of medications has been shown to significantly decrease cocaine's subjective effects and craving without decreasing either cocaine self-administration or cocaine abuse by patients. These negative data combined with recent positive findings with modafinil suggest that self-administration procedures are an important intermediary step between pre-clinical and clinical studies. In terms of cannabis, a recent study suggests that medications that improve sleep and mood during cannabis withdrawal decrease the resumption of marijuana self-administration in abstinent volunteers. Clinical data on patients seeking treatment for their marijuana use are needed to validate these laboratory findings. Finally, in contrast to cannabis or cocaine dependence, there are three efficacious Food and Drug Administration-approved medications to treat opioid dependence, all of which decrease both heroin self-administration and subjective effects in the human laboratory. In summary, self-administration procedures provide meaningful behavioral data in a small number of individuals. These studies contribute to our understanding of the variables maintaining cocaine, marijuana and heroin intake, and are important in guiding the development of more effective drug treatment programs [08038].

**Educational programs**

Continuing educational programs developed for these at-risk populations by national olympic
organizations and athletic federations are important first steps to curb these doping behavior. Medical professionals, teachers, coaches and sports organizations must all be made aware of this continuing problem in our adolescent and at-risk populations and contribute to its solution by open, honest discussion. Most importantly, professional athletes must serve as role models and spokesmen for drug-free sport and lifestyle. This position must be actively supported by the media, owners of teams and international sports federations by providing consistent leadership and advocacy of anti-doping programs in sport, regardless of costs and consequences. Accepting the magnitude of doping in at-risk populations and developing education, prevention and treatment programs is the only way we can prevent the continuing spread of the abuse of doping in sport and its spread into the most fragile groups in our society, our youth and at-risk populations [08006].

**Social perceptions**

It was explored social perceptions related to the use of anabolic steroids in sports. More specifically, 78 women and 102 men read one of two scenarios depicting a male athlete facing either a drug use or non-drug use situation. Then, participants reported their perceptions of the scenario protagonist in terms of self-determined sport motivation, sportspersonship orientations, and athletic aggression. Results of a multivariate analysis of covariance indicated that, in comparison with a non-using protagonist, the anabolic steroid-using athlete was regarded as less self-determined in one's motivation (i.e. sport participation based on predominant feelings of pressure to obtain external rewards or avoid punishment) and as displaying weaker sportspersonship orientations (i.e. lesser concerns for opponents, the social conventions of sport, and for one's own athletic commitment). In addition, the steroid-using athlete was perceived as resorting more readily to reactive aggression than to instrumental aggression (i.e. intent to injure one's opponent vs merely hinder his performance). Finally, the analyses did not disclose significant gender or interaction effects [08040].

The aim of one study was to improve understanding of the development of multiple drug use in patients seeking treatment at an addiction clinic for steroid-related problems. It was interviewed six patients (four men and two women) with experience of AAS use who were attending an addiction clinic for what they believed were AAS-related problems. The patients were interviewed in-depth about their life stories, with special emphasis on social background, substance use, the development of total drug use and subjective experienced psychological and physical side effects. There was significant variation in the development of drug use in relation to social background, onset of drug use, relationship to AAS use and experience of steroid effects. All patients had initially experienced positive effects from AAS but, over time, the negative experiences had outweighed the positive effects. All patients were dedicated to excess training and took AAS in combination with gym training, indicating that the use of these drugs is closely related to this form of training. Use of multiple drugs was common either in parallel with AAS use or serially. The study shows the importance of understanding how AAS use can develop either with or without the concomitant use of other drugs of abuse. The use of anabolic steroids can, however, progress to the use of other drugs. The study also indicates the importance of obtaining accurate, comprehensive information about the development of AAS use in designing treatment programmes and prevention strategies in this area [08041].

**Medical risks with illegal drugs**
Unfortunately, cadaver extracts of pituitary human growth hormone may still be in circulation. It has been reported that a Russian coach was arrested and, upon searching his apartment in Moscow, over 1000 cadaver pituitary glands were found preserved in a large container [08042]. Moreover, the problem of counterfeit drugs also exists with hGH: illegal pharmaceutical manufacturers are now flooding the black market with hGH vials of unknown quality and safety [08006].

Human growth hormone is marketed on the internet in many forms: pills, drops and aerosol formulations; most are ineffective and shams. The normal route of administration of hGH is injection, posing an additional health risk of infection from non-sterile counterfeit drugs and the risk of HIV and hepatitis transmission caused by shared needles. However, also using high quality human growth hormone may lead to life-threatening health conditions, especially since some estimates report that athletes who use growth hormone to enhance performance are taking 10 times the therapeutic dosage. Some reported side effects of hGH are abnormal bone growth, hypertension, cardiovascular disease, cardiomyopathy, glucose intolerance, colonic polyps, decreased life span, and cancer [08043].

As with steroids and growth hormone, doping with erythropoietin is often injected in supernormal doses that could cause increased blood viscosity, deep vein and coronary thromboses, cerebral thromboses, pulmonary embolism, arrhythmias, stroke and death. It has been estimated that 20 European cyclists have died since 1987 due to abuse of erythropoietin, making it one of the most deadly doping agents [08006].

**Doping and the respiratory system**

Historically many different drugs have been used to enhance sporting performances. The magic elixir is still elusive and the drugs are still used despite the heavy adverse effects. The respiratory system is regularly involved in this research probably because of its central location in the body with several connections to the cardiovascular system. Moreover people are aware that O$_2$ consumption and its delivery to mitochondria firstly depend on ventilation and on the respiratory exchanges. The second step consists in the tendency to increase VO$_{2\max}$ and to prolong its availability with the aim of improving the endurance time and to relieve the fatigue. Many methods and substances had been used in order to gain an artificial success. Additional oxygen, autologous and homologous transfusion and erythropoietin, mainly the synthetic type, have been administered with the aim of increasing the amount of oxygen being delivered to the tissues. Some compounds like stimulants and caffeine are endowed of excitatory activity on the CNS and stimulate pulmonary ventilation. They did not prove to have any real activity in supporting the athletic performances. Beta-adrenergic drugs, particularly clenbuterol, when administered orally or parenterally develop a clear illicit activity on the myosin fibres and on the muscles as a whole. Salbutamol, terbutaline, salmeterol and formoterol are legally admitted when administrated by MDI in the treatment of asthma. The prevalence of asthma and bronchial hyperactivity is higher in athletes than amongst the general population. This implies that clear rules must be provided to set a correct diagnosis of asthma in the athletes and a correct therapy to align with the actual guidelines according to the same rights of the "other" asthmatic patients [07132].

The purpose of one study was to investigate the effects of resistance training and long-term anabolic androgenic steroids (AASs) administration on respiratory function. Subject groups consisted of AAS users (n=9) who were still using AAS at time of testing (SU); AAS users (n=6) who had been abstinent for > 3 months (SA), bodybuilding controls (n=8) (BC), and (n=8) sedentary male controls (SC). FEV$_1$, FVC, and PEF were measured. The results found that all subjects were within normal range, and there were no differences between groups.
Maximum inspiratory pressure (MIP), and grip strength were both significantly greater in SU compared with SC; no significant difference was found between the other groups. Their MIP and grip strength was significantly correlated. The data from this study suggest that the combination of resistance training and AAS administration produce a significant increase in MIP in a cohort of long-term AAS users [11569].

Information on doping

Many sporting organisations in Australia conduct drug information seminars for their athletes; however, it is uncertain whether these programs provide athletes with pertinent drug information in formats that are conducive to information retention. The aims of one study were to investigate self-reported confidence in knowledge of illicit drugs and information seeking behaviours among elite athletes. Data were collected from two sources: quantitative surveys with elite Australian athletes; and qualitative interviews with key experts who come into contact with elite athletes. Athletes were confident in their knowledge of the effects of illicit drugs such as cannabis and meth/amphetamine, but less confident in their knowledge of the effects of illicit drugs such as GHB and ketamine. A substantial proportion felt that athletes in their sport would benefit from more information concerning illicit drugs. Both athletes and key expert believed that information on illicit drugs should be delivered to athletes in a specific and relevant manner. There may be stigma attached to information seeking within a sports club or organisation. Accordingly, improving the accessibility to creditable information via the Internet may prove to be an effective means by which to educate athletes on the effects of illicit drugs [11022].

Internet

Identifying the use of non-approved drugs by cheating athletes has been a great challenge for doping control laboratories. This is due to the additional complexities associated with identifying relatively unknown and uncharacterized compounds and their metabolites as opposed to known and well-studied therapeutics. In 2010, the prohibited drug candidates and gene doping substances AICAR and GW1516, together with the selective androgen receptor modulator (SARM) MK-2866 were obtained by the Cologne Doping Control Laboratory from Internet suppliers and their structure, quantity, and formulation elucidated. All three compounds proved authentic as determined by liquid chromatography-high resolution/high accuracy (tandem) mass spectrometry and comparison to reference material. While AICAR was provided as a colourless powder in 100 mg aliquots, GW1516 was obtained as an orange/yellow suspension in water/glycerol (150 mg/mL), and MK-2866 (25 mg/mL) was shipped dissolved in polyethylene glycol (PEG) 300. In all cases, the quantified amounts were considerably lower than indicated on the label. The substances were delivered via courier, with packaging identifying them as containing “amino acids” and “green tea extract”, arguably to circumvent customs control. Although all of the substances were declared “for research only”, their potential misuse in illicit performance-enhancement cannot be excluded; moreover sports drug testing authorities should be aware of the facile availability of black market copies of these drug candidates [11023].

Internet websites offering androgenic anabolic steroids (AAS) were identified and available products were examined. Keywords for the website search were: "anabolic steroids," "anabolic steroids buy," "anabolic steroid purchase." The first 10 websites offering AAS in the first 10 pages of results were considered. At least two AAS-containing products per website were selected. Thirty AAS-selling websites were identified, mainly located in the United States (47 %) and Europe (30 %). Most websites sold other anabolic/ergogenic products
(clenbuterol, 77 %; GH/IGF, 60 %; thyroid hormones, 47 %; erthropoietin, 30 %; insulin, 20 %) or products for AAS-related adverse effects (mainly: estrogen antagonists, 63 %; products for erectile dysfunction, 57 %; 5alpha-reductase inhibitors, 33 %; anti-acne products, 33.3%). AAS were sold as medicines (70 %) or as dietary supplements (30 %). AAS in medicines were mainly: nandronole (20 %), methandrostenolone (18 %), and testosterone (12 %). Dietary supplements contained mainly DHEA and included several fake compounds. Manufacturers were declared for 98 percent of medicines and 67 percent of dietary supplements; however, several manufacturers were not found on the Internet. Described benefits were usually few adverse effects and no estrogenicity. Toxicity was seldom reported and presented as mild. Recommended doses were two-fourfold higher than current medical recommendations. In conclusion, misleading information and deceiving practices were common findings on AAS-selling websites, indicating their deleterious potential for public health [11024].

This study examined whether different types of media affect the use of dietary proteins and amino acid supplements, and intent to use anabolic-androgenic steroids. A random sample of 618 boys aged 11-18 years from eight schools in the Flemish part of Belgium completed standardized questionnaires as part of the Media and Adolescent Health Study. The survey measured exposure to sports media, appearance-focused media, fitness media, use of dietary supplements, and intent to use anabolic-androgenic steroids. Data were analyzed using logistic regressions and are presented as adjusted odds ratios (OR); 9 percent indicated to have used dietary proteins, 4 percent indicated to have used amino acid supplements, and 12 percent would consider using anabolic-androgenic steroids. After adjusting for fitness activity, exposure to fitness media was associated with the use of dietary proteins (OR 7.2) and amino acid supplements (5.2). Intent to use anabolic-androgenic steroids was associated with exposure to fitness media (2.4) and appearance-focused media (6.0). Sports media did not correlate with the use of dietary supplements and intent to use anabolic-androgenic steroids. Specific types of media are strong predictors of the use of supplements in adolescent boys. This provides an opportunity for intervention and prevention through the selection of fitness media as a communication channel. Health practitioners should also be aware that the contemporary body culture exerts pressure not only on girls but also on boys [13044].

Telephone hot-line

The aim of one retrospective study was to analyze the calls concerning anabolic products (AP), received at Écoute Dopage, a French anti-doping hot-line. It was reviewed all phone calls handled between 2000 and 2008, among them 214 concerned AP. Information collected include demographic data, reason for the phone call, name of AP, characteristic of consumption, adverse reactions. Fifteen different AP (mainly testosterone) were reported. Calls concerned information about side-effects (42 % of calls), risk for doping (28 %), and risk for health (10 %), psychological assistance (10 %), and legislation (2 %). Most calls came from fitness practitioners or bodybuilders (85 %). The reason for use was documented in 137 subjects: to increase muscular strength (76 %), improve social life ability (15 %), improve sporting ability (6 %), and losing weight (3 %). Eighty subjects (37 %) reported at least one side-effect mainly uro-genital (40 cases) or psychic disorders (25 cases), both 15 cases. Among these 80 patients, 17 patients (21.25%) presented signs of AP dependence. The abuse of AP in sport is a public health problem well known, but data on the dependence on AAS are sparser. Information and education should be emphasise to fight against doping. [13055].

Media medicine
One paper uses UK media coverage of the sleep drug modafinil to investigate the medicalisation of sleep at a conceptual level. Using metaphorical frame analysis it was investigated the conceptual links created in media discourse between sleep and health, and the body and technology in the UK. Using this novel analytical tool it was explored under what circumstances modafinil is constructed as a necessary medical treatment or a (il)legitimate performance enhancement and, how in this process, various images of the body are constructed. It was found that media discourse on modafinil was structured through four types of sleep discourse: patient, sports, recreational, and occupational. Each discourse was built up around the specific deployment of three central metaphorical frames “war”, “commodity” and “competition” that acted to construct the biological body in a particular way. How the body was framed in each discourse impacted upon how modafinil use was portrayed in terms of therapy or enhancement and the level of engagement with a medical rhetoric. This had distinct normative implications strongly influencing the legitimacy afforded to modafinil use in each domain. It was argued that medical authority acts to legitimise modafinil use for repair, restoration and relief of suffering, whilst being deployed to pass judgment on its use in bodies already perceived as functioning normally. This led the authors to conclude that conceptually, the acceptability of “enhancement” is strongly tied to context of use and intricately related to medical social control [08044].

An integrated approach

Doping use is an important issue in both competitive and non-competitive sports, and poses potentially irreversible health consequences to users. Scholars increasingly call for theory-driven studies on the psychosocial processes underlying doping use that will inform subsequent policy-making and prevention interventions. The aim of one study was to implement an integrative theoretical model to assess the direct and indirect effects of motivational variables, moral orientations, and social cognitions on doping intentions. A randomly selected and representative sample of 750 elite athletes anonymously completed a battery of questionnaires on motivational and moral constructs, and social cognitions related to doping. Hierarchical linear regression analysis and multiple mediation modeling were used. The effects of achievement goals and moral orientations were significantly mediated by attitudinal, normative, and self-efficacy beliefs, in both lifetime ever and never doping users. Moral orientations indirectly predicted the doping intentions of never users, but did not predict ever users' doping intentions. Achievement goals and sportspersonship orientations influence doping intentions indirectly, through the effects of attitudes and self-efficacy beliefs. Sportspersonship (moral) orientations were relevant to doping intentions among athletes with no prior experiences with doping, while achievement goals and situational temptation were relevant to both lifetime never and ever dopers [13043].
INADVERTENT DOPING

In the past years, an increasing number of dietary supplements containing undeclared doping substances has been identified. The consumption of these supplements can lead to inadvertent doping cases. Although warnings about the risk of inadvertent doping have been communicated, recent studies show that athletes' knowledge of the problem is inadequate. Furthermore, it seems that the risk has been growing due to the increased availability of pharmaceutical substances via the internet, which are admixed by criminal manufacturers to their, arguably, non-effective supplement products. The main candidates from the dietary supplement market for inadvertent doping with stimulants are products containing ephedrine and analogues, sibutramine and methylhexaneamine. Such products are mainly advertised as fat burners or mood enhancers, and their use may lead to positive doping results in competition. The risk of inadvertent doping with such supplements is based on different reasons. In the case of supplements containing ephedrines, the natural sources of ephedrine such as Ma Huang or ephedra sinica are frequently mentioned on the label rather than the names of the active ingredients (ephedrine, pseudoephedrine, methylephedrine, etc). Despite extensive education of athletes regarding unclear labelling, or the variety of names by which banned substances may be referred to, many athletes still fall into this doping trap.

In the past years, an increasing number of dietary supplements containing undeclared doping substances has been identified. The consumption of these supplements can lead to inadvertent doping cases. Although warnings about the risk of inadvertent doping have been communicated, recent studies show that athletes' knowledge of the problem is inadequate. Furthermore, it seems that the risk has been growing due to the increased availability of pharmaceutical substances via the internet, which are admixed by criminal manufacturers to their, arguably, non-effective supplement products. The main candidates from the dietary supplement market for inadvertent doping with stimulants are products containing ephedrine and analogues, sibutramine and methylhexaneamine. Such products are mainly advertised as fat burners or mood enhancers, and their use may lead to positive doping results in competition. The risk of inadvertent doping with such supplements is based on different reasons. In the case of supplements containing ephedrines, the natural sources of ephedrine such as Ma Huang or ephedra sinica are frequently mentioned on the label rather than the names of the active ingredients (ephedrine, pseudoephedrine, methylephedrine, etc). Despite extensive education of athletes regarding unclear labelling, or the variety of names by which banned substances may be referred to, many athletes still fall into this doping trap.

In case of supplements enriched with sibutramine, the ingredient is not declared on the label and the consumer is only provided with the information that the product contains 'pure herbal ingredients' that are advertised to have considerable weight loss capabilities. Sibutramine can be found in therapeutically or even supratherapeutically doses in slimming capsules, powders and even slimming teas. Sibutramine is a synthetic anorectic drug, only approved as a pharmaceutical preparation and available only on prescription. Because of its enormous side effects (stroke and heart attack risk for patients with a history of cardiovascular disease), the European Medicines Agency recommended in January 2010 that this drug be withdrawn from the market. Sibutramine has been on the list of prohibited substances from the World Anti-Doping Agency (WADA) since 2006. Since 2006–2009, there has been a high risk for inadvertent doping with the stimulant methylhexaneamine, which was added to the WADA prohibited list in 2009. The issue of inadvertent doping arises from the fact that methylhexaneamine can be found on the labels in numerous different names such as dimethylamylamine, dimethylpentylamine, pentylamine, geranamine, forthane and 2-amino-4-methylhexane. On WADA's 2011 prohibited list, only the names methylhexaneamine and dimethylpentylamine are mentioned in the group of stimulants, which complicates the identification of the substance as a prohibited compound. In some supplements, geranium
root extract or geranium oil is mentioned as an alleged natural source of methylhexaneamine. However, recent investigations have shown that methylhexaneamine is not a natural ingredient of geranium oil, which means that synthesised methylhexaneamine must have been added. Despite warnings by different national antidoping agencies in 2009 and 2010, numerous elite athletes in competition have been found to have a positive test for methylhexaneamine [11425].

It is clear that there is a real risk that athletes who use dietary supplements may unknowingly ingest a banned substance that will cause them to record a positive doping outcome. There are cases in which a doping infringement can be traced back to supplement use and for which the athlete has undertaken some strategies to reduce this risk. For example, the athlete has received written advice from a supplement manufacturer that their produce does not contain banned substances, but following a positive doping test, a sealed container of the dietary supplement has been examined and found to contain the banned ingredient. Unfortunately, strict liability applies to these situations and even if athletes have been successful in having the terms of their ban from sport reduced, a doping infringement will still be recorded against their name. The loss of a career, livelihood and reputation are stakes that an athlete must take into account when using dietary supplements [11425].

Until now only two cases have been detected in which dietary supplements contained therapeutic (30 µg per tablet) and supratherapeutic (2 mg/capsule) doses of the beta2-agonist clenbuterol. In the supratherapeutically dosed product, clenbuterol was not declared on the label. Both supplements were advertised as weight loss products. Because of the extremely high concentration of clenbuterol in the second product (100-fold more than the therapeutic dose), severe side effects could be expected; in addition, a high risk of cross-contaminations of other products with clenbuterol is likely. Because WADA has classified clenbuterol as an anabolic agent, its detection in doping control may lead to severe sanctions. In 2009 and 2010, dietary supplements containing the prohibited growth hormone-releasing peptide-2 (GHRP-2) were detected. The products were advertised to produce anabolic, fat-reducing and anticasabolic effects and to improve regeneration. One product, in an ampoule of a drinking solution, contained an orally active concentration of GHRP-2. Such a product may lead to inadvertent doping cases because the name GHPR-2 is not specifically listed on the WADA prohibited list and is unknown to the majority of the sports community. However, GHRP-2 belongs as a releasing factor to the prohibited substance group S2 on the WADA list [11425].

**Sibutramine**

In case of supplements enriched with sibutramine, the ingredient is not declared on the label and the consumer is only provided with the information that the product contains “pure herbal ingredients” that are advertised to have considerable weight loss capabilities. Sibutramine can be found in therapeutic or even supratherapeutic doses in slimming capsules, powders and even slimming teas. Sibutramine is a synthetic anorectic drug, only approved as a pharmaceutical preparation and available only on prescription. Because of its enormous side effects (stroke and heart attack risk for patients with a history of cardiovascular disease), the European Medicines Agency recommended in January 2010 that this drug be withdrawn from the market. Sibutramine has been on the list of prohibited substances from the World Anti-Doping Agency (WADA) since 2006 [11010].

**Methylhexaneamine**
Since 2008-2009, there has been a high risk for inadvertent doping with the stimulant methylhexaneamine, which was added to the WADA prohibited list in 2009. The issue of inadvertent doping arises from the fact that methylhexaneamine can be found on the labels in numerous different names such as dimethylamylamine, dimethylpentylamine, pentyramine, geranamine, forthane and 2-amino-4-methylhexane. On WADA's 2011 prohibited list, only the names methylhexaneamine and dimethylpentylamine are mentioned in the group of stimulants, which complicates the identification of the substance as a prohibited compound. In some supplements, geranium root extract or geranium oil is mentioned as an alleged natural source of methylhexaneamine. However, recent investigations have shown that methylhexaneamine is not a natural ingredient of geranium oil, which means that synthesised methylhexaneamine must have been added. Despite warnings by different national antidoping agencies in 2009 and 2010, numerous elite athletes in competition have been found to have a positive test for methylhexaneamine [11010]

**Illicit blue tablets containing anabolic androgen steroids**

The necessity of specific, confirmatory tests in the identification of seized illicit products was highlighted by the analysis of eighteen heart shaped, blue tablets confiscated by Police at a street control in the North East of Italy. The tablets responded as amphetamines to a preliminary color test (Marquis); a subsequent, confirmatory assay by gas chromatography-mass spectrometry revealed the presence of two anabolic androgen steroids (AAS), methandienone and methyltestosterone, in concentration of 1.7 and 1.5 mg respectively per tablet; no trace of amphetamine-like or nitrogen containing compounds was found. The observed orange coloration was due to the reaction of concentrated sulphuric acid, contained in the Marquis reagent, with keto group of steroids. The two AAS, banned under the world antidoping code, are not considered as psychoactive drugs of abuse in most countries, although their trafficking may entangle severe public health concerns [13076].

**Dietary supplements containing prohibited anabolic agents**

The extent of the contamination of dietary supplements with anabolic agents was evaluated in 2001 and 2002. A well-publicised study showed that about 15 percent of non-hormonal supplements such as vitamins, minerals, proteins and creatine contained anabolic androgenic steroids (mainly prohormones) that were not declared on the label. The reason for the contamination was most probably the fact that manufacturers of prohormones also manufactured other supplements on the production line without sufficient cleaning. Another source of cross-contamination could have been the unclean transport containers from raw material suppliers of prohormones. The amount of detected prohormones, especially prohormones of nandrolone, could produce positive doping cases. Since 2002, dietary supplements have appeared on the market, which are probably intentionally spiked with high amounts (more than 1 mg/g) of “classic” anabolic steroids, not declared or declared with non-approved or fancy names on the label. Among these, steroids including stanozolol, metandienone, dehydrochloromethyltestosterone and oxandrolone have been identified. All these steroids are orally effective drugs based on their 17-alkyl group. These dietary supplements are advertised as leading to enormous enhancement of strength and lean body mass. The concentrations of the anabolic androgenic steroids are in the therapeutic or supratherapeutic range per serving leading to positive doping cases detectable for several days and weeks, respectively, depending on the type of steroid administered. Because the manufacturers of these faked products also prepare other nutritional supplements on the
same production line, the risk of cross-contaminations with such "classic" anabolic androgenic steroids is very high. Such contaminations have been found in fizzy tablets of vitamin C, magnesium and multivitamins produced for Spanish and German supermarkets containing, for example, small amounts of stanozolol and metandienone with the potential to produce a positive doping response [11425].

Since 2002, dietary supplements have appeared on the market, which are probably intentionally spiked with high amounts (more than 1 mg/g) of "classic" anabolic steroids, not declared or declared with non-approved or fancy names on the label. Among these, steroids including stanozolol, metandienone, dehydrochloromethyltestosterone and oxandrolone have been identified. All these steroids are orally effective drugs based on their 17-alkyl group. These dietary supplements are advertised as leading to enormous enhancement of strength and lean body mass. The concentrations of the anabolic androgenic steroids are in the therapeutic or supratherapeutic range per serving leading to positive doping cases detectable for several days and weeks, respectively, depending on the type of steroid administered. Because the manufacturers of these faked products also prepare other nutritional supplements on the same production line, the risk of cross-contaminations with such classic anabolic androgenic steroids is very high. Such contaminations have been found in fizzy tablets of vitamin C, magnesium and multivitamins produced for Spanish and German supermarkets containing, for example, small amounts of stanozolol and metandienone with the potential to produce a positive doping response. Since 2002, the so-called designer steroids can also be found on the dietary supplement market. These steroids are neither listed as ingredients in any currently available medication, nor do their names appear in the WADA list of prohibited substances. Most of these designer steroids have been synthesized in the 1960s and were tested only in animal studies for their anabolic and androgenic effects. Nowadays, these steroidal agents are produced exclusively for the nutritional supplement market and are advertised for their anabolic- or aromatase-inhibiting capacities. With regard to the effects and side effects of these steroids for humans, there is limited or no knowledge. In most cases, the labelling of these products contains non-approved or fancy names of the steroids. More than 40 such designer steroids have been detected. The detection of metabolites of such a steroid in an athlete's urine sample is likely to lead to a positive doping case [11010].

Nutritional supplements can be a source of positive doping cases as some supplements contain prohibited substances without showing this on their label. This problem has existed for some time and has been extensively studied in the past 8 years. The sport of tennis has played a particular role in this problem because of some peculiar doping cases within its community. For more than a decade, it has been known that nutritional supplements can be "contaminated" with doping substances, which means that the contents of the supplements are not identical to the list of ingredients on the label. Tennis has played a particular role in this debate because of the complexity of the cases of Bohdan Ulìhrach and Greg Rusedski, who tested positive for nandrolone or nandrolone prohormones in 2002 and 2003, respectively. In June 2007, Guillermo Coria sued an American nutritional company for the financial damages he suffered during his 2 year suspension after also testing positive for nandrolone in 2001. This problem is of major concern to elite athletes, who can test positive in a doping test without knowingly taking banned substances. This so-called "inadvertent doping use" has resulted in an unknown number of positive cases because doping tests often rely on the presence of metabolites of banned substances in urine, and cannot discern between intentional and inadvertent use [07025].
**Dietary supplements contaminated with prohormones**

The extent of the contamination of dietary supplements with anabolic agents was evaluated in 2001 and 2002. A well-publicised study showed that about 15 percent of non-hormonal supplements such as vitamins, minerals, proteins and creatine contained anabolic androgenic steroids (mainly prohormones) that were not declared on the label. The reason for the contamination was most probably the fact that manufacturers of prohormones (legally marketed as dietary supplements in the USA until 2004) also manufactured other supplements on the production line without sufficient cleaning. Another source of cross-contamination could have been the unclean transport containers from raw material suppliers of prohormones. The amount of detected prohormones, especially prohormones of nandrolone, could produce positive doping cases [11010].

**Dietary supplements with clenbuterol**

Until summer 2011 only two cases have been detected in which dietary supplements contained therapeutic (30 microg per tablet) and supratherapeutic (2 mg/capsule) doses of the beta2-agonist clenbuterol. In the supratherapeutically dosed product, clenbuterol was not declared on the label. Both supplements were advertised as weight loss products. Because of the extremely high concentration of clenbuterol in the second product (100-fold more than the therapeutic dose), severe side effects could be expected; in addition, a high risk of cross-contaminations of other products with clenbuterol is likely. Because WADA has classified clenbuterol as an anabolic agent, its detection in doping control may lead to severe sanctions [11010].

**Dietary supplements containing prohibited peptide hormones**

In 2009 and 2010, dietary supplements containing the prohibited growth hormone–releasing peptide-2 (GHRP-2) were detected. The products were advertised to produce anabolic, fat-reducing and anticatabolic effects and to improve regeneration. One product, in an ampoule of a drinking solution, contained an orally active concentration of GHRP-2. Such a product may lead to inadvertent doping cases because the name GHRP-2 is not specifically listed on the WADA prohibited list and is unknown to the majority of the sports community. However, GHRP-2 belongs as a releasing factor to the prohibited substance group S2 on the WADA list [11010].

**Designer drugs**

Since 2002, the so-called designer steroids can also be found on the dietary supplement market. These steroids are neither listed as ingredients in any currently available medication, nor do their names appear in the WADA list of prohibited substances. Most of these designer steroids have been synthesised in the 1960s and were tested only in animal studies for their anabolic and androgenic effects. Nowadays, these steroidal agents are produced exclusively for the nutritional supplement market and are advertised for their anabolic- or aromatase-inhibiting capacities. With regard to the effects and side effects of these steroids for humans, there is limited or no knowledge. In most cases, the labelling of these products contains non-approved or fancy names of the steroids. More than 40 such designer steroids have been detected. The detection of metabolites of such a steroid in an athlete’s urine sample is likely to lead to a positive doping case [11425].
Emerging drugs

In 2009 and 2010, the first prohibited selective androgen receptor modulators (SARMs) and the gene doping substances AICAR and GW1516 were detected on the black market. All these substances are still in clinical trials and have not yet been approved as medications. From the experience, it can be expected that these substances will appear very soon on the dietary supplement market, with advertising that the SARM products will achieve anabolic effects whereas the gene doping substances will enhance endurance. If these substances are added to other supplement products without being declared on the label, new sources of risk for inadvertent doping will be created [11010].
PREVENTION OF DOPING

The potential for adverse effects and the prevailing attitudes towards “unethical” performance-enhancing substances have prompted various efforts to prevent anabolic steroids use in adolescent athletes over the past 25 years. Principal among these has been a punitive approach consisting of in- and out-of-competition doping controls and suspension or expulsion for refusing testing or failed tests. Although these actions may have some impact on elite-level adolescents athletes, they are of questionable utility for those at lower levels where testing is not conducted and of no use for young AAS users not involved in organised sport. Prevention programs founded on cognitive-behavioural or social environment paradigms that do not focus on a fear-based philosophy may be more effective. Based on their findings that a significant proportion of steroid users “have access to models that have used or use anabolic steroids.” It has also been recommended interventions that focus on “environments and groups where the general level of drug use is high.” Furthermore, as these adolescents know users, the claims by authorities of the significant adverse effects of steroid use “may be perceived as unsubstantiated.” Therefore, a different model than “fear based” is needed to deter use among children and adolescents, whether involved in organised sports or not. This view is supported by early prevention efforts when it was compared a “balanced education program (potential risks and benefits)” to a “risks-only (negative or scare tactics) program” of AAS use and found that while the balanced approach resulted in significant improvements in the athletes’ attitudes to adverse AAS effects, there was no change in the fear-based group [09023].

Anti-doping activities in sport have shifted from secondary prevention (intervening after athletes have used) to educational strategies focused on primary prevention through promoting abstinence. There is no empirical evidence to guide targeting of anti-doping education initiatives. In one paper, a heuristic to guide education initiatives was derived by re-analysing a series of interviews (n=20) with athletes, coaches, sports managers, physiotherapists and sports nutritionists. The findings indicate primary prevention of doping may be enhanced by timing it around periods of career instability where athlete vulnerability to doping may increase as a function of winning or losing sponsorship. Sponsorship is broadly defined as financial (e.g. salary stipend) and non-financial support (e.g. training facilities). This provides a basis for targeting education interventions to promote abstinence. Two options are offered to mitigate the need to time prevention activity around career instability by lessening the effect of sponsorship on athlete doping. The first is liberalising access to legitimate performance enhancing technologies (e.g. training techniques or nutritional supplements). The second is to delay access to financial sponsorship (beyond living expenses) until retirement, with monetary gains (e.g. prize money) deposited into an account where penalties are debited if the athlete is caught doping [10304].

Anti-doping activities in sport have shifted from secondary prevention (intervening after athletes have used) to educational strategies focused on primary prevention through promoting abstinence. There is no empirical evidence to guide targeting of anti-doping education initiatives. In this paper, a heuristic to guide education initiatives was derived by re-analysing a series of interviews (n=20) with athletes, coaches, sports managers, physiotherapists and sports nutritionists. The findings indicate primary prevention of doping may be enhanced by timing it around periods of career instability where athlete vulnerability to doping may increase as a function of winning or losing sponsorship. Sponsorship is broadly defined as financial (e.g. salary stipend) and non-financial support (e.g. training facilities). This provides a basis for targeting education interventions to promote abstinence. Two options are offered to mitigate the need to time prevention activity around career instability by lessening the effect of sponsorship on athlete doping. The first is liberalising
access to legitimate performance enhancing technologies (e.g. training techniques or nutritional supplements). The second is to delay access to financial sponsorship (beyond living expenses) until retirement, with monetary gains (e.g. prize money) deposited into an account where penalties are debited if the athlete is caught doping [11025].

One study examined the extent to which the trajectory of participation in sports, athletics or exercising (PSAE) covaried with substance use in early adulthood controlling for team sports participation using parallel process latent growth curve modeling. Analysis of data collected from a series of panel studies using a cohort-sequential design. Specifically, the analyses used longitudinal data from 11 741 individuals from the graduating classes of 1986-2001, first surveyed as seniors in American high schools. Up to four additional follow-up surveys were administered to age 26 years. Data were collected using in-school and mailed self-administered questionnaires. Level of PSAE, past-30-day alcohol, cigarette and marijuana use frequency and any past-30-day use of illicit drugs other than marijuana (IOTM) were the main processes of interest. Self-reported race/ethnicity, college status at age 19/20 years, parental education, gender and team sports participation during high school were included as covariates. Results indicate that higher initial levels of PSAE related to lower initial substance use prevalence rates other than alcohol, and lower initial prevalence rates of substance use then corresponded with lower substance use rates throughout early adulthood. Further, as individuals increased PSAE levels throughout early adulthood, the frequency of their use of cigarettes, marijuana and IOTM correspondingly decreased. It was concluded that increased participation in sports, athletics or exercising (PSAE) is related to significantly lower substance use frequency at modal age 18 and through significantly and negatively correlated growth trajectories through early adulthood. Encouraging PSAE among adolescents and early adults may relate to lower substance use levels throughout early adulthood [11026].

The US National Institute on Drug Abuse has called for increased research into the use of physical activity in substance abuse prevention, specifically research into physical activity type and context. One paper examines the relationships between secondary school student substance use and exercise in general and school athletic team participation, and examines such relationships over time. Nationally representative cross-sectional samples of 8th-, 10th-, and 12th-grade students were surveyed each year from 1991 to 2009. Substance use measures included past 2-week binge drinking and past 30-day alcohol, cigarette, smokeless tobacco, marijuana, and steroid use. Analyses were conducted during 2009-2010. Across grades, higher levels of exercise were associated with lower levels of alcohol, cigarette, and marijuana use. Higher levels of athletic team participation were associated with higher levels of smokeless tobacco use and lower levels of cigarette and marijuana use across grades and to higher levels of high school alcohol and steroid use. Exercise helped suppress the undesired relationship between team participation and alcohol use; exercise and athletic team participation worked synergistically in lowering cigarette and marijuana use. Observed relationships were generally stable across time. In conclusion, there appear to be substantive differences between exercise and team sport participation in relation to adolescent substance use. These findings from cross-sectional data suggest that interventions to improve levels of general physical activity should be evaluated to determine if they help delay or reduce substance use among youth in general as well as among student athletes [11027].

**Athletes Targeting Healthy Exercise and Nutrition Alternatives (ATHENA)**

To explain, through mediation analyses, the mechanisms by which ATHENA (Athletes Targeting Healthy Exercise and Nutrition Alternatives), a primary prevention and health promotion intervention was designed to deter unhealthy body shaping behaviors among
female high school athletes, produced immediate changes in intentions for unhealthy weight loss and steroid/creatine use, and to examine the link to long-term follow-up intentions and behaviors. In a randomized trial of 1668 athletes, intervention participants completed coach-led peer-facilitated sessions during their sport season. Participants provided pre-test, immediate post-test, and 9-month follow-up assessments. ATHENA decreased intentions for steroid/creatine use and intentions for unhealthy weight loss behaviors at post-test. These effects were most strongly mediated by social norms and self-efficacy for healthy eating. Low post-test intentions were maintained 9 months later and predicted subsequent behavior. It was concluded that ATHENA successfully modified mediators that in turn related to athletic-enhancing substance use and unhealthy weight loss practices. Mediation analyses aid in the understanding of health promotion interventions and inform program development [09030].

Almost one half of male and female students participate in high school-sponsored athletics, and high school also is a time when classroom health promotion curricula are less effective. The Athletes Training and Learning to Avoid Steroids is a sport team-centered drug-use prevention program for male high school athletes, which has been shown to reduce alcohol and illicit drug use. Just as anabolic steroid use is associated with male athletes, female sport participants may be at a greater risk for disordered eating and body-shaping drug use. Extending sport team-centered programs to young women athletes required defining and ranking factors related to developing those harmful behaviors. Survey results from a cross-sectional cohort of female middle and high school student athletes were used to identify and prioritize potential curriculum components, including mood and self-esteem, norms of behavior, perceptions of healthy body weight, effects of media depictions of women, and societal pressures to be thin. The derived sport team-centered program was prospectively assessed among a second group of female student athletes from 18 high schools, randomized to receive the intervention or the usual care control condition. The Athletes Targeting Healthy Exercise and Nutrition Alternatives (ATHENA) intervention is a scripted, coach-facilitated, peer-led 8-session program, which was incorporated into a team’s usual training activities. The ATHENA program significantly altered the targeted risk factors and reduced ongoing and new use of diet pills and body-shaping substances (amphetamines, anabolic steroids, and sport supplements). These findings illustrate the utility of a structured process to define curriculum content, and the program’s positive results also confirm the sport team’s potential as a vehicle to effectively deter health-harming behaviors [06030].

**Telephone counseling**

Drug abuse, most notably anabolic-androgenic steroid (AAS) use, in athletes is widespread. As a result, athletes and exercise enthusiasts who abuse these drugs are troubled by the side effects of these illicit drugs, especially AAS. In an attempt to improve this situation, since 1993, it was counseled athletes who abuse drugs and others with questions about AAS via telephone and tabulated the results. Counseling sessions took place by telephone every Monday between 19:00-23:00 h. The number of cases was tabulated each year and the specific items discussed during each consultation were categorized by key words. Cases consisted of both drug abusers and athletes who did not abuse drugs and were concerned about the side effects or other various problems surrounding the use of AAS. From 1993 to 1996, there were about 50 cases yearly; thereafter, the number of consultations dropped to about 30 to 40 cases each year. In 2002, consultations with drug abusers accounted for 52 percent of all consultations, compared with 46 percent of all consultations from 1993 to 2002. It was found that abusers of hormones exist in Japan, as well as elsewhere. It was hoped these results will demonstrate the necessity of employing public institutional counseling systems for athletes who are drug abusers in Japan, similar to the successful system instituted by the Swedish National Service [07029].
National policy against doping

Sweden

In 2003, the Swedish Parliament adopted a cross-sectorial national public health policy based on the social determinants of health, with an overarching aim – to create societal conditions that will ensure good health, on equal terms, for the entire population – and eleven objective domains. At that time the policy was globally unique, and serves as guidance for public health practice at the national, regional and local levels. The development of the public health policy and the determinants of health are presented regularly in various reports by the Swedish National Institute of Public Health. In order to provide a holistic approach to analysing implemented measures and providing new recommendations within the eleven objective domains of the Swedish national public health policy, we have divided these in three strategic areas. These are: Good Living Conditions, Health-Promoting Living Environments and Living Habits, and Alcohol, Illicit Drugs, Doping, Tobacco and Gambling, each described in the respective introductions for Chapters 3-5. The production of the report was supported by a common analytical model that clarified the societal prerequisites for health in the eleven objective domains. These are factors that can be influenced by political actions in order to create a change. Economic analyses have also been developed to provide a priority basis for political decisions. Analyses of the development of public health determinants were based on data from the National Public Health Survey and data delivered from about 15 various national agencies. Measures that have been implemented between 2004 and 2009 are analysed in details, as the basis for new recommendations for future measures [13060].

Brazil

A retrospective study reports data obtained from the National Institute of Criminalistics of the Brazilian Federal Police Department (DPF) on 3676 anabolic products seized between 2006 and 2011. Anabolic androgenic steroids (AAS) were declared on the labels of 96 percent of the products. About one third of the products declared to be from Paraguay, and 14 percent from Brazil. Stanozolol, testosterone and nandrolone were the substances most declared on the labels. Package and qualitative chemical analyses (performed on 2818 products) found that 32 percent of the seized products were counterfeit, with an increase in the counterfeit detection rate during the period. Almost half of the fake products did not contain the declared substances, and 28 percent had only non-declared substances. Testosterone and its esters were responsible for 45 percent of the 582 cases of non-declared drug detection. Package analysis alone was responsible for the identification of 5 percent of all counterfeit products. These results indicate the need for a continuous effort by the government aimed at decreasing the availability of these products in the country [13061].
OVERVIEWS OF GENERAL LABORATORY TECHNIQUES

Unification of the screening protocols for a wide range of doping agents has become an important issue for doping control laboratories. This study presents the development and validation of a generic liquid chromatography/time-of-flight mass spectrometry (LC/TOFMS) screening method of 241 small molecule analytes from various categories of prohibited substances (stimulants, narcotics, diuretics, beta-2-agonists, beta-blockers, hormone antagonists and modulators, glucocorticosteroids and anabolic agents). It is based on a single-step liquid-liquid extraction of hydrolyzed urine and the use of a rapid-resolution liquid chromatography/high-resolution time-of-flight mass spectrometric system acquiring continuous full scan data. Electrospray ionization in the positive mode was used. Validation parameters consisted of identification capability, limit of detection, specificity, ion suppression, extraction recovery, repeatability and mass accuracy. Detection criteria were established on the basis of retention time reproducibility and mass accuracy. The suitability of the methodology for doping control was demonstrated with positive urine samples. The preventive role of the method was proved by the case where full scan acquisition with accurate mass measurement allowed the retrospective reprocessing of acquired data from past doping control samples for the detection of a designer drug, the stimulant 4-methyl-2-hexanamine, which resulted in re-reporting a number of stored samples as positives for this particular substance, when, initially, they had been reported as negatives [10027].

The PubMed and Google Scholar search engines were used to identify publications addressing various forms of doping, methods employed in their detection, and adverse effects associated with their use. The list of drugs prohibited by the World Anti-Doping Agency (WADA) has grown in the last decade. The newer entries into this list include gonadotropins, estrogen antagonists, aromatase inhibitors, androgen precursors, and selective androgen receptor modulators. The use of mass spectrometry has revolutionized the detection of various compounds; however, challenges remain in identifying newer designer androgens because their chemical signature is unknown. Development of high throughput bioassays may be an answer to this problem. It appears that the use of anabolic steroids continues to be associated with premature mortality (especially cardiovascular) in addition to suppressed spermatogenesis, gynecomastia, and virilization. The attention that androgen abuse has received lately should be used as an opportunity to educate both athletes and the general population regarding their adverse effects. The development of sensitive detection techniques may help discourage (at least to some extent) the abuse of these compounds [10028].

The increasing number of samples and target substances in doping control requires continuously improved screening methods, combining high-throughput analysis, simplified sample preparation, robustness and reliability. The issue of doping in sport is multifaceted. New drugs not only with anabolic properties such as selective androgen receptor modulators, synthetic insulins, blood doping with erythropoietins or homologous and autologous blood transfusions but also with sample manipulation have necessitated sensitive, comprehensive and specific detection assays allowing for the identification of cheats. New methods based on mass spectrometry, flow cytometry and immunological techniques have been introduced and improved in the past years to support and enhance the antidoping fight [08051].

The analysis of sports samples for prohibited substances began in the 1960s and has developed since then using modern technologies close to the latest scientific discoveries. For small molecules, apart from the routine use of GC-MS, the newer techniques include the use of isotope ratio MS to detect testosterone and nandrolone administration and LC-MS/MS
(liquid chromatography-tandem MS) to detect diuretics. For large molecules, several applications of LC-MS/MS are described as well as immunoprocesses for erythropoietin and human growth hormone [08052].

The ability to measure isotope distribution at natural abundance with high accuracy and precision has increased the application of gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS) to doping control in recent years. GC-C-IRMS is capable of measuring the carbon isotope ratio (delta$^{13}$C) of urinary steroids and confirm their synthetic origin based on the abnormal $^{13}$C content. One tutorial describes some of the complexities encountered by obtaining valid delta$^{13}$C measurements from GC-C-IRMS and the need for careful interpretation of all relevant information concerning an individual's metabolism in order to make an informed decision with respect to a doping violation [08053].

Technical advances are being made in many areas of biotechnology and genetics that are facilitating the detection of doping in sport. These improvements have been catalyzed by the need to counter the ever-increasing sophistication of the community of athletes and their retinues who are intent on the illicit use of physical, pharmacological and genetic tools and methods to enhance athletic performance, in contravention of established international ethical and legal standards and of international treaty. The methods described in one article present a partial and general picture of only some of these advances [12047].

**Olympic laboratories**

Summer and Winter Olympic anti-doping laboratories, accredited by the International Olympic Committee in the past and the World Anti-Doping Agency in the present times, acquire worldwide interest to apply all new analytical advancements in the fight against doping in sports, hoping that this major human event will not become dirty by association with this negative phenomenon. One article summarized the new analytical progresses, technologies and knowledge used by the Olympic laboratories, which for the vast majority of them are, eventually, incorporated into routine anti-doping analysis [12048].

2005 London was awarded the Games of the XXX Olympiad. Following the IOC motto of “Citius, Altius, Fortius”, it was decided that this would be an appropriate strategy to ensure faster analysis with higher sensitivity, and stronger proof in cases of doping. A number of new analytical methods were developed. Faster analysis was obtained with excellent sensitivity using a modified gas chromatography–tandem mass spectrometry (GC-MS/MS) screening method. After extensive development and optimisation, the run-times were reduced from 40 min to 14 min using short capillary GC columns. This GC-MS/MS screen was complemented with an ultra high pressure chromatography (UHPLC) with high resolution mass spectrometry (HRMS) screen. For the first time, and after much research, it was concluded that UHPLC with HRMS could reliably screen over 200 analytes. This needed both positive and negative ionisation modes together with collision induced dissociation with all three MS experiments occurring rapidly so as not to compromise chromatographic performance. Working in full scan mode, the volume of data acquired was enormous and review of the vast amount of data was a challenge. After extensive collaboration with the manufacturer there was a software that will identify the targeted analytes in 2 min after a 10 min acquisition time. Any new designer substance can now be readily searched for since we are working in full scan mode. Furthermore, now that multiple samples are collected from a single athlete over time (the athlete biological passport) it can review such data to search for any change in biomarkers. Indeed, as the electronic files, like the samples, are stored for 8
years, it will now be possible to review the data at a later date to confirm that no prohibited substance had been taken at the time of sample collection. Although the qualitative identification of a foreign substance is all that is required to provide such evidence, for some substances, WADA rules establish a quantitative threshold. This requires the laboratory to quantify the substance with less than a documented uncertainty and establish that the concentration exceeds the reporting threshold. Proving the administration of a pseudo-endogenous substance, i.e. one that is virtually identical to the endogenous substance, is an even more difficult task. Combustion isotope ratio mass spectrometry is used to evidence exogenous administration by identification of a foreign substance [12049].

Practical testing in Brazil

It was summarized the results obtained from the doping control analysis during the period of the 2007 Pan American Games held in Rio de Janeiro, Brazil. Approximately 5600 athletes from 42 different countries competed in the games. Testing was performed in accordance to World Anti-Doping Agency technical note for prohibited substances. One 8 mL urine sample was used for the analysis of five steroid metabolites with two separate analyses by gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS). Urine samples were submitted to GC/C/IRMS for confirmation analysis to determine the $^{13}$C/$^{12}$C ratio of selected steroids. Fifty-seven urine samples were analyzed by GC/C/IRMS and the delta $^{13}$C values (per thousand) of androsterone, etiocholanolone, 5beta-androstane-3alpha, 17beta-diol (5beta-diol), 5alpha-androstane-3alpha, 17beta-diol (5alpha-diol) and 5beta-pregnane-3alpha, 20alpha-diol (5beta-pdiol), and the endogenous reference compound were presented. One urine sample with a testosterone/epitestosterone (T/E) ratio of 4.7 was confirmed to be positive of doping by GC/C/IRMS analysis. The delta values of 5beta-diol and 5alpha-diol were 3.8 and 10.8, respectively, compared to the endogenous reference compound 5beta-pdiol, which exceeded the WADA limit of 3 per thousand [09046].

The worldwide network of World Anti-Doping Agency (WADA)-accredited anti-doping laboratories plays a fundamental role in supporting the global fight against doping in sport. This role is dependent on the ability to provide accurate, reliable and comparable data in identifying and measuring the presence of prohibited substances and methods. The accredited laboratories participate in WADA's External Quality Assessment Scheme (EQAS) program, which provides the structure to continuously assess and improve laboratory performance in compliance to the requirements of the International Standard for Laboratories and related Technical Documents. The WADA EQAS is comprised of various programs, including a blind EQAS, a double-blind EQAS and an educational EQAS, each with specific goals with regard to monitoring and improving laboratory competence. In this article, the anti-doping rules and processes that govern granting and maintenance of WADA laboratory accreditation, aimed at ensuring a high-quality of laboratory operations within the framework of the global fight against doping in sport, are reviewed [12050].

Transportation

The transportation of urine samples, collected for doping control analysis, does not always meet ideal conditions of storage and prompt delivery to the World Anti-Doping Agency (WADA) accredited laboratories. Because sample collection is not conducted under sterile conditions, microbial activity may cause changes to the endogenous steroid profiles of samples. In one work, funded by WADA, a chemical mixture consisting of antibiotics, antimycotic substances and protease inhibitors was applied in urine aliquots fortified with
conjugated and deuterated steroids and inoculated with nine representative microorganisms. Aliquots with and without the chemical mixture were incubated at 37 degrees C for 7 days to simulate the transportation period, whereas another series of aliquots was stored at -20 degrees C as reference. Microbial growth was assessed immediately after inoculation and at the end of the incubation period. Variations in pH and specific gravity values were recorded. Gas chromatography-mass spectrometry (GC-MS) analysis was performed for the detection of steroids in the free, glucuronide, and sulfate fractions. The addition of the chemical stabilization mixture to urine samples inhibited microorganism growth and prevented steroid degradation at 37 degrees C. On the other hand, four of the nine microorganisms induced alterations in the steroid profile of the unstabilized samples incubated at 37 degrees C [09034].

Quality of doping testing

Large amount of efforts are wasted on anti-doping testing and courts, while the current anti-doping practices are not deem to be infallible or thoughtfully foolproof according to one author. In one article published in the Journal of Applied Physiology, eight human subjects were studied for 7 weeks and treated with recombinant human erythropoietin (rHuEpo) for 4 weeks and a post period of 3 weeks. Urine samples were obtained during all periods and sent to two WADA-accredited laboratories. Whereas one of the two laboratories determined rHuEpo misuse in all subjects during the boosting period, the second laboratory found no misuse, with one sample to be negative, and the remaining seven to be suspicious. More interestingly, while one laboratory found only two of 24 samples to be positive and three to be suspicious during maintenance and post period, the second laboratory found no positive or suspicious samples. As in other areas of healthcare, errors might also occur in laboratory diagnostics. Given the high amount of tests performed every day in clinical laboratories, even a low prevalence still reflects meaningful numbers, harbouring important public health and patient safety implications. For a variety of reasons, false-positive and false-negative results can occur in any area of laboratory diagnostics, including anti-doping testing. One may support the hypothesis that the International anti-doping system might fail or, incidentally, do fail. As such, it might produce contradictory outcomes, because false-negative results may reassure the athletes that some forms of doping are hardly detectable, whereas falsepositive results might lead to adverse clinical, ethical and economical consequences for those found guilty. It is also to mention that the high number of athletes testing positive during anti-doping controls clearly attests that the current strategy is probably ineffective to prevent athletes to dope and modify this otherwise upsetting trend. A more suitable and less expensive strategy might be planned, where identification of abnormal deviations from reference individual values, regardless of pathological or artificial (doping) sources, would allow to follow and target the athlete by an armamentarium of conventional and relatively inexpensive laboratory tests, which are affordable to Governments and healthcare systems, and are also available to vast majority of clinical laboratories [09035].

Blood sampling and blood samples handling

Although not (yet) a frequent doping control specimen, blood samples are advantageous over urine specimens in a doping control context in at least two ways

- they commonly contain the intact drug rather than metabolites, which represents a work-around when new or entirely unknown (designer) compounds are misused and metabolism studies are not (or not publicly) available
they provide information on drug concentrations at the time of sampling, which is of uttermost importance concerning those drugs prohibited in-competition only.

As a consequence, the option to expand doping controls from urine and (less frequently) plasma or serum to whole blood shortly before or after competition was evaluated and assays for the analysis of minimal-invasively collected dried blood spots (DBS) were reported in 2011 and 2012. DBS, created from a volume of 25 microl, were excised from blood collection cards and consecutively extracted into methanol/tert.-butyl-methyl ether and acetone. The combined extracts were concentrated, reconstituted and analyzed on a C-18 UHPLC column (2.1 × 50 mm, 1.9 microm particle size) with 0.2 percent formic acid (solvent A) and acetonitrile (solvent B) connected via ESI to a quadrupole-orbitrap hybrid mass spectrometer. Here, various MS modes were successively used comprising scan-to-scan polarity switching combined with accurate mass full scan MS and target analyte inclusion list (for online single-event product ion scan experiments) as well as all-ion fragmentation. Hence, the combined targeted qualitative and quantitative analysis was possible and data for non-target substances for retrospective evaluation or homology searches based on conserved and common molecular structures were recorded. The model assay included a total of 24 substances covering the prohibited classes S1, S3-S6, S8, S9, and P2, and LODs ranged from 0.05-0.5 ng/mL. Moreover, LOQs were determined for four model substances (tetrahydrocannabinol, cocaine, clenbuterol, and salbutamol) and were found between 0.25 and 2 ng/mL, meeting the required sensitivity to measure physiologically relevant concentrations of these drugs [13012].

Handling of urine

Stability of doping substances in urine

For a correct interpretation of analytical results in doping control, knowledge on the stability of prohibited substances in the urinary matrix is a prerequisite. So far, limited data is available on the stability of prohibited substances in unaltered urine because most of the studies investigating the stability of drugs have used stabilized, sterilized, or filtered urine. In this work, the long-term stability of ephedrine, methylephedrine, cathine, 19-norandrosterone glucuronide, and a wide range of diuretics was determined over a period of 9 months at -20 degrees C, 4 degrees C, 22 degrees C, and 37 degrees C. Short-term stability, including the influence of 6 freeze-thaw cycles and 15 h storage at 60 degrees C, was also investigated. Often, a tolerance limit of 15 percent, similar to what is commonly used in the evaluation of precision data during method validation, is used to evaluate stability. One paper described an alternative approach, using measurement uncertainty data to evaluate long-term stability with a probability of 95 percent, and proposes a simple alternative for investigating the stability for non-threshold substances. The results indicate that all the investigated substances are stable when stored at -20 degrees C and 4 degrees C, but that at higher temperatures significant degradation effects can occur. The study also shows that degradation can be dependent on the urinary matrix and that the results from stability studies using stabilized, filtered, or sterilized urine can underestimate degradation effects [07041].

Transportation of doping control urine samples from the collection sites to the World Anti-doping Agency (WADA) Accredited Laboratories is conducted under ambient temperatures. When sample delivery is not immediate, microbial contamination of urine, especially in summer, is a common phenomenon that may affect sample integrity and may result in misinterpretation of analytical data. Furthermore, the possibility of intentional contamination of sports samples during collection with proteolytic enzymes, masking the abuse of
prohibited proteins such as erythropoietin (EPO) and peptide hormones, is a practice that has already been reported. Consequently, stabilization of urine samples with a suitable method in a way that protects samples’ integrity is important. Currently, no stabilization method is applied in the sample collection equipment system in order to prevent degradation of urine compounds. An overview of a study, funded by WADA, on degradation and stabilization aspects of sports urine samples against the above threats of degradation. Was presented. Extensive method development resulted in the creation of a mixture of chemical agents for the stabilization of urine. Evaluation of results demonstrated that the stabilization mixture could stabilize endogenous steroids, recombinant EPO, and human chorionic gonadotropin in almost the entire range of the experimental conditions tested [11033].

**Diluted urine**

Excessive fluid intake can substantially dilute urinary drug concentrations and result in false-negative reports for drug users. Methods for correction (“normalization”) of drug/metabolite concentrations in urine have been utilized by anti-doping laboratories, pain monitoring programs, and in environmental monitoring programs to compensate for excessive hydration, but such procedures have not been used routinely in workplace, legal, and treatment settings. It was evaluated two drug normalization procedures based on specific gravity and creatinine. These corrections were applied to urine specimens collected from three distinct groups (pain patients, heroin users, and marijuana/cocaine users). Each group was unique in characteristics, study design, and dosing conditions. The results of the two normalization procedures were highly correlated. Increases in percent positives by specific gravity and creatinine normalization were small for heroin users (normally hydrated subjects), modest for pain patients (unknown hydration state), and substantial (2- to 38-fold increases) for marijuana/cocaine users (excessively hydrated subjects). Despite some limitations, these normalization procedures provide alternative means of dealing with highly dilute, dilute, and concentrated urine specimens. Drug/metabolite concentration normalization by these procedures is recommended for urine testing programs, especially as a means of coping with dilute specimens [09036].

**Urinary screening**

The general strategy to perform anti-doping analyses of urine samples starts with the screening for a wide range of compounds. This step should be fast, generic and able to detect any sample that may contain a prohibited substance while avoiding false negatives and reducing false positive results. The experiments presented in one work were based on ultra-high-pressure liquid chromatography coupled to hybrid quadrupole time-of-flight mass spectrometry. Thanks to the high sensitivity of the method, urine samples could be diluted 2-fold prior to injection. One hundred and three forbidden substances from various classes (such as stimulants, diuretics, narcotics, anti-estrogens) were analysed on a C(18) reversed-phase column in two gradients of 9 min (including two 3 min equilibration periods) for positive and negative electrospray ionisation and detected in the MS full scan mode. The automatic identification of analytes was based on retention time and mass accuracy, with an automated tool for peak picking. The method was validated according to the International Standard for Laboratories described in the World Anti-Doping Code and was selective enough to comply with the World Anti-Doping Agency recommendations. In addition, the matrix effect on MS response was measured on all investigated analytes spiked in urine samples. The limits of detection ranged from 1 to 500 ng/mL, allowing the identification of all tested compounds in urine. When a sample was reported positive during the screening, a fast additional pre-confirmatory step was performed to reduce the number of confirmatory analyses [09037].

Lots of the steroids are extensively metabolised in the human body. Thus, knowledge of
urinary excretion is extremely important for the sensitive detection of steroid misuse in doping control. The methods routinely used in steroid screening mainly focus on substances, that are excreted unconjugated or as glucuronides. Common procedures include deconjugation using a beta-glucuronidase enzyme. Following extraction and concentration the analytes are submitted to LC-MS/(MS) analysis and/or GC-MS/(MS) analyses. Besides the classical steroids, more and more products appear on the market for "dietary supplements" containing steroids that have never been marketed as approved drugs, mostly without proper labelling of the contents. To cover the whole range of potential products comprehensive screening tools have to be utilised in addition to the classical methods. Endogenous steroids, e.g. testosterone, represent a special group of compounds. As classical chemical methodology is incapable of discriminating synthetic hormones from the biosynthesised congeners, the method of steroid profiling is used for screening purpose. Additionally, based on isotope signatures a discrimination of synthetic and natural hormones can be achieved [09038].

Direct injection of urine

Direct injection of urine has gained interest in the field of analytical toxicology, including doping control analysis. However, implementation of a direct urinalysis method for the LC-MS/MS detection of 34 diuretics and 9 other doping agents yielded several analytical problems, which were not observed using a traditional liquid-liquid extraction. Therefore a comparative study was made between liquid-liquid extraction and direct injection. Comparison of validation results showed that the liquid-liquid extraction at pH 7 allows to analyze samples without major drawbacks regarding matrix effects. Hence, good sensitivity was observed and detection limits ranged between 1 and 250 ng/mL for all compounds. In the direct injection approach shifted retention times were observed for several acidic and basic compounds due to unwanted matrix effects. This shift was reduced by a 25-fold dilution of the urine samples. Besides the improved retention time stability the diluted samples also exhibited lower ion suppression than the undiluted ones. After 25-fold dilution, detection limits ranged between 10 and 250 ng/mL for all compounds. Since these detection limits are at or below the minimum required performance level, imposed by the World Anti-Doping Agency, the method could be applied to routine anti-doping analysis. Samples, previously declared positive, were reanalysed using both the liquid-liquid extraction and direct injection. With both techniques all 26 samples were found to be positive, showing the applicability of direct injection for the analysis of diuretics [09039].

Proteases in doping control analysis.

Urine manipulation in sports drug testing has become a serious problem for doping control laboratories, and recent scandals in elite endurance sports have revealed the problem of urine manipulation presumably using proteases, which will impede the detection of drugs such as erythropoietin (EPO) or other peptide hormones. Using commonly accepted analytical strategies, a protocol was developed enabling the determination of elevated protease activities in doping control specimens followed by the visualization of protein degradation and identification of proteases such as chymotrypsin, trypsin and papain. Therefore, protease detection kits based on fluorescein isothiocyanate-labeled casein were employed, and protease concentrations greater than 15 microg/mL of urine entailed subsequent 1-dimensional gel electrophoretic visualization of urinary proteins. The presence of 20 microg of proteases per mL of urine caused a complete degradation of proteins usually observed in urinary matrices ("trace of burning"), while respective proteases were still detected in spiked urine samples after 10 days of storage at + 4 and - 20 degrees C. Identification of target proteases at respective molecular weights was accomplished using bottom-up sequencing approaches based on in-gel digestion of separated enzymes followed
Forensic toxicology

Forensic toxicology has developed as a forensic science in recent years and is now widely used to assist in death investigations, in civil and criminal matters involving drug use, in drugs of abuse testing in correctional settings and custodial medicine, in road and workplace safety, in matters involving environmental pollution, as well as in sports doping. Drugs most commonly targeted include amphetamines, benzodiazepines, cannabis, cocaine and the opiates, but can be any other illicit substance or almost any over-the-counter or prescribed drug, as well as poisons available to the community. The discipline requires high level skills in analytical techniques with a solid knowledge of pharmacology and pharmacokinetics. Modern techniques rely heavily on immunoassay screening analyses and mass spectrometry (MS) for confirmatory analyses using either high-performance liquid chromatography or gas chromatography as the separation technique. Tandem MS has become more and more popular compared to single-stage MS. It is essential that analytical systems are fully validated and fit for the purpose and the assay batches are monitored with quality controls. External proficiency programs monitor both the assay and the personnel performing the work. For a laboratory to perform optimally, it is vital that the circumstances and context of the case are known and the laboratory understands the limitations of the analytical systems used, including drug stability. Drugs and poisons can change concentration postmortem due to poor or unequal quality of blood and other specimens, anaerobic metabolism and redistribution. The latter provides the largest handicap in the interpretation of postmortem results [10029].

Testing in famous cases

Katrin Krabbe et al

Manipulation of urine sampling in sports drug testing is considered a violation of anti-doping rules and is consequently sanctioned by regulatory authorities. In 2003, three identical urine specimens were provided by three different athletes, and the identity of all urine samples was detected and substantiated using numerous analytical strategies including gas chromatography-mass spectrometry with steroid and metabolite profiling, gas chromatography-nitrogen/phosphorus detector analysis, high-performance liquid chromatography-UV fingerprinting, and DNA-STR (short tandem repeat) analysis. None of the respective athletes was the donor of the urine provided for doping analysis, which proved to be a urine sample collected from other unidentified individual(s). Samples were considered suspicious based on identical steroid profiles, one of the most important parameters for specimen individualization in sports drug testing. A database containing 14,224 urinary steroid profiles of athletes was screened for specific values of 4 characteristic parameters (ratios of testosterone/epitestosterone, androsterone/etiocholanolone, androsterone/testosterone, and 5alpha-androstane-3alpha,17beta-diol/5beta-androstane-3alpha,17beta-diol) and only the three suspicious samples matched all criteria. Further metabolite profiling regarding indicated medications and high-performance liquid chromatography-UV fingerprinting substantiated the assumption of manipulation. DNA-STR analyses unequivocally confirmed that the 3 urine samples were from the same individual and not from the athletes who provided DNA from either buccal cell material or blood specimens. This supportive evidence led to punishment of all three athletes according to the rules of the World Anti-Doping Agency. Application of a new multidisciplinary strategy employing
common and new doping control assays enables the detection of urine substitution in sports drug testing [07043].

**Lance Armstrong**

One article examined the metabolic performance of an elite cyclist, Lance Armstrong, before and after his diagnosis with testicular cancer. Although a champion cyclist in 1-day events prior to his diagnosis of testicular cancer at age 25, he was not a contender in multi-day endurance cycle races such as the 3-week Tour de France. His genetic makeup and physiology (high VO$_{2\text{max}}$, long femur, strong heavy build) coupled with his ambition and motivation enabled him at an early age to become one of the best 1-day cyclists in the world. Following his cancer diagnosis, he underwent a unilateral orchiectomy, brain surgery and four cycles of chemotherapy. After recovering, he returned to cycling and surprisingly excelled in the Tour de France, winning this hardest of endurance events 7 years running. This dramatic transformation from a 1-day to a 3-week endurance champion has led many to query how this is possible, and under the current climate, has led to suggestions of doping as to the answer to this metamorphosis. Physiological tests following his recovery indicated that physiological parameters such as VO$_{2\text{max}}$ were not affected by the unilateral orchiectomy and chemotherapy. It was proposed that his dramatic improvement in recovery between stages, the most important factor in winning multi-day stage races, is due to his unilateral orchiectomy, a procedure that results in permanent changes in serum hormones. These hormonal changes, specifically an increase in gonadotropins (and prolactin) required to maintain serum testosterone levels, alter fuel metabolism; increasing hormone sensitive lipase expression and activity, promoting increased free fatty acid (FFA) mobilization to, and utilization by, muscles, thereby decreasing the requirement to expend limiting glycogen stores before, during and after exercise. Such hormonal changes also have been associated with ketone body production, improvements in muscle repair and haematocrit levels and may facilitate the loss of body weight, thereby increasing power to weight ratio. Taken together, these hormonal changes act to limit glycogen utilization, delay fatigue and enhance recovery thereby allowing for optimal performances on a day-to-day basis. These insights provide the foundation for future studies on the endocrinology of exercise metabolism, and suggest that Lance Armstrong's athletic advantage was not due to drug use [07044].

**Parallel investigations of saliva and urine**

Stimulants are banned by the World Anti-Doping Agency (WADA) if used “in competition”. Being the analysis of stimulants presently carried out on urine samples only, it might be useful, for a better interpretation of analytical data, to discriminate between an early intake of the substance and an administration specifically aimed to improve the sport performance. The purpose of one study was to investigate the differences, in terms of excretion/disappearance of drugs, between urine and oral fluid, a sample that can reflect plasmatic concentrations. Oral fluid and urine samples were collected following oral administration of the following stimulants: modafinil (100 mg), selegiline (10 mg), crotetamide/cropropamide (50 mg each), pentetrazol (100 mg), ephedrine (12 mg), sibutramine (10 mg), mate de coca (a dose containing about 3mg of cocaine); analysis of drugs/metabolites was carried out by gas chromatography/mass spectrometry (GC/MS) in both body fluids. The results show that both the absolute concentrations and their variation as a function of time, in urine and in oral fluid, are generally markedly different, being the drugs eliminated from urine much more slowly than from oral fluid. The results also suggest that the analysis of oral fluid could be used to successfully complement the data obtained from urine for “in competition” anti-doping tests; in all those cases in which the metabolite(s)
concentration of a substance in urine is very low and the parent compound is not detected, it is indeed impossible, relying on urinary data only, to discriminate between recent administrations of small doses and remote administrations of higher doses [07045].

**Effects of sample storage condition on salivary hormones**

Measurement of steroid hormones in saliva is increasingly common in elite sport settings. However, this environment may enforce handling and storage practices that introduce error in measurement of hormone concentrations. It was assessed the influence of storage temperature and duration on reproducibility of salivary steroid levels. Nine healthy adults provided morning and afternoon saliva samples on two separate occasions. Each sample was divided into identical saliva aliquots which were stored long-term (i.e. 28 and 84 days) at -80°C or -20°C (testing day 1), and short-term (i.e. 1, 3, 7 and 14 days) at 4°C or 20°C (testing day 2). Samples were analyzed for cortisol, testosterone and estradiol using ELISA. In non-freezer conditions, there was a decrease from baseline to 7 days in testosterone (-26 ± 15 %) and estradiol (-58 ± 17 %) but not cortisol concentrations. This decrease was larger in samples stored at room temperature than in the refrigerator. There were small but significant changes in measured concentrations of all hormones after 28 and/or 84 days of storage in freezer conditions, but these were generally within 12 percent of baseline concentrations, and may be partly explained by inter-assay variability. Whole saliva samples to be analyzed for cortisol, testosterone and estradiol should be frozen at -20°C or below within 24 h of collection, and analyzed within 28 days. Storage of samples for measurement of testosterone and estradiol at temperatures above -20°C can introduce large error variance to measured concentrations [13113].

**Non-approved substances**

Since 2011, this category (S0) of banned substances has been a part of WADA’s prohibited list and encompasses a virtually infinite number of compounds currently not covered by any of the other sections (e.g. anabolic agents, peptide hormones, growth factors and related substances). New representatives of this class of compounds are low molecular weight luteinizing hormone (LMWLH) receptor agonists, the characterization and identification of which was presented. Focusing on two series of drug candidates based on either pyrazole or thienopyrimidine core structures, two model substances were synthesized and used to establish a targeted/non-targeted screening method employing both diagnostic precursor-product ion pair detection and precursor ion scanning. In the absence of metabolism study data, the presence of the intact drug or at least a conserved nucleus must be present to allow the detection using the proposed strategy [13012].

**Screening methods**

A comprehensive screening method for the detection of prohibited substances in doping control is described and validated. This method is capable of detecting over 150 components mentioned on the list of the World Anti-Doping Agency including anabolic androgenic steroids, stimulants and all narcotic agents that are currently analysed using different analytical methods. The analytes are extracted from urine by a combined extraction procedure using freshly distilled diethyl ether and tert-butyl methyl ether as extraction solvents at pH 9.5 and 14 respectively. Prior to GC-MS analysis the residues are combined and derivatised using a mixture of N-methyl-N-trimethylsilyl trifluoroacetamide, NH₄I and ethanethiol. The mass spectrometer is simultaneously operated in the full scan mode (mass
range varies along with GC-oven temperature program) and in the selected ion monitoring mode. Besides narcotics, stimulants and anabolic androgenic agents, this method is also capable of detecting several agents with anti-estrogenic activity and some beta-agonists. This comprehensive screening method reduces the amount of urine needed and increases the sample throughput without a loss in sensitivity and selectivity [08054].

A comprehensive screening method for the detection of prohibited substances in doping control is described and validated. This method is capable of detecting over 150 components mentioned on the list of WADA including anabolic androgenic steroids, stimulants and all narcotic agents that are currently analysed using different analytical methods. The analytes are extracted from urine by a combined extraction procedure using freshly distilled diethyl ether and tert-butyl methyl ether as extraction solvents at pH 9.5 and 14 respectively. Prior to GC-MS analysis the residues are combined and derivatised using a mixture of N-methyl-N-trimethylsilyltrifluoroacetamide, NH₄I and ethanethiol. The mass spectrometer is simultaneously operated in the full scan mode (mass range varies along with GC-oven temperature program) and in the selected ion monitoring mode. The obtained limits of detection are in compliance with the requirements set by the World Anti-Doping Agency. Besides narcotics, stimulants and anabolic androgenic agents, this method is also capable of detecting several agents with anti-estrogenic activity and some beta-agonists. This comprehensive screening method reduces the amount of urine needed and increases the sample throughput without a loss in sensitivity and selectivity [08055].

A simple and rapid multicomponent screening method of 130 substances for direct injections of urine samples has been developed. The fully automated method based on ultra-performance liquid chromatography (UPLC) and tandem mass spectrometry (MS/MS) is used for three different classes of doping agents: diuretics, central nervous system stimulants and opiates. The samples are diluted with buffer containing internal standards (IS) by a pipetting robot system into 96-well plates. Samples are injected on a reversed phase sub 2-microm particle column connected to a fast polarity switching and rapid scanning tandem mass spectrometer with an electrospray interface. The software used to evaluate the results produced reports containing a small-sized window for each component and a data table list with flags to indicate any adverse analytical findings in the sample. The report can also be processed automatically using an application software, which interpret the data and indicate if there is a suspicious sample. One 96-well plate can be analyzed within 16 hours [08056].

A new doping control screening method has been developed, for the analysis of doping agents in human urine, using HPLC/orbitrap with in-source collision-induced dissociation and atmospheric pressure chemical ionization. The developed method allows the detection of 29 compounds, including agents with antiestrogenic activity, beta₂ agonists, exogenous anabolic steroids, and other anabolic agents. The mass accuracy of this method is better at 2 ppm using an external reference. The detection limit for all compounds tested was better than 100 pg/ml. The recoveries of most analytes were above 70 percent. The measured median repeatability values for doping agents included in the method at concentrations of 1 and 10 ng/ml were 21 and 17 percent, respectively. The relative standard deviation (RSD) of the intraday precision (n=6) ranged from RSD 16-22 percent, whereas the interday precision (n=18), ranged from RSD 17-26 percent, depending on the solute concentration investigated [08057].

One paper presented a general screening method, based on liquid chromatography/mass spectrometry (LC/MS), for the simultaneous detection in human urine of 72 xenobiotics (21 diuretics, 16 synthetic glucocorticoids, 17 beta-adrenergic drugs, 10 stimulants, 5 anti-oestrogens and 3 anabolic steroids), excreted free or as glucuro-conjugates in urine.
Although the method has been specifically designed and evaluated in view of its potential application to anti-doping analyses, it can also be effective in other areas of analytical toxicology. Sample preparation was based on two liquid/liquid separation steps (performed at alkaline and at acid pH, respectively) of hydrolyzed human urine, and then an assay by LC/MS-MS in positive and negative ionization mode using an electrospray ionization source (ESI) and multiple reaction monitoring as the acquisition mode. The overall time needed for an LC run was less than 15 minutes. All compounds showed good reproducibility in terms of both the retention times (CV %<1) and the relative abundances of the diagnostic transitions (CV %<10). The limits of detection were in the range of 1-50 ng/mL for glucocorticoids, anti-oestrogens and steroids, and 50-500 ng/mL for diuretics, beta-adrenergic drugs and stimulants, thus satisfying the minimum required performance limits (MRPL) set by the World Anti-Doping Agency for the accredited anti-doping laboratories [08058].

**Multi-analyte testing**

Traditionally, doping control analytical assays have been drug-class dedicated and tailored to address requirements concerning sample preparation and chromatography/mass spectrometry resulting from specific physicochemical properties of target compounds. Improved analytical instrumentation (particularly based on liquid chromatography-(tandem) mass spectrometry, LC-MS/(MS)), have enabled the development of numerous cost-effective and rapid alternatives, allowing for multi-class/multi-analyte test methods. The trend towards comprehensive and preferably combined targeted/non-targeted screening procedures has been motivated in part in the requirement for analytical approaches to meet the minimum required performance levels (MRPLs) stipulated by WADA. Within 2012, several LC-MS/(MS)-based approaches were published representing options to complement or expand the currently employed methodologies of doping control laboratories. Employing targeted multiple-reaction monitoring (MRM), the detection of a total of 61 analytes (plus two internal standards) from urine covering seven classes of prohibited substances (S1–S7) and one agent categorized under M1 was reported. The apparatus employed consisted of a conventional LC equipped with a C-18 reversed-phase (RP) analytical column (2 × 50 mm, 3 μm particle size) interfaced to a triple-quadrupole MS (QqQ) via electrospray ionization (ESI), operated with scan-to-scan polarity switching. Urine samples were prepared for analysis by the addition of two internal standards. An aliquot of 5 μl was injected into the LC-MS/MS system. Gradient elution was conducted with 5 mM ammonium acetate (pH 3.5, adjusted with acetic acid, solvent A) and acetonitrile (solvent B), completing a single run within 10.75 min. For all target compounds, limits of detection (LODs) were far below the aforementioned MRPLs. The unique feature of this assay compared to other multi-analyte screening methods is the capability to detect polysaccharide-derived plasma volume expanders (e.g. hydroxyethyl starch and dextran) by combined in-source dissociation and subsequent MRM of diagnostic breakdown products was described. Another approach covering 62 analytes (plus two internal standards) and five classes of prohibited substances (S1, S3, S4, S9, and P2) was reported. Urine samples are enzymatically hydrolyzed and the liberated phase-I-metabolites (or intact drugs) are extracted into a mixture of pentane and diethylether. After evaporation to dryness and reconstitution, LC-MS/MS is conducted on two different systems, both of which use 5 mM ammonium acetate (solvent A) and acetonitrile (solvent B). Assay 1 is dedicated to the analytes of the categories S1, S3, S7, and S9 and utilizes gradient elution on a C-12 HPLC column (2 × 50 mm, 4 microm particle size) with a short overall run time of 4 min. Assay 2 aims at the detection of substances of the category S4 and employs isocratic chromatography on a C-8 HPLC column (2 × 150 mm, 5 microm particle size) at 70 percent solvent A, requiring a total run time of approximately 6 min. Mass spectrometry is conducted in both cases with QqQ instruments operated with positive ESI and MRM; unfortunately, no information on LODs is provided. In one study by, the value of hydrophilic interaction liquid chromatography (HLIC) tandem mass spectrometry compared
to the commonly used, reversed-phase chromatography (and mass spectrometry) was investigated and various options concerning column temperature, solvent composition, and stationary phase material were evaluated. Eventually, the use of a 2.1 × 150 mm HILIC column (5 µm particle size) operated at 35°C with 5 mM ammonium acetate (pH 4.5, eluent A) and acetonitrile (eluent B) was considered optimal to analyze 6, 17, 4, and 17 drugs belonging to the categories S3, S6, S7, and P2, respectively. Urine samples were prepared for analysis by liquid-liquid extraction (LLE), the extract was concentrated and analyzed by gradient elution on the above mentioned HILIC system followed by ESI in positive mode and subsequent MRM detection in a single run of 14 min. The estimated LODs sufficiently met WADA's MRPLs and the method's fitness-for-purpose was demonstrated with the required validation process; it remains to be clarified however if omitting any hydrolysis compromises the detection capability concerning agents largely excreted as conjugates. An assay enabling the determination of 23 diuretics (S5) and 23 stimulants (S6) from a single urine extract was described employing solid-phase extraction (SPE) of 1 ml of urine. The LC used in this study was equipped with a C-18 HPLC column (2.1 × 50 mm, 3 microm particle size) and employed 0.2% formic acid (eluent A) and methanol (containing 0.2% formic acid, eluent B) for gradient elution. In contrast to earlier methods, two separate injections for positive and negative ESI-MS/MS (in MRM mode) were required at run times of 17 and 16 min, respectively, necessitating the non-competitive overall measurement time per sample of 33 min. Moreover, only one internal standard that is preferably ionized in positive mode was apparently used, which is questionable when two separate analyses are conducted. The procedure was validated according to applicable guidelines and LODs were accomplished satisfying WADA's requirements. Consequently, the methodology might be fit-for-purpose if the sample/instrument ratio and thus required analysis and reporting turn-around times are met. While these assays are all designed to specifically measure a multitude of target compounds with dedicated precursor-/product-ion pairs and thus gate out all other information (for the advantage of sensitivity and speed), a trend towards combined targeted/non-targeted analytical methods has been recognized over the last few years. Here, particularly LC-MS(ESI/MS) approaches with high resolution/high accuracy mass analyzers such as time-of-flight (TOF) and orbitrap as well as hybrids consisting of quadrupole or ion trap mass selective devices and TOF or orbitraps have been used for a variety of reasons comprehensively summarized and reviewed in recent articles. The benefit of analytical information being recorded in utmost extent (limited essentially only by sample preparation and/or ionization capability) has been especially recognized and appreciated. Ionization capability was subject to investigation in the development of a complementary LC-high resolution/high accuracy MS (LC-HRMS) method in 2012. Using the so-called wrong-way-round ionization, a total of 137 analytes belonging to the prohibited substance classes S1, S3, S4-S7, S9, and P2 were measured in a single run (17 min) with positive ESI and HRMS. The LC consisted of a conventional C-18 RP ultrahigh performance liquid chromatography column (UHPLC, 2.1 × 50 mm, 1.7 µm particle size) operated under alkaline conditions with 3 mM ammonium hydroxide (pH = 10.3, solvent A) and 90% methanol (containing 3 mM ammonium hydroxide, solvent B). Despite the use of positive ESI, the alkaline milieu supported the generation and sensitive detection of protonated molecular species, adduct or product ions (hence "wrong-way-round" ionization) on an LTQ-Orbitrap mass spectrometer in full scan mode (m/z 100-650, 60,000 resolution@400 Da). Prior to analysis, urine samples underwent enzymatic hydrolysis and LLE and all target compounds were detected in this initial test method below respective MRPLs. Although not explicitly discussed, the presented assay should allow retrospective data evaluation concerning compounds that possess similar physicochemical properties as the ones tested. Covering 120 target analytes (34 diuretics, 83 stimulants, and 3 other analytes), the utility of a benchtop orbitrap mass analyzer for the combined targeted/non-targeted analysis of drugs relevant for doping controls was also presented. Following a ten-fold urine dilution (with addition of two internal standards), chromatography was conducted by means of a C-8 UHPLC column (2.1 × 50 mm, 1.8 microm.
particle size) and 1 mM ammonium acetate/0.001 percent acetic acid (solvent A) and 1 mM ammonium acetate/0.001 percent acetic acid in methanol (solvent B). Gradient elution was used yielding an overall run time of 10 min and the effluent was directed via ESI with scan-to-scan polarity switching to the orbitrap analyzer. The detector was operated in full scan mode (m/z 100–2000, 50.000 resolution@200 Da), and with the exception of glycerol, all analytes were detected at LODs between 5 and 500 ng/ml, thus fulfilling the MRPLs stipulated by WADA. Although included in the study, no further information on the capability to determine glycerol at (or below) the suggested threshold of 200 microg/ml was given. Also here it is worth mentioning that the generated and recorded data enable retrospective data mining, facilitating follow-up or prevalence studies concerning newly observed or potential future prohibited substances [13012].

Automation of sample preparation procedures in a doping control laboratory is of great interest due to the large number of samples that have to be analyzed, especially in large events where a high throughput protocol is required to process samples over 24 h. The automation of such protocols requires specific equipment capable of carrying out the diverse mechanical tasks required for accomplishing these analytical methodologies, which include pipetting, shaking, heating, or crimping. An automated sample preparation procedure for the determination of doping-related substances by gas chromatography-mass spectrometry (GC-MS) and gas chromatography-tandem mass spectrometry (GC-MS/MS) analysis, including enzymatic hydrolysis, liquid-phase extraction and derivatization steps, was developed by using an automated liquid handling system. One paper presents a description of the equipment, together with the validation data for 72 doping-related compounds including extraction efficiency, evaluation of carry-over, interferences, and robustness. Validation was approached as a comparison between the results obtained using the manual protocol and the transferred automated one. The described methodology can be applied for sample preparation in routine anti-doping analysis with high sample throughput and suitable performance [13085].

During the past five years, various multi-class and multi-analyte test methods have been developed for sports drug testing purposes, fuelled by the increasing demand of incorporating more and more substances (and respective metabolites) into routine doping controls without sacrificing the sample volume, faster turnaround times (particularly in case of great sport events), as well as the capability of modern mass spectrometers to provide the required scan speed and/or resolving power to cover hundreds of analytes per analytical run. Its fitness-for-purpose was impressively demonstrated by its use during the 2012 Olympic Games in London, where over 5000 samples were analyzed within a period of one month. Moreover, the generated data allow for the nowadays frequently requested re-evaluation concerning additional compounds and metabolites that were not screened for at the time of the Games [13009].

Aiming at faster and/or simpler analytical approaches for drug testing in general, the potential utility of evolving ambient mass spectrometry techniques has continued to be discussed. In proof-of-concept studies, the analyses of drugs of abuse and occasionally doping agents by means of, for example, desorption electrospray ionization (DESI), extractive electrospray ionization (EESI), or electric discharge-based methodologies such as direct analysis in real time (DART) were presented. Despite their ease-of-use and rapid generation of results, the lack in comprehensiveness and capability to allow for the often required separation of isomeric compounds, which is often required in sports drug testing, has been a major obstacle in introducing these techniques in routine doping controls. Similarly, the undisputed swiftness of matrix-assisted laser desorption ionization (MALDI)-MS/(MS) in drug detection in biological matrices has so far not been considered a viable means for sports drug testing.
mainly due to the limitations resulting from omitting chromatographic separation of analytes and, in selected cases, insufficient detection limits [13009].

"Alternative" specimens

The use of alternative specimens in the field of toxicology was first described in 1979, when hair analysis was used to document chronic drug exposure. Since then, the use of this "alternative" samples has gained tremendous importance in forensic toxicology, as well as in clinic toxicology, doping control and workplace drug testing. It is not surprising, therefore, that a large number of papers dealing with the determination of several classes of drugs in saliva, sweat, meconium and hair have been published ever since, owing to the fact that chromatographic equipment is becoming more and more sensitive, mass spectrometry (and tandem mass spectrometry) being the most widely used analytical tool, combined with gas or liquid chromatography. "Alternative" specimens present a number of advantages over the traditional samples normally used in toxicology (e.g. blood, urine and tissues), namely the fact that their collection is not invasive, their adulteration is difficult, and they may allow increased windows of detection for certain drugs. The main disadvantage of this kind of samples is that drugs are present in very low concentrations, and therefore high-sensitivity techniques are required to accomplish the analysis [08059].

Drug identification

Except for proteins, such as EPO, most prohibited drugs are identified by GC-MS, the workhorse of doping-control laboratories. LC-MS is used increasingly for diuretics, some anabolic steroids, and corticosteroids. Doping-control scientists identify a substance, in the laboratory and in court, by matching chromatographic retention time and mass spectra between unknown and standard. They need an authentic reference standard – a sample of the substance, certified to be correct. The standard may be a white powder or an excretion urine from a volunteer who took the drug. Chromatography coupled with MS makes it possible to identify not just drug classes, but specific chemicals, with absolute certainty. Pharmaceuticals include some synthetic compounds that do not occur naturally (e.g. the anabolic steroid stanozolol) and some that do (e.g. testosterone). Unfortunately, GC-MS and LC-MS cannot distinguish natural, endogenous testosterone from pharmaceutical, exogenous testosterone; however, normal human urine samples contain a testosterone isomer with no known function, epitestosterone. The urinary ratio of testosterone to epitestosterone (T/E ratio) is roughly 1:1 in most normal men, and it increases upon testosterone administration. Since the 1984 Olympics, the T/E ratio has been used to screen for testosterone use. Adverse analytical findings are defined by a T/E cut-off, which currently is 4. The two problems with any cut-off are that rare, drug-free individuals might have a naturally elevated T/E and that T/E may never exceed the cut-off in some users, either because their T/E is not responsive to administration or because they use small doses and titrate themselves. To distinguish users from nonusers, longitudinal profiling consists of plotting T/E and other urinary androgen parameters over time, expecting stability for nonusers and a spike for users. In the 1990s a new approach was introduced: isotope ratio MS (IRMS) [07046].

Blood tests

Serum can be tested by LC-MS-MS to detect hemoglobin-based oxygen carriers and by immunoassay to detect recombinant human growth hormone (GH). Natural GH is a family of isoforms, including a major one of 22 kd (22,000 atomic mass units) and some non–22-kd
isoforms, whereas recombinant GH is 100 percent 22-kd isoforms. Administration of recombinant GH suppresses endogenous GH production. The current approach to recombinant GH detection in serum is based on estimating the ratio of the 22-kd isoform to non–22-kd isoforms by immunoassay; it can detect administration for 3 hours after the last dose [07046].

Laboratory report interpretation

The laboratory urine drug test can determine what substance is present in the urine sample, not the brand, formulation, route of administration, dose, or how long before urine collection the drug was taken. Reasons why a urine drug test is negative include the drug is not prohibited by this program; the drug was never used; the drug was used long enough ago to have been eliminated completely; the drug is present below the cut-off; the drug is present below the limit of detection of the test; the drug is a prohibited (designer) drug that the laboratory does not look for; the sample was manipulated; and the sample was not real urine. The latter can be revealed by steroid screen data devoid of natural steroids in cases that would be missed by commercial adulteration tests and dipsticks. Many factors determine test retrospectivity, or how long after the end of administration the test can detect the drug in urine: among them is the dose, body burden, elimination pharmacokinetics, and test sensitivity. Anabolic steroids can be detected for as little as only a few days or as long as many months after the user stops taking them, depending on the type used (e.g. short-acting pill or long-acting oily injection), how much was used, and for how long. In addition, some steroids are easier to detect than others because of chemical differences. Individuals who have been in a drug-testing program for some time are less likely to use long-acting, easy-to-detect steroids.

The test results on a follow-up sample collected some times after an initial, positive sample needs to be interpreted in light of the above. If the follow-up test is positive for the same drug, it may be because the drug was not completely eliminated yet or because the athlete used the drug again in the meantime. Comparing the laboratory data from both tests may or may not provide an indication of which is the case. The follow-up test is expected to be negative if the drug was eliminated completely. This is why a negative follow-up test is not relevant to determining the accuracy or inaccuracy of a positive result on a sample collected previously. Conversely, a negative follow-up test is a valid check that the athlete has stopped using the drug. Drug users who expect to be tested at events try to time their discontinuation to pass the test; this is why no-notice, out-of-competition testing was implemented in the 1980s [07046].

Accuracy of testing

It is said that the test is blind to designer steroids, because the test is targeted and finds only
what it looks for. Typically, WADA-accredited laboratories screen for most anabolic steroids by GC-MS in the more sensitive SIM mode, monitoring only a few ions per target compound (e.g. an ion of 415 atomic mass units). A designer steroid could differ from a known one by only two extra hydrogens, give an ion of 417 atomic mass units upon fragmentation, and escape detection because the test monitors 415, not 417. Or the designer steroid could fragment to ions that happen to be monitored, in which case data readers would see suspicious signals and investigate further. The first reported designer steroid (norbolethone) was a pharmaceutical abandoned decades before, during clinical trials. It resurfaced upon further investigation of an athlete’s urine sample devoid of normal endogenous androgens, a telltale sign of endocrine suppression, which is expected after androgen administration because of negative feedback. The second designer steroid (THG) was discovered because a coach turned in a used syringe. THG simply is not detected in the standard steroid screen, probably because its chemical properties are such that it disintegrates along the way. Different modifications of the screen now allow its detection [07046].

Are the tests accurate? What are the risks of “false positive” or “false negative”? Both phrases can have widely different meanings in common language compared with antidoping jargon. In common language, a “false positive” might be any adverse analytical finding that does not result in a sanction, perhaps because the athlete had a therapeutic use exemption, because a courier’s signature was missing on a shipping document, or because the prohibited drug was a supplement contaminant. A case in which on appeal, an arbitrators’ panel had purely legal reasons to exonerate the athlete, might casually be called a “false positive.” But for the laboratory, a false positive is only the case in which the laboratory reports the presence of a drug and it is later proven scientifically that the drug was not present. The same misinterpretation or mis-semantic is for a “false negative,” in common language that might be a case where the athlete used a drug but passed the test. This could be because the metabolite was accurately detected just below the cut-off – a perfectly accurate negative result [07046].

**Chromatography**

Chromatography is an analytical chemistry technique used to separate (resolve) the chemical compounds in a mixture. Gas chromatography (GC) is done in the gas phase. A gas chromatograph has three parts: a sample introduction system (injector), an oven containing a chromatography column to achieve separation, and a detector. Typically, a microliter of liquid urine extract is automatically injected into the injector, a chamber at a high temperature. The sample is vaporized and swept along a hair-thin glass tube (capillary column, many meters long, flexible enough to be rolled up in a coil) by a carrier gas (mobile phase), such as helium. Different compounds travel at different speeds because of the differences in boiling point, polarity, and relative solubility in the carrier gas versus the coating of the inner wall of the column (stationary phase). The compounds emerge from the column outlet at different times after injection (the chromatographic retention time), separated from each other. Under identical operating conditions, the retention time is characteristic of each chemical compound. If two compounds have the same retention time, they may be identical (e.g. testosterone). If two compounds have different retention times, they certainly are different (e.g. testosterone and methyltestosterone). Matching retention times between an unknown and a reference standard is one element of identification. A graph of the amount of substance as a function of the retention time is a chromatogram. Two common GC detectors in antidoping laboratories are the nitrogen-phosphorus detector (NPD) and the mass spectrometer. The NPD detector is ideal for detecting nitrogen-containing compounds, such as stimulants [07046].
Mass spectrometry

One review introduced fundamental aspects of mass spectrometry (MS) based proteomics and illustrates how MS is an effective tool for the analysis of glycoprotein hormones. Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) and electrospray ionization (ESI) MS are complementary approaches that have been applied for the analysis of gonadotropins, e.g. to characterize differences in the oligosaccharide distribution of commercial human chorionic gonadotropin preparations, for isolated nicked beta-subunit, and identification of a metabolite of placental transforming growth factor in pharmaceutical hCG preparations. Immunoaffinity trapping and concentration of digested sample extract prior to MS analysis confers analytical sensitivity akin to immunoassay. A desirable objective would be to develop for clinical purposes a rapid procedure for MS detection and characterization of gonadotropins. Refinement of on-target immobilization and digestion for subsequent ionization by MALDI may eventually help to provide this capability. The advent of hybrid mass spectrometers will further advance the characterization of these complex molecules [06036].

Mass spectrometry (MS) is an analytical chemistry technique used for structure elucidation of unknowns or identification of known compounds. A mass spectrometer has three parts: an ion source where the compound is ionized to form a molecular ion and fragmented into smaller ions; a mass filter that separates ions by mass-to-charge ratio (m/z); and a detector. The graph of ion abundance as a function of m/z is a mass spectrum. The fragmentation pattern is determined by weak bonds and other physicochemical characteristics; therefore, fragmentation is reproducible and characteristic of the molecular structure, and the mass spectrum is like a fingerprint of the compound. Matching mass spectra between an unknown and a reference standard is another element of identification. Significant ions are so characteristic that matching only three ions (e.g. 143, 345, 360) and their percent abundance relative to the most intense of the three (e.g 143) has long been widely accepted as proof of chemical identification [07046].

The identification power of mass spectrometry has enabled the determination of hundreds of prohibited drugs in doping-control analysis. A few years ago, its utility was extended to peptide hormones such as erythropoietins, synthetic insulins and corticotrophins detectable in blood or urine. New assays have been established to improve the fight against doping, employing highly selective and sensitive detection methods based on chromatographic and tandem mass spectrometric techniques [07047].

Owing to the sensitive, selective, and unambiguous nature of mass spectrometric analyses, chromatographic techniques interfaced to various kinds of mass spectrometers have become the most frequently employed strategy in the fight against doping. To obtain utmost confidence in analytical assays, mass spectrometric characterization of target analytes and typical dissociation pathways have been utilized as basis for the development of reliable and robust screening as well as confirmation procedures. Methods for qualitative and/or quantitative determinations of prohibited low and high molecular weight drugs have been established in doping control laboratories preferably employing gas or liquid chromatography combined with electron, chemical, or atmospheric pressure ionization followed by analyses using quadrupole, ion trap, linear ion trap, or hyphenated techniques. The versatility of modern mass spectrometers enable specific as well as comprehensive measurements allowing sports drug testing laboratories to determine the misuse of therapeutics such as anabolic-androgenic steroids, stimulants, masking agents or so-called designer drugs in
athletes’ blood or urine specimens, and a selection of recent developments was summarized in one review [07048].

Fast and unequivocal drug detection is of considerable importance in numerous fields of analytical chemistry, and today mass spectrometry-based approaches are often the method of choice due to their sensitive and specific nature. Mass spectrometry is in constant flux with innovations and thus supports the development of new, complementary assays for rapid determination of drugs and toxins as well as their metabolic products in clinical, forensic, and doping control laboratories. Examples of such innovations that have greatly aided the worldwide bioanalytical efforts are the modern improvements in ion trap, for example, Fourier transform-ion cyclotron resonance (FT-ICR) mass spectrometer – Orbitrap, and time-of-flight (TOF) mass analyzers when coupled with sensitive ionization techniques such as electrospray ionization. In this perspective, the utility of state-of-the-art mass spectrometers and recent instrumental developments such as new and/or improved hybrid analyzers were discussed and selected applications presented [12066].

Small molecules

Recent developments in MS for the detection of small molecules in the context of doping control analysis are reviewed. Doping control analysis is evolving together with MS, which is the technique of choice in order to accomplish the analytical requirements in this field. Since these analytical requirements for the detection of a doping agent depend on the substance, in the first section we review the different scenarios. The commonly established approaches, together with their achievements and drawbacks are described. New developments in hyphenated MS techniques (both GC-MS/MS and LC-MS/MS) concerning interfaces and analyzers are mentioned. The use (or potential use) of these developments in order to minimize the limitations of the commonly established approaches in the doping control field is discussed. Finally, a brief discussion about trends and remaining limitations is presented [12067].

Small peptides in the urine

Although significant progress has been achieved during the past few years with the introduction of new assays and analytical methodologies, the detection and quantification of protein analytes, in particular of peptide hormones, continues to pose analytical challenges for the World Anti-Doping Agency-accredited anti-doping laboratories. In one article, the latest achievements in the application of MS-based methodologies and specific biochemical and immunological assays to detect some of the prohibited substances listed in section S2 of the World Anti-Doping Agency List of Prohibited Substances and Methods are reviewed. In addition, it was looked towards the future by focusing on some of the most promising analytical approaches under development for the detection of so-called biomarkers of doping [068].

In one study, a screening assay was developed comprising 11 prohibited peptides (<1.5 kDa) that are sufficiently purified from urine using weak cation exchange with subsequent determination of all substances by means of nanoUHPLC separation coupled to high resolution tandem mass spectrometry. These peptides included Gonadorelin (LH-RH), Desmopressin and 9 growth hormone releasing peptides (GHRP-1, -2, -4, -5, -6, Hexarelin, Alexamorelin, Ipamorelin and a GHRP-2 metabolite); however, the procedure is expandable to further target analytes or metabolites. The method was validated with a main focus on qualitative result interpretation considering the parameters specificity, linearity (0-500 pg/mL), recovery (45-95 %), precision (<20 % at 100 pg/mL), limits of detection (2-10 pg/mL), robustnesss and ion suppression. The proof-of-principle was shown by analysing excretion
study urine samples for LHRH, desmopressin and GHRP-2 [12065].

For most peptide hormones prohibited in elite sports the concentrations in plasma or urine are very low (pg/mL). Accordingly, hyphenated purification and enrichment steps prior to mass spectrometric detection are required to obtain sufficient doping control assays. Immunoaffinity purification in combination with nano-scale liquid chromatography coupled to high resolution/high accuracy mass spectrometry was found to have the potential of providing the necessary sensitivity and unambiguous specificity to produce reliable results. With the presented methodology 12 prohibited peptides (porcine insulin, Novolog, Apidra, Lantus DesB30-32 metabolite, Humalog and human insulin, Synacthen (synthetic ACTH analogue), luteinizing hormone-releasing hormone (LH-RH), growth hormone releasing hormone (GH-RH(1-29)) and CJC-1295 (GH-RH analogue), LongR(3)-IGF-1 and IFG-1) were simultaneously purified from plasma/serum or urine. With limits of detection for each target compound ranging in the low pg/mL level (urine), the method enables the determination of urinary peptides at physiologically relevant concentrations. For each class of peptides an appropriate antibody and a respective internal standard was implemented ensuring robust analysis conditions. Due to the fast and simple sample preparation procedure (about 25 samples per day) and the fact that all materials are commercial available, the implementation of the methodology to laboratories from other analytical fields (forensics, pharmacokinetic sciences, etc.) is enabled [12070].

Detection of misuse of peptides and proteins as growth promoters is a major issue for sport and food regulatory agencies. The limitations of current analytical detection strategies for this class of compounds, in combination with their efficacy in growth-promoting effects, make peptide and protein drugs highly susceptible to abuse by either athletes or farmers who seek for products to illicitly enhance muscle growth. Mass spectrometry (MS) for qualitative analysis of peptides and proteins is well-established, particularly due to tremendous efforts in the proteomics community. Similarly, due to advancements in targeted proteomic strategies and the rapid growth of protein-based biopharmaceuticals, MS for quantitative analysis of peptides and proteins is becoming more widely accepted. These continuous advances in MS instrumentation and MS-based methodologies offer enormous opportunities for detection and confirmation of peptides and proteins. Therefore, MS seems to be the method of choice to improve the qualitative and quantitative analysis of peptide and proteins with growth-promoting properties. This review aims to address the opportunities of MS for peptide and protein analysis in veterinary control and sports-doping control with a particular focus on detection of illicit growth promotion. An overview of potential peptide and protein targets, including their amino acid sequence characteristics and current MS-based detection strategies is, therefore, provided. Furthermore, improvements of current and new detection strategies with state-of-the-art MS instrumentation are discussed for qualitative and quantitative approaches [13091].

*Isotope ratio mass spectrometry or carbon isotope ratio*

It so happens that there is a measurable difference in carbon-13 content between endogenous and pharmaceutical testosterone. Most carbon atoms in nature are carbon-12, with a nucleus containing six protons and six neutrons. Radiocarbon dating relies on the rare carbon-14, an unstable, radioactive isotope, with a nucleus containing six protons and eight neutrons, which decays over time. Between the two is carbon-13, a stable isotope with six protons and seven neutrons. Roughly 1.1 percent of carbon in nature is carbon-13. Pharmaceutical testosterone contains a few parts per thousand less carbon-13 than does natural testosterone. This is because they arise from biosynthetic pathways that are sufficiently different. Humans make endogenous testosterone from cholesterol, itself made...
from acetate or coming from the diet. Pharmaceutical companies make testosterone by semisynthesis from plant sterols. All carbon in living beings is ultimately derived from atmospheric carbon dioxide (CO\textsubscript{2}), fixed in plants by photosynthesis. Different plants make the first multicarbon intermediates and downstream biosynthetic compounds differently. Animals eat plants, humans eat plants and animals, and “we are what we eat”. At every biosynthetic step, carbon-13 is left behind. This is because of the isotopic effect: chemical reactions go faster with lighter compounds; the molecule with a carbon-12 reacts sooner than the molecule with a carbon-13 instead. Because the pathways from atmospheric CO\textsubscript{2} to endogenous or pharmaceutical testosterone are different enough, carbon-13 is depleted to different extents; the difference happens to be measurable \[07011\].

**Full-capillary sample injection combined with sweeping CE stacking**

One study described an on-line stacking CE approach by sweeping with whole capillary sample filling for analyzing five anabolic androgenic steroids in urine samples. The five anabolic steroids for detection were androstenedione, testosterone, epitestosterone, boldenone, and clostebol. Anabolic androgenic steroids are abused in sport doping because they can promote muscle growth. Therefore, a sensitive detection method is imperatively required for monitoring the urine samples of athletes. In this research, an interesting and reliable stacking capillary electrophoresis method was established for analysis of anabolic steroids in urine. After liquid-liquid extraction by n-hexane, the supernatant was dried and reconstituted with 30 mM phosphate buffer (pH 5.00) and loaded into the capillary by hydrodynamic injection (10 psi, 99.9 s). The stacking and separation were simultaneously accomplished at -20 kV in phosphate buffer (30 mM, pH 5.0) containing 100 mM sodium dodecyl sulfate and 40 percent methanol. During the method validation, calibration curves were linear over a range of 50-1,000 ng/mL for the five analytes. In the evaluation of precision and accuracy for this method, the absolute values of the RSD and the RE in the intra-day (n=3) and inter-day (n=5) analyses were all less than 6.6 percent. The limit of detection for the five analytes was 30 ng/mL (S/N = 5, sampling 99.9 s at 10 psi). Compared with simple MECK, this stacking method possessed a 108- to 175-fold increase in sensitivity. This simple and sensitive stacking method could be used as a powerful tool for monitoring the illegal use of doping \[12064\].

**Benchtop quadrupole-orbitrap hybrid mass spectrometry**

Sensitive and unequivocal determination of analytes/contaminants in complex matrices is a challenge in the field of food safety control. In this study, various acquisition modes (Full MS/AIF, Full MS+tMS/MS, Full MS/dd MS/MS and tSIM/ddMS/MS) and parameters of a quadrupole-orbitrap hybrid mass spectrometer (Q Exactive) were studied in detail. One of the main conclusions has been that, reducing the scan range for Full MS (using the quadrupole) and targeted modes give higher signal-to-noise (S/N) ratios and thereby better detection limits for analytes in matrix. The use of Q Exactive in a complex case, for the confirmatory analysis of hormones in animal urine is presented. A targeted SIM data dependent MS/MS (tSIM/ddMS/MS) acquisition method for determination of eight synthetic hormones (trenbolone, 17\textalpha ethinylestradiol, zeranol, stanozolol, dienestrol, diethylstilbestrol, hexestrol, taleanol) and a naturally occurring hormone (zearalenone) in animal urine were optimized to have sensitive precursors from targeted SIM mode and trigger MS/MS scans over the entire chromatograph peak. The method was validated according to EC/657/2002. CC\textalpha (decision limit) for the analytes ranged between 0.11 microg/L and 0.69 microg/L and CC\textbeta (detection capability) ranged between 0.29 microg7L and 0.90 microg/L \[13094\].

**Chromatographic-mass spectrometry**
Urine samples have been the predominant matrix for doping controls for several decades. However, owing to the complementary information provided by blood (as well as serum or plasma and dried blood spots (DBS)), the benefits of its analysis have resulted in continuously increasing appreciation by anti-doping authorities. On the one hand, blood samples allow for the detection of various different methods of blood doping and the abuse of erythropoiesis-stimulating agents (ESAs) via the Athlete Biological Passport; on the other hand, targeted and non-targeted drug detection by means of chromatographic-mass spectrometric methods represents an important tool to increase doping control frequencies out-of-competition and to determine drug concentrations particularly in in-competition scenarios. Moreover, blood analysis seldom requires in-depth knowledge of drug metabolism, and the intact substance rather than potentially unknown or assumed metabolic products can be targeted. In this review, the recent developments in human sports drug testing concerning mass spectrometry-based techniques for qualitative and quantitative analyses of therapeutics and emerging drug candidates are summarized and reviewed. The analytical methods include both low and high molecular mass compounds (e.g., anabolic agents, stimulants, metabolic modulators, peptide hormones, and small interfering RNA (siRNA)) determined from serum, plasma, and DBS using state-of-the-art instrumentation such as liquid chromatography (LC)-high resolution/high accuracy (tandem) mass spectrometry (LC-HRMS), LC-low resolution tandem mass spectrometry (LC-MS/MS), and gas chromatography-mass spectrometry (GC-MS) [13096].

Liquid chromatography

A unification of doping-control screening procedures of prohibited small molecule substances may conceptually be achieved by the use of a combination of one gas chromatography-time-of-flight mass spectrometry method and one liquid chromatography-time-of-flight mass spectrometry method. In one work a quantitative screening method using high-resolution liquid chromatography in combination with accurate-mass time-of-flight mass spectrometry was developed and validated for determination of glucocorticosteroids, beta2-agonists, thiazide diuretics, and narcotics and stimulants in urine. To enable the simultaneous isolation of all the compounds of interest and the necessary purification of the resulting extracts, a generic extraction and hydrolysis procedure was combined with a solid-phase isolation modified for these groups of compounds. All 56 compounds are determined using positive electrospray ionisation with the exception of the thiazide diuretics for which the best sensitivity was obtained by using negative electrospray ionisation. The results show that, with the exception of clenhexyl, procaterol, and reprotoerol, all compounds can be detected below the respective minimum required performance level and the results for linearity, repeatability, and accuracy show that the method can be used for quantitative screening. If qualitative screening is sufficient the instrumental analysis may be limited to positive ionisation, because all analytes including the thiazides can be detected at the respective minimum required levels in the positive mode. The results show that the application of accurate-mass time-of-flight mass spectrometry in combination with generic extraction and purification procedures is suitable for unification and expansion of the window of screening methods of doping laboratories. Moreover, the full-scan accurate-mass data sets obtained still allow retrospective examination for emerging doping agents, without re-analyzing the samples [10034].

Whereas GC is done in the gas phase, liquid chromatography (LC) is done in the liquid phase. This is a crucial difference because it works for thermolabile compounds (destroyed by GC) and polar compounds (cannot be vaporized). The separation principles are the same.
A typical high-pressure or high-performance LC (HPLC) column is a steel tube the size of a fat marker pen, packed with microbeads on the surface of which is the stationary phase. The mobile phase is a liquid solvent, often a mixture whose composition is programmed to change during the run (gradient elution). Two common HPLC detectors are the diode-array detector (DAD) and the mass spectrometer. The DAD monitors UV absorption over a range of wavelengths or at selected wavelengths; it detects only those compounds that absorb UV light. When the HPLC is connected to an MS, the instrument is called LC-MS. The most advanced type of LC-MS can do tandem MS by one of several choices of conceptual and hardware approaches. It is called LC-MS-MS or LC-tandem MS. For a given class of drugs, such as diuretics, the LC-tandem MS screen is far superior to the GC-MS screen. Sample preparation time can be well less than 1 hour, down from a full day's work, because unlike GC, LC does not require the removal of water or salts, deconjugation or derivatization. Typically, the instrumental analysis run-time is two to three times shorter, well under 10 minutes per sample, because LC-MS-MS is blind to interferences; therefore, chromatographic resolution is not required, and LC run times can be shortened [07046].

The technique of liquid chromatography used in concert with (tandem) mass spectrometry (LC-MS/MS) has complemented sports drug testing strategies ever since soft ionization interfaces such as electrospray or atmospheric pressure chemical ionization (ESI or APCI, respectively) became commercially available. Numerous applications have been developed that allow the determination of prohibited therapeutics that are barely detectable or undetectable with conventional gas chromatographic-mass spectrometric techniques (GC-MS). Due to the progressive nature of doping controls, the continuously changing demands originating from the dynamic pharmaceutical market, new illegal approaches that presumably increase athletic performance, and modifications to the lists of prohibited compounds of regulative authorities such as the World Anti-Doping Agency (WADA), numerous new applications and drug-testing strategies based on LC-MS/(MS) are frequently developed in order to improve the portfolios of drug-testing laboratories. Liquid chromatography-(tandem) mass spectrometry (LC-MS/MS) has therefore revolutionized the detection assays used in doping control analysis. New methods have enabled the determination of drugs that were formerly difficult to detect or undetectable at preceding sample concentrations, and complex and/or time-consuming procedures based on alternative chromatographic-mass spectrometric or immunochemical principles have been replaced by faster, more comprehensive and robust assays. Analytical assay sensitivity and throughput are key factors for the LC-MS/(MS) approaches used in sports drug testing. Considerable improvements in liquid chromatography (such as using monolithic or UPLC columns) have resulted in shorter analysis times and significantly narrower peaks, which in turn lead to enhanced signal-to-noise ratios, better detection limits, and increased productivity. However, these fast analytical runs require very short mass spectrometric cycle times in order to obtain sufficient data points per compound and corresponding peak. In order to incorporate newly developed methods into sports drug testing systems, identification criteria are required, which have only been established for low molecular weight drugs. Several aspects are applicable and transferable to peptide and protein analysis, but specific issues such as molecular weight determination from multiply charged species or bottom-up sequencing [07050].

Doping control analytical laboratories for human sports predominantly employ nowadays chromatographic-mass spectrometric test methods for routine, high throughput screening and confirmation assays concerning low and high molecular mass analytes. Liquid chromatography-(tandem) mass spectrometry (LC-MS/(MS)) and particularly ultrahigh pressure liquid chromatography (UHPLC)-MS/MS instruments have become devices of choice due to their indispensable capabilities that compensate for limitations inherent to other commonly used strategies such as immunological and gas chromatography-(tandem) mass
spectrometry (GC-MS(/MS)) based detection methods. UHPLC-MS/MS-based assays at low mass spectrometric resolution have been established allowing for fast and sensitive targeted analyses focusing on pre-selected target analytes with diagnostic precursor-product ion pairs. Combining UHPLC to high resolution/high accuracy MS(/MS) further expanded the targeted approach (i.e., plotting extracted ion chromatograms of protonated or deprotonated molecules as well as product ions measured with accurate masses) toward non-targeted analyses enabling also retrospective data mining. In one review, recent applications of UHPLC-MS/MS in sports drug testing procedures published between 2008 and 2012 were presented and advantages as well as limitations in a short- and long-term perspective are discussed [12057].

Drug testing for sports doping control programs is extensive and includes numerous classes of banned compounds including anabolic androgenic steroids, beta2-agonists, hormone antagonists and modulators, diuretics, various peptide hormones, and growth factors. During competition, additional compounds may also be prohibited such as stimulants, narcotics, cannabinoids, glucocorticosteroids, and beta-blockers depending both on the sport and level of competition. Each of these classes of compounds can contain many prohibited substances that must be identified during the testing procedure. Various methods that have been designed to detect a large number of compounds in different drug classes are highly desirable as initial screening tools. Liquid chromatography/tandem mass spectrometry (LC-MS/MS) is widely used by anti-doping testing laboratories for this purpose and several rapid methods have been described to simultaneously detect different classes of compounds. Here, we describe a simple urine sample cleanup procedure that can be used to detect numerous anabolic androgenic steroids, beta2-agonists, hormone antagonists and modulators, glucocorticosteroids, and beta-blockers by LC-MS/MS [12058].

**Hydrophilic interaction liquid chromatography**

The chromatographic behaviour of 44 polar compounds (23 beta-adrenergic agents, 11 stimulants, 4 narcotics and 6 phenolalkylamines) included in the list of prohibited substances and methods of the World Anti-Doping Agency, has been investigated under hydrophilic interaction liquid chromatography conditions by application of different mobile phase compositions (percentage of the organic solvent, type and amount of mobile phase additive and ionic strength) and column temperatures. Detection of analytes was performed by a triple quadrupole mass spectrometer in positive ionization mode and selected reaction monitoring acquisition mode after liquid/liquid extraction. Data collected using as stationary phase type-B silica materials from different producers, showed that the best chromatographic conditions in terms of peak shape, selectivity and chromatographic retention were obtained using an initial percentage of acetonitrile of 90 percent, a column temperature of 35 °C, a mobile phase pH of 4.5 and ammonium acetate (5 mM) and acetic acid (0.1 %) as mobile phase additives. The selected chromatographic conditions were used to develop screening and confirmation analytical procedures to detect polar compounds in human urine for antidoping purpose. The developed methods were validated in terms of specificity, matrix effect, linearity, precision, accuracy, sensitivity, robustness and repeatability of retention times and relative ion abundances. Such methods offer attractive alternatives and considerable advantages over traditional approaches especially for the analysis of the phenolalkylamines [11566].

**Ultra-high-performance liquid chromatography**

Doping control analyses are generally performed in urine, a matrix that provides a prolonged detection time window, and less often in blood, serum, plasma, hair, saliva, and nails. To
identify the chemical structures of anabolic steroids the use of mass spectrometry detection is very advantageous. Gas chromatography–mass spectrometry (GC-MS) techniques allowed for the development of comprehensive screening methods. GC-MS methods are sensitive and robust but present the disadvantages of time-consuming sample pretreatment, that is often based on hydrolysis and derivatisation reactions. Liquid chromatography–mass spectrometry (LC-MS) methods have been successfully used to identify and determinate steroids in different matrices, as well as to study their metabolisms. Nowadays, automatic rapid ultra high performance liquid chromatography (UHPLC) tandem mass spectrometry has become the technique of choice for steroid analysis. Due to its generally higher speed, sensitivity, reproducibility and specificity with respect to HPLC, it can be used to simultaneously separate and determinate multi component steroid mixtures. The technique is of huge interest to separate conjugates anabolic androgenic steroids, as it allows efficiency enhancement due to the small particle (sub-2μm) column packing, which provides high peak capacity within analysis times even 5-10 fold shorter than conventional HPLC methods. Modern multiplex instruments can analyze thousands of samples per month so that, notwithstanding the generally high instrumental costs, the cost of the individual assay is affordable. In addition, the improved specificity and resolution offered by time-of-flight or quadrupole time-of-flight mass spectrometry allow their application in doping control analysis or in steroid profiling for accurate and sensitive full mass range acquisition. Aim of one review was to consider, compare and discuss the applications of the UHPLC/MS methods present in literature for the identification and determination of forbidden steroids and their metabolites in human biological matrices [12001].

Liquid chromatography/mass spectrometry (LC/MS) has been successfully applied to the detection of anabolic steroids in biological samples. However, the sensitive detection of saturated hydroxysteroids, such as androstanediols, by electrospray ionisation (ESI) is difficult because of their poor ability to ionise. In view of this, chemical derivatisation has been used to enhance the detection sensitivity of hydroxysteroids by LC/MS. One paper described the development of a sensitive ultra-high-performance liquid chromatography/tandem mass spectrometry (UHPLC/MS/MS) method for the screening of anabolic steroids in horse urine by incorporating a chemical derivatisation step, using picolinic acid as the derivatisation reagent. The method involved solid-phase extraction (SPE) of both free and conjugated anabolic steroids in horse urine using a polymer-based SPE cartridge. The conjugated steroids in the eluate were hydrolyzed by methanolysis and the resulting extract was further cleaned up by liquid-liquid extraction. The resulting free steroids in the extract were derivatised with picolinic acid to form the corresponding picolinoyl esters and analysed by UHPLC/MS/MS in the positive ESI mode with selected-reaction-monitoring. Separation of the targeted steroids was performed on a C18 UHPLC column. The instrument turnaround time was 10.5 min inclusive of post-run equilibration. A total of thirty-three anabolic steroids (including 17β-estradiol, 5(10)-estrene-3β,17α-diol, 5α-estrane-3β,17α-diol, 17α-ethyl-5α-estrane-3α,17β-diol, 17α-methyl-5α-androstan-3,17β-diols, androstanediols, nandrolone and testosterone) spiked in negative horse urine at the QC levels (ranging from 0.75 to 30 ng/mL) could be consistently detected. The intra-day and inter-day precisions (% RSD) for the peak area ratios were around 7-51 percent and around 1-72 percent, respectively. The intra-day and inter-day precisions (% RSD) for the relative retention times were both less than 1 percent for all analytes, except the inter-day precision for boldione at 1.2 percent. The extraction recoveries for all targets were not less than 48 percent. With exceptional separation achieved by the UHPLC system, matrix interferences were minimal at the expected retention times of the selected transitions. As detection was performed with an UHPLC system coupled to a fast-scanning triple quadrupole mass spectrometer, the method could easily be expanded to accommodate additional steroid targets. This method has been validated for recovery and precision, and could be used regularly for doping control testing of anabolic steroids in horse urine samples [12060].

364
It was described a sensitive, comprehensive and fast screening method based on liquid chromatography-high resolution mass spectrometry for the detection of a large number of analytes in sports samples. UHPLC coupled to high resolution mass spectrometry with polarity switching capability is applied for the rapid screening of a large number of analytes in human urine samples. Full scan data are acquired alternating both positive and negative ionisation. Collision-induced dissociation with positive ionisation is also performed to produce fragment ions to improve selectivity for some analytes. Data are reviewed as extracted ion chromatograms based on narrow mass/charge windows (± 5 ppm). A simple sample preparation method was developed, using direct enzymatic hydrolysis of glucuronide conjugates, followed by solid phase extraction with mixed mode ion-exchange cartridges. Within a 10 min run time (including re-equilibration) the method presented allows for the analysis of a large number of analytes from most of the classes in the World Anti-Doping Agency (WADA) Prohibited List, including anabolic agents, beta2-agonists, hormone antagonists and modulators, diuretics, stimulants, narcotics, glucocorticoids and beta-blockers, and does so while meeting the WADA sensitivity requirements. The high throughput of the method and the fast sample pre-treatment reduces analysis cost and increases productivity. The method presented has been used for the analysis of over 5000 samples in about one month and proved to be reliable [13092].

Fast liquid chromatographic/mass spectrometric screening

A fast liquid chromatographic/mass spectrometric (LC/MS/MS) screening method for the detection, in urine, of synthetic glucocorticoids, stimulants (formoterol, modafinil and mesocarb), anti-oestrogens (finasteride, exemestane, anastrozole, letrozole and formestane) and synthetic anabolic steroids (stanozolol, gestrinone and tetrahydrogestrinone) is described. All these drugs (and/or their urinary metabolites) can be simultaneously extracted by a single liquid/liquid extraction step, at alkaline pH, after enzymatic hydrolysis with beta-glucuronidase, and assayed in 7 min by LC/MS/MS using electrospray ionization in positive ion mode and multiple reaction monitoring as the acquisition mode. All compounds show good reproducibility of both the retention times (CV% <2%) and the relative abundances (CV% <10 %). The limits of detection for the anti-oestrogens, glucocorticoids and steroids are in the range of 1-30 ng/mL, and for the stimulants are in the range of 100-200 ng/mL, thus satisfying the minimum required performance limits of the World Anti-Doping Agency [06037].

Orbitrap

A new doping control screening method for the analysis of diuretics and stimulants using ultra high pressure liquid chromatography-high resolution Orbitrap mass spectrometry has been developed. The screening was performed in full scan MS with scan-to-scan polarity switching which allowed to detect more than 120 target analytes. Sample preparation was limited to 10-fold dilution of the urine into the internal standard solution followed by injection. Total run time per sample was 10 min. Validation of the method yielded detection limits for diuretics between 25 and 250 ng/mL and for stimulants between 5 and 500 ng/mL. The screening method has been implemented in routine doping control [12071].

Liquid chromatography-tandem mass spectrometry

A screening method for the urinary detection of 34 exogenous anabolic steroids has been developed. The method involves an enzymatic hydrolysis, liquid-liquid extraction and detection by liquid chromatography-tandem mass spectrometry. The use of some adducts
such as (M+NH₄⁺, M+CH₃COO⁻ and M+H+MeOH⁺) was necessary in order to detect some analytes at the required level (lower than 10 ng/ml). Two transitions were selected for each analyte. Different concentration factors have been studied in order to increase the sensitivity. A concentration factor of 50 was selected for the screening method although the high ion suppression observed under these conditions can hamper its application as a quantitative method. The method was validated and limits of detection were obtained by spiking ten different blank urine samples at five different concentration levels. Up to 29 analytes were detected in all spiked urines at the required level. Limits of detection between 1 and 10 ng/ml were obtained for most analytes which fulfil current requirements. The applicability of the method was shown by analysing positive samples [07051].

A simple and accurate liquid chromatography/tandem mass spectrometry (LC/MS/MS) method has been developed and validated for the quantitative determination of ephedrine, pseudoephedrine, methylephedrine, cathine, salbutamol, morphine and epitestosterone in human urine. Urine samples were spiked with internal standard and diluted with acetonitrile. After centrifugation, the supernatants were directly analyzed by LC/MS/MS using the selected reaction monitoring (SRM) mode. The linearity, intra- and inter-day precision, accuracy, limit of detection (LOD) and limit of quantification (LOQ) were evaluated and the method was found to be accurate and reproducible for the quantitation of threshold substances. When the method was applied to the analysis of blind urine samples for the proficiency test, the results were close to the nominal concentrations, within 88-107 percent of nominal values, suggesting that the developed methods can be successfully applied to routine doping analyses [11429].

Liquid chromatography-(tandem) mass spectrometry (LC-MS/MS) has become an integral part of modern sports drug testing as it offers unique capabilities complementing immunological and gas chromatography-(tandem) mass spectrometry (GC-MS/MS)-based detection methods for prohibited compounds. The improved options of fast and sensitive targeted analysis as well as untargeted screening procedures utilizing high resolution/high accuracy mass spectrometry have considerably expanded the tools available to anti-doping laboratories for initial testing and confirmation methods. One approach is to focus on pre-selected target analytes that are measured with utmost specificity and sensitivity using diagnostic precursor-product ion pairs in low resolution tandem mass spectrometers. The other scenario is to measure and plot extracted ion chromatograms of protonated or deprotonated molecules as well as product ions as recorded in the full scan mode with high resolution/high accuracy mass spectrometry. Examples of recent applications of sports drug testing procedures published between 2007 and 2010 were presented and discussed, outlining the particular advantages of the selected approaches as well as their limitations in a short- and long-term perspective [11036].

**Liquid chromatography-mass spectrometry (LC-MS)**

Matrix effects (ion suppression/enhancement) are a well-observed phenomenon in analyses of biological matrices by high-performance liquid chromatography-mass spectrometry (LC-MS). However, few simple solutions for detecting and minimizing these adverse effects have been described so far in multianalyte analysis, especially in the field of doping control. This study describes an exhaustive characterization of matrix effects in one hundred urine samples fortified with 41 analytes (glucocorticoids and diuretics). It introduces a novel marker to identify samples in which the reliability of the results is compromised because of acute ion suppression. This new strategy strengthens the rigor of the analysis for screening purposes. Once the matrix effect is identified, a selective sample preparation is introduced to minimize the adverse ion suppression effect. That selective extraction together with the use of a deuterated internal standard permits enhancing the ruggedness of the estimation of
glucocorticoid concentration in urine [12059].

**Ultrahigh pressure liquid chromatography-(tandem) mass spectrometry**

Doping control analytical laboratories for human sports predominantly employ nowadays chromatographic-mass spectrometric test methods for routine, high throughput screening and confirmation assays concerning low and high molecular mass analytes. Liquid chromatography-(tandem) mass spectrometry [(LC-MS/(MS))] and particularly ultrahigh pressure liquid chromatography (UHPLC)-MS/MS instruments have become devices of choice due to their indispensable capabilities that compensate for limitations inherent to other commonly used strategies such as immunological and gas chromatography-(tandem) mass spectrometry [(GC-MS/(MS))] based detection methods. UHPLC-MS/MS-based assays at low mass spectrometric resolution have been established allowing for fast and sensitive targeted analyses focusing on pre-selected target analytes with diagnostic precursor-product ion pairs. Combining UHPLC to high resolution/high accuracy MS/(MS) further expanded the targeted approach (i.e., plotting extracted ion chromatograms of protonated or deprotonated molecules as well as product ions measured with accurate masses) toward non-targeted analyses enabling also retrospective data mining. In one review, applications of UHPLC-MS/MS in sports drug testing procedures published between 2008 and 2012 are presented and advantages as well as limitations in a short- and long-term perspective were discussed [13092].

**Metabolite-based liquid chromatography-mass spectrometry**

Today, immunoassays and several chromatographic methods are in use for drug screening in clinical and forensic toxicology and in doping control. For further proof of the authors' new metabolite-based liquid chromatography-mass spectrometry (LC-MS$_n$) screening concept, the detectability of drugs of abuse and their metabolites using this screening approach was studied. As previously reported, the corresponding reference library was built up with MS$_2$ and MS$_3$ wideband spectra using a LXQ linear ion trap with electrospray ionization in the positive mode and full scan information-dependent acquisition. In addition to the parent drug spectra recorded in methanolic solution, metabolite spectra were identified after protein precipitation of urine from rats after administration of the corresponding drugs and added to the library. This consists now of data of over 900 parent compounds, including 87 drugs of abuse, and of over 2,300 metabolites and artifacts, among them 436 of drugs of abuse. Recovery, process efficiency, matrix effects, and limits of detection for selected drugs of abuse were determined using spiked human urine, and the resulting data have been acceptable. Using two automatic data evaluation tools (ToxID and SmileMS), the intake of 54 of the studied drugs of abuse could be confirmed in urine samples of drug users after protein precipitation and LC separation. The following drugs classes were covered: stimulants, designer drugs, hallucinogens, (synthetic) cannabinoids, opioids, and selected benzodiazepines. The presented LC-MS$_n$ method complements the well-established gas chromatography-mass spectroscopy procedure in the authors' laboratory [11035].

**High-resolution/accurate-mass LC-MS**

Detection of androgenic-anabolic steroid abuse in equine sports requires knowledge of the drug's metabolism in order to target appropriate metabolites, especially where urine is the matrix of choice. Studying “designer” steroid metabolism is problematic since it is difficult to obtain ethical approval for in vivo metabolism studies due to a lack of toxicological data. In this study, the equine in vitro metabolism of eight steroids available for purchase on the Internet is reported; including androst-1,4,6-triene-3,17-dione, 4-chloro,17alpha-methyl-androsta-1,4-diene-3,17beta-diol, estra-4,9-diene-3,17-dione, 4-hydroxyandrostenedione,
20-hydroxyecdysone, 11-keto-androstenedione, 17a-methyldrostanolone, and tetrahydrogestrinone. In order to allow for retrospective analysis of sample testing data, the use of a high-resolution (HR) accurate-mass Thermo LTQ-Orbitrap liquid chromatography-mass spectrometry (LC-MS) instrument was employed for metabolite identification of underivatized sample extracts. The full scan LC-HRMS Orbitrap data were complimented by LC-HRMS/MS and gas-chromatography-mass spectrometry (GC-MS) experiments in order to provide fragmentation information and to ascertain whether GC-MS was capable of detecting any metabolite not detected by LC-HRMS. With the exception of 20-hydroxyecdysone, all compounds were found to be metabolized by equine liver S9 and/or microsomes. With the exception of 17alpha-methyldrostanolone, which produced metabolites that could only be detected by GC-MS, the metabolites of all other compounds could be identified using LC-HRMS, thus allowing retrospective analysis of previously acquired full-scan data resulting from routine equine drug testing screens. In summary, while in vitro techniques do not serve as a replacement for more definitive in vivo studies in all situations, their use does offer an alternative in situations where it would not be ethical to administer untested drugs to animals [11044].

With information dependent acquisition

Diuretics are a class of compounds largely used for either therapeutic or illegal (doping) purposes. Probably owing to the substantial variety of their chemical structures, which makes them hardly extractable from a biological matrix in a single procedure, a quite short list of screening methods can be retrieved in the literature. One work presented a screening procedure for 24 diuretics based on the direct injection of urine (after 50 folds dilution) in a LC-ESI-MS/MS system (Applied Biosystems 4000 QTrap). Two information dependent acquisitions (IDA), one in positive, one in negative ionization, allowed the acquisition of one selected reaction monitoring transition for each compound, which, when a significant peak was found, triggered the acquisition of the enhanced product ion (EPI) spectrum. EPI spectra were stored in a library and the procedure was able to recognize by library matching various diuretics in real positive samples. The limits of detection were comprised between 0.002 and 0.25 ml/L and ion suppression was not found to significantly influence the analysis [07052].

Liquid chromatography/time-of-flight mass spectrometry

The development of comprehensive methods able to tackle with the systematic identification of drug metabolites in an automated fashion is of great interest. In this article, a strategy based on the combined use of two complementary data mining tools is proposed for the screening and systematic detection and identification of urinary drug metabolites by liquid chromatography full-scan high resolution mass spectrometry. The proposed methodology is based on the use of accurate mass extraction of diagnostic ions (compound-dependent information) from in-source CID fragmentation without precursor ion isolation along with the use of automated mass extraction of accurate-mass shifts corresponding to typical biotransformations (non compound-dependent information) that xenobiotics usually undergo when metabolized. The combined strategy was evaluated using LC-TOFMS with a suite of nine sport drugs representative from different classes (propranolol, bumetanide, clenbuterol, ephedrine, finasteride, methoxypenamine, mephedrine, salbutamol and terbutaline), after single doses administered to rats. The metabolite identification coverage rate obtained with the systematic method (compared to existing literature) was satisfactory, and provided the identification of several non-previous reported metabolites. In addition, the combined information obtained helps to minimize the number of false positives. As an example, the systematic identification of urinary metabolites of propranolol enabled the identification of up
to 24 metabolites, 15 of them non previously described in literature, which is a valuable indicator of the usefulness of the proposed systematic procedure [13098].

A general screening method based on solid phase extraction (SPE) and liquid chromatography/time-of-flight mass spectrometry (LC/TOFMS) was developed and investigated with 124 different doping agents, including stimulants, beta-blockers, narcotics, beta2-adrenergic agonists, agents with anti-estrogenic activity, diuretics and cannabinoids. Mixed mode cation exchange/C8 cartridges were applied to SPE, and chromatography was based on gradient elution on a C18 column. Ionization of the analytes was achieved with electrospray ionization in the positive mode. Identification by LC/TOFMS was based on retention time, accurate mass and isotopic pattern. Validation of the method consisted of analysis of specificity, analytical recovery, limit of detection and repeatability. The minimum required performance limit (MRPL), established by World Anti-Doping Agency (WADA), was attained to 97 doping agents. The extraction recoveries varied between 33 and 98 percent and the median was 58 percent. Mass accuracy was always better than 5 ppm, corresponding to a maximum mass error of 0.7 mDa. The repeatability of the method for spiked urine samples, expressed as median of relative standard deviations (RSD%) at concentrations of MRPL and 10 times MRPL, were 14 and 9 percent, respectively. The suitability of the LC/TOFMS method for doping control was demonstrated with authentic urine samples [06038].

The development of comprehensive methods able to tackle with the systematic identification of drug metabolites in an automated fashion is of great interest. In this article, a strategy based on the combined use of two complementary data mining tools is proposed for the screening and systematic detection and identification of urinary drug metabolites by liquid chromatography full-scan high resolution mass spectrometry. The proposed methodology is based on the use of accurate mass extraction of diagnostic ions (compound-dependent information) from in-source CID fragmentation without precursor ion isolation along with the use of automated mass extraction of accurate-mass shifts corresponding to typical biotransformations (non compound-dependent information) that xenobiotics usually undergo when metabolized. The combined strategy was evaluated using LC-TOFMS with a suite of nine sport drugs representative from different classes (propranolol, bumetanide, clenbuterol, ephedrine, finasteride, methoxyphenamine, methylephedrine, salbutamol and terbutaline), after single doses administered to rats. The metabolite identification coverage rate obtained with the systematic method (compared to existing literature) was satisfactory, and provided the identification of several non-previously reported metabolites. In addition, the combined information obtained helps to minimize the number of false positives. As an example, the systematic identification of urinary metabolites of propranolol enabled the identification of up to 24 metabolites, 15 of them non previously described in literature, which is a valuable indicator of the usefulness of the proposed systematic procedure [12062].

High performance liquid chromatography retention time of small molecules

Quantitative structure-retention relationship (QSRR) is a technique capable of improving the identification of analytes by predicting their retention time on a liquid chromatography column (LC) and/or their properties. This approach is particularly useful when LC is coupled with a high-resolution mass spectrometry (HRMS) platform. The main aim of one study was to develop and describe appropriate QSRR models that provide usable predictive capability, allowing false positive identification to be removed during the interpretation of metabolomics data, while additionally increasing confidence of experimental results in doping control area. For this purpose, a dataset consisting of 146 drugs, metabolites and banned compounds from World Anti-Doping Agency (WADA) lists, was used. A QSRR study was carried out
separately on high quality retention data determined by reversed-phase (RP-LC-HRMS) and hydrophilic interaction chromatography (HILIC-LC-HRMS) systems, employing a single protocol for each system. Multiple linear regression (MLR) was applied to construct the linear QSRR models based on a variety of theoretical molecular descriptors. The regression equations included a set of three descriptors for each model: ALOGP, BEl6, R2p and ALOGP(2), FDI, BLTA96, were used in the analysis of reversed-phase and HILIC column models, respectively. Statistically significant QSRR models indicate a strong correlation between retention time and the molecular descriptors. An evaluation of the best correlation models, performed by validation of each model using three tests (leave-one-out, leave-many-out, external tests), demonstrated the reliability of the models [13088].

**Nano-liquid chromatography/benchtop quadrupole orbitrap tandem-mass spectrometry**

In one study, a screening assay was developed comprising 11 prohibited peptides (<1.5 kDa) that are sufficiently purified from urine using weak cation exchange with subsequent determination of all substances by means of nanoUHPLC separation coupled to high resolution tandem mass spectrometry. These peptides included Gonadorelin (LH-RH), Desmopressin and 9 growth hormone releasing peptides (GHRP-1, -2, -4, -5,-6, Hexarelin, Alexamorelin, Ipamorelin and a GHRP-2 metabolite); however, the procedure is expandable to further target analytes or metabolites. The method was validated with a main focus on qualitative result interpretation considering the parameters specificity, linearity (0-500 pg/mL), recovery (45-95 %), precision (<20 % at 100 pg/mL), limits of detection (2-10 pg/mL), robustness and ion suppression. The proof-of-principle was shown by analysing excretion study urine samples for LHRH, desmopressin and GHRP-2 [12065].

**Liquid and gas chromatography time-of-flight mass spectrometry**

A new combined doping control screening method for the analysis of anabolic steroids in human urine using liquid chromatography/electrospray ionization orthogonal acceleration time-of-flight mass spectrometry (LCoaTOFMS) and gas chromatography/electron ionization orthogonal acceleration time-of-flight mass spectrometry (GCoaTOFMS) was developed in order to acquire accurate full scan MS data to be used to detect designer steroids. The developed method allowed the detection of representative prohibited substances, in addition to steroids, at concentrations of 10 ng/mL for anabolic agents and metabolites, 30 ng/mL for corticosteroids, 500 ng/mL for stimulants and beta-blockers, 250 ng/mL for diuretics, and 200 ng/mL for narcotics. Sample preparation was based on liquid-liquid extraction of hydrolyzed human urine, and the final extract was analyzed as trimethylsilylated derivatives in GCoaTOFMS and underivatized in LCoaTOFMS in positive ion mode. The sensitivity, mass accuracy, advantages and limitations of the developed method were presented [07053].

**Gas chromatography**

The application of comprehensive two-dimensional gas chromatography coupled to time-of-flight mass spectrometry (GCxGC-TOFMS) for the analysis of six anabolic agents (AAs) in doping control is investigated in this work. A non-polar-polar column configuration with 0.2 microm film thickness second dimension column was employed, offering much better spread of the components on second dimension when compared to the alternative 0.1 microm column. The proposed method was tested on the “key” AAs that the World Anti-Doping Agency (WADA) had listed at the low ngm/L levels (clenbuterol, 19-norandrosterone,
epimethandiol, 17alpha-methyl-5alpha-androstane-3alpha,17beta-diol, 17alpha-methyl-5beta-androstane-3alpha,17beta-diol and 3'-OH-stanozolol). The compounds were spiked in a blank urine extract obtained by solid-phase extraction, hydrolysis and liquid-liquid extraction; prior to analysis they were converted to the corresponding trimethylsilyl (TMS) derivatives. The limit of detection (LOD) was below or equal to the minimum required performance limit (MRPL) of 2ngmL(-1) defined by WADA, and the correlation coefficient was in the range from 0.995 to 0.999. The method allows choosing an ion from the full mass spectra which shows the least interference from the matrix and/or the best sensitivity; this can only be done if full scan mass spectral data are available. The advantage of GCxGC over classical one-dimensional GC, in terms of separation efficiency and sensitivity, is demonstrated on a positive urine control sample at a concentration of 5ngm/L. The obtained similarity to the in-house created TOFMS spectra library at this level of concentration was in the range from 822 to 932 (on the scale from 0 to 999). Since full mass spectral information are recorded, the method allows the retro-search of non-target compounds or new "designer steroids", which cannot be detected with established GC-MS methods that use selected ion monitoring mode [10035].

Urine samples have been the predominant matrix for doping controls for several decades. However, owing to the complementary information provided by blood (as well as serum or plasma and dried blood spots (DBS)), the benefits of its analysis have resulted in continuously increasing appreciation by anti-doping authorities. On the one hand, blood samples allow for the detection of various different methods of blood doping and the abuse of erythropoiesis-stimulating agents (ESAs) via the Athlete Biological Passport; on the other hand, targeted and non-targeted drug detection by means of chromatographic-mass spectrometric methods represents an important tool to increase doping control frequencies out-of-competition and to determine drug concentrations particularly in in-competition scenarios. Moreover, blood analysis seldom requires in-depth knowledge of drug metabolism, and the intact substance rather than potentially unknown or assumed metabolic products can be targeted. In this review, the recent developments in human sports drug testing concerning mass spectrometry-based techniques for qualitative and quantitative analyses of therapeutics and emerging drug candidates are summarized and reviewed. The analytical methods include both low and high molecular mass compounds (e.g., anabolic agents, stimulants, metabolic modulators, peptide hormones, and small interfering RNA (siRNA)) determined from serum, plasma, and DBS using state-of-the-art instrumentation such as liquid chromatography (LC)-high resolution/high accuracy (tandem) mass spectrometry (LC-HRMS), LC-low resolution tandem mass spectrometry (LC-MS/MS), and gas chromatography-mass spectrometry (GC-MS) [13086].

Employing gas chromatography – triple quadrupole (QqQ) tandem mass spectrometry (GC-MS/MS), a complementary methodology was presented in 2012, allowing for the qualitative and partly quantitative identification of 173 analytes including representatives of anabolic agents, beta2-agonists, hormone and metabolic modulators, masking agents, stimulants, narcotics, beta-blockers, and cannabinoids. By means of targeted multiple reaction monitoring (MRM) and 11 ISTDs (10 of which were isotopically labelled), a robust and sensitive assay was established enabling the routine screening for over 150 xenobiotic compounds plus the provision of the individual's steroid profile from a total of 1 mL of urine. In agreement with earlier approaches, the urine was subjected to enzymatic hydrolysis, liquid-liquid extraction (LLE) and finally trimethylsilylation prior to gas chromatography-tandem mass spectrometry (GC-MS/MS) analysis [13019].
Gas chromatography-microchip atmospheric pressure photoionization-mass spectrometry

A gas chromatography-microchip atmospheric pressure photoionization-tandem mass spectrometry (GC-microAPPI-MS/MS) method was developed for the analysis of anabolic androgenic steroids in urine as their trimethylsilyl derivatives. The method utilizes a heated nebulizer microchip in atmospheric pressure photoionization mode (microAPPI) with chlorobenzene as dopant, which provides high ionization efficiency by producing abundant radical cations with minimal fragmentation. The performance of GC-microAPPI-MS/MS was evaluated with respect to repeatability, linearity, linear range, and limit of detection (LOD). The results confirmed the potential of the method for doping control analysis of anabolic steroids. Repeatability, linearity, and sensitivity (LODs 0.05-0.1 ng/mL) were acceptable. Quantitative performance of the method was tested and compared with that of conventional GC-electron ionization-MS, and the results were in good agreement [13087].

Gas chromatography-mass spectrometry

Gas chromatography-mass spectrometry (GC-MS) is the technique that is used most widely in anti-doping labs. The GC effluent enters the mass spectrometer continuously, and the mass spectrometer continuously records roughly one mass spectrum (scan) per second. There are two main modes of MS operation: the full-scan mode and the selected ion monitoring (SIM) mod. In the full-scan mode, the mass spectrometer records the whole mass spectrum (from m/z 70 to 400), monitoring hundreds of ions. In the SIM mode, only selected ions are monitored (e.g. 143, 345, 360); therefore, a longer time is spent recording each ion. In physics, signal strength (signal-to-noise ratio) increases with the time spent collecting data. Therefore, on the same instrument SIM is more sensitive than full scan; it can detect smaller amounts of drug. Other types of MS that are more sensitive include high-resolution MS, tandem MS, and ion traps. High-resolution MS is designed to measure m/z not only to the nearest unit or decimal, but out to several more decimals. This makes it possible to mathematically deduce the molecular formula (how many carbon, hydrogen, oxygen, and other atoms it contains); the more decimals, the fewer combinations of atoms fit, the narrower the possibilities. High-resolution MS instruments happen to be inherently more sensitive. Tandem MS instruments have two mass spectrometers back to back. The first one can be used to select only one ion, the precursor ion, which can be the molecular ion. The second mass spectrometer monitors only one (or at most a few) characteristic fragmentations (transitions to product ions). This is called the multiple reaction monitoring or selected reaction monitoring mode. (Alternatively, the first mass spectrometer can be used to select only the molecular ion and the second mass spectrometer can be used to record a full scan.) Tandem MS is more sensitive because it is blind to interferences. Unlike all of the above MS types, which let all ions formed continually escape from the ion source, ion traps trap all ions until they are released, one m/z at a time, to determine their abundance [07046].

One paper described a fast gas chromatographic/mass spectrometric (GC/MS) screening method for the detection, in urine, of 36 xenobiotics (30 synthetic anabolic steroids, four narcotics, one diuretic and one stimulant) excreted free or as glucuro-conjugates in urine and detectable as trimethylsilyl (TMS) derivatives. These drugs (and/or their urinary metabolites) can be simultaneously extracted by a single liquid/liquid separation step, at alkaline pH, after enzymatic hydrolysis with beta-glucuronidase and then assayed as TMS derivatives by GC/MS using electron ionisation (EI) and single ion monitoring (SIM) acquisition mode. The total time needed for the GC run is less than 8 min. Good reproducibility of the retention times (CV % <1) and the relative abundances of the diagnostic fragment ions (CV % <10)
was observed for all target analytes. The sensitivity of the method is sufficient to match the requirements of the World Anti-Doping Agency (WADA) for the accredited laboratories, with limits of detection (LODs) that are lower than the corresponding WADA minimum required performance limits (MRPLs) for all target compounds [07049].

Gas chromatography-combustion-IRMS (GC-C-IRMS).

Before application to doping control, it had long been used to detect the fraudulent substitution of synthetic compounds in place of natural compounds in the food, flavor, and fragrance industries. The anabolic steroids are extracted from urine and separated by GC. The separated testosterone enters the pencil-size combustion oven where it is pyrolyzed. Every carbon atom in the molecule is converted to CO₂, and every hydrogen atom is converted to water (H₂O). The water is scrubbed out and only the CO₂ enters the IRMS. This type of MS measures only three m/z: 44 for 12C16O₂, and 45 and 46 for variants containing carbon-13, oxygen-17, or oxygen-18. From the relative abundances, the instrument software calculates the delta¹³C (delta) value. It reflects the ¹³C/¹²C ratio, but it actually is the difference between the ¹³C/¹²C ratio of the sample and that of an international standard. The units are ‰ (per mil). By definition, the delta value of the international standard is 0‰. Examples of values are -24 ‰ for natural testosterone and -29 ‰ for pharmaceutical testosterone. The values are negative because both compounds contain less carbon-13 than the international standard: 29 fewer parts per thousand for the pharmaceutical testosterone. After exogenous testosterone administration, the delta values of urinary testosterone metabolites become more negative. In contrast, the delta values of testosterone precursors, or of endogenous steroids not involved in testosterone metabolism, remain unchanged; therefore, they can be used as endogenous reference compounds. A gap in delta value between testosterone or its metabolites and an endogenous reference compound indicates the use of testosterone or of any steroid in its metabolism. If the difference between the delta values of one metabolite and the endogenous reference compound is three delta units or more, the WADA requirement for reporting an adverse analytical finding has been met. The power of this approach is that it can detect the use of not only testosterone itself, but also of any one of many testosterone precursors and metabolites. The second advantage is that it is not affected by factors that might influence baseline delta values. For example, diet influences the carbon-13 content of endogenous steroids – all of them to a similar extent. Although interpreting vastly different delta values from one individual to the next might be difficult, a difference in delta values between a testosterone metabolite and an endogenous reference compound clearly reveals drug use. In short, the approach compensates for individual variability. The third advantage is that it does not require identifying or even knowing what exact compound was taken. RMS testing has been applied to various testosterone precursors, testosterone metabolites, and endogenous reference compounds. It is currently done for samples with T/E greater than 4 or on request by the sports authority [07011].

An alternative calibration procedure for use when performing carbon isotope ratio measurements by gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS) has been developed. This calibration procedure does not rely on the corrections in-built in the instrument software, as the carbon isotope ratios of a sample are calculated from the measured raw peak areas. The method was developed for the certification of a urine reference material for sports drug testing, as the estimation of measurement uncertainty is greatly simplified. To ensure that the method is free from bias arising from the choice of calibration material and instrument, the carbon isotope ratios of steroids in urine extracts were measured using two different instruments in different laboratories, and three different reference materials (CU/USADA steroid standards from Brenna Laboratory, Cornell University; NIST RM8539 mineral oil; methane calibrated against
NIST RM8560 natural gas). The measurements were performed at LGC and the Australian National Measurement Institute (NMI). It was found that there was no significant difference in measurement results when different instruments and reference materials were used to measure the carbon isotope ratio of the major testosterone metabolites androsterone and etiocholanolone, or the endogenous reference compounds pregnanediol, 11-ketoetiocholanolone and 11beta-hydroxyandrosterone. The measurement results of this comparison were used to estimate a measurement uncertainty of delta$^{13}$C for the certification of the urine reference material being performed on a single instrument using a single reference material at NMI [11037].

The confirmation by GC/C/IRMS of the exogenous origin of pseudo-endogenous steroids from human urine samples requires extracts of adequate purity. A strategy based on HPLC sample purification prior to the GC/C/IRMS analysis of human urinary endogenous androgens (i.e. testosterone, androsterone and/or androstenediols), is presented. A method without any additional derivatization step is proposed, allowing to simplify the urine pretreatment procedure, leading to extracts free of interferences permitting precise and accurate IRMS analysis, without the need of correcting the measured delta values for the contribution of the derivatizing agent. The HPLC extracts were adequately combined to both reduce the number of GC/C/IRMS runs and to have appropriate endogenous reference compounds (ERC; i.e. pregnanediol, 11-keto-etiocholanolone) on each GC-IRMS run. The purity of the extracts was assessed by their parallel analysis by gas chromatography coupled to mass spectrometry, with GC conditions identical to those of the GC/C/IRMS assay. The method has been validated according to ISO17025 requirements (within assay precision below 0.3‰ $^{13}$C delta units and between assay precision below 0.6‰ $^{13}$C delta units for most of the compounds investigated) fulfilling the World Anti-Doping Agency requirements [12051].

In gas chromatographic-combustion-isotope ratio mass spectrometry (GC-C-IRMS) doping control analysis, endogenous androgenic anabolic steroids and their metabolites are commonly acetylated using acetic anhydride reagent, thus incorporating exogenous carbon that contributes to the measured isotope ratio. Comparison of the endogenous delta$^{13}$C of free, mono-, and di-acetylated steroids requires application of corrections, typically through straightforward use of the mass balance equation. Variability in kinetic isotope effects (KIE) due to steroid structures could cause fractionation of endogenous steroid carbon, resulting in inaccurate results. To test for possible KIE influence on delta$^{13}$C, acetic anhydride of graded isotope ratio within the natural abundance range was used under normal derivatization conditions to test for linearity. In all cases, plots of measured steroid acetate delta$^{13}$C versus acetic anhydride delta$^{13}$C were linear and slopes were not significantly different. Regression analysis of the delta$^{13}$C of enriched acetic anhydrides versus delta$^{13}$C of derivatized steroids shows that KIE are similar in all cases. It was concluded that delta$^{13}$C calculated from the mass balance equation is independent of the delta$^{13}$C of the acetic anhydride reagent, and that net KIE under normal derivatization conditions do not bias the final reported steroid delta$^{13}$C [12061].

Gas chromatography-triple quadrupole mass spectrometry

The use of performance enhancing drugs in sports is prohibited. For the detection of misuse of such substances gas chromatography or liquid chromatography coupled to mass spectrometry are the most frequently used detection techniques. In this work the development and validation of a fast gas chromatography tandem mass spectrometric method for the detection of a wide range of doping agents is described. The method can determine 13 endogenous steroids (the steroid profile), 19-norandrosterone, salbutamol and 11-nor-delta9-tetrahydrocannabinol.9-carboxylic acid in the applicable ranges and to detect
qualitatively over 140 substances in accordance with the minimum required performance levels of the World Anti-Doping Agency in 1ml of urine. The classes of substances included in the method are anabolic steroids, beta2-agonists, stimulants, narcotics, hormone antagonists and modulators and beta-blockers. Moreover, using a short capillary column and hydrogen as a carrier gas the run time of the method is less than 8 min [11038].

Gas chromatography-QqQ-MS

A gas chromatography-QqQ-MS method was developed for the detection of over 150 compounds from different classes (steroids, narcotics, stimulants, beta-blockers, beta-2-agonists and hormone antagonists) in a qualitative way. In the quantitative part, the traditional steroid profile with the most important endogenous steroids is expanded with six minor metabolites, which further improves the detection and identification of endogenous steroid abuse. In addition to these, norandrosterone, salbutamol and the major metabolite of cannabis are also quantified. Methods developed for anti-doping purposes should be subjected to the highest level of quality. Here, the addition of a combination of (deuterated) internal standards allows for an accurate quality control of every single step of the methodology: hydrolysis efficiency, derivatization efficiency and microbiological degradation are monitored in every single sample. Additionally, special attention is paid to the relationships between parameters indicating degradation by micro-organisms and the reliability of the steroid profile. The impact of the degradation is studied by evaluation of the quantities and percentages of 5alpha-androstane-3,17-dione and 5beta-androstane-3,17-dione. The concept of measurement uncertainty was introduced for the evaluation of relative abundances of mass-to-charge ratios and the obtained ranges were compared with the World Anti-Doping Agency regulations on tolerance windows for relative ion intensities. The results indicate that the approaches are similar [12063].

Carbon isotope (CIR)-based analyses

The Achilles’ heel of all carbon isotope ratio (CIR)-based assays however is the necessity of a significant difference between the CIR of the administered steroid and the employed endogenous reference compounds (ERCs). As demonstrated earlier various testosterone formulations of mostly illicit origin exhibit CIRs at natural 13C-values. Here, IRMS analyses focusing on carbon isotope signatures only might disallow determining the prohibited administration of a natural steroid. Further to this, the effect of hormones influencing testicular activity such as human chorionic gonadotrophin (hCG) on steroid profiles and CIRs necessitated consideration [12017].

The detection of steroids originating from synthetic precursors against a background of their chemically identical natural analogues has proven to be a significant challenge for doping control laboratories accredited by the World Anti-Doping Agency (WADA). The complementary application of gas chromatography-mass spectrometry (GC-MS) and gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS) has been demonstrated to provide specific detection of endogenous steroid misuse for improved anti-doping analysis. Markers of synthetically derived steroids are reviewed on the basis of abnormal urinary excretions and low 13C content. A combinatorial approach is presented for the interpretation of GC-MS and GC-C-IRMS data in the anti-doping context. This methodology can allow all relevant information concerning an individual’s metabolism to be assessed in order to make an informed decision with respect to a doping violation [12077].
**IRMS (isotope ratio mass spectrometry)**

Today, many scientists concerned with forensic and environmental analytics will appreciate the introduction of isotope ratio mass spectrometry (IRMS) as a most innovative tool. Significant IRMS-based knowledge about the systematic variation of $^{13}\text{C}/^{12}\text{C}$ ratios in nature was, however, available around 1950. The fundamental depletion of $^{13}\text{C}$ in organic material was even recognized as early as 1939. This development essentially was brought forward by Alfred Nier. Any scientist currently concerned with IRMS will immediately be familiar with Nier's mass spectrometer design from 1947. In fact, significant development of the ion optics, source design, etc., has taken place in the meanwhile. But ever since Nier's inventions, these instruments feature multiple collectors and the characteristic magnetic sector field. Even more striking, the fundamental design of isotope ratio mass spectrometers has not changed since 1940. Nier built his first mass spectrometer in 1936. But on principle, the concept even dates back to 1918, when AJ Dempster advocated the 180° design as “A New Method of Positive Ray Analysis” Five years earlier, Jj Thomson had shown the usefulness of “Positive Rays as a Method of Chemical Analysis”. So, IRMS is a well proven, rather traditional methodology. The term “continuous-flow isotope ratio mass spectrometry” (CFIRMS) was presumably introduced in 1988 when Preston and McMillan coupled an elemental analyzer to an isotope ratio mass spectrometer via a variable leak. Recent improvements in the methodology mainly concern online coupling and analytical peripherals. The breakthrough thus achieved for doping control can hardly be overestimated. If still challenging, $^{13}\text{C}/^{12}\text{C}$ analysis of urinary steroids by gas chromatography coupled to IRMS is now a standard procedure. However, it merely represents one out of a multitude of emerging applications of stable isotope analysis at natural abundance. The relative nature of $d$ scales must always be kept in mind. As a most important consequence, divisions are not feasible. It follows immediately that measurement uncertainties must not be expressed as coefficients of variation. Due to the design of Nier-type mass spectrometers, the analytical error is largely independent of the measured isotope ratio anyway. When emphasis is on quantitation of the respective contributions, the term source apportionment is more appropriate. In doping control, it is implicitly assumed that there are two distinct sources for urinary steroids: Endogenous steroids and/or synthetic steroids. Therefore, low $^{13}\text{C}/^{12}\text{C}$ ratios are often immediately associated with synthetic origin. However, theoretically and practically the situation is more complicated and this should fundamentally be considered. Terms and definitions for possible sources of urinary steroids are not very consistent. For instance, endogenous steroid is mostly used for a compound synthesized physiologically in an organism. But sometimes it is also used to classify pharmaceuticals with chemical structures identical to those of the physiological compounds [12072].

Delta $^{13}\text{C}$ and delta$^{13}\text{C}$ values of endogenous urinary steroids represent physiological random variables. Measurement uncertainty and biological scatter likewise contribute to the variances. The statistical distributions of negative controls are well investigated, but there is little knowledge about the corresponding distributions of steroid-users. For these reasons valid discrimination of steroid users from non-users by ($^{13}\text{C}/^{12}\text{C}$ analysis of endogenous steroids requires elaborate statistical treatment. Corresponding Bayesian approaches are presented following an introduction to the rationale. The use of mixture models appears appropriate. The distribution of routine data has been deconvolved and characterized accordingly. The mixture components, which presumably represent steroid users and non-users, exhibit considerable overlap. The validity of a given result depends on both the analytical uncertainty and the prior probability of doping offenses. Low analytical uncertainties but high prior probabilities facilitate valid detection of doping offenses. Two recommendations can be deduced. First, before starting an $^{13}\text{C}/^{12}\text{C}$ analysis, any initial suspicion should be well-substantiated. This precludes use of permissive criteria derived
from the steroid profile. Secondly, knowledge of relevant $^{13}\text{C}/^{12}\text{C}$ distributions is required. This must cover representative numbers of authentic steroid users. Finally, it is desirable that the conditional probability for steroid administration rather than the measurement uncertainty is calculated and reported. This quantity possesses superior validity and it is largely independent of laboratory bias. The findings suggest and facilitate flexible handling of decision limits [12073].

The detection of steroids originating from synthetic precursors against a background of their chemically identical natural analogues has proven to be a significant challenge for doping control laboratories accredited by the World Anti-Doping Agency (WADA). The complementary application of gas chromatography-mass spectrometry (GC-MS) and gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS) has been demonstrated to provide specific detection of endogenous steroid misuse for improved anti-doping analysis. Markers of synthetically derived steroids are reviewed on the basis of abnormal urinary excretions and low $^{13}\text{C}$ content. A combinatorial approach is presented for the interpretation of GC-MS and GC-C-IRMS data in the anti-doping context. This methodology can allow all relevant information concerning an individual's metabolism to be assessed in order to make an informed decision with respect to a doping violation [12074].

Isotope ratio mass spectrometry (IRMS) testing is performed to determine if an atypical steroid profile is due to administration of an endogenous steroid. Androsterone (Andro) and etiocholanolone (Etio), and/or the androstanediols (5alpha- and 5beta-androstane-3alpha,17beta-diol) are typically analyzed by IRMS to determine the $^{13}\text{C}/^{12}\text{C}$ ratio. The ratios of these target compounds are compared to the $^{13}\text{C}/^{12}\text{C}$ ratio of an endogenous reference compound (ERC) such as 5beta-pregnane-3alpha,20alpha-diol (Pdiol). Concentrations of Andro and Etio are high so $^{13}\text{C}/^{12}\text{C}$ ratios can easily be measured in most urine samples. Despite the potentially improved sensitivity of the androstanediols for detecting the use of some testosterone formulations, additional processing steps are often required that increase labour costs and turnaround times. Since this can be problematic when performing large numbers of IRMS measurements, we established thresholds for Andro and Etio that can be used to determine the need for additional androstanediol testing. Using these criteria, 105 out of 2639 urine samples exceeded the Andro and/or Etio thresholds, with 52 of these samples being positive based on Andro and Etio IRMS testing alone. The remaining 53 urine samples had androstanediol IRMS testing performed and 3 samples were positive based on the androstanediol results. A similar strategy was used to establish a threshold for Pdiol to identify athletes with relatively $^{13}\text{C}$-depleted values so that an alternative ERC can be used to confirm or establish a true endogenous reference value. Adoption of a similar strategy by other laboratories can significantly reduce IRMS sample processing and analysis times, thereby increasing testing capacity [13095].

Complementary to carbon isotope ratios (CIR), isotope ratio analysis concerning hydrogen and deuterium (HIR) has received increasing attention in doping controls. Particularly the 2-dimensional analysis of urinary steroids, i.e. combined evaluation of CIR and HIR, was considered as a powerful (though time- and cost-intensive) means allowing to lower reference limits in doping controls and to enable the determination of exogenous steroids comprising CIR signatures close to endogenous values. In that respect, potentially confounding factors have to be assessed and the influence of the deuterium content in drinking water on urinary steroid HIR was measured in a recent study. Despite the drastic influence on the HIR of the body water, only shifts of approximately 30 ‰ in urinary steroids were observed. Hence, the HIR analysis proved robust against diet-induced changes, specifically the ingestion of drinking water with different isotopic signature [13009].
Isoelectric focusing

Isoelectric focusing (IEF) is used to detect recombinant EPO in the urine EPO test. Historically, the EPO test at the Olympics (2000 to 2006) was done on paired blood and urine samples collected simultaneously. The blood test is an indirect test because it does not detect the presence of recombinant EPO. Instead, it measures multiple parameters (e.g., hemoglobin, hematocrit, percentage of reticulocytes) and calculates a score that indicates whether the individual is on or recently off recombinant EPO. Since 2002, EPO tests done by United States sports authorities have included only the urine test, a direct test that identifies recombinant EPO. EPO tests are done on only some of all of the urine samples, upon request by the sports authority. Endogenous human EPO is a glycoprotein with a known amino acid sequence and glycosylation pattern. More precisely, it consists of a family of isoforms (molecules that differ only by their degrees of glycosylation). As a result, the pH at which each isoform bears as many negative charges as positive charges (isoelectric point or PI) is different. Recombinant human EPO differs from endogenous human EPO only by its overall glycosylation pattern (i.e., it consists of a different family of isoforms). The difference in overall pattern of isoforms allows differentiation between recombinant and endogenous human EPO. The urine EPO test, also known as the French test or the IEF test, consists of four steps: sample preparation, IEF, double blotting, and visualization. Sample preparation concentrates EPO by multiple ultrafiltrations that leave the proteins of desired molecular weight in the filtration "retentate." Next, the retentate is deposited on a gel with an embedded pH gradient, and a current is applied to achieve electrophoretic separation of the isoforms (IEF). Unknown samples, reference standards, and known positive and negative quality controls are normally run on each gel. Each sample, standard, or control spreads out in its own "lane." Each isoform is charged; therefore, it migrates in the electrical field until it reaches the distance on the gel at which the pH is equal to its PI. There, the isoform is electrically neutral so it stops migrating. Its position or distance up the gel is key, and the goal of the remaining steps is to visualize it. The first blotting step transfers all proteins (erythropoietic and other) to a first membrane. The membrane is incubated with antibodies specific to erythropoietic proteins. The second blot transfers only these specific antibodies to the second membrane, thus transferring the isoform pattern, but leaving behind all proteins, including some that otherwise would obscure the final image. Visualization is based on chemiluminescence; it involves incubation with a second antibody that binds to the first antibody and a chemical reaction that emits light. The image (electropherogram) is captured with a special digital camera. All steps use commonplace molecular biology techniques. The electropherogram contains one lane per sample, standard, or quality control sample. In each lane, the isoform pattern consists of bands. The pattern (number of bands, positions, relative intensities) allows identification. In common language, a negative EPO test often is discussed as if it reflects the absence of EPO, but of course what it means is that there was no recombinant erythropoietic protein in the urine sample, which normally would (hopefully!) contain natural, endogenous EPO [07011].

Electrospray ionization

Electrospray ionization (ESI) mass spectra of 15 anti-estrogenic substances, beta2-agonists and mesocarb were investigated in terms of fragmentation patterns. On the basis of this product ion information, a simultaneous screening method for anti-estrogenic substances, beta2-agonists and mesocarb was developed for doping control purposes. After hydrolysis, liquid-liquid extraction was adopted for the sample preparation. The recoveries for all compounds were 30 and 96 percent. A single liquid chromatography/tandem mass
spectrometry (LC/MS/MS) analysis could be performed in 13 min for the analysis of 15 anti-
estrogenic substances, beta2-agonists and mesocarb. A quantitative analysis was also validated. Inaccuracies were below ± 12 percent and precisions varied from 0 to 16 percent. The limit of detection was below 10 ng/mL except formestane (300 ng/mL) and aminoglutethimide (100 ng/mL). The validated method was applied for the analysis of excretion samples [07054].

**Capillary electrophoresis**

During the past two decades, chiral capillary electrophoresis (CE) emerged as a promising, effective and economic approach for the enantioselective determination of drugs and their metabolites in body fluids, tissues and in vitro preparations. This review discusses the principles and important aspects of CE-based chiral bioassays, provides a survey of the assays developed during the past 10 years and presents an overview of the key achievements encountered in that time period. Applications discussed encompass the pharmacokinetics of drug enantiomers in vivo and in vitro, the elucidation of the stereoselectivity of drug metabolism in vivo and in vitro, and bioanalysis of drug enantiomers of toxicological, forensic and doping interest. Chiral CE was extensively employed for research purposes to investigate the stereoselectivity associated with hydroxylation, dealkylation, carboxylation, sulfoxidation, N-oxidation and ketoreduction of drugs and metabolites. Enantioselective CE played a pivotal role in many biomedical studies, thereby providing new insights into the stereoselective metabolism of drugs in different species which might eventually lead to new strategies for optimization of pharmacotherapy in clinical practice [10320].

At present the role of capillary electrophoresis in the detection of doping agents in athletes is, for the most part, nonexistent. More traditional techniques, namely gas and liquid chromatography with mass spectrometric detection, remain the gold standard of antidoping tests. This Feature will investigate the in-roads that capillary electrophoresis has made, the limitations that the technique suffers from, and where the technique may grow into being a key tool for antidoping analysis [13093].

**Capillary electrophoresis time-of-flight mass spectrometry**

Capillary electrophoresis coupled to orthogonal accelerated time-of-flight mass spectrometry (CE/TOFMS) was used for the analysis of O- and N-glycopeptides of recombinant human erythropoietin (rhEPO), O(126) and N(83) with a tetraantennary complex type glycan (N(83)-4Ant) were selected as glycopeptide models to develop an optimum CE/TOFMS methodology capable of detecting and characterizing the wide variety of glycopeptides present in the glycoprotein digest. Glycopeptide adsorption in the inner surface of the fused-silica capillary was prevented after using a capillary conditioning of 1 M HAc between runs. On the other hand, different acidic conditions in the sheath liquid (SL) and in the background electrolyte (BGE) were tested with the aim of studying their influence in glycopeptide fragmentation. Finally, the fragmentor voltage value of the TOF-MS instrument was optimized to avoid the involuntary fragmentation of the native glycopeptides. Hence, the established method may be regarded as an excellent starting point to obtain reliable glycopeptide maps of complex glycoproteins such as rhEPO by CE/TOFMS [11430].

**Vacuum MALDI-linear ion trap mass spectrometry**

379
Detection of doping agents in urine frequently requires extensive separation prior to chemical analyses. Gas or liquid chromatography coupled to mass spectrometry has produced accurate and sensitive assays, but chromatographic separations require time and, sometimes, chemical derivatization. To avoid such tedious and lengthy procedures, vacuum matrix-assisted laser desorption ionization (vMALDI) coupled with the linear ion trap mass spectrometry (LIT/MS) technique is tested for its applicability as a rapid screening technique. Commonly used doping agents like nandrolone, boldenone, trenbolone, testosterone, and betamethasone were chosen as study compounds. Different MALDI matrixes like alpha-cyano-4-hydroxycinnamic acid (CHCA), dihydroxy benzoic acid (DHB) with and without cetyl trimethyl ammonium bromide (CTAB), a surfactant, and meso-tetrakis(pentafluorophenyl) porphyrin (F20TPP) were tested. Among them, F20TPP (MW 974.57 Da) was selected as the preferred matrix owing to the lack of interfering matrix peaks at the lower mass range (m/z 100-700). Urine samples spiked with study compounds were processed by solid-phase extraction (SPE) and consistently detected through a linear range of 0.1-100 ng/mL. The limit of detection and lower limit of quantification for all five analytes have been determined to be 0.03 and 0.1 ng/mL, respectively, in urine samples. Testosterone-d3 was used as an internal standard, and the quantitative measurements were achieved by the selective reaction monitoring (SRM) mode. The method was validated and showed consistency in the results. Hence, vMALDI-LIT/MS can be used as a rapid screening method to complement the traditional GC/MS and LC/MS techniques for simultaneous identification, confirmation, and quantification of doping agents in urine [06039].

Hyphenated mass spectrometric techniques

Hyphenated mass spectrometric techniques, particularly gas chromatography/mass spectrometry (GC/MS) and liquid chromatography/mass spectrometry (LC/MS), are indispensable tools in clinical and forensic toxicology and in doping control owing to their high sensitivity and specificity. They are used for screening, library-assisted identification and quantification of drugs, poisons and their metabolites, prerequisites for competent expertise in these fields. In addition, they allow the study of metabolism of new drugs or poisons as a
basis for developing screening procedures in biological matrices, most notably in urine, or toxicological risk assessment. Concepts and procedures using GC/MS and LC/MS techniques in the areas of analytical toxicology and the role of mass spectral libraries are presented and discussed in this feature article [06040].

**siRNA**

Small interfering ribonucleic acid (siRNA) molecules can effect the expression of any gene by inducing the degradation of mRNA. Therefore, these molecules can be of interest for illicit performance enhancement in sports by affecting different metabolic pathways. An example of an efficient performance-enhancing gene knockdown is the myostatin gene that regulates muscle growth. One study was carried out to provide a tool for the mass spectrometric detection of modified and unmodified siRNA from plasma samples. The oligonucleotides are purified by centrifugal filtration and the use of an miRNA purification kit, followed by flow-injection analysis using an Exactive mass spectrometer to yield the accurate masses of the sense and antisense strands. Although chromatography and sensitive mass spectrometric analysis of oligonucleotides are still challenging, a method was developed and validated that has adequate sensitivity (limit of detection 0.25-1 nmol/mL and performance (precision 11-21 %, recovery 23-67 %) for typical antisense oligonucleotides currently used in clinical studies [10442].

Uncovering manipulation of athletic performance via small interfering (si)RNA is an emerging field in sports drug testing. Due to the potential to principally knock down every target gene in the organism by means of the RNA interference pathway, this facet of gene doping has become a realistic scenario. In the present study, two distinct model siRNAs comprising 21 nucleotides were designed as double strands which were perfect counterparts to a sequence of the respective messenger RNA coding the muscle regulator myostatin of Rattus norvegicus. Several modified nucleotides were introduced in both the sense and the antisense strand comprising phosphothioates, 2'-O-methylation, 2'-fluoro-nucleotides, locked nucleic acids and a cholesterol tag at the 3'-end. The model siRNAs were applied to rats at 1 mg/kg (i.v.) and blood as well as urine samples were collected. After isolation of the RNA by means of a RNA purification kit, the target analytes were detected by liquid chromatography-high resolution/high accuracy mass spectrometry (LC-HRMS). Analytes were detected as modified nucleotides after alkaline hydrolysis, as intact oligonucleotide strands (top-down) and by means of denaturing SDS-PAGE analysis. The gel-separated siRNA was further subjected to in-gel hydrolysis with different RNases and subsequent identification of the fragments by untargeted LC-HRMS analysis (bottom-up, “experimental RNomics”). Combining the results of all approaches, the identification of several 3'-truncated urinary metabolites was accomplished and target analytes were detected up to 24 h after a single administration. Simultaneously collected blood samples yielded no promising results. The methods were validated and found fit-for-purpose for doping controls [13106].

**Mass spectrometric detection of siRNA**

Small interfering ribonucleic acid (siRNA) molecules can effect the expression of any gene by inducing the degradation of mRNA. Therefore, these molecules can be of interest for illicit performance enhancement in sports by affecting different metabolic pathways. An example of an efficient performance-enhancing gene knockdown is the myostatin gene that regulates muscle growth. One study was carried out to provide a tool for the mass spectrometric detection of modified and unmodified siRNA from plasma samples. The oligonucleotides are
purified by centrifugal filtration and the use of an miRNA purification kit, followed by flow-injection analysis using an Exactive mass spectrometer to yield the accurate masses of the sense and antisense strands. Although chromatography and sensitive mass spectrometric analysis of oligonucleotides are still challenging, a method was developed and validated that has adequate sensitivity (limit of detection 0.25-1 nmol/mL) and performance (precision 11-21 %, recovery 23-67 %) for typical antisense oligonucleotides currently used in clinical studies [10322].

High-resolution liquid chromatography-time-of-flight mass spectrometry

A unification of doping-control screening procedures of prohibited small molecule substances – including stimulants, narcotics, steroids, beta2-agonists and diuretics – is highly urgent in order to free resources for new classes such as banned proteins. Conceptually this may be achieved by the use of a combination of one gas chromatography-time-of-flight mass spectrometry method and one liquid chromatography-time-of-flight mass spectrometry method. In this work a quantitative screening method using high-resolution liquid chromatography in combination with accurate-mass time-of-flight mass spectrometry was developed and validated for determination of glucocorticosteroids, beta2 agonists, thiazide diuretics, and narcotics and stimulants in urine. To enable the simultaneous isolation of all the compounds of interest and the necessary purification of the resulting extracts, a generic extraction and hydrolysis procedure was combined with a solid-phase extraction modified for these groups of compounds. All 56 compounds are determined using positive electrospray ionisation with the exception of the thiazide diuretics for which the best sensitivity was obtained by using negative electrospray ionisation. The results show that, with the exception of clenhexyl, procaterol, and reproterol, all compounds can be detected below the respective minimum required performance level and the results for linearity, repeatability, within-lab reproducibility, and accuracy show that the method can be used for quantitative screening. If qualitative screening is sufficient the instrumental analysis may be limited to positive ionisation, because all analytes including the thiazides can be detected at the respective minimum required levels in the positive mode. The results show that the application of accurate-mass time-of-flight mass spectrometry in combination with generic extraction and purification procedures is suitable for unification and expansion of the window of screening methods of doping laboratories. Moreover, the full-scan accurate-mass data sets obtained still allow retrospective examination for emerging doping agents, without re-analyzing the samples [10036].

Ultra-high-pressure liquid chromatography-quadrupole time-of-flight mass spectrometry

For doping control, analyses of samples are generally achieved in two steps: a rapid screening and, in the case of a positive result, a confirmatory analysis. A two-step methodology based on ultra-high-pressure liquid chromatography coupled to a quadrupole time-of-flight mass spectrometry (UHPLC-QTOF-MS) was developed to screen and confirm 103 doping agents from various classes (e.g., beta-blockers, stimulants, diuretics, and narcotics). The screening method was presented in a previous article as part I (i.e. fast analysis of doping agents in urine by ultra-high-pressure liquid chromatography-quadrupole time-of-flight mass spectrometry. part I: screening analysis). For the confirmatory method, basic, neutral and acidic compounds were extracted by a dedicated solid-phase extraction (SPE) in a 96-well plate format and detected by MS in the tandem mode to obtain precursor and characteristic product ions. The mass accuracy and the elemental composition of
precursor and product ions were used for compound identification. After validation including matrix effect determination, the method was considered reliable to confirm suspect results without ambiguity according to the positivity criteria established by the World Anti-Doping Agency. Moreover, an isocratic method was developed to separate ephedrine from its isomer pseudoephedrine and cathine from phenylpropanolamine in a single run, what allowed their direct quantification in urine [10037].

The urinary steroid profile is constituted by anabolic androgenic steroids, including testosterone and its relatives, that are extensively metabolized into phase II sulfated or glucuronidated steroids. The use of liquid chromatography coupled to mass spectrometry (LC-MS) is an issue for the direct analysis of conjugated steroids, which can be used as urinary markers of exogenous steroid administration in doping analysis, without hydrolysis of the conjugated moiety. In this study, a sensitive and selective ultra high-pressure liquid chromatography coupled to quadrupole time-of-flight mass spectrometer (UHPLC-QTOF-MS) method was developed to quantify major urinary metabolites simultaneously after testosterone intake. The sample preparation of the urine (1 mL) was performed by solid-phase extraction on Oasis HLB sorbent using a 96-well plate format. The conjugated steroids were analyzed by UHPLC-QTOF-MS(E) with a single-gradient elution of 36 min (including re-equilibration time) in the negative electrospray ionization mode. MS(E) analysis involved parallel alternating acquisitions of both low- and high-collision energy functions. The method was validated and applied to samples collected from a clinical study performed with a group of healthy human volunteers who had taken testosterone, which were compared with samples from a placebo group. Quantitative results were also compared to GC-MS and LC-MS/MS measurements, and the correlations between data were found appropriate. The acquisition of full mass spectra over the entire mass range with QTOF mass analyzers gives promise of the opportunity to extend the steroid profile to a higher number of conjugated steroids [11034].

Isotachophoresis sample stacking

A simple and effective method of capillary electrophoresis-amperometric detection (CE-AD) coupled with transient isotachophoresis (tITP) was developed for the trace determination of doping substances. Compared with the conventional capillary electrophoresis method, the maximum enhancement factor in terms of peak heights was up to 5500-fold when the tITP technique was adopted. Under the optimum conditions, detection limit for methylephedrine (MDP), celiprolol (CEL), sotalol (SOT) and indapamide (IDP) were $4.2 \times 10^{-14}$, $6.3 \times 10^{-13}$, $5.8 \times 10^{-14}$ and $9.5 \times 10^{-13}$ mol/L, respectively. The proposed method was successfully applied to determine the contents of SOT and IDP in real urine sample, and the excretion curve of IDP within 48 h was also investigated. The recoveries of the four doping in urine ranged from 90 to 102 percent [10031].

Polar organic chemical integrative samplers (POCIS)

Polar organic chemical integrative samplers (POCIS) were calibrated in situ for selected illicit drugs and their metabolites at a sewage treatment works. Eleven out of 13 target compounds were detected and eight of those exhibited linear uptake kinetics with sampling rates between 0.035 and 0.150 L/d. Subsequently POCIS were deployed for 2 week periods over the course of a whole year, in order to examine trends in drug usage. Amphetamine and methamphetamine showed several similar peaks in concentration during the course of the year as did cocaine and two of its metabolites. Low levels of ecstasy were observed, with a
prominent peak in May and a steady increase toward the end of the year. The antihistamine Cetirizine showed a clear increase in use during the summer months as expected and back calculation of the yearly dosage from POCIS accumulations yielded very similar results to that registered in the Norwegian prescription database. Estimations of cocaine usage using the parent compound averaged between 0.31 and 2.8 g/d per 1000 inhabitants. POCIS is a cost-effective technique for the long-term monitoring of drug usage of a defined population and may overcome the difficulties of representative sampling associated with autosampling equipment [11431].

AICAR

Recently, a new class of prohibited substances reached in the focus of doping control laboratories and their misuse was classified as gene doping. The adenosine monophosphate activated protein kinase activator 5-amino-4-imidazolecarboxamide ribonucleoside (AICAR) was found to significantly enhance the endurance even in sedentary mice after treatment. Due to endogenous production of AICAR in healthy humans, considerable amounts were present in the circulation and, thus, were excreted into urine. Considering these facts, one study was initiated to fix reference values of renally cleared AICAR in elite athletes. Therefore a quantitative analytical method by means of isotope-dilution liquid chromatography (analytical column: C$_6$-phenyl) coupled to tandem mass spectrometry, after a sample preparation consisting of a gentle dilution of native urine, was developed. Doping control samples of 499 athletes were analysed, and AICAR concentrations in urine were determined. The mean AICAR value for all samples was 2,186 ng/mL with a standard deviation of 1,655 ng/mL. Concentrations were found to differ depending on gender, type of sport and type of sample collection (in competition/out of competition). The method was fully validated for quantitative purposes considering the parameters linearity, inter- (12 %, 7 % and 10 %) and intraday precision (14 %, 9 % and 12 %) at low, mid and high concentration, robustness, accuracy (approximately 100 %), limit of quantification (100 ng/mL), stability and ion suppression effects, employing an in-house synthesised $^{13}$C$_5$-labelled AICAR as internal standard [10032].

Microwave assisted extraction

It was described a fast and efficient method for the liquid/liquid extraction from human urine of different classes of drugs, included in the list of prohibited substances published every year by the World Anti-doping Agency, using microwave irradiation. Liquid/liquid extraction was conducted in a temperature controlled single beam microwave oven equipped with an extraction unit and closed vessels. The effects of microwave power and time on the liquid/liquid extraction process were investigated utilizing different organic solvents. The optimum power was found to be 600 W (generating a temperature of 70 degrees C) with an incubation time of 30-60 s for the most thermolable constituents such as triamcinolone, prednisolone, chlorthiazide, chlorthalidone, epi-trembolone and oxandrolone, and 1020 W (generating a temperature of 150 degrees C) with an incubation time of 30-60 s for the other compounds considered in this study. The effectiveness of this approach was evaluated by GC-MS (anabolic steroids, beta$_2$-agonists and narcotics) and by LC-MS/MS (diuretics, glucocorticoids and beta-blockers) analyzing more than 20 different urine samples spiked with the compounds considered in this study. The results showed that the effect of microwave irradiation on the liquid/liquid extraction process was very remarkable: the total sample preparation time can be shortened by 9 min compared to the traditional method (30-60 s instead of 10 min); furthermore, a significant increase in the recovery was recorded for
specific compounds such as terbutaline and several diuretics. In addition to the above the repeatability of the extraction recoveries, the limits of detection and the matrix interferences were comparable with the reference methods, presently accredited under the ISO17025, followed by the World Anti-doping Agency accredited anti-doping laboratory of Rome [10030].

In one contribution it was tested the possibility to use microwave irradiation for the screening and confirmation pre-treatment steps of hydroxyethylstarch, with the aim to speed up gas chromatography-mass spectrometric procedures. Acid hydrolysis and derivatization processes were conducted in a temperature-controlled single beam microwave oven for organic synthesis. The kinetics of hydroxyethylstarch chemical hydrolysis and derivatization were investigated at different microwave power, incubation temperature and incubation time. The best hydrolysis conditions were found at a microwave power value of 1200W (T 100°C) with an incubation time of 2 min; whereas the best derivatization conditions were found at a microwave power value of 1020W (T 100°C) with an incubation time of 5 min. The effectiveness of this approach was evaluated by gas chromatography-mass spectrometry analyzing more than 20 different pools of blank urine samples spiked with hydroxyethylstarch at a concentration of 1mg/mL. The results showed that the effect of microwave irradiation on the chemical hydrolysis process was very remarkable: the total sample preparation time can be shortened by 58 min compared to the reference method (2 min instead of 60 min). In addition to this, the time necessary for the derivatization process can also be drastically shortened with respect to the reference procedure (5 min instead of 30 min). The repeatability of the hydrolysis and derivatization recoveries, the limit of detection and the matrix interferences were comparable to the reference method accredited under the ISO 17025 guidelines and presently followed by the accredited sports anti-doping laboratory of Rome [10321].

Ultrasound and microwave

A comparison between ultrasonication and microwave irradiation as tools to achieve a rapid sample treatment for the analysis of banned doping substances in human urine by means of gas chromatography-mass spectrometry (GC-MS) was performed. The following variables were studied and optimised: time of treatment, temperature, microwave power and ultrasonic amplitude. The results were evaluated and compared with those achieved by the routine method used in the World Anti-Doping Agency (WADA) accredited Antidoping Laboratory of Rome. Only under the effect of the ultrasonic field was it possible to enhance the enzymatic hydrolysis reaction rate of conjugated compounds. Similar reaction yield to the routine method was achieved after 10 min for most compounds. Under microwave irradiation, denaturation of the enzyme occurs for high microwave power. The use of both ultrasonic or microwave energy to improve the reaction rate of the derivatisation of the target compounds with trimethylidosilane/methyl-N-trimethylsilyl trifluoroacetamide (TMSI/MSTFA/NH(4)I/2-mercaptoethanol) was also evaluated. To test the use of the two systems in the acceleration of the reaction with TMSI, a pool of 55 banned substances and/or their metabolites were used. After 3 min of ultrasonication, 34 of the 55 compounds had recoveries similar to those obtained with the classic procedure that lasts for 30 min, 18 increased to higher silylation yields, and for the compounds 13beta,17alpha-diethyl-3alpha,17beta-dihydroxy-5alpha-3alpha,17beta,21-triol (norethandrolone metabolite 1), metoprolol and metipranolol the same results were obtained increasing the ultrasonication time to 5 min. Similar results were obtained after 3 min of microwave irradiation at 1,200 W. In this case, 30 of the 55 compounds had recoveries similar to the classic procedure whilst 18 had higher silylation yields. For the compounds 3alpha-hydroxy-1alpha-methyl-5alpha-androstan-17-one (mesterolone metabolite 1), 17alpha-ethyl-5beta-estrane-3alpha,17beta,21-triol (norethandrolone metabolite 1),
epoxandrolone, 4-chloro-6beta,17beta-dihydroxy-17alpha-methyl-1,4-androstadien-3-one (chlormetandienone metabolite 1), carphedon, esmolol and bambuterol the same results were obtained after 5 min under microwave irradiation [11045].

**Liquid/liquid extraction**

It was described a fast and efficient method for the liquid/liquid extraction from human urine of different classes of drugs, included in the list of prohibited substances published every year by the World Anti-doping Agency, using microwave irradiation. Liquid/liquid extraction was conducted in a temperature controlled single beam microwave oven equipped with an extraction unit and closed vessels. The effects of microwave power and time on the liquid/liquid extraction process were investigated utilizing different organic solvents. The optimum power was found to be 600W (generating a temperature of 70 degrees C) with an incubation time of 30-60s for the most thermolable constituents such as triamcinolone, prednisolone, chlorthiazide, chlorthalidone, epi-trembolone and oxandrolone, and 1020W (generating a temperature of 150 degrees C) with an incubation time of 30-60s for the other compounds considered in this study. The effectiveness of this approach was evaluated by GC-MS (anabolic steroids, beta2-agonists and narcotics) and by LC-MS/MS (diuretics, glucocorticoids and beta-blockers) analyzing more than 20 different urine samples spiked with the compounds considered in this study. The results showed that the effect of microwave irradiation on the liquid/liquid extraction process was very remarkable: the total sample preparation time can be shortened by 9min compared to the traditional method (30-60s instead of 10min); furthermore, a significant increase in the recovery was recorded for specific compounds such as terbutaline and several diuretics [10033].

**Two step derivatization**

Two-step derivatization procedures were developed for the enhancement of the positive ESI in LC-MS detection of anabolic androgenic steroids, a class of prohibited substances with limited ionization efficiency in atmospheric pressure interfaces. The developed procedures are based on the esterification of hydroxyl groups of anabolic steroids with picolinic acid, followed by conversion of carbonyl groups to Schiff bases by either Girard's reagent T or 2-hydrazino pyridin. Ionization efficiency for the model derivatized compounds 19-norandrosterone (nandrolone main metabolite) and methasterone was higher by almost two orders of magnitude compared with the respective efficiency of the underivatized compounds. The obtained derivatives provided a significant improvement in the ESI sensitivity, compared with those of underivatized molecules in positive LC-ESI-ion trap-MS full-scan mode [12082].

**Adsorption to metallic plasmonic nanoparticles**

A comparative study of different plasmonic nanoparticles with different morphologies (nanospheres and triangular nanoprisms) and metals (Ag and Au) was done in this work and applied to the ultrasensitive detection of aminoglutethimide (AGI) drug by surface enhanced Raman spectroscopy (SERS) and plasmon resonance. AGI is an aromatase inhibitor used as an antitumoral drug with remarkable pharmacological interest and also in illegal sport doping. The application of very sensitive spectroscopic techniques based on the localization of an electromagnetic field on plasmonic nanoparticles confirms the previous study of the adsorption of drugs onto a metal surface due to the near field character of these techniques.
The adsorption of AGI on the above substrates was investigated at different pH values and surface coverages, and the results were analyzed on the basis of AGI/metal affinity, considering the interaction mechanism, the existence of two binding sites in AGI, and the influence of the interface on the adsorption in terms of surface charge due to the presence of other ions linked to the surface. Finally, a comparative quantitative detection of AGI was performed on both spherical and triangular nanoprisnm nanoparticles, and a limit of detection lower than those reported so far was deduced on the latter nanoparticles [12083].

Surface plasmon resonance

Within this communication, consistent evidence of a quantitative biosensing principle for steroidal residue analysis is presented. One approach uses a simple method for the quantitative determination of an anabolic agent called stanozolol (Sz). Sz (Mw 328) is widely used in sports, horse racing and as a growth promoter in animals for human consumption. Through the use of localised surface plasmons (LSPs), sustained by three-dimensional noble metal nanostructures, we have developed a highly specific, label-less immunosensor for the detection of this small organic molecule to low levels (nM range). A main practical advantage over conventional flat extended film surface plasmon resonance (SPR) systems is the simplicity of the optical configuration, since there is no need for cumbersome total internal reflection illumination, thus making integration easier. In addition, the active area of the LSP-based sensor is smaller, decreasing the minimum detectable number of molecules involved in the binding event. Assay times are short and the set-up is comprised of relatively cheap instrumentation. Detection levels found here are comparable with SPR, even at this early stage of development and with further modifications, we envisage sensing down to pM (10^{-12}) levels [06042].

Doping analysis relies on the determination of prohibited substances that should not be present in the body of an athlete or that should be below a threshold value. In the case of xenobiotics their mere presence is sufficient to establish a doping offence. However, in the case of human biotics the analytical method faces the difficulty of distinguishing between endogenous and exogenous origin. For this purpose ingenious strategies have been implemented, often aided by state-of-the-art technological advancements such as mass spectrometry in all its possible forms. For larger molecules, i.e. protein hormones, the innate structural complexity, the heterogeneous nature, and the extremely low levels in biological fluids have rendered the analytical procedures heavily dependent of immunological approaches. Although approaches these confer specificity and sensitivity to the applications, most rely on the use of two, or even three, antibody incubations with the consequent increment in assay variability. Moreover, the requirement for different antibodies that separately recognise different epitopes in screening and confirmation assays further contributes to differences encountered in either measurement. The development of analytical techniques to measure interactions directly, such as atomic force microscopy, quartz crystal microbalance or surface plasmon resonance, have greatly contributed to the accurate evaluation of molecular interactions in all fields of biology, and expectations are that this will only increase. Here, an overview is provided of surface plasmon resonance, and its particular value in application to the field of doping analysis [11040].

Isotope ratio mass spectrometry

Detecting the misuse of endogenously occurring steroids, i.e. steroids such as testosterone that are produced naturally by humans, is one of the most challenging issues in doping
control analysis. The established thresholds for urinary concentrations or concentration ratios such as the testosterone/epitestosterone quotient are sometimes inconclusive owing to the large biological variation in these parameters. For more than 15 years, doping control laboratories focused on the carbon isotope ratios of endogenous steroids to distinguish between naturally elevated steroid profile parameters and illicit administration of steroids. A variety of different methods has been developed throughout the last decade and the number of different steroids under investigation by isotope ratio mass spectrometry has recently grown considerably. Besides norandrostosterone, boldenone was found to occur endogenously in rare cases and the misuse of corticosteroids or epitestosterone can now be detected with the aid of carbon isotope ratios as well. In addition, steroids excreted as sulfoconjugates were investigated, and the first results regarding hydrogen isotope ratios recently became available. All of these will were presented in detail within the review together with some considerations on validation issues and on identification of parameters influencing steroidal isotope ratios in urine [11041].

ETD and CID tandem mass spectrometry

Identification of an unknown substance without any information remains a daunting challenge despite advances in chemistry and mass spectrometry. However, an unknown cyclic peptide in a sample with very limited volume seized at a Pennsylvania racetrack has been successfully identified. The unknown sample was determined by accurate mass measurements to contain a small unknown peptide as the major component. Collision-induced dissociation (CID) of the unknown peptide revealed the presence of Lys (not Gln, by accurate mass), Phe, and Arg residues, and absence of any y-type product ion. The latter, together with the tryptic digestion results of the unusual deamidation and absence of any tryptic cleavage, suggests a cyclic structure for the peptide. Electron-transfer dissociation (ETD) of the unknown peptide indicated the presence of Gln (not Lys, by the unusual deamidation), Phe, and Arg residues and their connectivity. After all the results were pieced together, a cyclic tetrapeptide, cyclo[Arg-Lys-N(C(6)H(9))Gln-Phe], is proposed for the unknown peptide. Observations of different amino acid residues from CID and ETD experiments for the peptide were interpreted by a fragmentation pathway proposed, as was preferential CID loss of a Lys residue from the peptide. ETD was used for the first time in sequencing of a cyclic peptide; product ions resulting from ETD of the peptide identified were categorized into two types and named pseudo-b and pseudo-z ions that are important for sequencing of cyclic peptides. The ETD product ions were interpreted by fragmentation pathways proposed. Additionally, multi-stage CID mass spectrometry cannot provide complete sequence information for cyclic peptides containing adjacent Arg and Lys residues. The identified cyclic peptide has not been documented in the literature, its pharmacological effects are unknown, but it might be a "designer" drug with athletic performance-enhancing effects [11042].

Protein chips

Sport and doping are a contradiction in terms, however, doping abuse in sports has been a serious problem for many years. The systematic screening of every athlete for all prohibited drugs should be an indispensable feature of the Olympic Games. The gas chromatography mass spectrometry method is reserved as a reference method, but is limited by its low throughput. The advent of protein chip technology may enable the screening of all athletes for any illegal use of drugs [06043].
SIRT1-activating drugs

The NAD(+) depending enzyme SIRT1 regulates the mitochondrial biogenesis, fat and glucose metabolism through catalyzing the deacetylation of several metabolism-related protein-substrates. Recently, synthetic activators of SIRT1 referred to as STACs (Sirtuin activating compounds, e.g. SRT2104) were identified and tested in clinical studies for the treatment of aging-related diseases such as type 2 diabetes, Alzheimer's and obesity. Although the mechanism of SIRT1 activation by small molecules has caused considerable controversy, STACs demonstrated a significant performance enhancement in mice experiments including an improvement of endurance, muscle strength, and locomotor behavior. Due to their potential to increase exercise tolerance in healthy individuals, SIRT1 activators are currently being monitored by anti-doping authorities. In the present study, the in vivo metabolic clearance of three SIRT1 activators was investigated in rats by the collection of urine, DBS (dried blood spots) and plasma samples following a single oral administration. The resulting metabolic products were studied by positive electrospray ionization - (tandem) mass spectrometry and confirmed by the comparison with in vitro generated metabolites using human and rat liver microsomal preparations. Subsequently, a screening procedure for five SIRT1 activators and the metabolite M1-SRT1720 in DBS specimens was developed. Liquid-liquid-extraction and liquid chromatography/tandem mass spectrometry was employed based on diagnostic ion transitions recorded in multiple reaction monitoring mode and two deuterated internal standards namely d8-SRT1720 and d8-M1-SRT1720 were utilized. The doping control assay was characterized with regard to specificity, limit of detection (10-50 ng/mL), recovery (65-83 %) and imprecision (7-20 %) and ion suppression/enhancement effects (<10 %), demonstrating its fitness-for-purpose for sports drug testing applications [13101].

The efficiency of Sirtuin1, a major target for the treatment of various metabolic disorders such as inflammation and type 2 diabetes mellitus, can be modulated via low molecular mass SIRT1 activators (e.g. resveratrol, SRT1720, and SRT2104). The administration of such compounds results in increased deacetylation of substrates including p53, FOXO1, and PGC1alpha, potentially leading to an improved physical performance. Consequently, proactive and preventive anti-doping measures are required and an assay dedicated to serum and plasma was desirable. Model substances of emerging SIRT1 drug candidates were obtained and synthesized and their mass spectrometric behavior following positive or negative electrospray ionization and collision-induced dissociation was elucidated using low and high resolution/high accuracy (tandem) mass spectrometry. Subsequently, a screening and confirmation procedure necessitating 100 microL of plasma was established employing liquid chromatography/tandem mass spectrometry (LC/MS/MS) based on diagnostic ion transitions recorded in multiple reaction monitoring mode. Sample preparation consisted of the addition of two deuterated internal standards (D(8)-SRT1720 and D(4)-resveratrol) to the plasma specimen and subsequent protein precipitation. Characteristic product ions indicative of the core structures of the model analytes were characterized and utilized for the development of a multi-analyte LC/MS/MS detection method applicable to sports drug testing programs. The doping control assay was validated with regard to specificity, limits of detection (0.1-1 ng/mL), recoveries (90-98 %), intraday and interday precisions (2-18%), and ion suppression/enhancement effects. It was concluded that the fragmentation pathways of SRT1720 and 4 SIRT1 activator models based on a common thiazole-imidazole nucleus as well as two different complementary activators (SIRT1 activator 3 and CAY10602), comprising a quinoxaline core, were studied. The resulting information was used to establish and validate a sports drug testing methodology relevant for an efficient and timely anti-doping procedure, targeting a new class of emerging therapeutics possessing significant potential for misuse in elite and amateur sport [13102].
The enzyme SIRT1 is a metabolic key regulator in mitochondrial biogenesis, fat and glucose metabolism. Its activation through pharmaceutical SIRT1 activators such as SRT2104 results in an increased deacetylation of substrates representing important targets for the treatment of metabolic diseases. Moreover, SRT1720 was found to enhance the physical performance of mice. As SIRT1 activators might therefore be relevant in a doping control context, metabolism studies of target substances need be conducted in order to develop a detection assay for SIRT1 activators in urine. In the present study, the in vitro metabolism of five SIRT1 activators was investigated using human liver microsomes. The mass spectrometric behavior of the resulting metabolites following positive electrospray ionization and collision-induced dissociation was elucidated by high-resolution/high-accuracy (tandem) mass spectrometry, and confirmation of the structure of a major metabolite of SRT1720 was accomplished by chemical synthesis. Subsequently, a screening procedure for urine samples was developed employing liquid-liquid-extraction and liquid chromatography/tandem mass spectrometry based on diagnostic ion transitions recorded in multiple reaction monitoring mode and the use of d8-SRT1720 as deuterated internal standard. The method was validated with regard to specificity, sensitivity (limit of detection 0.5 ng/ml), recovery (88-99 %) and imprecision (7-18 %) as well as ion suppression/enhancement effects (<10 %), demonstrating its fitness-for-purpose for sports drug testing applications [13097].

Bioassay-guided fractionation

Biological tests can be used to screen samples for large groups of compounds having a particular effect, but it is often difficult to identify a specific compound when a positive effect is observed. The identification of an unknown compound is a challenge for analytical chemistry in environmental analysis, food analysis, as well as in clinical and forensic toxicology. In this study bioassay-guided fractionation, ultra high performance liquid chromatography combined with time-of-flight mass spectrometry (UHPLC/TOFMS) and accurate mass database searching was tested to detect and identify unknown androgens. Herbal mixtures and sport supplements were tested using an androgen bioassay and modifications in sample preparations were carried out in order to activate inactive pro-androgens, androgen esters and conjugated androgens to enable their detection in the bioassay. Two of the four herbal mixtures tested positive and bioassay-guided fractionation followed by UHPLC/TOFMS of positive fractions resulted in the identification of nortestosterone phenylpropionate, testosterone cyclohexanecarboxylate and methyltestosterone. Three of the four sport supplements reacted toxic in the bioassay or gave inconclusive results and were further investigated using UHPLC/TOFMS in combination with data processing software and an accurate mass database having approximately 40,000 entries. This accurate mass database was derived from the PubChem database on the internet and coupled to the TOFMS software. This resulted in the tentative identification of several androgens, including methylboldenone, testosterone and the androgen esters methyltestosterone propionate or testosterone isobutyrate, testosterone buciclate and methylenetestosterone acetate. The study showed that bioassay-guided fractionation in combination with UHPLC/TOFMS analysis is a useful procedure to detect, isolate and identify unknown androgens in suspected samples. As an alternative, the use of data processing software in combination with an accurate mass database and coupled on-line with the TOFMS instrument software enabled the identification of androgens and androgen esters in the chromatogram even without bioassay-guided fractionation [10038].
In one study, the use of equine liver/lung microsomes and S9 tissue fractions were used to study the metabolism of the androgenic/anabolic steroid stanozolol as an example of the potential of in vitro technologies in sports drug surveillance. In vitro incubates were analysed qualitatively alongside urine samples originating from in vivo stanozolol administrations using LC-MS on a high-resolution accurate mass Thermo Orbitrap Discovery instrument, by LC-MS/MS on an Applied Biosystems Sciex 5500 Q Trap and by GC-MS/MS on an Agilent 7000A. Using high-resolution accurate mass full scan analysis on the Orbitrap, equine liver microsome and S9 in vitro fractions were found to generate all the major phase-1 metabolites observed following in vivo administrations. Additionally, analysis of the liver microsomal incubates using a shallower HPLC gradient combined with various MS/MS functions on the 5500 Q trap allowed the identification of a number of phase 1 metabolites previously unreported in the equine or any other species. Comparison between liver and lung S9 metabolism showed that the liver was the major site of metabolic activity in the equine. Furthermore, using chemical enzyme inhibitors that are known to be selective for particular isoforms in other species suggested that an enzyme related to CYP2C8 may be responsible for the production of 16-hydroxy-stanozolol metabolites in the equine. In summary, the in vitro and in vivo phase 1 metabolism results reported herein compare well and demonstrate the potential of in vitro studies to compliment the existing in vivo paradigm and to benefit animal welfare through a reduction and refinement of animal experimentation [10039].

Mammalian reporter gene bioassays

Anabolic androgenic steroids (AAS) share the activation of the androgen receptor (AR) as common mechanism of action. The mammalian androgen responsive reporter gene assay (AR CALUX bioassay), measuring compounds interacting with the AR can be used for the analysis of AAS without the necessity of knowing their chemical structure beforehand, whereas current chemical-analytical approaches may have difficulty in detecting compounds with unknown structures, such as designer steroids. One study demonstrated that AAS prohibited in sports and potential designer AAS can be detected with this AR reporter gene assay, but that also additional steroid activities of AAS could be found using additional mammalian bioassays for other types of steroid hormones. Mixtures of AAS were found to behave additively in the AR reporter gene assay showing that it is possible to use this method for complex mixtures as are found in doping control samples, including mixtures that are a result of multi drug use. To test if mammalian reporter gene assays could be used for the detection of AAS in urine samples, background steroidal activities were measured. AAS-spiked urine samples, mimicking doping positive samples, showed significantly higher androgenic activities than unspiked samples. GC-MS analysis of endogenous androgens and AR reporter gene assay analysis of urine samples showed how a combined chemical-analytical and bioassay approach can be used to identify samples containing AAS. The results indicate that the AR reporter gene assay, in addition to chemical-analytical methods, can be a valuable tool for the analysis of AAS for doping control purposes [10040].

Transcriptome analysis

Evolving challenges require evolving responses. The use of illicit performance enhancing drugs by athletes permeates the reality and the perception of elite sports. New drugs with ergogenic or masking potential are quickly adopted, driven by a desire to win and the necessity of avoiding detection. To counter this trend, anti-doping authorities are continually refining existing assays and developing new testing strategies. In the post-genome era,
genetic- and molecular-based tests are being evaluated as potential approaches to detect new and sophisticated forms of doping. Transcriptome analysis, in which a tissue's complement of mRNA transcripts is characterized, is one such method. The quantity and composition of a tissue's transcriptome is highly reflective of milieu and metabolic activity. There is much interest in transcriptional profiling in medical diagnostics and, as transcriptional information can be obtained from a variety of easily accessed tissues, similar approaches could be used in doping control. One article briefly reviewed current understanding of the transcriptome, common methods of global analysis of gene expression and non-invasive sample sources. While the focus of the article is on anti-doping, the principles and methodology described could be applied to any research in which non-invasive, yet biologically informative sampling is desired [10041].

Over the course of the past decade, technical progress has enabled scientists to investigate genome-wide RNA expression using microarray platforms. This transcriptomic approach represents a promising tool for the discovery of basic gene expression patterns and for identification of cellular signalling pathways under various conditions. Since doping substances have been shown to influence mRNA expression, it has been suggested that these changes can be detected by screening the blood transcriptome. In one review, it was critically discuss the potential but also the pitfalls of this application as a tool in doping research. Transcriptomic approaches were considered to potentially provide researchers with a unique gene expression signature or with a specific biomarker for various physiological and pathophysiological conditions. Since transcriptomic approaches are considerably prone to biological and technical confounding factors that act on study subjects or samples, very strict guidelines for the use of transcriptomics in human study subjects have been developed. Typical field conditions associated with doping controls limit the feasibility of following these strict guidelines as there are too many variables counteracting a standardized procedure. After almost a decade of research using transcriptomic tools, it still remains a matter of future technological progress to identify the ultimate biomarker using technologies and/or methodologies that are sufficiently robust against typical biological and technical bias and that are valid in a court of law [11564].

**Compound-specific isotope analysis (CSIA)**

Compound-specific isotope analysis (CSIA) by gas chromatography combustion isotope ratio mass spectrometry (GCC-IRMS) is a powerful technique for the sourcing of substances, such as determination of the geographic or chemical origin of drugs and food adulteration, and it is especially invaluable as a confirmatory tool for detection of the use of synthetic steroids in competitive sport. We review here principles and practices for data processing and calibration of GCC-IRMS data with consideration to anti-doping analyses, with a focus on carbon isotopic analysis ($^{13}$C/$^{12}$C). After a brief review of peak definition, the isotopologue signal reduction methods of summation, curve-fitting, and linear regression were described and reviewed. Considerations for the anti-doping analyst are reviewed [12075].

**Dual-color bioluminescent bioreporter**

Bioassays represent promising complementary techniques to conventional analytical approaches used in doping analysis to detect illicit drugs like anabolic-androgenic steroids (AAS). The fact that all AAS share a common mechanism of action via the human androgen receptor (hAR) enables the use of bioassays, relying on the activation of hAR as antidoping screening tools. Previously, it was developed a dual-color bioreporter based on yeast cells
engineered to express hAR and androgen response elements driving the expression of the bioluminescent (BL) reporter protein Photinus pyralis luciferase. A second reporter protein, the red-emitting luciferase PpyRE8, was introduced in the bioreporter as internal viability control. Here, we report the first forensic application of a straightforward, accurate, and cost-effective bioassay, relying on spectral resolution of the two BL signals, in 96-microwell format. The bioreporter responds to dihydrotestosterone as reference androgen in a concentration-dependent manner from 0.08 to 1,000 nM with intra- and inter-assay variation coefficients of 11.4 and 13.1 percent, respectively. It was also demonstrated the suitability of this dual-color bioreporter to assess (anti)-androgenic activity of pure AAS, mixtures of AAS, and other illicit drugs provided by the Scientific Police. Significant anti-androgenic activity was observed in samples labeled as marijuana and hashish, containing delta(9)-tetrahydrocannabinol as major constituent [13100].

Two-dimensional gas chromatography with heart-cutting

The accuracy and precision of gas chromatography combustion isotope ratio mass spectrometry (GC-C-IRMS) measurements are highly dependent on analyte purity. Reliable analysis of urinary steroids for doping control therefore requires extensive and time-consuming sample preparation (i.e. liquid chromatography fraction collection) prior to GC-C-IRMS analysis. The use of two-dimensional GC (GC-GC) with heart-cutting (Deans Switch) as a possible approach to reduce the sample purification required for IRMS analysis is described herein. The system uses a low thermal mass oven (LTM) incorporated into an existing GC-C-IRMS system. GC-GC allowed the use of a cyanopropyl/phenyl column in the first dimension to optimize the separation of underivatized steroids, while a phenyl-methylpolysiloxane column in the second dimension focuses the selectively cut analytes into narrower peaks for more sensitive and reliable MS analysis. In addition, to confirm analyte identity, eluent from the second GC was split, with 20 percent entering a scanning MS, and 80 percent flowing to the IRMS. As a proof concept, the developed method was then used to analyze a single spot urine (5 ml) from an individual receiving T therapy (2 × 50 mg sachets of Testogel®). The T delta value (-27.8 ‰, [T] = 38 ng/ml) was clearly distinct from 11-ketoetiocholanolone (-22.5 ‰) (used as an endogenous reference compound (ERC)), indicating T as being of exogenous origin. The simultaneous analysis by the scanning MS yielded a full scan mass spectrum of the same chromatographic peak, thus confirming the peak to be T [12078].

RNA sequencing

The abuse of anabolic substances in animal husbandry is forbidden within the EU and well controlled by detecting substance residues in different matrices. The application of newly designed drugs or substance cocktails represents big problems. Therefore developing sensitive test methods is important. The analysis of physiological changes caused by the use of anabolic agents on the molecular level, for example, by quantifying gene expression response, is a new approach to develop such screening methods. A novel technology for holistic gene expression analysis is RNA sequencing. In one study, the potential of this high-throughput method for the identification of biomarkers was evaluated. The effect of trenbolone acetate plus estradiol on gene expression in liver from Nguni heifers was analyzed with RNA sequencing. The expression of 40 selected candidate genes was verified via RT-qPCR, whereby 20 of these genes were significantly regulated. To extract the intended information from these regulated genes, biostatistical tools for pattern recognition were applied and resulted in a clear separation of the treatment groups. Those candidate
genes could be verified in boars and in calves treated with anabolic substances. These results show the potential of RNA sequencing to screen for biomarker candidates to detect the abuse of anabolics. The verification of these biomarkers in boars and calves leads to the assumption that gene expression biomarkers are independent of breed or even species and that biomarkers, identified in farm animals could also act as potential biomarker candidates to detect the abuse of anabolic substances in human sports [12079].

Hydrogen isotope ratio of urinary steroids

The hydrogen isotope ratio (HIR) of body water and, therefore, of all endogenously synthesized compounds in humans, is mainly affected by the HIR of ingested drinking water. As a consequence, the entire organism and all of its synthesized substrates will reflect alterations in the isotope ratio of drinking water, which depends on the duration of exposure. To investigate the effect of this change on endogenous urinary steroids relevant to doping-control analysis the hydrogen isotope composition of potable water was suddenly enriched from -50 to 200 ‰ and maintained at this level for two weeks for two individuals. The steroids under investigation were 5beta-pregnane-3alpha,20alpha-diol, 5alpha-androst-16-en-3alpha-ol, 3alpha-hydroxy-5alpha-androstan-17-one (Andro), 3alpha-hydroxy-5beta-androstan-17-one (Etio), 5alpha-androstane-3alpha,17beta-diol, and 5beta-androstane-3alpha,17beta-diol (excreted as glucuronides) and Etio, Andro and 3beta-hydroxyandrost-5-en-17-one (excreted as sulfates). The HIR of body water was estimated by determination of the HIR of total native urine, to trace the induced changes. The hydrogen in steroids is partly derived from the total amount of body water and cholesterol-enrichment could be calculated by use of these data. Although the sum of changes in the isotopic composition of body water was 150 ‰, shifts of approximately 30 ‰ were observed for urinary steroids. Parallel enrichment in their HIR was observed for most of the steroids, and none of the differences between the HIR of individual steroids was elevated beyond recently established thresholds. This finding is important to sports drug testing because it supports the intended use of this novel and complementary methodology even in cases where athletes have drunk water of different HIR, a plausible and, presumably, inevitable scenario while traveling [12080].

Dried blood spots (DBS)

Although not (yet) a frequent doping control specimen, blood samples are advantageous over urine specimens in a doping control context in at least two ways they commonly contain the intact drug rather than metabolites, which represents a workaround when new or entirely unknown (designer) compounds are misused and metabolism studies are not (or not publicly) available, and they provide information on drug concentrations at the time of sampling, which is of utmost importance concerning those drugs prohibited in-competition only. As a consequence, the option to expand doping controls from urine and (less frequently) plasma or serum to whole blood shortly before or after competition was evaluated and assays for the analysis of minimal-invasively collected dried blood spots (DBS) were reported in 2011 and 2012. DBS, created from a volume of 25 ml, were excised from blood collection cards and consecutively extracted into methanol/ tert.-butyl-methyl ether and acetone. After processing the blood spots, the combined targeted qualitative and quantitative analysis was possible and data for non-target substances for retrospective evaluation or homology searches based on conserved and common molecular structures were recorded [12017].

In one study, a new type of mass spectrometer combining a quadrupole mass filter, a higher
collision dissociation (HCD) cell and an Orbitrap detector, was evaluated for the analysis of dried blood spots (DBS) in doping controls. DBS analysis is characterized by the necessity to detect prohibited compounds in sub-nanogram-per-milliliter levels with high identification capacity. After extraction of DBS with an organic solvent and liquid chromatographic separation (using a regular C18-RP-analytical UHPLC-column) of target analytes, mass spectrometry is performed with a high-resolution full scan in positive and negative mode by means of electrospray ionisation. Single-product ion mass spectra are acquired using the data-dependent analysis mode (employing an inclusion list) for previously selected precursors of known prohibited compounds with fixed retention time ranges. Besides, a sensitive screening in a targeted approach, non-targeted analysis for retrospective data evaluation is thus possible. The chosen experimental design enables the determination of various drugs from different classes with one generic sample preparation which is shown for 26 selected model compounds delta-9-tetrahydrocannabinol (THC), tetrahydrocannabinol-9-carboxylic acid (THC-COOH), methylhexanamine, methylphenidate, cocaine, nikethamide, 3,4-methylenedioxyamphetamine, N-methyl-3,4-methylenedioxyamphetamine, strychnine, mesocarb, salbutamol, formoterol, clenbuterol, metandienone, stanozolol, bisoprolol, propranolol, metoprolol, anastrazole, clomiphene, exemestane, dexamethasone, budesonide, selective androgen receptor modulator (SARM) S4 (andarine), SARM S1, hydrochlorothiazide. Generally, only qualitative result interpretation was focussed upon, but for target analytes with deuterium-labelled internal standards (salbutamol, clenbuterol, cocaine, dexamethasone, THC-COOH and THC) quantitative analysis was also possible. Especially the most challenging analytes, THC and its carboxy metabolite, were detected in DBS at relevant concentrations (<0.5 ng/mL) using targeted HCD experiments. The method was validated for the parameters: specificity, linearity (0-20 ng/mL), precision (<25 %), recovery (mean 60 %), limit of detection/quantification, ion suppression, stability and accuracy (80-120 %). Six isotope-labelled analogues used as internal standards facilitate a quantitative result interpretation which is of utmost importance especially for in-competition drug sports testing [12081].

Whole blood sample collection on cellulose paper has a more than 30-year-long tradition, especially in neonatal screening. The sampling is minimally invasive, fast, discreet, and robust against manipulation. The present approach highlights the potential to determine doping agents in dried blood spots (DBS) after extraction and subsequent analysis by liquid chromatography-mass spectrometry (LC-MS). The assay is focused on selected model compounds of which the circulating target concentration is of particular interest. Here, pre- or post-competition testing with DBS allows probing for the conditions (i.e. presence or absence of relevant drugs) in the athlete’s circulation during competition, which complements earlier approaches towards the identification of urinary indicators for the temporal application of substances prohibited in-competition only. Precise (< 20 %), linear, and robust conditions with limits of detection in low ng/ml range were accomplished by means of LC coupled to high resolution/high accuracy mass spectrometry for the selected model compounds benzoylecgonine, cocaine, pseudoephedrine, amphetamine, salbutamol, and JWH-018. Deuterium-labelled internal standards were used to yield reliable quantitative results. In addition, the non-targeted screening approach (positive/negative switching combined with tandem mass spectrometry (MS/MS) experiments) enables the retrospective qualitative data evaluation for a comprehensive selection of known and unknown substances as exemplarily shown by the extraction of 20 target compounds (corticosteroids, aromatase inhibitors, anabolic steroids, beta-blockers, etc.) at 20 ng/mL. The simple and fast nature of the assay allows for an easy implementation into existing procedures and will potentially enhance the effectiveness of testing by reducing costs and effort of pre-analysis workload. The automation of laboratory processes has continuously been improved, and the simplification and acceleration of pre-analytical steps such as sample collection, transfer, and storage are desirable benefits in most medico-analytical arenas. The collection of whole blood samples,
dried on a piece of paper, offers various advantages over conventional venopuncture-based blood sampling concerning time consumption, workload and costs without compromising the required quality. The use of dried blood spots (DBS) was reported as early as the 1960s when this technique was applied to the sample collection for testing for phenylketonuria in newborns by a simple heel prick. In comparison to conventional venous cannula sampling, the collection of a drop of blood (usually 10-30 microL) from a heel, finger, or ear prick is considerably less invasive. This minimizes the risk of infections especially for sensitive patients such as infants on the one hand, and enables the more frequent collection of samples in pharmacokinetic studies with small laboratory animals (mice, rats, etc) on the other hand. The stability of the cellulose-fixed target analytes is generally described to be superior to plasma, serum, or urine storage conditions due to inactivation of enzymatic degradation processes. All assays follow the common strategy to perform a more or less simple extraction, whereby the extraction conditions (organic/aqueous solvent ratio) strongly depend on the chemical properties of the target analytes. In the present study, an assay for selected prohibited threshold substances by means of liquid chromatographic separation coupled to high resolution/high mass accuracy mass spectrometry (LC-MS) is reported. Samples are manually punched from DBS cards, fortified with labelled internal standards, and extracted with an organic solvent prior to the LC-MS measurement. Target substances implemented in the method are cocaine, benzoylecgonine, salbutamol, ephedrine/pseudoephedrine, amphetamine and JWH-018, and validation for qualitative and quantitative purposes has been performed [11565].

A new hyphenated mass spectrometry

Occasionally, doping analysis has been recognized as a competitive challenge between cheating sportsmen and the analytical capabilities of testing laboratories. Both have made immense progress during the last decades, but obviously the athletes have the questionable benefit of frequently being able to switch to new, unknown and untested compounds to enhance their performance. Thus, as analytical counteraction and for effective drug testing, a complementary approach to classical targeted methods is required in order to implement a comprehensive screening procedure for known and unknown xenobiotics. One study provided a new analytical strategy to circumvent the targeted character of classical doping controls without losing the required sensitivity and specificity. Using 50 microL of plasma only, the method potentially identifies illicit drugs in low ng/mL concentrations. Plasma provides the biological fluid with the circulating, unmodified xenobiotics; thus the identification of unknown compounds is facilitated. After a simple protein precipitation, liquid chromatographic separation and subsequent detection by means of high resolution/high accuracy orbitrap mass spectrometry, the procedure enables the determination of numerous compounds from different classes prohibited by the World Anti-Doping Agency (WADA). A new hyphenated mass spectrometry technology was employed without precursor ion selection for higher collision energy dissociation (HCD) fragmentation experiments. Thus the mass spectra contained all the desired information to identify unknown substances retrospectively. The method was validated for 32 selected model compounds for qualitative purposes considering the parameters specificity, selectivity, limit of detection (<0.1-10 ng/mL), precision (9-28 %), robustness, linearity, ion suppression and recovery (80-112 %). In addition to the identification of unknown compounds, the plasma samples were simultaneously screened for known prohibited targets [10042].

mRNA transcripts
MicroRNAs (miRNAs) are small non-coding RNAs that regulate a variety of biological processes. Cell-free miRNAs detected in blood plasma are used as specific and sensitive markers of physiological processes and some diseases. Circulating miRNAs are highly stable in body fluids, for example plasma. Therefore, profiles of circulating miRNAs have been investigated for potential use as novel, non-invasive anti-doping biomarkers. This review describes the biological mechanisms underlying the variation of circulating miRNAs, revealing that they have great potential as a new class of biomarker for detection of doping substances. The latest developments in extraction and profiling technology, and the technical design of experiments useful for anti-doping, are also discussed. Longitudinal measurements of circulating miRNAs in the context of the athlete biological passport are proposed as an efficient strategy for the use of these new markers. It was also emphasized potential challenges for the translation of circulating miRNAs from research into practical anti-doping applications [13105].

Evolving challenges require evolving responses. The use of illicit performance enhancing drugs by athletes permeates the reality and the perception of elite sports. New drugs with ergogenic or masking potential are quickly adopted, driven by a desire to win and the necessity of avoiding detection. To counter this trend, anti-doping authorities are continually refining existing assays and developing new testing strategies. In the post-genome era, genetic- and molecular-based tests are being evaluated as potential approaches to detect new and sophisticated forms of doping. Transcriptome analysis, in which a tissue's complement of mRNA transcripts is characterized, is one such method. The quantity and composition of a tissue's transcriptome is highly reflective of milieu and metabolic activity. There is much interest in transcriptional profiling in medical diagnostics and, as transcriptional information can be obtained from a variety of easily accessed tissues, similar approaches could be used in doping control. One article briefly reviewed current understanding of the transcriptome, common methods of global analysis of gene expression and non-invasive sample sources. While the focus of the article was on anti-doping, the principles and methodology described could be applied to any research in which non-invasive, yet biologically informative sampling is desired [09040].

**Deuterium/hydrogen ratio**

The hydrogen isotope ratio (HIR) of body water and, therefore, of all endogenously synthesized compounds in humans, is mainly affected by the HIR of ingested drinking water. As a consequence, the entire organism and all of its synthesized substrates will reflect alterations in the isotope ratio of drinking water, which depends on the duration of exposure. To investigate the effect of this change on endogenous urinary steroids relevant to doping-control analysis the hydrogen isotope composition of potable water was suddenly enriched from -50 to 200 permille and maintained at this level for two weeks for two individuals. The steroids under investigation were 5beta-pregnane-3alpha,20alpha-diol, 5alpha-androst-16-en-3alpha-ol, 3alpha-hydroxy-5alpha-androstan-17-one (ANDRO), 3alpha-hydroxy-5beta-androstan-17-one (ETIO), 5alpha-androstane-3alpha,17beta-diol, and 5beta-androstane-3alpha,17beta-diol (excreted as glucuronides) and ETIO, ANDRO and 3beta-hydroxyandrost-5-en-17-one (excreted as sulfates). The HIR of body water was estimated by determination of the HIR of total native urine, to trace the induced changes. The hydrogen in steroids is partly derived from the total amount of body water and cholesterol-enrichment could be calculated by use of these data. Although the sum of changes in the isotopic composition of body water was 150 permille, shifts of approximately 30 permille were observed for urinary steroids. Parallel enrichment in their HIR was observed for most of the steroids, and none of the differences between the HIR of individual steroids was elevated beyond recently established thresholds. This finding is important to sports drug testing.
because it supports the intended use of this novel and complementary methodology even in cases where athletes have drunk water of different HIR, a plausible and, presumably, inevitable scenario while traveling [13099].

The development and application of a combined gas chromatography/thermal conversion/isotope ratio mass spectrometry (GC/TC/IRMS) method for D/H ratio determination of endogenous urinary steroids are presented. The key element in sample preparation was the consecutive cleanup with high-performance liquid chromatography of initially native and subsequently acetylated steroids. This strategy enabled sufficient cleanup of all target analytes for determination of their respective D/H values. Ten steroids (11beta-hydroxyandrostosterone, 5alpha-androst-16-en-3alpha-ol, pregnanediol, androsterone, etiocholanolone, testosterone, epitesto-sterone, 5alpha-androstan-3alpha,17beta-diol, 5beta-androstan-3alpha,17beta-diol and dehydroepiandrosterone) were measured from a single urine specimen. Depending on the biological background, the determination limit for all steroids ranged from 10 to 15 ng/mL for a 20 mL specimen. The method was validated by application of linear mixing models on each steroid and covered repeatability and reproducibility. The specificity of the procedure was ensured by gas chromatography/mass spectrometry (GC/MS) analysis of the sample using equivalent chromatographic conditions to those employed in the GC/TC/IRMS measurement. Within the sample preparation, no isotopic fractionation was observed, and no amount-dependent shift of the D/H ratios during the measurement was noticed. Possible memory effects occurring during IRMS measurements were corrected by applying a simple rule of proportion. In order to determine the naturally occurring D/H ratios of all implemented steroids, a population of 18 male subjects was analyzed. Relevant mean delta values among selected steroids were calculated which allowed us to study the metabolic pathways and production sites of all the implemented steroids with additional consideration of the corresponding $^{13}$C/$^{12}$C ratios [09041].

Quantitative structure-retention relationships

Quantitative structure-retention relationship (QSRR) is a technique capable of improving the identification of analytes by predicting their retention time on a liquid chromatography column (LC) and/or their properties. This approach is particularly useful when LC is coupled with a high-resolution mass spectrometry (HRMS) platform. The main aim of the present study was to develop and describe appropriate QSRR models that provide usable predictive capability, allowing false positive identification to be removed during the interpretation of metabolomics data, while additionally increasing confidence of experimental results in doping control area. For this purpose, a dataset consisting of 146 drugs, metabolites and banned compounds from World Anti-Doping Agency (WADA) lists, was used. A QSRR study was carried out separately on high quality retention data determined by reversed-phase (RP-LC-HRMS) and hydrophilic interaction chromatography (HILIC-LC-HRMS) systems, employing a single protocol for each system. Multiple linear regression (MLR) was applied to construct the linear QSRR models based on a variety of theoretical molecular descriptors. The regression equations included a set of three descriptors for each model: ALogP, BELe6, R2p and ALogP(2), FDI, BLTA96, were used in the analysis of reversed-phase and HILIC column models, respectively. Statistically significant QSRR models indicate a strong correlation between retention time and the molecular descriptors. An evaluation of the best correlation models, performed by validation of each model using three tests (leave-one-out, leave-many-out, external tests), demonstrated the reliability of the models. One paper provided a practical and effective method for analytical chemists working with LC/HRMS platforms to improve predictive confidence of studies that seek to identify small molecules [13089].
Solid phase extraction (SPE) procedure

The development of a generic analytical method remains difficult when a high number of compounds has to be simultaneously considered. One study proposed an innovative strategy for the development of a solid phase extraction (SPE) procedure before liquid chromatography-mass spectrometry analysis of 34 diuretics and beta-blockers in urine samples. These compounds have been selected since they are often encountered in antidoping control. The principle is based on the selection of representative analytes during SPE protocol optimization, allowing a drastic reduction of generated data and development time. To select the representative compounds, all substances were classified based on their SPE behavior with a generic method and groups were formed with the help of a chemometric tool, namely hierarchical cluster analysis (HCA). One representative analyte per group was selected and used for subsequent SPE method development. Once the SPE method was developed, compounds were analyzed by LC-MS and matrix effects were evaluated to determine the influence of the matrix on the SPE process and MS signal alteration due to endogenous compounds. As a result, matrix effects evaluation must be performed on all analytes; representative compounds previously selected for SPE development were unable to predict matrix effects [09042].

17beta-19-nortestosterone (17beta-NT) has been illegally used in antifatigue functional foods to promote muscle growth and improve endurance. A rapid and sensitive solid-phase extraction-enzyme-linked immunosorbent assay (SPE-ELISA) method was developed and successfully applied to analyze the levels of 17beta-NT in antifatigue functional foods. A polyclonal antibody against 17beta-NT was produced from rabbits immunized with the 17beta-NT-BSA conjugate, and a competitive direct enzyme-linked immunosorbent assay was developed for the rapid detection of 17beta-NT. The concentration causing 50 percent inhibition (IC50) and the limit of detection (LOD) were found to be 0.08 and 0.0055 ng/mL, respectively; this was better than methods previously reported that had a LOD of 2.4 ng/mL. 18C cartridges were investigated for use in removing the effects of matrix in foods, and the sample purification protocol was optimized. Using the developed SPE-ELISA method, recoveries of functional food samples were obtained in the range of 71 percent to 92 percent. Moreover, two kinds of antifatigue functional foods were analyzed using the established ELISA and HPLC methods. The correlation coefficient of the results obtained using the 2 methods was greater than 0.98. Thus, the preliminary evaluation of the SPE-ELISA method proved that it is a specific, sensitive, and precise tool that can be used for the practical detection of 17beta-NT in various antifatigue functional food samples [09043].

Solid-phase microextraction

A fully automated, high-throughput method based on thin-film solid-phase microextraction (SPME) and liquid chromatography-mass spectrometry was developed for simultaneous quantitative analysis of 110 doping compounds, selected from ten classes and varying in physical and chemical properties. Among four tested extraction phases, C18 blades were chosen, as they provided optimum recoveries and the lowest carryover effect. The SPME method was optimized in terms of extraction pH, ionic strength of the sample, washing solution, extraction and desorption times for analysis of urine samples. Chromatographic separation was obtained in reversed-phase model; for detection, two mass spectrometers were used: triple quadrupole and full scan orbitrap. These combinations allowed for selective analysis of targeted compounds, as well as a retrospective study for known and unknown compounds. The developed method was validated according to the Food and Drug
Administration (FDA) criteria, taking into account Minimum Required Performance Level (MRPL) values required by the World Anti-Doping Agency (WADA). In addition to analysis of free substances, it was also shown that the proposed method is able to extract the glucuronated forms of the compounds. The developed assay offers fast and reliable analysis of various prohibited substances, an attractive alternative to the standard methods that are currently used in anti-doping laboratories [13090].

Yeast analysis

The classical analytical method for detection of anabolic steroid abuse is gas chromatography followed by mass spectrometry (GC/MS). However, even molecules with a chemical structure typical for this class of substances, are sometimes not identified in routine screening by GC/MS when their precise chemical structure is still unknown. A supplementary approach to identify anabolic steroid abuse could be a structure-independent identification of anabolic steroids based on their biological activity. To test the suitability of such a system, it was analyzed the yeast androgen receptor (AR) reporter gene system to identify anabolic steroids in human urine samples. Analysis of different anabolic steroids dissolved in buffer demonstrated that the yeast reporter gene system is able to detect a variety of different anabolic steroids and their metabolites with high specificity, including the so-called "designer steroid" tetrahydrogestrinone. In contrast, other non-androgenic steroids, like glucocorticoids, progestins, mineralocorticoids and estrogens had a low potency to stimulate transactivation. To test whether the system would also allow the detection of androgens in urine, experiments with spiked urine samples were performed. The androgen reporter gene in yeast responds very sensitive to 5alpha-dihydrotesto-sterone (DHT), even at high urine concentrations. To examine whether the test system would also be able to detect anabolic steroids in the urine of anabolic steroid abusers, anonymous urine samples previously characterized by GCMS were analyzed with the reporter gene assay. Even when the concentration of the anabolic metabolites was comparatively low in some positive samples it was possible to identify the majority of positive samples by their biological activity. In conclusion, the results demonstrated that the yeast reporter gene system detects anabolic steroids and corresponding metabolites with high sensitivity even in urine of anabolic steroid abusing athletes. But most importantly, a biological test system does not require knowledge of the chemical structure of androgenic substances and therefore suitable to detect previously unidentified substances, especially those of the class of so-called designer steroids [08189].

Yeast transactivation system

Anabolic-androgenic steroids are frequently misused compounds in sports, and they belong to the controlled substances according to the requirements of the World Anti-Doping Agency. The classical techniques of steroid detection are mass spectrometry coupled to gas or liquid chromatography. Biological methods that base on the ability of substances to bind the steroid receptor are not applied in routine doping control procedures so far, but they appear to be useful for characterization of steroid androgenic potential. In this study we used the yeast androgen receptor reporter system (YAS), which in the past has already successfully been applied to both various androgenic substances and also urine samples. Giving attention to the androgenic potential of steroidal dietary supplements, we exemplified the analysis using both mass spectrometry techniques and the YAS-based assay on the product "Syntrax Tetrabol" which was a confiscated dietary supplement and marketed as a steroid precursor. Identification, structure and the kinetic behavior of its excreted metabolites were analyzed by NMR, GC-MS and LC-MS/MS. The androgenic potential of the parent compound as well as
its metabolites in urine was evaluated with the help of the YAS. The application of urine samples with a previous deconjugation and the inclusion of urine density values were carried out and led to increased responses on the YAS. Further, the possibility of a complementary application of structure-based instrumental analysis and biological detection of androgenicity with the help of the YAS seems to be desirable and is discussed [12084].

Yeast and mammalian cell-based androgen bioassays

Androgenic steroids marketed online as nutraceuticals are a growing concern in sport doping. The inability of conventional mass spectrometry (MS)-based techniques to detect structurally novel androgens has led to the development of in vitro androgen bioassays to identify such designer androgens by their bioactivity. The objective of this study was to determine the androgenic bioactivity of novel steroidal compounds isolated from nutraceuticals using both yeast and mammalian cell-based androgen bioassays. We developed two new in vitro androgen bioassays by stably transfecting HEK293 and HuH7 cells with the human androgen receptor (hAR) expression plasmid together with a novel reporter gene vector (enhancer/ARE/SEAP). The yeast β-galactosidase androgen bioassay was used for comparison. Our new bioassay featuring the enhancer/ARE/SEAP construct (S) displayed simpler assay format and higher specificity with lower sensitivity compared with the commonly used mouse mammary tumour virus (MMTV)-luciferase. The relative potencies (RP), defined as EC50 of testosterone of steroid, of nutraceutical extracts in the yeast, HEK293-S, and HuH7-S, were 34, 333, and 80,000 for Hemapolin; 208, 250, and 80 for Furazadrol; 0.38, 10, and 106 for Oxyguna; 2.7, 0.28, and 15 for Trena; and 4.5, 0.1, and 0.4 for Formadrol, respectively. The wide discrepancies in rank RP of these compounds was reconciled into a consistent potency ranking when the cells were treated with meclofenamic acid, a nonselective inhibitor of steroid metabolizing enzymes. These findings indicate that steroids extracted from nutraceuticals can be converted in vitro into more or less potent androgens in mammalian but not in yeast cells. It was conclude that the putative androgenic bioactivity of a new compound may depend on the bioassay cellular format and that mammalian cell bioassays may have an added benefit in screening for proandrogens but sacrifice specificity for sensitivity in quantitation [11043].

Laser desorption

New data on sample preparation and matrix selection for the fast screening of androgenic anabolic steroids (AAS) by matrix-assisted laser desorption/ionisation time-of-flight mass spectrometry (MALDI-TOF-MS) was presented. The rapid screening of 15 steroids included in the WADA prohibited list using MALDI was evaluated. Nine organic and two inorganic matrices were assessed in order to determine the best matrix for steroid identification in terms of ionisation yield and interference by characteristic matrix ions. The best results were achieved for the organic matrices 2-(4-hydroxyphenylazo)benzoic acid (HABA) and trans-3-indoleacrylic acid (IAA). Good signals for all the steroids studied were obtained for concentrations as low as 0.010 and 0.050 microg/mL on the MALDI sample plate for the HABA and IAA matrices, respectively. For these two matrices, the sensitivity achieved by MALDI is comparable with the sensitivity achieved by gas chromatography/mass spectrometry (GC/MS), which is the conventional technique used for AAS detection. Furthermore, the accuracy and precision obtained with MALDI are very good, since an internal mass calibration is performed with the matrix ions. For the inorganic matrices, laser fluences higher than those used with organic matrices are required to obtain good MALDI signals. When inorganic matrices were used in combination with glycerol as a dispersing
agent, an important reduction of the background noise was observed. Urine samples spiked with the study compounds were processed by solid-phase extraction (SPE) and the screening was consistently positive [09045].

Non-target metabolomics

The molecular diversity of the human urinary metabolome is very well reflected by the existing databases displaying thousands of metabolites classified in as much as 70 different structural classes. The majority of these metabolites are small molecular weight compounds having molecular weights between 100 and 800 Dalton (Da) and small peptide fragments with very different physico-chemical properties (solubility, polarity, proton affinity, etc). Despite this astonishing chemo-diversity, for quite some time, mainly targeted studies, often restricted to a particular chemical family or to compounds having similar properties have been applied into doping control studies. Moreover, the metabolites and the changes were often regarded in an univariate manner and the correlations between them were often disregarded. Nowadays, the progresses made in analytical fields like sample preparation, chemical analysis and data processing offer a wider view of the metabolome and greatly contribute to our understanding of the biochemical transformations. Among these, two are believed to have played a key role: the introduction of high (Time of Flight mass spectrometry, TOF) and ultra-high resolution techniques (Fourier Transform Ion Cyclotron Resonance mass spectrometry, FT-ICR/MS) and the development of algorithms capable of handling the thousands of signals generated by such analytical platforms. Indeed, techniques such as FT-ICR/MS are becoming more and more available and their advantages can be now fully exploited. Thus, molecular formulae generation based on exact masses and relevant database search are now possible due to the high resolution and accuracy of this type of technique. Of equal importance, the recent advances in the pre-processing, mathematical modeling and the statistical analysis lead to more comprehensive biological interpretation of the metabolomics data. Up to present, this strategy has been applied in a variety of fields, including drug discovery, nutrition, toxicology, clinical trials and more recently chemical submission. It is of particular interest in areas like doping control as new approaches are needed to fight the ongoing development of performance-enhancing methods. It was therefore detected differences in metabolite levels between doped athletes, clean athletes, and volunteers (non athletes). This outcome is obtained by comparing results of measurements from two analytical platforms: UHPLC-QTOF/MS and FT-ICR/MS. Twenty-seven urine samples tested positive for glucocorticoids or beta-2-agonists and twenty samples coming from volunteers and clean athletes were analyzed with the two different mass spectrometry approaches using both positive and negative electrospray ionization modes. Urine is a highly complex matrix containing thousands of metabolites having different chemical properties and a high dynamic range. It was used multivariate analysis techniques to unravel this huge data set. Thus, the several groups created were studied by Principal Components Analysis (PCA) and Partial Least Square regression (PLS-DA and OPLS) in the search of discriminating m/z values. The selected variables were annotated and placed on pathway by using MassTRIX [13107].

FCMIA

There are a range of applications that require the measurement of multiple drugs such as urine analysis, drug determination in water, and screening for drug contamination on surfaces. Some of the procedures used such as enzyme-linked immunosorbent assay (ELISA) are simple but can only determine one drug at a time, and others such as GC-MS or
LC-MS are complex, time-consuming, and expensive. In one study, fluorescence covalent microbead immunosorbent assay (FCMIA) was investigated as a simple method for the measurement of multiple drugs simultaneously in three matrices: diluted urine, water, and on surfaces. Five different drugs of abuse or their metabolites (methamphetamine, caffeine, benzoylecgonine (a metabolite of cocaine), tetrahydrocannabinol (THC), the active ingredient in marijuana, and oxycodone) were studied over the range 0-15 ng/ml. There was no measureable cross-reactivity among the drugs at the concentrations studied. Urine dilutions from 1/50 to 1/2.5 were studied and dilutions less than 1/20 had a significant effect on the methamphetamine assay but limited effects on the benzoylecgonine and oxycodone assays and almost no effect on the THC assay. For assays performed in 1/20 urine dilution, water, and diluted surface sampling buffer, least detectable doses (LDD) were 1 ng/ml or less for the drugs. Surfaces spiked with drugs were sampled with swabs wetted with surface sampling buffer and recoveries were linear over the range 0-100 ng/100 cm² surface loading for all drugs. FCMIA has potential to be used for the measurement of multiple drugs in the matrices studied [10443].

In hair

Alternative matrices are steadily gaining recognition as biological samples for toxicological analyses. Hair presents many advantages over traditional matrices, such as urine and blood, since it provides retrospective information regarding drug exposure, can distinguish between chronic and acute or recent drug use by segmental analysis, is easy to obtain, and has considerable stability for long periods of time. For this reason, it has been employed in a wide variety of contexts, namely to evaluate workplace drug exposure, drug-facilitated sexual assault, pre-natal drug exposure, anti-doping control, pharmacological monitoring and alcohol abuse. In this article, issues concerning hair structure, collection, storage and analysis are reviewed. The mechanisms of drug incorporation into hair are briefly discussed. Analytical techniques for simultaneous drug quantification in hair are addressed. Finally, representative examples of drug quantification using hair are summarized, emphasizing its potentialities and limitations as an alternative biological matrix for toxicological analyses [13108].

The detection of a single drug exposure in hair (doping offence, drug-facilitated crime) is based on the presence of the compound of interest in the segment corresponding to the period of the alleged event. However, in some cases, the drug is detected in consecutive segments. As a consequence, interpretation of the results is a challenge that deserves particular attention. Literature evaluation and data obtained from the 20-year experience in drug testing in hair of the author are used as the basis to establish a theory to validate the concept of single exposure in authentic forensic cases where the drug is detected in 2 or 3 segments. The gained experience recommends to wait for 4-5 weeks after the alleged event and then to collect strands of hair. Assuming normal hair growth rate (1 cm/mo), it is advisable to cut the strand into 3 segments of 2 cm to document eventual exposure. Administration of a single dose would be confirmed by the presence of the drug in the proximal 2 cm segment (root), whereas not detected in the 2 other segments. However, in the daily experience of the author, it was noticed that sometimes (about 1 case from 10 examinations), the drug can be detected in 2 or 3 consecutive segments. Such a disposition was even observed in volunteer experiments in the literature. As it was also described for cocaine in early 1996, there is considerable variability in the area over which incorporated drug can be distributed in the hair shaft and in the rate of axial distribution of drug along the hair shaft. This can explain why a small amount of drug, as compared with the concentration in the proximal segment, can be measured in the second segment, as a result of an irregular
movement. Another explanation for broadening the band of positive hair from a single dose is that drugs and metabolites are incorporated into hair during formation of the hair shaft via diffusion from sweat and other secretions. The presence of confounding interferences in the hair matrix or changes in the hair structure due to cosmetic treatments might mislead the final result of hair analysis. To qualify for a single exposure in hair, the author proposes to consider that the highest drug concentration must be detected in the segment corresponding to the period of the alleged event (calculated with a hair growth rate at 1 cm/mo) and that the measured concentration be at least 3 times higher than those measured in the previous or the following segments. This must only be done using scalp hair after cutting the hair directly close to the scalp [13109].

In recent years hair has become a fundamental biological specimen, alternative to the usual samples blood and urine, for drug testing in the fields of forensic toxicology, clinical toxicology and clinical chemistry. Moreover, hair-testing is now extensively used in workplace testing, as well as, on legal cases, historical research etc. This article reviews methodological and practical issues related to the application of hair as a biological indicator of drug use/abuse or of chronic exposure to environmental toxicants. Hair structure and the mechanisms of drug incorporation into it are commented. The usual preparation and extraction methods as well as the analytical techniques of hair samples are presented and commented on. The outcomes of hair analysis have been reviewed for the following categories: drugs of abuse (opiates, cocaine and related, amphetamines, cannabinoids), benzodiazepines, prescribed drugs, pesticides and organic pollutants, doping agents and other drugs or substances. Finally, the specific purpose of the hair testing is discussed along with the interpretation of hair analysis results regarding the limitations of the applied procedures [06044].

The monitoring of anabolic steroid residues in hair is undoubtedly one of the most efficient strategies to demonstrate the long-term administration of these molecules in meat production animals. A multi-residue sample preparation procedure was developed and validated for 28 steroids. A 100 mg hair sample was grinded into powder and extracted at 50 degrees C with methanol. After acidic hydrolysis and extraction with ethyl acetate, phenolsteroids, such as estrogens, resorcylic acid lactones and stilbens in one hand, are separated from androgens and progestagens in the other hand. Solid phase extractions were performed before applying a specific derivatisation for each compound sub-group. Detection and identification were achieved using gas chromatography-tandem mass spectrometry with acquisition in the selected reaction monitoring mode after electron ionisation. The method was validated according to the 2002/657/EC guideline. Decision limits (CCalpha) for main steroids were in the 0.1-10 microg/kg range [06045].

Given the limitations of self-reports on drug use, testing for drugs of abuse is important for most clinical and forensic toxicological situations, both for assessing the reality of the intoxication and for evaluation of the level of drug impairment. It is generally accepted that chemical testing of biological fluids is the most objective means of diagnosis of drug use. The presence of a drug analyte in a biological specimen can be used to document exposure. The standard in drug testing is the immunoassay screen, followed by the gas chromatographic-mass spectrometric confirmation conducted on a urine sample. In recent years, remarkable advances in sensitive analytical techniques have enabled the analysis of drugs in unconventional biological specimens such as hair. The advantages of this sample over traditional media, like urine and blood, are obvious: collection is noninvasive, relatively easy to perform, and in forensic situations it may be achieved under close supervision of law enforcement officers to prevent adulteration or substitution. The window of drug detection is dramatically extended to weeks, months or even years when testing hair. It seems that the value of alternative specimen analysis for the identification of drug users is steadily gaining
recognition. This can be seen from its growing use in preemployment screening, in forensic sciences, in clinical applications and for doping control. Hair analysis may be a useful adjunct to conventional drug testing in urine. Methods for evading urinalysis do not affect hair analysis. The aim of one review was to document toxicological applications of hair analysis in drug detection [06046].

The abuse of esters of natural androgenic steroids in cattle fattening and sports is hard to control via routine urine testing. The esters are rapidly hydrolysed in vivo into substances which are also endogenously present in urine. In veterinary control strange findings of 17beta-testosterone and 17alpha-testosterone in urine are often ignored because of the lack of statistically sound reference data of naturally occurring levels. An interesting alternative for inconclusive urine analyses in veterinary control can be provided by the analysis of the administered steroids themselves, i.e. the analysis of intact steroid esters in hair. Unfortunately, the analysis of intact steroid esters is complicated not only by the vulnerability of the esters which precludes alkaline hydrolysis of the hair, but also by the wide polarity range of short and long-chain esters yielding very poor recoveries for either the one or the other. In one study, a multi-steroid esters LC/MS/MS screening method is presented for trace analysis of the synthetic intact esters of 17beta-testosterone and the undecylenate ester of 17beta-boldenone in bovine hair. The method, requiring only 200 mg of pulverised hair, features a mild digestion procedure using tris(2-carboxyethyl)phosphine hydrochloride (TCEP) and the use of four deuterium-labelled steroid esters as internal standards covering the wide polarity range of the analytes. In spiked hair samples for most of the analytes the limit of detection and the accuracy using isotope dilution were 2-5 ng/g and 97-105 percent, respectively. The applicability was demonstrated using hair samples from a controlled experiment in which six bovines were injected intramuscularly with two different doses of two commercial mixtures of testosterone esters, and with two different doses of boldenone undecylenate. Depending on the dose all administered testosterone- and boldenone esters were found to be incorporated in bovine hair following a single intramuscular injection, except testosterone propionate which dose might have been too low [06047].

Sensitive, specific, and reproducible methods for the quantitative determination of eight anabolic steroids in guinea pig hair have been developed using LC/MS/MS and GC/MS/MS. Methyltestosterone, stanozolol, methandienone, nandrolone, trenbolone, boldenone, methenolone and DHEA were administered intraperitoneally in guinea pigs. After the first injection, black hair segments were collected on shaved areas of skin. The analysis of these segments revealed the distribution of anabolic steroids in the guinea pig hair. The major components in hair are the parent anabolic steroids. The time courses of the concentrations of the steroids in hair (except methenolone, which does not deposit in hair) demonstrated that the peak concentrations were reached on days 2-4, except stanozolol, which peaked on day 10 after administration. The concentrations in hair appeared to be related to the physicochemical properties of the drug compound and to the dosage. These studies on the distribution of drugs in the hair shaft and on the time course of their concentration changes provide information relevant to the optimal time and method of collecting hair samples. Such studies also provide basic data that will be useful in the application of hair analysis in the control of doping and in the interpretation of results [09044].

Doping control of anabolic substances is normally carried out with urine samples taken from athletes and horses. Investigation of alternative specimens, e.g. hair samples, is restricted to special cases, but can also be worthwhile, in addition to urine analysis. Moreover, hair material is preferred in cases of limited availability or complicated collection of urine samples, e.g. from horses. In this work, possible ways of interpretation of analytical results in hair samples are discussed and illustrated by practical experiences. The results demonstrate the applicability of hair analysis to detect anabolic steroids and also to obtain further information
about previous abuse. Moreover, the process of incorporation of steroids into hairs is described and the consequences on interpretation are discussed, e.g. on the retrospective estimation of the application date. The chosen examples deal with the detection of the anabolic agent testosterone propionate. Hair samples of an application study, as well as a control sample taken from a racing horse, were referred to. Hair material was investigated by a screening procedure including testosterone, nandrolone and several esters (testosterone propionate, phenylpropionate, decanoate, undecanoate, cypionate; nandrolone decanoate, dodecanoate and phenylpropionate; limits of detection (LODs) between 0.1 and 5.0 pg/mg). Confirmation of testosterone propionate (LOD 0.1 pg/mg) was carried out by an optimised sample preparation. Trimethylsilyl (TMS) and tert-butyl dimethylsilyl derivatives were detected by gas chromatography-high-resolution mass spectrometry (GC-HRMS) and gas chromatography-tandem mass spectrometry (GC-MS/MS) [08190].

Beside the traditionally used body-fluids, defining the abuse-material by the use of hair samples is more and more widespread in the forensic toxicological practice. Using the hair allows the retrospective examination of the abuse-material, and due to the sensitive measuring technics, even one-time use can be proven. A further possibility is the segment-analysis which allows investigation of the abuse-history retroactive for months depending on the length of the hair. The quantitative parameters of the abuse can not always be estimated precisely since the details of the build-up in the hair are complicated and are not clear even today. Furthermore, the sampling, sample preparation and the measuring method will all influence the results. One paper reviewed the opiates, cocaine, amphetamine derivatives, cannabinoids, alcohol-consumption markers and the frequently found drugs in the forensic toxicology as determined by using hair samples [10430].

Hair and saliva

Alternative specimens (e.g. hair and saliva) are well established in forensic toxicology and provide significant benefits as noninvasive, inexpensive alternatives to blood with access to improved long-term retrospection. Based on these experiences, the question of potential applications and limitations of alternative specimens in doping control arose. Compounds prohibited at all times (e.g. clenbuterol, beta2 agonists, estrogen-receptor modulators) may be successfully tested and clearly interpreted in alternative specimens. In contrast, prohibition of certain compounds in sport are limited to time ranges (e.g., stimulants are only prohibited in-competition), dosages or administration routes (e.g. systemic uptake of glucocorticosteroids). This cannot be properly differentiated by semiquantitative tests (e.g. hair analyses), but may be distinguished in saliva. Similarly, proof of external administration of endogenous steroids (e.g. testosterone) only seems to be achievable by quantitative analysis of saliva. Moreover, the retrospective monitoring of the relevance of social drugs or upcoming (unapproved) substances represents promising applications of hair tests in doping control [12086].

The influence on drug incorporation of melanin affinity, lipophilicity, and membrane permeability is of paramount importance. Despite their high lipophilicity, some drugs have quite low incorporation rate into hair, suggesting that the higher incorporation rates of basic drugs (cocaine, amphetamines) than neutral (steroids, benzodiazepines, cannabinoids...) or acidic ones are strongly related to the penetrating ability of the drug to break through the membrane based on the pH gradient between blood and the acidic hair matrix. When using hair analysis as a matrix during investigative analysis, e.g. workplace drug testing, doping, driving under the influence, drug-facilitated crime, the question of importance is to know whether the analytical procedure was sensitive enough to identify traces of drugs; this is particularly important when the urine sample(s) of the subject was positive and the hair
sample(s) was negative. It has been accepted in the forensic community that a negative hair result cannot exclude the administration of a particular drug, or one of its precursors and the negative findings should not overrule a positive urine result. Nevertheless, the negative hair findings can, on occasion, cast doubt on the positive urine analysis, resulting in substantial legal debate and various consequences for the subject. The concept of minimal detectable dosage in hair is of interest to document the negative findings, but limited data is currently available in the scientific literature. Such data includes cocaine, codeine, ketamine, some benzodiazepines and some unusual compounds. Until laboratories will have sensitive enough methodologies to detect a single use of drug, care should be taken to compare urine and hair findings [12087].

Finger nails

In an attempt to obtain alternative doping control matrices, the utility of fingernails as a source of keratinaceous samples (comparable to hair) have been evaluated concerning testosterone, testosterone propionate, and stanozolol. Although the study demonstrated the incorporation of steroidal agents at the proximal nail fold and nail bed, the approach failed to provide the required sensitivity and most likely also the viability in an authentic doping control setting [12016].

In sweat

Sweat is an alternative biological matrix useful to detect drugs of abuse intake. It is produced by eccrine and apocrine glands originating in the skin dermis and terminating in secretory canals that flow into the skin surface and hair follicles. Since many years it has been demonstrated that endogenous and exogenous chemicals are secreted in this biological sample hence its collection and analysis could show the past intake of xenobiotics. From the seventies the excretion of drugs of abuse has been investigated in human skin excretion; later in nineties forensic scientists began to experiment some techniques to trap sweat for analyses. Even if the use of skin excretions for drug testing has been restricted mainly by difficulties in sample recovery, the marketing of systems for the sample collection has allowed successful sweat testing for several drugs of abuse. In the recent years sweat testing developed a noninvasive monitoring of drug exposure in various contexts as criminal justice, employment and outpatient clinical settings. This paper provides an overview of literature data about sweat drug testing procedures for various xenobiotics especially cocaine metabolites, opiates, cannabis and amphetamines. Issues related to collection, analysis and interpretation of skin excretions as well as its advantages and disadvantages are discussed. Moreover the chance to apply the technique to some particular situation such as workplace drug testing, drivers, doping or prenatal diagnosis, the comparison between sweat and other non conventional matrices are also reviewed. According to literature data the analysis of sweat may be usefully alternative for verifying drug history and for monitoring compliance [13103].

Sweat is a biofluid with present scant use as clinical sample. One review tried to demonstrate the advantages of sweat over other biofluids such as blood or urine for routine clinical analyses and the potential when related to metabolomics. With this aim, critical discussion of sweat samplers and equipment for analysis of target compounds in this sample is made. Well established routine analyses in sweat as is that to diagnose cystic fibrosis, and the advantages and disadvantages of sweat versus urine or blood for doping control have also been discussed. Methods for analytes such as essential metals and xenometals, ethanol and
electrolytes in sweat in fact constitute target metabolomics approaches or belong to any metabolomics subdiscipline such as metallomics, ionomics or xenometabolomics. The higher development of biomarkers based on genomics or proteomics as omics older than metabolomics is discussed and also the potential role of metabolomics in systems biology taking into account its emergent implementation. Normalization of the volume of sampled sweat constitutes a present unsolved shortcoming that deserves investigation [13104].

Sweat is an alternative biological matrix useful to detect drugs of abuse intake. It is produced by eccrine and apocrine glands originating in the skin dermis and terminating in secretory canals that flow into the skin surface and hair follicles. Since many years it has been demonstrated that endogenous and exogenous chemicals are secreted in this biological sample hence its collection and analysis could show the past intake of xenobiotics. From the seventies the excretion of drugs of abuse has been investigated in human skin excretion; later in nineties forensic scientists began to experiment some techniques to trap sweat for analyses. Moreover the chance to apply the technique to some particular situation such as workplace drug testing, drivers, doping or prenatal diagnosis, the comparison between sweat and other non conventional matrices are also reviewed. According to literature data the analysis of sweat may be usefully alternative for verifying drug history and for monitoring compliance [12085].

The potential role of oral fluid in antidoping testing

Currently, urine and blood are the only matrices authorized for antidoping testing by the World Anti-Doping Agency (WADA). Although the usefulness of urine and blood is proven, issues remain for monitoring some drug classes and for drugs prohibited only in competition. The alternative matrix oral fluid (OF) may offer solutions to some of these issues. OF collection is easy, noninvasive, and sex neutral and is directly observed, limiting potential adulteration, a major problem for urine testing. OF is used to monitor drug intake in workplace, clinical toxicology, criminal justice, and driving under the influence of drugs programs and potentially could complement urine and blood for antidoping testing in sports. Content: This review outlines the present state of knowledge and the advantages and limitations of OF testing for each of the WADA drug classes and the research needed to advance OF testing as a viable alternative for antidoping testing. Summary: Doping agents are either prohibited at all times or prohibited in competition only. Few OF data from controlled drug administration studies are available for substances banned at all times, whereas for some agents prohibited only in competition, sufficient data may be available to suggest appropriate analytes and cutoffs (analytical threshold concentrations) to identify recent drug use. Additional research is needed to characterize the disposition of many banned substances into OF; OF collection methods and doping agent stability in OF also require investigation to allow the accurate interpretation of OF tests for antidoping monitoring [13112].
Virtual screening

Parallel ligand- and structure-based virtual screenings of 269 steroids with anabolic activity evaluated in vivo were performed. The quantitative structure-activity relationship (QSAR) model expressed by selected descriptors as the octanol-water partition coefficient, the molar volume and the quantum mechanical calculated charge values on atoms C1, C2, C5, C9, C10, C14 and C17 of the steroid skeleton, expresses structural features of anabolic steroids (AS) contributing to the transport and steroid-receptor interaction. On the other hand, computational simulations of a candidate ligand binding to a receptor study (a “docking” procedure) predict the association of these AS with the human androgen receptor (AR). Fourteen compounds were identified as lead; the most potent was the 7alpha-methylestr-4-en-3, 17-dione. It was concluded that a good anabolic activity requires hydrogen bonding interactions between both Arg752 and Gln711 residues in the cycles A with O3 atom of the steroid and either Asn705 and Thr877 residues in the cycles D of steroid with O17 atom [13110].

Artificial networks

The computational generation of gradient retention time data for retrospective detection of suspected sports doping species in postanalysis human urine sample data is presented herein. Retention data for a selection of 86 compounds included in the London 2012 Olympic and Paralympic Games drug testing schedule were used to train, verify, and test a range of computational models for this purpose. Spiked urine samples were analyzed using solid phase extraction followed by ultrahigh-pressure gradient liquid chromatography coupled to electrospray ionization high-resolution mass spectrometry. Most analyte retention times varied ≤0.2 min over the relatively short runtime of 10 min. Predicted retention times were within 0.5 min of experimental values for 12 out of 15 blind test compounds (largest error: 0.97 min). Minimizing the variance in predictive ability across replicate networks of identical architecture is presented for the first time along with a quantitative discussion of the contribution of each selected molecular descriptor toward the overall predicted value. The performance of neural computing predictions for isobaric compound retention time is also discussed. One work presented the application of neural networks to the prediction of gradient retention time in archived high-resolution urine analysis sample data for the first time in the field of anti-doping [13111].

Appearance and Performance Enhancing Drug Use Schedule (APEDUS)

Appearance-and-performance enhancing drug (APED) use is a form of drug use that includes use of a wide range of substances such as anabolic-androgenic steroids (AASs) and associated behaviors including intense exercise and dietary control. To date, there are no reliable or valid measures of the core features of APED use. One study described the development and psychometric evaluation of the Appearance and Performance Enhancing Drug Use Schedule (APEDUS) which is a semi-structured interview designed to assess the spectrum of drug use and related features of APED use. Eighty-five current APED using men and women (having used an illicit APED in the past year and planning to use an illicit APED in the future) completed the APEDUS and measures of convergent and divergent validity. Inter-rater agreement, scale reliability, one-week test-retest reliability, convergent and divergent validity, and construct validity were evaluated for each of the APEDUS scales. The
APEDUS is a modular interview with 10 sections designed to assess the core drug and non-drug phenomena associated with APED use. All scales and individual items demonstrated high inter-rater agreement and reliability. Individual scales significantly correlated with convergent measures (DSM-IV diagnoses, aggression, impulsivity, eating disorder pathology) and were uncorrelated with a measure of social desirability. APEDUS subscale scores were also accurate measures of AAS dependence. The APEDUS is a reliable and valid measure of APED phenomena and an accurate measure of the core pathology associated with APED use. Issues with assessing APED use are considered and future research is considered [11567].
DETECTION OF DOPING AGENTS IN ENVIRONMENT, FOOD AND FOOD SUPPLEMENTS

As part of a regional screening to evaluate the risk, for the health of populations, to certain classes of emerging substances, several families of pharmaceuticals and hormones were looked for in waters intended to drinking. Thus, 52 substances were investigated in 71 surface waters and 70 groundwaters. Results indicate that no water was free of pollutants, regardless of its origin (surface or groundwater) and the season of collect. The pharmaceuticals most frequently detected and with the highest concentration levels were salicylic acid, carbamazepine and acetaminophen. Among hormones, testosterone, androstenedione and progesterone were detected in almost all the samples. Globally the groundwaters were less contaminated than surface waters in regards pharmaceuticals frequencies and levels. On the other side, androgens and progestagens were present with comparable frequencies and levels in both compartments. The risk linked to the presence of these substances on human health is discussed [11558].

Analytical strategies

Detection of the abuse of synthetic steroids in food production is nowadays relatively straightforward using modern techniques such as gas or liquid chromatography coupled to mass spectrometry (GC-MS/MS or LC-MS/MS, respectively). However, proving the abuse of “endogenous” (or naturally occurring) steroids is more difficult. Despite these difficulties, significant progress in this area has recently been made and a number of methods are now available. The aim of the current review was to systematically review the available analytical approaches, which include threshold concentrations, qualitative marker metabolites, intact steroid esters, gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS), longitudinal testing and omics biomarker profiling. The advantages/disadvantages of these methods are considered in detail, but the choice of which to adopt is dictated by a number of practical, political, and economic factors, which vary in different parts of the world. These include the steroid/species combination requiring analysis, the matrix tested, whether samples are collected from live or slaughtered animals, available analytical instrumentation, sample throughput/cost, and the relevant legal/regulatory frameworks. Furthermore, these approaches could be combined in a range of different parallel and/or sequential screening/confirmatory testing streams, with the final choice being determined by the aforementioned considerations. Despite these advances, more work is required to refine the different techniques and to respond to the ever increasing list of compounds classified as endogenous. At this advanced stage, however, it is now more important than ever for scientists and regulators from across the world to communicate and collaborate in order to harmonize and streamline research efforts [12355].

Metabolomics

Metabolomics is a science of interest in food analysis to describe and predict properties of food products and processes. It includes the development of analytical methods with the ultimate goal being the identification of so-called 'quality markers', (i.e. sets of metabolites that correlate with, for example, quality, safety, taste, or fragrance of foodstuffs). In turn, these metabolites are influenced by factors as genetic differences of the raw food ingredients (such as animal breed or crop species differences), growth conditions (such as climate, irrigation...
strategy, or feeding) or production conditions (such as temperature, acidity, or pressure). In cases where the routine-based measurement of a food property faces some limitations such as the lack of knowledge regarding the target compounds to monitor, monitoring based on a limited set of crucial biomarkers is a good alternative, which is of great interest for food safety purposes regarding growth promoting practices. Such an approach may be more efficient than using a classic approach based on a limited set of known metabolites of anabolic compounds. In this context, screening strategies allowing detection of the physiological response resulting from anabolic compound administration are promising approaches to detect their misuse. The global metabolomics workflow implemented for such studies is presented and illustrated through various examples of biological matrices profiling (tissue, blood, urine) and for different classes of anabolic compounds (steroids, beta-agonists and somatotropin) [12356].

**Screening for hormone residues in drug residues**

An emerging trend is recognised in hormone and veterinary drug residue analysis from liquid chromatography tandem mass spectrometry (LC/MS/MS) based screening and confirmation towards accurate mass alternatives such as LC coupled with time-of-flight (TOF), Fourier transform ion cyclotron resonance (FTICR) or Fourier transform orbitrap (FT Orbitrap) MS. In this study, mass resolution and accuracy are discussed for LC/MS screening and confirmation of targeted analytes and for the identification of unknowns using the anabolic steroid stanozolol and the designer beta-agonist "Clenbuterol-R" as model substances. It is shown theoretically and experimentally that mass accuracy criteria without proper mass resolution criteria yield false compliant (false negative) results, both in MS screening and MS/MS confirmation of stanozolol. On the other hand, previous medium resolution accurate mass TOFMS/MS data of the designer beta-agonist were fully confirmed by high resolution FT Orbitrap MS(n) experiments. A discussion is initiated through a proposal for additional criteria for the use of accurate mass LC/MS technologies, to be implemented in Commission Decision 2002/657/EC [06041].

**Anabolic steroids**

A method is described for screening and confirmation of synthetic and endogenous steroids in muscle tissue. The method is sensitive, selective, and rapid and the consumption of organic solvents is low, compared to previously published methods. The procedure involves hydrolysis, defattening with heptane and final clean up with SPE using C18 cartridge. After filtration, the analytes are analysed by LC/MS/MS and quantification is performed using deuterated internal standards. Decision limits (CCalpha) varied from 0.02 to 0.33 µg/kg and the detection capabilities (CCbeta) were <0.50 µg/kg. The mean within-laboratory reproducibility ranged 5-22 percent (%RSDm). Endogenous steroids (e.g. testosterone, epistosterone and androstenedione) have been included in the method, to provide an insight into their levels, as the presence of these steroids was detected several times during analysis of imported meat [11046].

For many years anabolic-androgenic steroids (AAS) are by far the most frequently detected pharmacological substances in doping control. In order to improve their performances, professional sportmen are often tempted to take dietary supplements. However, due to the frequent and widespread occurrence of contaminated supplements, the use of such products is not without risk for the athletes involved. In order to minimize the chances of an unattended positive doping test or serious health problems, fast and reliable screening
methods for the detection of anabolic steroids in dietary supplements are needed. A general screening procedure requires the fast and unambiguous detection of a large range of steroids. Gas chromatography-mass spectrometry (GC-MS) has been used intensively in the detection of doping substances for the past 40 years. Over time, many laboratories have delivered spectra to be included in standard reference databases, one of which is maintained by the National Institute of Standards and Technology (NIST) (Gaithersburg, MD, USA). In recent years, however, liquid chromatography coupled to mass spectrometry (LC-MS) has gained popularity. Unfortunately, existing GC-MS libraries are not applicable to LC-MS analysis. In one study, a new mass spectral library of 88 steroids was developed, along with a fast UPLC-MS method. For the construction of this mass spectral library, three different mass spectra were measured for each steroid, with a sample cone voltage of 30, 60 and 100 V, respectively. This method was then successfully tested on contaminated dietary supplements which had previously been tested by means of a targeted LC-MS/MS method. Overall, the library search was shown to identify the same compounds as the MRM method [11047].

The use of steroids as growth-promoting agents in food production is banned under European Union legislation. Detecting the abuse of testosterone, nandrolone, boldenone, oestradiol and progesterone is complicated by the fact that these steroids are known to be endogenous in certain situations. In one study, the concentrations of characteristic metabolites of each of these steroids were quantified in populations of untreated steers and heifers. Steroid concentration population data were then used by a statistical to produce threshold concentrations for screening and confirming the abuse of these steroids in steer and non-pregnant heifer urine. In addition to thresholds based on testing one animal, new methods based on testing multiple animals from a herd allowed threshold concentrations to be significantly reduced and hence false compliances to be minimised. In the majority of cases, the suggested thresholds were found to be capable of confirming the abuse of endogenous steroids in steers and heifers. In the case of estradiol abuse in the female, however, confirmation based on a threshold is not possible and alternative methods such as gas chromatography-combustion-isotope ratio mass spectrometry are required. In addition to the steer and heifer populations, a small number of pregnant animals were also tested, yielding insights into the biosynthetic pathways of some of the steroids [11048].

Recently, the effect of illicit growth promoters (GPs) upon the cattle transcriptome has drawn the increasing attention of the scientific community. In the present study, the pre-transcriptional effects of three different illicit protocols on a set of target genes, including steroidogenic enzymes and three related transcription factors, were estimated in cattle testis. Beef cattle were administered with dexamethasone (DEX) orally (group D1) or intramuscularly in experiment 1 (group DIM). In experiment 2, DEX was orally administered alone (group D2) or with 17beta-estradiol (group DE), and in experiment 3, dehydroepiandrosterone and boldione were orally administered alone (group DHEA and group ADD) or in combination (group DHAD). The GP effects were measured by quantitative real time RT-PCR. The results of our study were significant but not univocal. A GP-dependent effect on target gene mRNA levels was noticed for 3beta-hydroxysteroid dehydrogenase type 1, the cytochrome P450 side chain cleavage, the cytochrome P450 17A1, HSD17beta3, aromatase, the androgen receptor and the mineralocorticoid receptor-like. The results suggest that different GP schedules are likely to affect genes involved in steroid synthesis and regulation in cattle testis. Thus, this tissue might be considered a potential surrogate tissue that warrants further study into its usefulness in the screening of GP abuse [11049].

A sensitive rapid resolution liquid chromatography-tandem mass spectrometry (RRLC-MS/MS) method, combined with solid-phase extraction, ultrasonic extraction and silica gel
cartridge cleanup, was developed for 28 steroids including 4 estrogens (estrone (E1), 17beta-estradiol (E2), 1alpha-ethynyl estradiol (EE2), diethylstilbestrol (DES)), 14 androgens (androsta-1,4-diene-3,17-dione (ADD), 17alpha-trenbolone, 17beta-trenbolone, 4-androstene-3,17-dione, 19-nortestosterone, 17beta-boldenone, 17alpha-boldenone, testosterone (T), epi-androsterone (EADR), methytestosterone (MT), 4-hydroxy-androst-4-ene-17-dione (4-OHA), 5alpha-dihydrotestosterone (5alpha-DHT), androsterone (ADR), stanozolol (S)), 5 progestagens (progesterone (P), ethynyl testosterone (ET), 19-norandrosterone, medroxyprogesterone (MP)), and 5 glucocorticoids (cortisol, cortisone, prednisone, prednisolone, dexamethasone) in surface water, wastewater and sludge samples. The recoveries of surface water, influents, effluents and sludge samples were 91-119 percent (except 5alpha-DHT was 143 %), 44-200 percent, 61-123 percent and 63-138 percent, respectively. The method detection limits for the 28 analytes in surface water, influents, effluents and freeze-dried sludge samples were 0.01-0.24 ng/L, 0.02-1.44 ng/L, 0.01-0.49 ng/L and 0.08-2.06 ng/g, respectively. This method was applied in the determination of the residual stilboidal hormones in two surface water of one river, 12 wastewater and 8 sludge samples from two wastewater treatment plants in Guangdong (China). Ten analytes were detected in surface water samples with concentrations ranging between 0.4 ng/L (17beta-boldenone) and 55 ng/L (5alpha-DHT); twenty analytes in the wastewater samples with concentrations ranging between 0.3 ng/L (progesterone) and 621 ng/L (5alpha-DHT); and 12 analytes in the sludge samples with concentrations ranging between 1.6 ng/g (E1) and 372 ng/g (EADR) [11050].

In the present paper it was reported the LC-MS/MS determination of residues of 12 anabolic steroids in bovine serum, as an expansion of the work protocols for steroids determination in biological matrices. Steroids analyzed included alpha-zearalanol, beta-zearalanol, alpha-trenbolone, beta-trenbolone, methytestosterone, alpha-estradiol, beta-estradiol, ethynylestradiol, alpha-boldenone, beta-boldenone, alpha-nortestosterone, and beta-nortestosterone. Following protein precipitation, serum samples were cleaned up by solid-phase extraction using Oasis HLB and Amino cartridges. Atmospheric pressure chemical ionization (APCI) in both positive and negative ionization modes was used and mass spectrometry detection was carried out in multiple reaction monitoring mode following two or (in most cases) three product ions per precursor ion. The method was validated in accordance with the Commission Decision 2002/657/EC. The decision limit (CCalpha) values obtained, ranged from 0.01 to 0.07 ng/mL and the detection capability (CCbeta) values obtained ranged from 0.02 to 0.12 ng/mL. The recoveries ranged from 70 to 118 percent. The developed method is suitable for routine and confirmatory purposes such as control of illegal use in livestock production [11051].

Anabolic steroids are banned in food producing livestock in Europe. Efficient methods based on mass spectrometry detection have been developed to ensure the control of such veterinary drug residues. Nevertheless, the use of "cocktails" composed of mixtures of low amounts of several substances as well as the synthesis of new compounds of unknown structure prevent efficient prevention. New analytical tools able to detect such abuse are today mandatory. In this context, metabolomics may represent new emerging strategies for investigating the global physiological effects associated to a family of substances and therefore, to suspect the administration of steroids. The purpose of one study was to set up, assess and compare two complementary mass spectrometry-based metabolomic strategies as new tools to screen for steroid abuse in cattle and demonstrate the feasibility of such approaches. The protocols were developed in two European laboratories in charge of residues analysis in the field of food safety. Apart from sample preparation, the global process was different in both laboratories from LC-HRMS fingerprinting to multivariate data analysis through data processing and involved both LC-Orbitrap-XCMS and UPLC-ToF-MS-MetAlign strategies. The reproducibility of both sample preparation and MS measurements
were assessed in order to guarantee that any differences in the acquired fingerprints were not caused by analytical variability but reflect metabolome modifications upon steroids administration. The protocols were then applied to urine samples collected on a large group of animals consisting of 12 control calves and 12 calves administrated with a mixture of 17β-estradiol 3-benzoate and 17β-nandrolone laurate esters according to a protocol reflecting likely illegal practices. The modifications in urine profiles as indicators of steroid administration have been evaluated in this context and proved the suitability of the approach for discriminating anabolic treated animals from control ones. Such an approach may therefore open a new way for the screening of anabolic steroid administration through targeted monitoring of relevant biomarkers highlighted as a result of the metabolomics study [11052].

The presence and metabolism of endogenous steroid hormones in meat-producing animals has been the subject of much research over the past 40 years. While significant data are available, no comprehensive review has yet been performed. Species considered in this review are bovine, porcine, ovine, equine, caprine and cervine, while steroid hormones include the androgenic-anabolic steroids testosterone, nandrolone and boldenone, as well as their precursors and metabolites. Information on endogenous steroid hormone concentrations is primarily useful in two ways: (1) in relation to pathological versus “normal” physiology and (2) in relation to the detection of the illegal abuse of these hormones in residue surveillance programmes. Since the major focus of one review was on the detection of steroids abuse in animal production, the information gathered to date is used to guide future research. A major deficiency in much of the existing published literature is the lack of standardization and formal validation of experimental approach. Key articles are cited that highlight the huge variation in reported steroid concentrations that can result when samples are analysed by different laboratories under different conditions. These deficiencies are in most cases so fundamental that it is difficult to make reliable comparisons between data sets and hence it is currently impossible to recommend definitive detection strategies. Standardization of the experimental approach would need to involve common experimental protocols and collaboratively validated analytical methods. In particular, standardization would need to cover everything from the demographic of the animal population studied, the method of sample collection and storage (especially the need to sample live versus slaughter sampling since the two methods of surveillance have very different requirements, particularly temporally), sample preparation technique (including mode of extraction, hydrolysis and derivatization), the end-point analytical detection technique, validation protocols, and the statistical methods applied to the resulting data. Although efforts are already underway to produce more definitive data and promote communication among the scientific community on this issue, the convening of a formal European Union working party is recommended [09078].

In livestock production, illegal use of natural steroids is hard to prove because metabolites are either unknown or not significantly above highly fluctuating endogenous levels. In one work it was outlined for the first time a metabolomics based strategy for anabolic steroid urine profiling. Urine profiles of controls and bovines treated with the prohormones dehydroepiandrosterone (DHEA) and pregnenolone were analyzed with ultraperformance liquid chromatography in combination with time-of-flight accurate mass spectrometry (UPLC-TOFMS). The obtained full scan urinary profiles were compared using sophisticated preprocessing and alignment software (MetAlign) and multivariate statistics, revealing hundreds of mass signals which were differential between untreated control and prohormone-treated animals. Moreover, statistical testing of the individual accurate mass signals showed that several mass peak loadings could be used as biomarkers for DHEA and pregnenolone abuse. In addition, accurate mass derived elemental composition analysis and verification by standards or Orbitrap mass spectrometry demonstrated that the observed
differential masses are most likely steroid phase I and glucuronide metabolites excreted as a direct result from the DHEA and pregnenolone administration, thus underlining the relevance of the findings from this untargeted metabolomics approach. It is envisaged that this approach can be used as a holistic screening tool for anabolic steroid abuse in bovines and possibly in sports doping as well [09079].

An existing gas chromatography-mass spectrometry-based quantitative screening method for the regulatory analysis of the resorcylic acid lactones zeranol, taleranol, and zearalanone and the stilbene anabolic steroids diethylstilbestrol and dienestrol was extended to include natural precursors of zeranol (zearalenone, alpha-zearalenol, and beta-zearalenol) in veal liver. No changes in sample preparation were required; the instrumental conditions were selected to effect a suitable chromatographic separation and detection of the analytes. Validation experiments were performed to verify the performance and applicability of the extended method for the quantitative screening of the original and additional analytes in veal liver in the concentration range from 0.5 to 2.0 microg/kg. The limits of detection were 0.08-0.19 microg/kg. The limits of quantitation were 0.27-0.64 microg/kg. Recoveries were 29-67 percent. Combined relative measurement uncertainty estimates were 6-21 percent [09080].

The administration of anabolic steroids, for the purposes of growth promotion, to food-producing animals is banned in the EU. Among the compounds covered by this prohibition is ss-nortestosterone (beta-NT). This hormone is known to occur naturally in stallions and boars, and its main bovine metabolite, alpha-nortestosterone (alpha-NT), occurs naturally in pregnant cows and neonatal calves. However, neither compound is believed to occur naturally in male cattle. During 2006, the presence of alpha-NT and, on occasion, beta-NT was confirmed in male cattle (bulls and steers) slaughtered in Northern Ireland on welfare grounds, as a result of acute injury. Subsequent investigations revealed no evidence of abuse at any of the farms involved and revealed that the phenomenon also occurred in three other regions of the EU, in similarly injured animals. A hypothetical link to release of the adrenal steroid, dehydroepiandrosterone (DHEA), in response to the stress of the injury was tested. Following the intravenous administration of DHEA to two normal steers, beta-NT (but not alpha-NT) was confirmed in the urine of one steer. Thus, it may be concluded that both beta-NT and, by implication, alpha-NT can occur naturally in male cattle (or a specific cohort thereof) in contrast to previously accepted scientific knowledge [09081].

A new LC-MS/MS method was developed for the analysis of 29 veterinary drug residues, spanning three different drug classes, in animal tissues. The procedures used to measure the characteristic performance parameters of the method and the results obtained using fortified blank bovine muscle and kidney tissue are described. For a quantitative and confirmatory method, the characteristic performance parameters to be determined are the limits of quantification, trueness, recovery, precision, selectivity, ruggedness, and stability. The characteristic performance parameters defined for the method will be verified during a validation study by an independent experienced analyst to determine whether the method is suitable for use in a regulatory monitoring and control program for residues of the 29 analytes [09082].

The abuse of synthetic esters of natural steroids such as testosterone and estradiol in cattle fattening and sports is hard to detect via routine urine testing. The esters are rapidly hydrolysed in vivo into substances which are also endogenously present in urine. An interesting alternative can be provided by the analysis of the administered synthetic steroids themselves, i.e. the analysis of intact steroid esters in hair by liquid chromatography tandem mass spectrometry (LC/MS/MS). However, retrospective estimation of the application date following a non-compliant finding is hindered by the complexity of the kinetics of the incorporation of steroid esters in hair. In this study, the incorporation of intact steroid esters in
hair following pour-on treatment has been studied and critically compared with results from intramuscular treatment. To this end animals were pour-on treated with a hormone cocktail containing testosterone cypionate, testosterone decanoate and estradiol benzoate in different carriers. The animals were either treated using injection and pour-on application once or three times having 1 week between treatments using injection and pour-on application. Animals were slaughtered from 10-12 weeks after the last treatment. Both hair and blood plasma samples were collected and analysed by LC/MS/MS. From the results, it is concluded that after single treatment the levels of steroid esters in hair drop to CCbeta levels (5-20 microg/kg) after 5-7 weeks. When treatment is repeated two times, the CCbeta levels are reached after 9-11 weeks. Furthermore, in plasma, no steroid esters were detected; not even at the low microgramme per litre level but – in contrast with the pour-on application – after intramuscular injection, significant increase of 17beta-testosterone and 17beta-estradiol were observed. These observations suggest that transport of steroid esters after pour-on application is not only performed by blood but also by alternative fluids in the animal so probably the steroid esters are already hydrolysed and epimerized before entering the blood [09083].

The detection of hormone abuse for growth promotion in food animal production is a global concern. Initial testing for hormones in Canada was directed at the compounds approved for use in beef cattle, melengestrol acetate, trenbolone acetate and zeranol, and the banned compound diethylstilbestrol (DES). No hormonal growth promoters are approved for use in veal production in Canada. However, instances of use of trenbolone and clenbuterol were detected in Canada in the 1990s. During the development of a new analytical method for testosterone and progesterone, there were reports of suspicious injection sites being found in veal calves. Upon implementation of the method, analysis of investigative samples revealed significant residues of testosterone in some injection sites. To prove that the source of these residues was exogenous, a fully validated method for hormone esters was developed to confirm the presence of exogenous hormones in these injection sites. The QUECHERS model was employed in methods development and resulted in a simple, effective extraction technique that consisted of sample pre-homogenization, liquid/liquid partitioning, extract dilution, filtration and use of LC/MS/MS to provide detection selectivity. The result was an adaptable MS/MS confirmation technique that meets the needs of Canadian regulatory authorities to confirm the misuse of injectable testosterone, and potentially other hormones, in food animal production [09084].

**Nandrolone**

17beta-Nandrolone (17beta-NT) is one of the most recurrent forbidden anabolic steroid used in meat producing animals breeding. Because efficient control must both take into account metabolic patterns and associated kinetics of elimination, the metabolism of 17beta-NT in bovines has already been investigated and is well documented, but only focussing on its main metabolites (i.e. 17alpha-nandrolone, 19-noretiocholanolone and 19-norandrostenedione). The goal of one study was to enlarge this panel of 17beta-NT metabolites, especially through the urinary estranediols fraction in order to perform a more global steroid profiling upon 17beta-nortestosterone laureate ester administration in calves. A GC-MS/MS method has been developed to monitor and quantify 5 estranediols isomers including 5alpha-estrane-3beta,17beta-diol (abb), 5beta-estrane-3alpha,17beta-diol (bab), 5alpha-estrane-3beta,17alpha-diol (aba), 5alpha-estrane-3alpha,17beta-diol (aab) and 5beta-estrane-3alpha,17alpha-diol (baa). Their urinary elimination kinetics have been established allowing detection of 4 estranediols up to several days after administration. All animals demonstrated homogeneous patterns of elimination both from a qualitative (metabolite profile) and quantitative point of view (elimination kinetics in urine). 5alpha-Estrane-3beta,17alpha-diol (aba) was found as the major metabolite with concentrations up to 100microg/L [10345].
Trenbolone

Over the last years, extensive research has documented endocrine-disrupting activities for a significant number of substances including, among others, hormones, pharmaceuticals, pesticides and surfactants. Nonetheless, for most endocrine disruptors, toxicological profiles are still incomplete or even lacking. A systematic review has shown that a number of endocrine disruptors with steroid-modulating effects may also exert mutagenic and carcinogenic activities. For trenbolone, an androgenic compound, there is controversy about its genotoxic properties in the literature, apparently with a strong dependence on the choice of the test system. Since fish and other aquatic animals are at risk of exposure to run-offs from cattle feedlots or sewage-discharge sites containing trenbolone, potential consequences to aquatic ecosystems need to be assessed. To this end, the potential genotoxic hazard of trenbolone was tested in vitro in the permanent rainbow trout-liver cell-line RTL-W1, as well as in primary cell cultures derived from zebrafish (Danio rerio) embryos after in vivo exposure. In either test system, a potential genotoxic hazard characterized by biphasic dose-response curves could be documented even at exposure concentrations of 30 microg/L. These results thus confirm the conclusion that the steroid trenbolone may act as a genotoxic substance [11053].

Trenbolone acetate (TbA) is a potent synthetic anabolic steroid that was approved by the FDA as a growth promoter in beef cattle in 1987. Given the endocrine-modulating activity of TbA and its metabolites in all vertebrates, a sensitive and reliable analytical method is needed to detect TbA and related residues in environmental matrices. It was developed a method that incorporates solid phase extraction and liquid chromatography-tandem mass spectrometry (LC-MS/MS) for the simultaneous determination of the three major TbA metabolites (trendione, 17beta-trenbolone, 17alpha-trenbolone) in total suspended particulate matter (TSP) samples. Sample preparation involved pressurized liquid extraction followed by cleanup on solid-phase extraction cartridges. The procedure was optimized to obtain maximum recovery and minimum signal suppression/enhancement from matrix effects. Analytes were separated with a Phenomenex Gemini-NX C18 analytical column (150 mm×2.0 mm, 3 microm particle size) using an aqueous methanol gradient at a flow rate of 0.2 mL/min. Column effluent underwent positive electrospray ionization (ESI). Two or more diagnostic product ions were acquired from analyte specific precursor ions for unambiguous confirmation and quantification. The method detection limit was 3.27-4.87 ng/g of particulate matter (PM). Method accuracy, determined with analyte recoveries, ranged between 68 and 117 percent, and method precision, expressed as relative standard deviation, was below 15 percent at spiked levels of 6.67, 33.3, and 167 ng/g PM. Analysis of TSP samples demonstrated the presence of the target species associated with PM in the vicinity of beef cattle feeding operations [11054].

Molecular mechanisms in skeletal muscle associated with anabolic steroid treatment of cattle are unclear and we aimed to characterize transcriptional changes. Cattle were chronically exposed (68 ± 20 days) to a steroid hormone implant containing 200 mg trenbolone acetate and 20 mg estradiol (Revalor-H). Biopsy samples from 48 cattle (half treated) from longissimus dorsi (LD) muscle under local anesthesia were collected. Gene expression levels were profiled by microarray, covering 16,944 unique bovine genes: 121 genes were differentially expressed (DE) due to the implant (99.99 % posterior probability of not being false positives). Among DE genes, a decrease in expression of a number of fat metabolism-associated genes, likely reflecting the lipid storage activity of intramuscular adipocytes, was observed. The expression of IGF1 and genes related to the extracellular matrix, slow twitch fibers, and cell cycle (including SOX8, a satellite cell marker) was increased in the treated muscle. Unexpectedly, a very large 21- (microarray) to 97 (real time quantitative PCR)-fold
higher expression of the mRNA encoding the neuropeptide hormone oxytocin was observed in treated muscle. We also observed an \( \sim 50 \)-fold higher level of circulating oxytocin in the plasma of treated animals at the time of biopsy. Using a coexpression network strategy OXTR was identified as more likely than IGF1R to be a major mediator of the muscle response to Revalor-H. A re-investigation of in vivo cattle LD muscle samples during early to mid-fetal development identified a \( >128 \)-fold increased expression of OXT, coincident with myofiber differentiation and fusion. It was propose that oxytocin may be involved in mediating the anabolic effects of Revalor-H treatment [11055].

**Methenolone acetate in a veal calf**

The use of anabolic steroids has been banned in the European Union since 1981. In this study, the metabolism of the anabolic steroid methenolone acetate, was investigated in a male veal calf. After daily oral administration of methenolone acetate, three main metabolites were detected in both urine and faeces samples. Among these metabolites, alpha-methenolone was apparently the main one, but 1-methyl-5alpha-androstan-3,17-diol and 3alpha-hydroxy-1-methyl-5alpha-androstan-17-one were also observed. The parent compound was still detectable in faeces. As a consequence, abuse of methenolone acetate as growth promoter can be monitored by analysing urine and faeces samples. A few days after the last treatment, however, no metabolites were observed. Alpha-methenolone was detectable in urine until 5 days after the last treatment, but in faeces no metabolites were detectable after 3 days [06240].

**Sexual behavior of fish after trenbolone**

Endocrine disrupting chemicals (EDCs) are a large group of environmental pollutants that can interfere with the endocrine system function of organisms at very low levels. One compound of great concern is trenbolone, which is widely used as a growth promoter in the cattle industry in many parts of the world. The aim of one study was to test how short-term (21-day) exposure to an environmentally relevant concentration of 17beta-trenbolone (measured concentration 6 ng/L) affects reproductive behaviour and fin morphology in the eastern mosquitofish (Gambusia holbrooki). The mosquitofish is a sexually dimorphic livebearer with males inseminating females using their modified anal fin, the gonopodium, as an intromittent organ. Although the species has a coercive mating system, females are able to exert some control over the success of male mating attempts by selectively associating with, or avoiding, certain males over others. It was found that females exposed to trenbolone approached males less and spent more time swimming away from males than non-exposed (control) females. By contrast, it was found no difference in the behaviour of exposed and non-exposed males. Furthermore, exposure did not affect the anal fin morphology of males or females. This is the first study to demonstrate that exposure to an androgenic EDC can impair female (but not male) behaviour. The study illustrates how anthropogenic contaminants can have sex-specific effects, and highlights the need to examine the behavioural responses of environmental contaminants in both sexes [13077].

**Growth hormone**

Black market products of a pharmaceutical nature and nutritional supplements have received substantial and increasing attention because of potential performance enhancement in elite and non-professional sports. In addition, improved general health is claimed for non-competing individuals. The risks and foreseeable dangers of the uncontrolled use of highly potent and non-approved pharmaceutical compounds in healthy individuals are of
considerable concern. In the present case report, the emerging drug candidate GHRP-2 with verified growth-hormone-releasing properties was identified and quantified in tablets offered as an over-the-counter nutritional supplement. The impact of this orally active peptide on the hGH/IGF-axis has been established for several years and its illicit use in elite sports has been assumed. As a releasing factor for hGH, GHRP-2 belongs to the list of substances prohibited by the World Anti-Doping Agency (WADA). Unfortunately, to date there is no routinely performed assay for the determination of these peptides potentially occurring in biological fluids of competing athletes, but the present data will facilitate the implementation by providing principle analytical information on liquid chromatographic and mass spectrometric behaviour. Qualitative identification of the target analyte after extraction from the tablet matrix was performed by high resolution/high accuracy mass spectrometry after liquid chromatographic separation under consideration of the accurate masses and the ratios of the protonated molecules and their fragment ions derived from their collisionally induced dissociation. Quantitative results were obtained by means of liquid chromatography coupled to a triple quadrupole mass spectrometer and linear regression using an external calibration curve (with GHRP-2 reference compound) adjusted via internal standard (Hexarelin). Hereby, the content of GHRP-2 was determined with approximately 50 microg per tablet [10154].

**Growth promoters given to livestock**

In vitro cell-based bioassays are also used to test for illegal substances such as growth promoters that are given to livestock. These androgens or androgen-like molecules enhance the growth of the animals and are used as a means to increase profit. Naturally occurring steroids such as testosterone or synthetic androgens such as 19-nortestosterone, trenbolone acetate, and medroxyprogesterone are used to illicitly augment growth of animal livestock. In addition, prohormones such as dehydroepiandrosterone (DHEA) are being used, and these are often hard to detect if they have been exogenously administered. GC-MS-based screening of material such as meat extracts, feed or urine may fail to detect these substances because deconjugating steps are required prior to GC-MS analysis and these processing steps can destroy the structures. GC-MS may also fail to detect novel structures or those with unknown metabolic profiles. Bioassays can complement the screening of samples as they are capable of detecting hormonally active compounds in prepared extracts and if the appropriate host cell is used for the bioassay such as hepatocytes then such assays may also detect prohormones. For these reasons, bioassays are ideal for the detection of androgens or proandrogens added to nutritional supplements [13084].

**Beta-agonists in pork**

A method was developed to determine 20 illegal residual beta-agonists in pork tissues, including muscle and liver simultaneously. The samples were hydrolyzed by betaglucuronidase, purified by PCX SPE cartridges, and detected by HPLC coupled with electrospray ionization MS/MS operating in the positive ion mode. Matrix-fortified calibration was performed to compensate for the matrix effect and loss in sample preparation. Decision limit ranged from 0.05 to 0.23 microg/kg in muscle and 0.05 to 0.57 microg/kg in liver. Decision capacity ranged from 0.11 to 0.4 microg/kg in muscle and 0.16 to 0.79 microg/kg in liver. In Food Analysis Performance Assessment Scheme proficiency test 0287, a pig liver test material containing 13 beta-agonists was analyzed using the method developed, and clenbuterol and ractopamine were confirmed as being present. Z-scores for clenbuterol and ractopamine were 0.2 and 0.6, respectively [11056].
Clenbuterol

The misuse of the sympathomimetic and anabolic agent clenbuterol has been frequently reported in professional sport and in the livestock industry. In 2010, a team of athletes returned from competition in China and regular doping control samples were taken within the next two days. All urine samples contained low amounts (pg/ml) of clenbuterol, drawing the attention to a well-known problem: the possibility of an unintended clenbuterol intake with food. A warning that Chinese meat is possibly contaminated with prohibited substances according to international anti-doping regulations was also given by Chinese officials just before the Beijing Olympic Games in 2008. To investigate if clenbuterol can be found in human urine, a study was initiated comprising 28 volunteers collecting urine samples after their return from China. For the quantification of clenbuterol at a low pg/ml level, a very sensitive and specific isotope dilution liquid chromatography-tandem mass spectrometry (LC-MS/MS) assay was developed using liquid/liquid re-extraction for clean-up with a limit of detection and quantification of 1 and 3 pg/ml, respectively. The method was validated demonstrating good precision, accuracy, and mean recovery. Clenbuterol was detectable in 22 (79%) of the analyzed samples, indicating a general food contamination problem despite an official clenbuterol prohibition in China for livestock [12358].

Clenbuterol in muscle

A new pretreatment method, solid-phase extraction combined with dispersive liquid-liquid microextraction (SPE-DLLME), was proposed in first time for the determination of clenbuterol (CLB) in porcine tissue samples. The tissue samples were firstly extracted by SPE, then its eluents were used as dispersant of the followed DLLME for further purification and enrichment of CLB. Various parameters (such as the type of SPE sorbent, the type and volume of elution solvent, the type and volume of extractant and dispersant, etc.) that affected the efficiency of the two steps were optimized. Good linearity of CLB was ranged from 0.19 microg/kg to 192 μg/kg with correlation coefficient (r²) of 0.9995. The limit of detection (LOD) was 0.07 μg/kg (S/N=3) and the recoveries at three spiked levels were ranged from 88 percent to 104 percent with the relative standard deviation (RSD) less than 3.9% (n=3). Under the optimized conditions, the enrichment factor (EF) for CLB could up to 62 folds. The presented method that combined the advantages of SPE and DLLME, had higher selectivity than SPE method and was successfully applied to the determination of CLB in tissue samples [11057].

Clenbuterol in pig retina

The aim of one study was to assess the persistence of clenbuterol residues in retinal tissue of pigs after repeated administration in a growth-promoting dose, using enzyme-linked immunosorbent assay (ELISA) as a screening method for quantitative determination. A growth-promoting dose of clenbuterol (20 μg/kg body mass per day) was administered orally to the experimental group (n=6) for 21 days, whereas control animals (n=3) were left untreated. Clenbuterol-treated pigs were randomly sacrificed (n=3) on days 0 and 45 of treatment discontinuation, and clenbuterol residues were determined in retinal tissue dissected from the eye. ELISA was found to be acceptable for quantitative determination of clenbuterol in retinal samples because previous method validation yielded mean recovery values of 84-97 percent with variation coefficients < 14 percent. The mean (± SD) retinal clenbuterol concentration was 1874 ± 114 ng/g immediately upon clenbuterol withdrawal (day 0) and 73 ± 4 ng/g on the last day post-withdrawal (day 45). Study results pointed to a
very high potential of clenbuterol accumulation in retinal tissue and marked persistence of clenbuterol residues upon anabolic dose administration, suggesting retinal tissue to be a very useful matrix for effective control of residual clenbuterol in food-producing pigs [11058].

**Clenbuterol in milk**

A simple and sensitive analytical method was developed for the simultaneous determination of clenbuterol, chloramphenicol and diethylstilbestrol in bovine milk by isotope dilution ultra performance liquid chromatography tandem mass spectrometry (UPLC-MS/MS). Samples were directly purified through HLB cartridge. The organic phase was dried under nitrogen and residues were redissolved in mobile phase. Samples were analyzed by UPLC-MS/MS on an Acquity UPLC® BEH C(18) column with gradient elution. The samples were quantified using clenbuterol-D(9), chloramphenicol-D(5) and diethylstilbestrol-D(8) as internal standards. The proposed method was validated according to the European Union regulation 2002/657/EC determining specificity, decision limit (CCalpha), detection capability (CCbeta), trueness, precision, linearity and stability. The method is demonstrated to be suitable for the determination of clenbuterol, chloramphenicol and diethylstilbestrol in bovine milk. The total time required for the analysis of one sample was about 50 min [11059].

**Screening of residues in food**

**Egg**

A cheap, reliable and practical high-performance liquid chromatography-tandem mass spectrometric method was developed for the simultaneous determination of seven anabolic steroids in eggs, including trenbolone, boldenone, nandrolone, stanozolol, methandienone, testosterone and methyl testosterone. The analytes were extracted from the egg samples using methanol. The extracts were subjected to the removal of fat by freezing-lipid filtration and then further purified by liquid-liquid extraction using tert-butyl methyl ether. The analytes were separated on a Luna C18 column by a gradient elution program with 0.1% formic acid and acetonitrile. This method was validated over 1.00-100 ng/g for all steroids of interest. The correlation coefficients (r) for each calibration curve are higher than 0.99 within the experimental concentration range. The decision limits of the steroids in eggs ranged from 0.20 to 0.44 ng/g, and the detection capabilities were below 1.03 ng/g. The average recoveries were between 66 and 83 percent in eggs at three spiked levels of 1.00, 1.50 and 2.00 ng/g for each analyte. The between-day and within-day relative standard deviations were in the range of 2-11 percent. High matrix suppression effects were observed for all compounds of interest [12357].

**Bovine**

One paper presents the generation of monoclonal antibodies (mAbs) with high specificity against 19-nortestosterone (NT) through cell fusion procedures, and the development of mAb-based heterologous direct competitive enzyme-linked immunoabsorbent assay (dcELISA) methods to detect NT residue using one of these hybridomas (clone 3B8-E6). Under optimal experimental conditions, this assay exhibited a working range of 0.004 to 19 ng/mL with IC₅₀ and limit of detection values of 0.28 and 0.002 ng/mL, respectively, when it was run in 0.01M phosphate-buffered saline (pH 7.4). Except for minor cross-reactivity with beta-boldenone (6.9 %) and trenbolone (1.2 %), other interference to the assay was negligible. No significant differences were found for IC₅₀ values when the pH of the assay buffer ranged from 6 to 8 and phosphate ion concentration was less than 20 mM. The
dcELISA can tolerate higher concentrations of methanol than other organic solvents tested. When applied to bovine sample, the correlation coefficients of the dcELISA and GC-MS data were 0.9918 in muscle, 0.9834 in liver, and 0.9976 in kidney. Therefore, this assay has the potential to be incorporated into a quantitative monitoring program for the rapid screening of NT residue in food [12359].

Swine

The occurrence and fate of fourteen androgens, four estrogens, five glucocorticoids and five progestagens were investigated by rapid resolution liquid chromatography-tandem mass spectrometry (RRLC-MS/MS) in a typical swine farm with lagoon waste disposal systems, in south China. Nineteen, 22 and 8 of 28 steroids were detected at concentrations ranging from 2.2 ± 0.1 ng/g (androsta-1,4-diene-3,17-dione) to 14,400 ± 394 ng/g (progesterone) in the feces samples, from 6.1 ± 2.3 ng/L (17beta-boldenone) to 10,800 ± 3190 ng/L (norgestrel) in the flush water samples, and from 5.0 ± 0.2 ng/g (progesterone) to 225 ± 79.4 ng/g (5alpha-dihydropregesterone) in the suspended particles, respectively. By comparing the types and concentrations of steroids in different treatment stages of the lagoon systems, it demonstrated that the lagoon systems used in the farm were not effective method to reduce various steroids in wastewater. Among the thirteen synthetic steroids detected in the swine feces and flush water, only seven (methyl testosterone, 17alpha-trenbolone, 17beta-trenbolone, 17alpha-ethynyl estradiol, dexamethasone, medroxyprogesterone, and norgestrel) were regarded as the parent/metabolite compounds of animal exogenous usage. According to the estimated masses of steroids from feces and flush water, the excretion of steroids for sows were mainly from feces, but for piglets or barrows, most excreted steroids were through flush water rather than feces. The total daily excreted masses of androgens, estrogens, glucocorticoids and progestagens in the sow feces were in the range of 91-6310 microg/d, which were up to a thousand fold of those in the feces of other growth stages indicating that the proportion of sow number in the swine farm directly influenced the total excretion mass of steroids. In addition, two natural steroids 4-androstene-3,17-dione and progesterone were worth notice due to their relatively high concentrations per sow excretion, 277 microg/d and 6380 microg/d, respectively, which are approximately equivalent to the daily excretion of 100 persons. Some steroids were also detected in the well water, vegetable field and receiving stream, and may pose potential high risks to some sensitive organisms in the receiving environment [12360].

Fish

A method was developed for the determination of 11 anabolic hormones (boldenone, androstenedione, nandrolone, methandienolone, methyltestosterone, testosterone, testosterone acetate, trenbolone, testosterone propionate, stanozolol, fluoxymesterone) in fish by multi-function impurity adsorption solid-phase extraction-ultrafast liquid chromatography-tandem mass spectrometry. After the sample was extracted by methanol, the extract was cleaned-up quickly by C18 adsorbent, neutral alumina adsorbent and amino-functionalized nano-adsorbent. The separation was performed on a Shim-Pack XR-ODS II column (100 mm x 2.0 mm, 2.2 microm) using the mobile phases of 0.1% (v/v) formic acid in acetonitrile and 0.1% (v/v) formic acid solution in a gradient elution mode. The identification and quantification were achieved by using electrospray ionization in positive ion mode (ESI+) in multiple reaction monitoring (MRM) mode. The matrix-matched external standard calibration curves were used for quantitative determination. The results showed that the calibration curves were in good linearity for the eleven analytes with the correlation coefficients more than 0.999. The limits of detection (LODs, S/N > 3) for the 11 anabolic hormones were from 0.03 microg/kg to 0.4 microg/kg and the limits of quantification (LOQs, S/N > 10) were from 0.1 microg/kg to 1.5 microg/kg. The method is simple, rapid, sensitive,
accurate and suitable for the quantitative determination and confirmation of the 11 anabolic hormones in fish [12361].

**Detection of doping agents in waste water**

The occurrence of 20 human pharmaceutical compounds and metabolites from 10 representative therapeutic classes was analysed from resource and drinking water in two catchment basins located in north-west France. Ninety-eight samples were analysed from 63 stations (surface water and drinking water produced from surface water). Of the 20 human pharmaceutical compounds selected, 16 were quantified in both the surface water and drinking water, with 22 percent of the values above the limit of quantification for surface water and 14 % for drinking water). Psychostimulants, non-steroidal anti-inflammatory drugs, iodinated contrast media and anxiolytic drugs were the main therapeutic classes of human pharmaceutical compounds detected in the surface water and drinking water. The results for surface water were close to results from previous studies in spite of differences in prescription rates of human pharmaceutical compounds in different countries. The removal rate of human pharmaceutical compounds at 11 water treatment units was also determined. Only caffeine proved to be resistant to drinking water treatment processes (with a minimum rate of 5 %). Other human pharmaceutical compounds seemed to be removed more efficiently (average elimination rate of over 50 %) by adsorption onto activated carbon and oxidation/disinfection with ozone or chlorine (not taking account of the disinfection by-products). These results add to the increasing evidence of the occurrence of human pharmaceutical compounds in drinking water that may represent a threat to human beings exposed to a cocktail of human pharmaceutical compounds and related metabolites and by-products in drinking water [11559].

Wastewater analysis can provide estimates of illicit drug consumption in local communities. It was used repeated raw wastewater analysis in urban wastewater treatment plants to estimate loads of cocaine, heroin, methamphetamine, and cannabis consumed daily by the inhabitants of two cities in Northern Italy, Milan and Como, from 2005 to 2009. Daily cocaine loads did not change in Milan from 2005 to 2008 but fell 45 percent in 2009 and there was a similar drop in Como. Heroin also fell from 2008 to 2009 in Milan (66 %) and Como (26 %). However, methamphetamine, which had risen in Milan from 2005 to 2008, rose further in 2009 and cannabis, which was falling from 2005 to March 2009, rose again in September 2009. The results suggest a trend toward a decrease in consumption of costly illicit drug, such as cocaine and heroin. This might be due to a reduction in the number of consumers and/or to a change in their behaviour since there was also an increase in the consumption of less expensive illicit drug. This itself might reflect a drop in consumers' money supply, caused by the economic crisis. Wastewater analysis was useful to estimate illicit drug consumption levels in local communities in real time and promptly identify changes in trends [11560].

A new method was developed for the analysis of natural and synthetic androgenic steroids and their selected metabolites in aquatic environmental matrixes using direct large-volume injection (LVI) high-performance liquid chromatography (HPLC) tandem mass spectrometry (MS/MS). Method accuracy ranged from 87.6 to 108% for analytes with well-matched internal standards. Precision, quantified by relative standard deviation (RSD), was less than 12 percent. Detection limits for the method ranged from 1.2 to 360 ng/L. The method was demonstrated on a series of 1 h composite wastewater influent samples collected over a day with the purpose of assessing temporal profiles of androgen loads in wastewater. Testosterone, androstenedione, boldenone, and nandrolone were detected in the sample
series at concentrations up to 290 ng/L and loads up to 535 mg/h. Boldenone, a synthetic androgen, had a temporal profile that was strongly correlated to testosterone, a natural human androgen, suggesting its source may be endogenous. An analysis of the sample particulate fraction revealed detectable amounts of sorbed testosterone and androstenedione. Androstenedione sorbed to the particulate fraction accounted for an estimated 5 to 7 percent of the total androstenedione mass [11060].

Municipal wastewater has been examined for steroids, beta_{2}-agonists, stimulants, diuretics, and phosphodiesterase type V inhibitors (PDE type V inhibitors), which are "dual-use-drugs" applied either as anabolic, doping, and lifestyle drugs or for treatment of diverse diseases. To identify their origin, fitness centre discharges under suspicion of being point sources and sewage-treatment plant feed and effluents were sampled and concentrations determined. Sensitive and selective methods for determination and quantification based on solid-phase extraction (SPE) followed by high-performance liquid chromatography-high resolution mass and tandem mass spectrometry (HPLC-(HR)MS and HPLC-MS-MS) were developed and established for analysis of these compounds in wastewater and to assess their effect on the environment. The methods developed enabled quantification at trace concentrations (limit of quantification (LOQ): 5 ng/L). Of the steroids and stimulants under investigation, testosterone, methyltestosterone, and boldenone or ephedrine, amphetamine, and MDMA (3,4-methylenedioxy-N-methylamphetamine) were observed at up to 5 microg/L (ephedrine). Of the beta_{2}-agonists salbutamol only, and of the diuretics furosemide and hydrochlorothiazide were confirmed in the extracts. Quite high concentrations of the PDE type V inhibitors sildenafil, tadalafil, and vardenafil and their metabolites were confirmed in fitness centre discharges (sildenafil: 1,945 ng/L) whereas their concentrations in municipal wastewater did not exceed 35 ng/L. The study thus identified anabolic and doping drugs in wastewater for the first time. Results obtained from wastewater treatment plant effluents proved that these "dual-use-drugs", with the exception of hydrochlorothiazide, were mostly eliminated [10342].

A wastewater treatment plant may receive various types of wastewater namely, urban, industrial, agricultural, washout from the streets, wet or dry atmospheric deposition. As such, scientists have detected in wastewaters all major categories of pollutants like persistent organic pollutants (POPs), polycyclic aromatic hydrocarbons (PAHs) and pesticides, but also substances that are widely used as pharmaceuticals and cosmetics, classified as "PPCPs" (pharmaceuticals and personal care products). Finally, the latest categories of compounds to be looked upon in these types of matrices are illicit drugs (drugs of abuse, like cocaine, etc.) and doping substances. This review article summarises major categories of organic microcontaminants that have been detected in wastewaters and studies their fate during the wastewater treatment process. Occurrence of these compounds in the influents and effluents are reported, as well as percents of removal, mass balances and phase distributions [12089].

It was reported a monitoring study analysing wastewater and associated suspended particulate matter (SPM) to determine the concentration of drugs of abuse and metabolites in wastewater influent. The monitoring of SPM is crucial for target analytes because, depending on their physico-chemical properties, they may partition to particulates; thus, analysis of wastewater only will result in under-reporting of the concentration of target analytes in the sample. A daily one week monitoring study was carried out at a WWTP serving one of the largest cities in the Czech Republic; representing the first comprehensive application of the sewage epidemiology approach in the Czech Republic. In total, 60 analytes were targeted in the monitoring programme including stimulants, opioid and morphine derivatives, benzodiazepines, antidepressants, dissociative anaesthetics, drug precursors and their metabolites. Analysis of SPM determined that significant proportions of some compounds
were present on the solids. For example, 21-50 percent of the total concentration of EDDP (2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine) in the sample was determined on SPM and 11-20 percent of methadone. The highest proportion on SPM was determined for fluoxetine in the range 68-80 percent, norfluoxetine 47-62 percent and amitriptyline 22-51 percent. In contrast, some compounds presented very little partitioning to SPM. Less than 5 percent was determined partitioned to SPM over the week period for analytes including cocaine, benzoylecgonine, cocaethylene, amphetamine, methamphetamine, MDMA (3,4-methylenedioxymethamphetamine), codeine, dihydrocodeine, tramadol, nortramadol, oxazepam and ephedrine. Determined concentrations in wastewater influent were subsequently utilised in the sewage epidemiology approach to estimate drug consumption, in the community from which the wastewater was derived. This back-calculcation was updated for the first time to include the concentration of analytes present on SPM. The consumption of methamphetamine and MDMA was determined to be especially high in the studied community in relation to other European countries, while cocaine and methadone consumption was relatively low. This manuscript shows that in order to apply the sewage epidemiology approach, SPM analysis is required for some compounds; whereas for others the partitioning is small and one may regard this as negligible [12090].

Fate and occurrence of fourteen androgens, four estrogens, five glucocorticoids and five progestagens were investigated in three swine farms and three dairy cattle farms with different farming scales and wastes disposal systems in China. Twenty-one, 22, and 12 of total 28 steroids were detected in feces samples with concentrations ranging from below method limit of quantitation (<LOQ for estrone) to 8100 ± 444 ng/g (progesterone), in wastewater samples with concentrations ranging from <LOQ (estrone) to 20,700 ± 1490 ng/L (androsterone), in suspended particles with concentrations ranging from <LOQ (17beta-trenbolone) to 778 ± 82.1 ng/g (5alpha-dihydrotestosterone) in the six farms, respectively. The steroids via swine farms and human sources were mainly originated from wastewater into the receiving environments while those steroids via cattle farms were mainly from cattle feces. The total contributions of steroids to the environment in China are estimated to be 139, 65.8 and 60.7 t/year from swine, dairy cattle and human sources, respectively [12091].

The occurrence and fate of fourteen androgens, four estrogens, five glucocorticoids and five progestagens were investigated in two different types of wastewater treatment plants (Plant A: activated sludge with chlorination, and Plant B: oxidation ditch with UV) of Guangdong province, China. 14, 14, and 10 of 28 target compounds were detected in the influent, effluent and dewatered sludge samples with the concentrations ranging from below 1.2 ± 0.0 ng/L (stanozolol) to 1368 ± 283 ng/L (epi-androsterone), below 1.0 ± 0.0 ng/L (progesterone) to 23.1 ± 1.0 ng/L (5a-dihydrotestosterone), 1.0 ± 0.1 ng/g (estrone) to 460 ± 4.4 ng/g (5alpha-dihydrotestosterone), respectively. The concentrations of total androgens (1554-1778 ng/L in influent, 13.3-47.8 ng/L in effluent, 377-923 ng/g in dewatered sludge) were much higher than those of total estrogens (41.5-60.2 ng/L in influent, 5.6-13.5 ng/L in effluent, 13.9-57.8 ng/g in dewatered sludge), glucocorticoids (171-192 ng/L in influent, 2.2-6.3 ng/L in effluent, N.D.-4.4 ng/g in dewatered sludge), and progestagens (39.6-40.5 ng/L in influent, 6.9-12.1 ng/L in effluent, N.D. in dewatered sludge) in these two WWTPs. According to mass balance analysis, the removal rates of most target steroids in Plant A had exceeded 90 percent, while those in Plant B for nearly half of detected target steroids were lower than 80 percent. It is obvious that the treatment capacity of the activated sludge system (Plant A) is superior to the oxidation ditch (Plant B) in the degradation of steroids in sewage treatment systems. Androgens, estrogens and progestagens were mainly removed by sorption and degradation, while the reduction of glucocorticoids was primarily due to degradation [12362].

Urine from urinals
Analysis of urine samples collected across a city centre, for the detection of novel psychoactive substances (NPS) was done in a cross-sectional study of anonymized urine samples used for the analysis of classical recreational drugs, NPS and metabolites. Pooled urine samples collected from portable stand-alone four-person urinals across a city centre were analysed using full-scan accurate-mass high-resolution liquid chromatography coupled to tandem mass spectrometry. Data were processed against compound databases containing >1700 drug compounds and metabolites. Seven established recreational drugs (3,4-methylenedioxyamphetamine, cocaine, cannabis, ketamine, 3,4-methylenedioxy-\(N\)-methylamphetamine, methamphetamine and amphetamine) and six potential NPS [hordenine (all 12 urinals), cathine (11), methylhexaneamine (9), 4-methylmethylcathinone (6), methiopropamine and metabolites (2) and methoxetamine and metabolites (1)] were detected. Methylhexaneamine, methiopropamine and hordenine are currently uncontrolled in the UK, whereas methoxetamine is currently subject to a Temporary Class Drug Order. Metabolites of the anabolic steroid nandrolone were found in two urinals and trenbolone metabolites and clenbuterol in one urinal. Thus, analysis of pooled urine samples collected anonymously from stand-alone urinals in a large inner city can detect the use of recreational drugs, NPS and anabolic steroids. Metabolite detection indicates actual drug use, metabolism and elimination rather than simply discarded drugs in the urinals. This technique by confirming the actual drug(s) used has the potential to be additive to currently used datasets/key indicators providing more robust information for healthcare authorities, legislative and law enforcement on the drugs actually being used [12092].

A cross-sectional study of anonymized urine samples collected across a city centre was used for the analysis of classical recreational drugs, novel psychoactive substances (NPS) and metabolites. Pooled urine samples collected from portable stand-alone four-person urinals across a city centre were analysed using full-scan accurate-mass high-resolution liquid chromatography coupled to tandem mass spectrometry. Metabolite detection indicates actual drug use, metabolism and elimination rather than simply discarded drugs in the urinals. This technique by confirming the actual drug(s) used has the potential to be additive to currently used datasets/key indicators providing more robust information for healthcare authorities, legislative and law enforcement on the drugs actually being used [12093].

Rests in other parts of nature

Land application of manure may contribute endocrine disrupting compounds (EDCs) such as steroid hormones to the environment. Little attention has been paid to the potential for degradation of steroid hormones by manure-borne bacteria and their degradation kinetics and pathways. In a laboratory study, the potential for biodegradation of testosterone, 17beta-estradiol (E\(_2\)) and progesterone by swine (Sus scrofa) manure-borne bacteria was examined. In addition, the impact of temperature, pH (6, 7, and 7.5), glucose amendments (0, 3, and 22 mmol L\((-1))\), and presence of oxygen on testosterone degradation kinetics was determined.
Testosterone, 17beta-estradiol and progesterone were biodegraded within 25 h of reaction initiation under aerobic conditions. The degradation of testosterone followed pseudo first-order and zero-order reaction kinetics under aerobic and anaerobic conditions, respectively, in tryptic soy broth (TSB) pre-enriched systems. The half-life ($t_{1/2}$) for the degradation of testosterone under anaerobic conditions was six times longer than aerobic conditions. Testosterone degradation was found to significantly increase (-17 %) when incubated at 37 degrees C versus 22 degrees C. The impact of pH ($t_{1/2}$ ranged from 4.4-4.9 h) and glucose amendments ($t_{1/2}$ ranged from 4.6-5.1 h) on the testosterone degradation rate were found to be small. Testosterone was transformed to dehydrotestosterone (DHT) (major degradation product), androstenedione (AD), and androstadienedione (ADD) under aerobic conditions as revealed by liquid chromatography-time-of-flight mass spectrometry (LC/TOF-MS). These results indicate that testosterone is rapidly degraded by manure-borne bacteria under a wide range of environmentally relevant conditions. However, the formed degradation products are still of potential concern due to their endocrine disrupting potential [10343].

**Beef palatability**

The use of anabolic implants has a long-standing place in the cattle feeding industry, due to their positive impact on growth performance and subsequent profitability. However, implants can have adverse effects on carcass quality, shear force, and eating quality depending on the dose and frequency, or what some refer to as the aggressiveness of the implant regimen administered. Within the past decade, a new class of growth promotants, known as beta-adrenergic agonists (beta-AA), has emerged in the beef feeding industry in the United States. Currently, 2 have gained U.S. Food and Drug Administration approval for use in beef finishing diets to improve performance and carcass yields. Much like anabolic implants, these repartitioning agents can have negative effects on Warner-Bratzler shear force (WBSF), but the differences do not necessarily translate directly to consumer responses for palatability and acceptance in some instances, especially when tenderness is managed through proper postmortem aging. As researchers continued to investigate the mechanisms responsible for the impact of beta-AA, inevitably this led to consideration of the interaction between beta-AA and anabolic implants. Early work combining zilpaterol hydrochloride (ZH) with anabolic implants improved performance, carcass yield, and meat yield with additive negative effects on WBSF. Similar results were produced when pairing ZH with anabolic steroids equipped with various release patterns. As with any tool, the key to success is proper management. Certain cattle populations may be better suited to receive growth promotants such as implants and beta-AA, and postmortem management of subprimal cuts becomes vital when producers take more aggressive approaches to improve performance and yield. The objective of one review is to overview research findings related to the impact of growth promotant technologies on beef palatability, focusing specifically on the role of implants and beta-AA on carcass quality, beef tenderness, and consumer responses for meat palatability [13115].

**Laboratory techniques**

*In meat*

Within the scope of the European Community member states' residue monitoring plan, illicit administration of anabolic steroids is monitored at slaughterhouse level as well as on living animals. At farm level, urine is one of the target matrices to detect possible abuse of anabolic steroid growth promoters. Optimisation of the routinely applied analysis method resulted in a
A gas chromatography/mass spectrometry (GC/MS) method was developed for the determination of multi-residues of steroid anabolic hormones epitestosterone (ETS), testosterone 17-propionate (PTS), nandrolone (17beta-NT), 17alpha-methyltestosterone (MTS), 17beta-estradiol (17beta-ES), estriol (EST), 17alpha-ethinylestradiol (EES), estrone (ESN) and 17beta-estradiol 3-benzoate (BES) in the muscle tissues of various animal species. Homogenized tissue samples were enzymatically digested in acetate buffer (pH 5.0). Consequently, methanol was added and the mixtures were extracted under ultrasonication incubation. Clean-up was carried out for at least two times with methyl tert-butyl ether (MTBE) liquid-liquid partitioning followed by a reversed-phase solid phase extraction (SPE) cartridge purification. The eluate with methanol was evaporated to dryness by N2 at 40 degrees C and derivatization was achieved with N-methyl-N-(trimethylsilyl) trifluoroacetamide/iodotrimethylsilane/dithioerythritol (MSTFA-TMIS-DTE) at 60 degrees C for 45 min. The reaction mixture was injected into a gas chromatograph with a DB-1 capillary column coupled with a mass spectrometer. The samples were tested by different selected ion monitoring modes with electron impact (EI) source for the androgens and estrogens. The limits of quantitation (LOQ) for the above 9 hormones were in the range of 1.0 - 2.0 microg/kg. At the 2.0 microg/kg LOQ spiked level, the mean recoveries were within 63-81 percent, and the relative standard deviations were within 13-27 percent. The real sample tests showed this method can be used for the sensitive and accurate determination of multi-steroid anabolic hormones residues in biological muscle samples [06330].

**Proteomics**

The use of beta-agonists, sexual steroids, and corticosteroids as growth-promoting agents (GPAs) in veal calves is forbidden in the European Union (EU) and subjected to restrictions in the US because it may be potentially noxious for both treated animals and the consumer. Although official controls performed in the EU have revealed a limited number of positive samples, the analysis of seized preparations indicate that the use of illegal GPAs is far from being abandoned. The presence of these compounds in matrixes of biological origin often goes unnoticed because of the use of very low dosages and/or of molecules of unknown chemical structure. It is therefore necessary to develop screening methods based on the biological effects of these substances that allow the simultaneous screening of many components, as proteome analysis. When hepatic cytosols and microsomes from calves treated with a combination of GPAs were analyzed by 2-DE, it was found changes in the expression of two proteins, which we identified as adenosine kinase and reticulocalbin. The aim was not to speculate about molecular mechanisms, but to show the ability of the proteomic approach to find biomarkers of illicit treatments and to use it as a basis to develop large-scale screening methods [06331].

**In faeces**

Feces are a possible medium to be used for horse doping control. Efficient methods for detecting drugs in feces collected from various animals are routinely applied in institutes of
food safety in Belgium. It has already tested whether they are applicable to horse feces. In this report, accelerated solvent extraction (ASE), an efficient method for extracting compounds from solid material, has been tested. ASE has been used to replace the diethyl ether liquid-liquid extraction step present in the method initially set up. This technique has been optimized for detecting several non-steroidal anti-inflammatory drugs (NSAIDs) in horse feces. Extraction recovery and limit of detection have been determined for several NSAIDs, such as meclofenamic acid, flunixin, vedaprofen, celecoxib, carprofen, diclofenac, and ketoprofen. The method has been successfully applied to meclofenamic acid, flunixin, and phenylbutazone post-administration feces samples, and the main metabolites identified in urine were also detected in feces. In the case of meclofenamic acid, the detection profile in feces presented in this report is in accordance with our previous finding in feces obtained with the original method. The use of ASE decreases the time necessary for sample preparation. This method is applicable on a large scale, which is useful for horse doping control [06332].

**Liquid chromatography tandem mass spectrometry**

A method had been developed for determination of residues of 10 anabolic steroids (ASs) in animal muscle tissues by liquid chromatography tandem mass spectrometry (LC/MS/MS). After enzymolysis, the sample was extracted with tert-butyl methyl ether, cleaned up through reverse solid-phase extraction and further determined by LC/MS/MS under multiple reaction monitoring (MRM) mode. The limits of detection (LOD) of LC/MS/MS method used for testing epitestosterone (ETS), nandrolone (17 beta-NT), 17 alpha-methyl-testosterone (MTS), testosterone 17-propionate (PTS), medroxyprogesterone (MED), progesterone (PG), estrone (ESN), 17 beta-estradiol (17 beta-ES), 17alpha-ethynylestradiol (EES) and estriol (EST) in animal muscle ranged from 0.06 to 0.22 microg/kg, and the limits of quantification (LOQ) were from 0.12 to 0.54 microg/kg. Experiments on spiked samples of pork, beef, chicken and fish showed that at addition level of 1.0 microg/kg, the average recoveries of the ASs ranged from 64 to 77 percent, and coefficients of variation from 7 to 20 percent, while at addition level of 2.0 microg/kg, the average recoveries ranged from 70 to 89 percent, and coefficient of variation from 7 to 19 percent [06241].

**High- and low-resolution mass spectrometry**

Within the European Union the use of anabolic steroids for promoting growth and improving meat-to-fat ratio in food-producing animals has been banned since 1988. For the unequivocal identification of hormone residues in a complex matrix such as meat we have developed a rapid, specific and sensitive liquid chromatography/tandem mass spectrometry (LC/MS/MS) method, in combination with a simple extraction procedure based on the matrix solid-phase dispersion (MSPD). The performances of a triple quadrupole (QqQ) and a quadrupole/time-of-flight (QqTOF) were compared: the QqQ mass spectrometer was found to be more sensitive for almost all studied analytes, but the selectivity was superior using the QqTOF system; the full-scan spectra (acquired without losing sensitivity), mass accuracy and resolution of the hybrid instrument enabled a more probatory analyte identification than that obtained selecting two multiple-reaction monitoring (MRM) transitions with a QqQ. Average recoveries ranged from 80 to 100 percent, and the detection capabilities (CCbetas) were less than 1.06 ppb with the QqQ instrument and less than 5.20 ppb with the QqTOF instrument for the bovine meat, which proved to be the most complex matrix [06242].
ANABOLIC ANDROGENIC SUBSTANCES

Overviews

Ever since the ancient Olympic Games, athletes have long sought the ability to enhance their performance in sports and continue to do so in the modern era of elite competition. Over the past few decades, athletes have attempted to enhance their performance with the use of exogenous hormones including androgens, erythropoietin and growth hormone. Androgens are the most effective form of sports doping and are the most common type of performance enhancing substances detected in screening tests. It was not until the 1972 Munich Olympic Games that the International Olympic Committee (IOC) introduced screening tests for exogenous androgens. Since then, the World Anti-Doping Agency (WADA) enforces the banning of androgens through urine screening to detect even trace amounts of an extensive list of banned and prohibited substances which athletes are screened for prior, and during, competition. This list relies on screening urine samples with highly specific and sensitive techniques such as gas chromatography-mass spectrometry (GC-MS). For some athletes, the prospect of success outweighs the health and unethical concerns of sports doping. In an attempt to bypass screening methods, designer androgens have been created that have different chemical structures to known androgens and, therefore, cannot be easily detected by GC-MS. However, because designer androgens have biological activity they activate the androgen receptor (AR), and therefore can be detected by androgen bioassays. Therefore, androgen bioassays may prove to be a suitable tool for routine screening of nutraceutical or biological samples suspected to contain an androgen [13084].

Androgens are the class of sex steroids responsible for male sexual characteristics, including increased muscle mass and decreased fat mass. Illicit use of androgen doping can be an attractive option for those looking to enhance sporting performance and/or physical appearance. The use of in vitro bioassays to detect androgens, especially designer or pro-androgens, is becoming increasingly important in combating androgen doping associated with nutritional supplements. The nutritional sports supplement market has grown rapidly throughout the past decade. Many of these supplements contain androgens, designer androgens or pro-androgens. Many designer or pro-androgens cannot be detected by the standard highly-sensitive screening methods such as gas chromatography-mass spectrometry because their chemical structure is unknown. However, in vitro androgen bioassays can detect designer and pro-androgens as these assays are not reliant on knowing the chemical structure but instead are based on androgen receptor activation. For these reasons, it may be advantageous to use routine androgen bioassay screening of nutraceutical samples to help curb the increasing problem of androgen doping [13084].

Anabolic steroids are widely used for doping, in professional and non-professional sports. The mechanism of action may differ somewhat depending on the specific molecule due to structural differences that influence the specificity of binding with steroid receptors. When used by athletes in training, they can improve performance to levels that cannot be attained by almost any combination of sophisticated nonchemical support by modern sport science. The severity of the undesired effects of anabolic steroids depends on a variety of factors, from the type and combination of them, the dose and duration of administration, as well as the gender of the person taking the drug. Younger individuals and women show greater effects caused by anabolic steroids in terms of performance, but are also at greater risk of side effects [09047].

The anabolic-androgenic steroids (AAS) have been used by elite athletes since the 1950s,
but they did not become widespread drugs of abuse in the general population until the 1980s. Thus, knowledge of the medical and behavioral effects of illicit AAS use is still evolving. Surveys suggest that many millions of boys and men, primarily in Western countries, have abused AAS to enhance athletic performance or personal appearance. AAS use among girls and women is much less common. Taken in supraphysiologic doses, AAS show various long-term adverse medical effects, especially cardiovascular toxicity. Behavioral effects of AAS include hypomanic or manic symptoms, sometimes accompanied by aggression or violence, which usually occur while taking AAS, and depressive symptoms occurring during AAS withdrawal. However, these symptoms are idiosyncratic and afflict only a minority of illicit users; the mechanism of these idiosyncratic responses remains unclear – the personality of the victim before taking the drugs seems to be of importance. AAS users may also ingest a range of other illicit drugs, including both "body image" drugs to enhance physical appearance or performance, and classical drugs of abuse. In particular, AAS users appear particularly prone to opioid use. There may well be a biological basis for this association, since both human and animal data suggest that AAS and opioids may share similar brain mechanisms. Finally, AAS may cause a dependence syndrome in a substantial minority of users. AAS dependence may pose a growing public health problem in future years but remains little studied [09048].

Anabolic Androgenic Steroids (AASs) are chemical and pharmacological derivatives of the male hormone testosterone which are widely used for increasing burst and sprinting activities in sports. Although AASs are thought to be transversal to the plurality of sports disciplines, they are principally misused by bodybuilders, weightlifters, shot, hammer, discus or javelin throwers, rugby and American football players as well as by swimmers and runners. AAS exert a kaleidoscope of effects on human biology, principally through the 5-alpha-reductase-mediated conversion into dihydrotestosterone, the aromatase-mediated conversion into female sex hormones, a competitive antagonism to the glucocorticoid receptors, the potential stimulation of erythropoietin secretion as well as psychoactive effects on the brain. The influence of AASs on physical performance is still undefined, since the large numbers of studies published so far have described discordant and often contradictory outcomes. Nevertheless, animal and human investigations support the hypothesis that the administration of AASs might increase lean body mass, muscle mass, and maximal voluntary strength especially in men, so that they would represent an appealing form of doping for increasing power capacity, sustaining intensive training periods and, last but not least, as a cosmetic muscle makeover [11061].

The World Anti-Doping Agency regulations governing anti-doping in elite sports found in 2005 anabolic compounds as the most frequently detected doping agents, accounting for about 43 percent of positive results in 2005. Among these testosterone, nandrolone and stanozolol were predominant [08011].

With increasing availability of designer androgens, significant efforts are needed by antidoping authorities to develop sensitive methods to detect their use. The PubMed and Google Scholar search engines were used to identify publications addressing various forms of doping, methods employed in their detection, and adverse effects associated with their use. It appears that the use of AAS continues to be associated with premature mortality (especially cardiovascular) in addition to suppressed spermatogenesis, gynecomastia, and virilization. The attention that androgen abuse has received lately should be used as an opportunity to educate both athletes and the general population regarding their adverse effects. The development of sensitive detection techniques may help discourage (at least to some extent) the abuse of these compounds. Investigations are needed to identify ways to hasten the recovery of the gonadal axis in anabolic androgenic steroids users and to determine the mechanism of cardiac damage by these compounds [10043].
Anabolic steroids regulate the building blocks for the adolescent growth spurt and body composition. Even the body uses the combination of testosterone, hGH and IGF-I to subserve the adolescent growth spurt and the "partitioning" of food energy into the various compartments of body composition. As noted previously the early attainment of pubertal development confers some advantage on adolescent athletes compared to their "on-time" peers, although this is likely less important later in puberty given that sport-specific skills become more important as the majority of athletes will have entered and progressed through pubertal development [10001].

An anabolic steroid is a sex hormone that promotes the development and maintenance of the male sex characteristics. Testosterone is the principal secreted androgen in men. Androgens have both masculinizing (development of male secondary sex characteristics, including hair growth) and anabolic effects (increase in skeletal muscle mass and strength). For decades, pharmaceutical companies have attempted to develop androgens that have preferential anabolic activity and reduced or no androgenic activity; these compounds have been referred to as anabolic steroids. There is feedback control of androgen synthesis and secretion involving the hypothalamus (GnRH) and the pituitary. During adolescence there are remarkable alterations in both secretion and feedback sensitivity that underpin male pubertal development. Testosterone is strongly bound to sex-hormone binding globulin (SHBG), loosely bound to albumin, and a small proportion circulates as the free hormone. The biological activity is thought to reside in the free and loosely bound (albumin-bound) fractions [10001].

Androgens mediate their action through their binding to the androgen receptor (AR) which is mainly expressed in androgen target tissues, such as the prostate, skeletal muscle, liver and central nervous system. There is a wide spectrum of testosterone and synthetic AAS structure modifications related to the intended enhancement in anabolic activity [08124].

Anabolic androgenic steroids are the most abused class of prohibited substances, with testosterone accounting for many positive cases. Testosterone abuse is problematic because synthetic testosterone is indistinguishable from endogenous testosterone by routine screening methods such as gas chromatography–mass spectrometry. In the 1980s, it was discovered that testosterone use alters the ratio of testosterone glucuronide to epitestosterone glucuronide (T/E ratio) in urine. Epitestosterone is a naturally occurring biologically inactive epimer of testosterone that remains relatively constant in urine. A population-based T/E ratio cutoff of 6.0 was initially used to indicate synthetic testosterone use; the T/E ratio cutoff was lowered to 4.0 in 2005. Based on data from several laboratories, the average T/E ratio ranges from 0.9 to 1.6 for healthy male adolescents and men. At the UCLA Olympic Analytical Laboratory, it was found that the average T/E ratio during a 31-month period was 1.1 (median 0.9 %). Approximately 99.6 percent of urine samples have a T/E ratio <4.0, and 99.8 percent have a T/E ratio <6.0 [08124].

The T/E ratio is typically used as a screening test, and urine samples with a ratio >4.0 are submitted for confirmation testing by gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS). GC/C/IRMS has excellent specificity and can measure very small differences in the $^{13}\text{C}$ to $^{12}\text{C}$ ratio of testosterone and steroid metabolites. The $^{13}\text{C}$ content of natural (endogenously produced) testosterone is influenced by plant and animal sources consumed in food. In contrast, synthetic (pharmaceutical) testosterone is produced from plant precursors (stigmasterol) containing less $^{13}\text{C}$. This results in smaller $^{13}\text{C}/^{12}\text{C}$ ratios for synthetic testosterone, compared to natural testosterone. Although GC/C/IRMS is used to confirm testosterone use, the technique has low analytical sensitivity and is labor-intensive (owing to extensive sample cleanup) and costly to perform, and thus cannot be used as a
screening test [08124].

An androgen (anabolic-androgenic steroid) is a derivative of the major sex steroid in men and most mammals, testosterone (T). Others might answer in the more generic sense: any compound that is an agonist (or partial agonist) at the androgen receptor (AR). There are seemingly enough forms of T activity available to satisfy the needs of the medical population with oral, buccal, cutaneous patches (really, drug delivery devices) and gels, injectables of various durations (days to months), and implantable forms with a duration of action of 6 months or more. It seems that performance enhancement for human (and at least equine) athletes provide the backbone for the design of new anabolic steroids to circumvent the sophisticated testing procedures that surround major national and international competitions [12113].

Anabolic steroids are synthetic derivatives of testosterone, modified to enhance its anabolic actions (promotion of protein synthesis and muscle growth). They have numerous side effects, and are on the International Olympic Committee's list of banned substances. Gas chromatography-mass spectrometry allows identification and characterisation of steroids and their metabolites in the urine but may not distinguish between pharmaceutical and natural testosterone. Indirect methods to detect doping include determination of the testosterone/epitestosterone glucuronide ratio with suitable cut-off values. Direct evidence may be obtained with a method based on the determination of the carbon isotope ratio of the urinary steroids. One paper aimed to give an overview of the use of anabolic-androgenic steroids in sport and methods used in anti-doping laboratories for their detection in urine, with special emphasis on doping with testosterone. It was made a review of the recent literature of anabolic steroid testing, athletic use, and adverse effects of anabolic-androgenic steroids. Procedures used for detection of doping with endogenous steroids are outlined. The World Anti-Doping Agency provided a guide in August 2004 to ensure that laboratories can report, in a uniform way, the presence of abnormal profiles of urinary steroids resulting from the administration of testosterone or its precursors, androstenediol, androstenedione, dehydroepiandrosterone or a testosterone metabolite, dihydrotestosterone, or a masking agent, epitestosterone. Technology developed for detection of testosterone in urine samples appears suitable when the substance has been administered intramuscularly. Oral administration leads to rapid pharmacokinetics, so urine samples need to be collected in the initial hours after intake. Thus there is a need to find specific biomarkers in urine or plasma to enable detection of long term oral administration of testosterone [06048].

Androgens remain the most effective and widely abused ergogenic drugs in sport. The use of particularly anabolic androgenic steroids has changed from being a problem restricted to sports to one of public-health concern. In a review the prevalence of misuse, the evidence that some drugs improve performance in sport, their side-effects, and the long-term consequences of AAS misuse for society at large were discussed. There is substantial under-reporting of the side-effects of AAS to health authorities. It was described neuropsychiatric side-effects of AAS and their possible neurobiological correlates, with particular emphasis on violent behaviour. Analytical methods and laboratories accredited by the World Anti-Doping Agency can detect the misuse of all doping agents; although the analysis of testosterone requires special techniques, and recently discovered interethnic differences in testosterone excretion should be taken into account. The prevention of misuse of doping agents should include random doping analyses, medical follow-ups, pedagogic interventions, tougher legislation against possession of AAS, and longer disqualifications of athletes who use AAS [08061].

Although androgen doping has been prohibited for over 3 decades with a ban enforced by mass spectrometric-based urine testing for synthetic and exogenous natural androgens,
attempts continue to develop increasingly complex schemes to circumvent the ban. A prominent recent approach has been the development of designer androgens. Such never-marketed androgens evade detection because mass spectrometry relies on identifying characteristic chemical signatures requiring prior knowledge of chemical structure. Although once known, designer androgens are readily detected and added to the Prohibited List. However, until their structures are elucidated, designer androgens can circumvent the ban on androgen doping. To combat this, in vitro androgen bioassays offer powerful new possibilities for the generic detection of unidentified bioactive androgens, regardless of their chemical structure. Another approach to circumvent the ban on androgen doping has been the development of indirect androgen doping, the use of exogenous drugs to produce a sustained increase in endogenous testosterone production. Apart from estrogen blockers, however, such neuroendocrine active drugs mostly provide only transient increases in blood testosterone. Finally the ban on androgen doping must allow provision for rare athletes with incidental, proven androgen deficiency who require testosterone replacement therapy. The Therapeutic Use Exemption (TUE) mechanism makes provision for such necessary medical treatment, subject to rigorous criteria for demonstrating a genuine ongoing need for testosterone and monitoring of testosterone dosage. Effective deterrence of sports doping requires novel, increasingly sophisticated detection options calibrated to defeat these challenges, without which fairness in sport is tarnished and the social and health idealization of sporting champions devalued [08062].

Anabolic-androgenic steroids (AASs) are synthetic derivatives of testosterone. The term “androgenic” indicates masculinizing. Androgens are responsible for stimulating the growth of the male reproductive tract and secondary sex characteristics. The term “anabolic” indicates tissue building and is the component of a steroid which is responsible for thickening of the vocal cords, enlargement of larynx, increasing libido, linear growth acceleration before epiphyseal plate closure, increasing muscle bulk and strength through dose-dependent hypertrophy, and decreasing body fat. The anabolic action is mediated by androgen receptors on skeletal muscle. Testosterone increases muscle protein synthesis, thus increasing the cross-sectional area of the fibers themselves, as well as increasing the myonuclear number [07007].

Research activity

The consumption of anabolic steroids (AS) has been growing continuously in recent years. It has gone beyond the sports world; AS are now widely used as drugs of abuse in connection with bodybuilding. This study sets out to assess the state of scientific research in the area. Bibliometrics were employed to evaluate the literature retrieved from the principal relevant bibliographic databases: MEDLINE, SportDiscus, the Science Citation Index Expanded and the Social Sciences Citation Index. The core journals were identified along with the leading authors and research groups and their institutional affiliations. Techniques based on social network analysis were applied in order to build up a concept map of research. 1325 documents were retrieved. They were produced by 3131 different researchers giving a Collaboration Index of 3.32. The institutions with the most productive authors were Ball State University (Muncie, IN, USA), the Ecole Nationale Vétérinaire de Nantes (ENVN), the Institut Municipal d’Investigació Mèdica (IMIM) (Barcelona, Spain), the Institute of Biochemistry of the German Sport University Cologne (DSHS), Iowa State University, Maastricht University and the University of Iowa. It was concluded that there has been an upward trend in the number of research projects. The sources used complemented one another, as 78 percent of the documents retrieved were unique to one source. The productivity ranking was headed by sports medicine journals, followed by journals of chemistry, physiology, endocrinology and
substance abuse. Besides sporting activities, the most important research clusters were those connected with bodybuilding and with youth groups [07057].

**Clinical use**

Anabolic-androgenic steroids were developed to treat hypogonadism, a condition in which the testes do not produce sufficient testosterone for normal growth, development, and sexual functioning. Clinical studies suggest that the use of AASs (e.g., nandrolone) or testosterone improves lean body mass in patients with mild to moderate cachexia secondary to chronic illness (e.g., human immune deficiency virus, HIV). The use of testosterone and AAS has not been effective for the treatment of the catabolic states associated with severe burns or muscle-wasting diseases. Historical uses of AASs include anemia, hereditary angioedema, metastatic breast cancer, protein deficiencies following trauma or severe infections, and certain psychiatric disorders (involutional psychoses and depression) [13002].

Androgens are used clinically to treat a range of different human disorders. Among these are several catabolic conditions such as obstructive pulmonary disease, severe burn injuries, and also HIV-related muscle wasting. It can also be used to treat a number of conditions resulting from deficiencies in androgen production, such as constitutional growth retardation and hypogonadism. Androgen therapy can be administered orally, by intramuscular injection, and as gels and creams. Synthetic alkyl esters of androgens have been used therapeutically for decades due to their high potency and prolonged action. The realization that androgen administration can augment muscle hypertrophy has led to the abuse of androgens to increase muscle size, strength and sport performance [13084].

The anabolic properties of AASs have proven beneficial for some therapeutic applications. They have been used in clinical practice since the 1940s for the treatment of trauma, burns, extensive surgery, radiation therapy, and chronic debilitating illnesses. Before the advent of bone marrow transplantation and synthetic erythropoietin, AASs were used often in the treatment of various types of anemias. AASs have shown promise in treating short stature, as in Turner's syndrome, or constitutional growth and puberty delay. 1985-2006, the clinical use of AASs has increased 400 percent, mostly due to the management of AIDS-associated wasting syndrome. AASs may enhance the effects of the increased caloric intake and exercise regimen. A pilot study in malnourished HIV-infected children as young as 4 years old showed that oxandrolone treatment was well-tolerated and improved nutritional status. After 3 months of treatment, the study subjects experienced an accelerated rate of weight gain, increased body mass index, increased muscle mass, and decreased fat stores as compared with pretreatment values. The results were supported further by the improved serum albumin levels noted during the course of treatment. Future studies using a larger study population and longer- or higher-dose AAS administration would strengthen the current data. In patients with severe burns, AASs may play an important role in reversing the catabolic state. A small prospective randomized study of patients who had burns showed that those receiving oxandrolone in addition to a high-protein diet experienced a significantly greater increase in weight and physical therapy index than did patients who were treated with diet alone. AAS therapy seems to be promising in the treatment of malnutrition and muscle wasting seen in patients who have end-stage renal disease. In addition to the increase in lean body mass, these patients also benefit from a stimulated erythropoiesis resulting from the administration of AASs [07008].

*Hereditary angioedema*
Androgen derivatives are regarded as standard in the long-term prophylaxis of swelling attacks in patients with hereditary angioedema (HAE). Because of their relatively slow onset of action, they are not suitable for acute therapy. Long-term prophylaxis with androgen derivatives must be regarded critically, especially on account of their androgenic and anabolic effects, some of which are severe. The risk of adverse events increases with the daily dose and the duration of treatment. Thus, treatment always calls for close monitoring of patients with regard to potential adverse events. In addition, androgens are subject to numerous contraindications and they show interactions with a large number of other drugs. Off-label use, doping issues, clarification of reimbursement and the need to import the androgen derivatives, which are no longer marketed in Germany, result in additional effort for the treating physician in terms of logistics and time involved. In symptomatic treatment of acute attacks the intravenous substitution of C1-INH and – since 2008 – subcutaneous administration of icatibant are available. The two substances are well tolerated and their effect occurs rapidly and, when the diagnosis has been confirmed, reliably. In the light of these two treatment options for controlling acute attacks, prophylactic treatment of HAE patients with androgen derivatives such as danazol should be reassessed. Patients might benefit from a dose reduction or the withdrawal of androgen prophylaxis and attacks can be controlled with demand-oriented acute treatment using C1-INH or icatibant [11064].

**Effect of androgen deprivation**

Indices of body composition and muscular strength were compared between men with prostate cancer (PCa) treated with androgen deprivation therapy (ADT) and asymptomatic matched men. Nine subjects aged 63-83 years with PCa who received ADT (PCa+ADT; duration 6-180 months) and 11 asymptomatic aged-matched eugonadal men (HM) aged 59-80 years were assessed for prostate-specific antigen (PSA) and total testosterone (TT). Total body non-osseous lean mass (TBLM) and right thigh non-osseous fat-free mass (RTLM) were assessed using dual-energy X-ray absorptiometry. Peak torque of the right knee extensors at 0° s⁻¹ and 60° s⁻¹, maximal handgrip strength of the dominant hand (MHS) and whole-body strength (WBS) were assessed. ISO and CON per unit mass of RTLM and MHS and WBS per unit mass of TBLM were calculated. Age, height, mass, body mass index and prostate-specific antigen were comparable between groups, while TT was lower in PCa+ADT. RTLM was similar between groups. Absolute peak torque of the right knee extensors were lower for PCa+ADT as were extensor effects per unit of RTLM. Absolute MHS, WBS and MHS per unit of TBLM and WBS per unit of TBLM were lower for PCa+ADT. Men with PCa who receive ADT experience significant losses in whole-body muscular strength compared with asymptomatic age-matched men, which may impair functional capacity. These losses in muscular strength appear to involve neuromuscular mechanisms that are yet to be identified [13124].

**Abuse**

One of the earliest accounts of androgen abuse dates back to the 1950s where Soviet weightlifters were allegedly taking testosterone. While the abuse of androgens is more commonly associated with the weightlifting industry, their use is widespread amongst many sports, both at the elite and amateur levels. Alarmingly, androgen use is not limited to adults, with reports that school-aged children use androgens. For bodybuilding and enhanced athletic performance enhancement, it is common that very high doses of androgens are consumed. Moreover, it is common practice to employ “stacking” regimes where a number of different androgens and/or metabolism inhibitors are simultaneously consumed. This can
lead to serious clinical consequences such as abnormal liver function, gynecomastia, severe psychological or psychiatric disorders, increased risk of cardiovascular disease; and in females, menstrual disorders and virilization. Many of the androgens that are used are 17-methylated compounds and are associated with high-liver toxicity [13084].

**Methods of abuse**

The pattern of AAS abuse among athletes is quite variable, and the dosing intervals are not usually regular. These patterns include stacking, tapering, plateauing, cycling, and pyramiding. Many AAS abusers are poly-drug users including the abuse of traditional recreational drugs and misuse of prescription drugs. Athletes typically administer AAS intramuscularly with or without oral preparations in cycles lasting 6-12 weeks with periods of abstinence between these cycles as a mean store due adverse effects. The abuse of transdermal patches, sublingual tablets, dermatologic gels, and nasal sprays is rare. In an attempt to maximize anabolic gains and minimize side effects, some AAS users start with low doses at the beginning of a cycle and then steadily increase the dose until a gradual “tapering” phase at the end of a cycle (i.e. “pyramid” regimen). Frequently, these athletes use more than 1 steroid simultaneously (i.e. “stacking”) or use several AASs in overlapping patterns to avoid the development of tolerance (i.e. “plateauing”). In an internet study of 207 weight lifters and bodybuilders using AASs, the steroid regimens included a mean of 3 agents with cycles ranging from 5 to 10 weeks and AAS doses 5-29 times above physiologic replacement doses. Often these athletes ingest other drugs (i.e. “array”) as a mean store due adverse effects and enhance the effect of AASs. These additional medications include human chorionic gonadotrophin, anti-acne drugs, oral hypoglycemic agents, analgesics, ketoconazole shampoo, stimulant aminoacids, erythropoietin, aminoglutethimide, diuretics, and estrogen antagonists. The abuse of AASs continues, in part, because of the effectiveness of these regimens with training programs and the perceived difficulty detecting AAS use, particularly in weight lifters. Commonly abused steroid supplements (i.e. precursors of testosterone and related hormones) include androstenedione and DHEA. The latter compound is an endogenous hormone secreted by the adrenal cortex in response to adrenocorticotropic (ACTH) [13003].

**Abuse dosage**

Athletes usually consume supraphysiologic doses of AAS. Steroids are generally taken in 4- to 12-week cycles. Athletes often “stack” multiple steroids simultaneously and “pyramid” the dosing schedule, beginning with low dosage and increasing amounts during the middle and end of a cycle. Between dosing cycles, it is typical for users to have a period of abstinence, known as a “drug holiday,” which usually occurs during the competition phases. This method provides 50 to 100 times the physiologically needed dose of steroids, resulting in levels that are far higher than physiological levels [12119].

Anabolic steroids may be taken orally or injected intramuscularly and are grouped into three main classes. Testosterone esters, such as testosterone propionate, are injected compounds and constitute class I. Class II agents include the nortestosterone derivatives (eg, nandrolone decanoate and nandrolone phenpropionate). Class I and II AASs exert effects at androgen receptors as well as at estrogen receptors by way of aromatization to estradiol. The third class of AASs are those alkylated at C-17 and are the orally administered compounds oxymetholone, methandrostenolone, and stanozolol. Alkylation of these compounds involves the addition of a methyl or ethyl group to the carbon at position 17 of the steroid backbone. The alkylation slows the hepatic metabolism of these agents. A typical pattern of use consists of a combination of injectable and oral steroids taken during 6- to 12-week cycles.
Injectable forms tend to be favored by users because they are less hepatotoxic than the oral forms. Because oral preparations are cleared from the system more quickly, they are the preferred form of steroids when drug testing is anticipated. The simultaneous use of multiple steroids is referred to as "stacking." A pattern of increasing a dose through a cycle is called "pyramiding." Pyramiding can lead to doses 10 to 40 times greater than the dose recommended for medical indications. By stacking and pyramiding doses, the user hopes to maximize steroid receptor binding, thereby reducing toxic side effects. These patterns have remained popular, despite the lack of scientific evidence of a benefit. Some users take other drugs concurrently in an effort to minimize side effects. These "accessory" medications include clomiphene and human chorionic gonadotropin and are administered to reverse the endogenous testosterone production. Additionally, tamoxifen and antiaromatase drugs can prevent or decrease gynecomastia by limiting estrogenic effects and the metabolism of excess testosterone derivatives to estradiol. It is not uncommon for users to take other legal performance-enhancing substances and dietary supplements, such as creatine, glutamine, and protein, while using AASs [07008].

It is worthy to note that the classification of anabolic steroids (AS) covers a number of structural variants. Classically, AS are classified as water-soluble orally active forms (17-alpha-alkylated) and lipid-soluble parenteral forms (17-beta-esterified). In addition, they are often also classified as either testosterone-based, dihydrotestosterone-based (DHT) or 19-nortestosterone-based (Nandrolone) all of which have differing properties and expected side effects. The situation is further complicated by belief among users, often stemming from anecdotal advice, that some AS are better for predominantly "bulking" (e.g. Deca-Durabolin) while others are better suited to losing body fat or "cutting" (e.g. Winstrol). Users will often use these different forms of AS in varying quantities. The use of AS is also characterised by periods of use followed by periods of abstinence, or "cycles". This helps to maximise the effects of the drugs while also limiting the negative consequences and allowing the body to normalise following an "on" cycle. Furthermore, users will often supplement their cycles with additional pharmaceutical agents both when bulking (e.g. insulin, human growth hormone) and when losing body fat (clenbuterol, cytomel, 2,4, dinitrophenol). Finally, there are a surprising number of drugs used to attempt to limit side effects of AS use or normalise the hypothalamo-pituitary-gonadal (HPG) axis following an AS cycle. These include estrogen receptor antagonists (tamoxifen), selective estrogen receptor inhibitors (clomifene), aromatase inhibitors (arimidex), 5-alpha reductase inhibitors (finesteride) and HPG axis stimulators such as HCG [12114].

**Dose effects**

The dose of AAS used by athletes depends on individual needs and the athletic requirements of the particular sport. Endurance athletes use AAS doses near or slightly below physiologic replacement concentrations (i.e. about 7 mg testosterone daily) as a means to block catabolism, while sprinters typically use 1.5-2 times replacement concentrations. Traditional strength athletes use much higher doses (i.e. 10-100 times replacement concentrations) to "bulk up." Generally, the dose of AASs is lower in women than in men. Data from human test participants indicate that AAS produce a dose-dependent and gender-dependent increase in lean body mass and strength, but the changes are highly variable and relatively small without an accompanying conditioning and strength program. The administration of AAS to men participating in weight training consistently produces increased strength when compared with controls (i.e. weight training alone). The endogenous testosterone production during male adolescence reproduces a sex-differential in lean body mass similar to the increment in lean body mass caused by the administration of exogenous AAS to adults. However, different androgen-dependent processes have different testosterone-dose-response relationships. In a study of 61 eugonadal men receiving a long-acting gonadotropin-releasing hormone agonist to suppress endogenous testosterone
secretion, changes in leg press strength, leg power, thigh and quadriceps muscle volumes, hemoglobin, and insulin-like growth factor 1 (somatomedin C) positively correlated to testosterone concentrations. Changes in fat mass and plasma high-density lipoprotein (HDL) cholesterol were negatively correlated to the testosterone dose. Although adverse effects following AAS administration are usually dose related, there are few data on the long-term physiologic effects of chronic AAS use, particularly in women. In addition to dose and duration of use, long-term toxicity depends on the age of initiation, gender, steroid structure, and concurrent illicit use of other drugs. The daily production of testosterone in healthy men is about 4-10 mg compared with about 1 mg in healthy women. Psychotic symptoms associated with AAS abuse typically occur in individuals using 41 g testosterone weekly, but the development to psychologic changes is highly variable. In a randomized, placebo-controlled, crossover trial of 56 healthy men aged 20-50 years, the administration of testosterone cypionate for 6 weeks in doses increasing to 600 mg/week caused little psychologic change in most participants (i.e. 84 %). The regimen produced mild hypomania in 12 percent and marked hypomania in 4 percent of the men [13003].

Different actions due to ways of administration

The route of administration has been found to have an effect on the detection of anabolic steroids since quantification of testosterone in urine samples is reliable only when the drug has been administered intramuscularly. Oral administration, by contrast, is more problematic since it results in rapid pharmacokinetics, this requiring urine samples to be collected as soon as possible following administration to enable reliable quantification. AAS bind with variably affinity in the cytoplasm to the androgen receptor (AR), a member of the steroid hormone receptor family, where they exert potent anabolic and endocrine activities. The AR’s binding to the androgen response element triggers its potential to act as a transcriptional modifier of various genes. The enzyme 5-alpha-reductase seems to possess an essential role by converting AAS into dihydrotestosterone (androstanoelone), which acts in the cell nucleus of target organs, while the enzyme aromatase converts AAS into female sex hormones (estradiol and estrone). By displacing cortisol from its receptors, they antagonize the catabolic effects of glucocorticoids. AAS increase strength (by about 5-20 %) and body weight (by about 2-5 kg) due to an increase of the lean body mass without reduction of fat mass, although no effects have been observed on endurance performance [12011].

Different anabolic androgenic steroids with different specific actions

Stanozolol is an anabolic steroid compound particularly favoured among athletes and body builders since it boosts strength without weight gain, while it is not converted to estradiol. Metribolone (methyltrienolone) is a potent anabolic steroid, a non-aromatizable androgen, the 17-methylated derivative of trenbolone, which is characterized by high potential for hepatotoxicity [12011].

Recognizing steroid abuse

Early recognition and intervention may prevent adverse and potentially irreversible consequences. New-onset acne on the back and chest, temporal hair loss, and alopecia are common signs. Subtle personality or mood changes are sometimes the only manifestation [07031]:

- Cardiac disease in absence of risk factors
- Thrombotic events in absence of risk factors
- Alopecia
Possible use in children and adolescents

The dietary supplements androstenedione, dehydroepiandrosterone, and androstenediol are precursors in the endogenous production of testosterone. The efficacy and safety of these prohormones are not well established but are promoted to have the same androgenic effects on building muscle mass and strength as anabolic-androgenic steroids. Studies have demonstrated repeatedly that acute and long-term administration of these oral testosterone precursors does not effectively increase serum testosterone levels and fails to produce any significant changes in lean body mass, muscle strength, or performance improvement compared with placebo. Testosterone precursors are banned by most major sports organizations [07083].

Clinical effects

Children seem to be the most susceptible to the adverse effects of AAS use. Children and adolescents experience accelerated maturation associated with changes in physique and earlier development of secondary sexual characteristics. An additional concern with adolescents is premature closure of growth plates in long bones, leading to a decrease in final height; this likely is due to aromatization to estrogens. Precocious puberty in boys and contrasexual precocity in girls also can occur. With adolescents, some of the effects may become irreversible with chronic use, particularly the virilizing effects in young women [07058].

One article was part of a Special Issue "Puberty and Adolescence". Puberty is a critical period for brain maturation that is highly dependent on gonadal sex hormones. Modifications in the gonadal steroid environment, via the use of anabolic androgenic steroids (AAS), have been shown to affect brain development and behavior. Studies in both humans and animal
models indicate that AAS exposure during adolescence alters normal brain remodeling, including structural changes and neurotransmitter function. The most commonly reported behavioral effect is an increase in aggression. Evidence has been presented to identify factors that influence the effect of AAS on the expression of aggression. The chemical composition of the AAS plays a major role in determining whether aggression is displayed, with testosterone being the most effective. The hormonal context, the environmental context, physical provocation and the perceived threat during the social encounter have all been found to influence the expression of aggression and sexual behavior. All of these factors point toward an altered behavioral state that includes an increased readiness to respond to a social encounter with heightened vigilance and enhanced motivation. This AAS-induced state may be defined as emboldenment. The evidence suggests that the use of AAS during this critical period of development may increase the risk for maladaptive behaviors along with neurological disorders [13123].

Aggresiveness
In a double-blind, placebo-controlled, crossover trial, it was given injections of testosterone in increasing doses to 35 boys and oral doses of conjugated estrogens to 14 girls with delayed puberty. Both treatment groups had more physical aggressive behavior and aggressive impulses than those receiving placebo. In another study it was compared plasma levels of hormones in 15 boys with conduct disorders and in 25 normal controls. The boys with conduct disorders had significantly higher levels of dehydroepiandrosterone sulfate, marginally significantly higher levels of androstenedione, and no differences in testosterone levels [07031].

Epiphyseal plate closure in adolescents
Premature closure of the epiphyseal plates during chronic AAS use can stunt bone growth [13003].

Prevalence of adolescent anabolic-androgenic steroid use
The first reported adolescent use of AASs was in 1959 by a high school football player. Estimates of high school steroid usage in 2007 ranged from 4 to 11 percent in boys and up to 3.3 percent in girls. A landmark study of prevalence involved a nationwide survey of more than 3000 boys. They found that 6.6 percent of male high school seniors had tried steroids, with 67 percent initiating use by 16 years of age and 40 percent using multiple cycles. These results have been confirmed in later studies and a 2003 Centers for Disease Control and Prevention report finding of a 6.4 percent use of steroids by 12th-grade boys. The largest nationwide cohort of nearly 50,000 students is being examined in the Monitoring the Future study. As of 2004, results of this ongoing study indicated a 1.3, 2.3, and 3.3 percent annual prevalence of male AAS users in the eighth, 10th, and 12th grades, respectively. Girls in the 12th grade had a 1.7 percent use rate in this study, whereas the Centers for Disease Control and Prevention reported a 3.3 percent lifetime prevalence in 12th-grade girls. AAS use by adolescents is not limited to the United States. Three Canadian studies, two Swedish surveys, two South African investigations, one British study, and one Australian investigation reported an overall prevalence range between 1 and 3 percent. Although slightly lower, these rates approximate those reported in the United States, demonstrating that the impact of AASs on athletic performance and physical appearance reaches across cultures. A considerable percentage of adolescents turn to AAS use to help them achieve an attractive physique. This is the second most popular reason for using AASs. One study of bodybuilders suggests that the drive for a muscular physique sometimes reaches an unhealthy extreme and likens the use of AAS to the “unhealthy extremes” that are characteristic of anorexic and bulimic individuals. Just as eating disordered women see their bodies as smaller than they actually are, some men perceive themselves as smaller than they actually are. This
phenomenon has been referred to as “bigamerexia” and suggests that this misperception may be a contributory factor in AAS use. This misperception is likely evident in many ninth-grade boys, who – in the early stages of puberty – are impatient with their muscular development. Perceiving themselves smaller than their peers, these boys may engage in AAS use as a shortcut to increasing muscle strength and size. Exposure to the media may intensify this body dysmorphia. Adolescent AAS use has been associated with the use of other harmful drugs, including cigarettes, smokeless tobacco, marijuana, alcohol, cocaine, and injected drugs. Thus, AAS use would be considered a part of this cluster rather than an isolated behavior [07008].

It was examined the prevalence, persistence, secular and longitudinal trends, and predictors of steroid use in a diverse sample of adolescents. Data are from Project EAT-II (Eating Among Teens), a 5-year longitudinal study of eating, activity, weight, and related variables in 2516 middle and high school students. Data were collected in 1999 (time 1) and 2004 (time 2). Approximately 1.5 percent of adolescents reported steroid use at time 2. Use differed by ethnicity but not socioeconomic status. Steroid use was not stable across time, although the risk of use at time 2 was higher for girls and (marginally) for boys who used steroids at time 1. No secular trends were noted in middle adolescents' steroid use between 1999 and 2004. Developmentally, steroid use decreased as adolescents grew older. Predictors of use for male adolescents included wanting to weigh more and reporting higher use of healthy weight-control behaviors. Female time 2 steroid users had higher BMIs and were less satisfied with their weight, had poorer nutrition knowledge and concern for health, and were marginally more likely to have participated in weight-related sports at time 1. It was concluded that the prevalence of steroid use in adolescents was low but of concern. Although use was not persistent over 5 years, time 1 use was a risk factor for time 2 use in female adolescents. There was no change in the prevalence of steroid use by middle adolescents between 1999 and 2004 despite a great deal of public interest in steroids during this time period. Steroid use decreased as adolescents grew older. Weight-related variables predicted adolescents' steroid use 5 years later, and health and nutrition knowledge and concern and (marginally) participation in weight-related sports further predicted use in female adolescents. These findings suggest that early preventive efforts may be most useful [07008].

**Girls**

Recent media reports have portrayed an alarming increase in apparent anabolic-androgenic steroid (AAS) use among American teenage girls; Congress even held hearings on the subject in June 2005. It was questioned whether AAS use among teenage girls was as widespread as claimed. It was reviewed four large national surveys and many smaller surveys examining the prevalence of AAS use among teenage girls. Virtually all of these surveys used anonymous questionnaires. It was asked particularly whether the language of survey questions might generate false-positive responses among girls who misinterpreted the term "steroid." It was also reviewed data from other countries, together with results from the only recent study in which investigators personally interviewed female AAS users. The surveys produced remarkably disparate findings, with the lifetime prevalence of AAS use estimated as high as 7.3 percent among ninth-grade girls in one study, but only 0.1 percent among teenage girls in several others. Upon examining the surveys reporting an elevated prevalence, it appeared that most used questions that failed to distinguish between anabolic steroids, corticosteroids, and over-the-counter supplements that respondents might confuse with "steroids." Other features in the phrasing of certain questions also seemed likely to further bias results in favor of false-positive responses. It was concluded that many anonymous surveys, using imprecise questions, appear to have greatly overestimated the lifetime prevalence of AAS use among teenage girls; the true lifetime prevalence may well be as low as 0.1 percent. Future studies can test this impression by using a carefully phrased
question regarding AAS use [07085].

Use of testosterone precursors by adolescents

The extent of the use of testosterone precursors, such as androstenedione and DHEA, in the pediatric and adolescent population is unknown. The initial over-the-counter dietary supplement status and availability more than likely led to a large increase in the number of adolescents using testosterone precursors. A 2002 survey of 475 high school students by revealed that 4 percent of athletes and nonathletes admitted to using steroid precursors in the past year. Surveys by the National Collegiate Athletic Association (NCAA) revealed that 5 percent of athletes admitted to using DHEA or androstenedione, 33 percent admitted to using nutritional supplements, and 1 percent admitted to using anabolic steroids. With the passage of the Anabolic Steroid Control Act of 2004, androstenedione became illegal to purchase; the only available source is through the black market or acquaintances. One would surmise that the use of testosterone precursors among adolescents would be higher than the use of AASs [07085].

Use in women

Prevalence

Anabolic-androgenic steroids (AAS) are synthetic derivatives of testosterone that maximize anabolic and minimize androgenic effects. Exogenous testosterone is rapidly metabolized and has no significant effect on performance. Men have traditionally used AAS for muscle gain. Women have also used AAS for increased strength and lean muscle mass. AAS use by women was first sensationalized when East German athletes routinely received steroids from team doctors. Surveys analyzing AAS prevalence in adolescent girls have found a range from 0.1 to 4.8 percent. The Centers for Disease Control and Prevention (CDC) reported an overall prevalence of lifetime steroid use in females, grades 9 to 12, of 3.2 percent. In another study surveying boys and girls between 9 and 13 years old, found that 2.8 percent of girls and 2.6 percent of boys reported AAS use. Steroid use by girls was found across various sports, with the highest prevalence in weight training. Steroid users were more likely to think that steroids improve athletic performance or enhance appearance Steroid use prevalence has also been studied in women collegiate athletes. A National Collegiate Athletic Association (NCAA) survey of more than 19,000 collegiate men and women found that between 2001 and 2005 AAS use increased in women's ice hockey, gymnastics, and volleyball. Between 2001 and 2005, AAS use increased in women's ice hockey from 0.8 to 2.4 percent, in women's gymnastics from 0 to 1 percent, and in volleyball from 0.1 to 0.6 percent [07086].

Effects

Studying AAS effects is difficult due to an incomplete understanding of how athletes use steroids. Athletes often combine AAS with other supplements, or use doses several times higher than recommended. Data on the performance-enhancing effect of AAS on women is limited. However, most studies in men found an increase in muscle mass and body weight by an average of 2 to 5 kg. Steroids have also been shown to increase strength, with improvements ranging from 5 to 20 percent. Clinical trials have not demonstrated improved endurance performance. A double-blind, placebo-controlled trial gave AAS to men 12 times over 1 month, showing no improvement in treadmill testing [07086].
**Side effects**

Women taking AAS are at risk for androgenic side effects, including deepened voice, acne, male pattern baldness, clitoromegaly, menstrual irregularities, and increased facial hair. A survey of steroid-using women bodybuilders found that 64 percent reported an adverse psychological effect, including labile mood, irritability, or aggressive behavior most frequently. More serious side effects include liver damage. Transient increases in hepatic enzymes that return to normal after steroids are discontinued have occurred. Other significant adverse effects include cholestasis, hepatic peliosis, and hepatocellular hyperplasia that may lead to hepatic carcinoma [07086].

In one study it was evaluated 75 female bodybuilders and weightlifters and found that 33 percent reported current or past anabolic-androgenic steroid use. Among steroid users, 56 percent reported hypomanic symptoms during use, and 40 percent reported depression when the steroids were discontinued. Some users developed a body image distortion similar to “reverse anorexia,” in which they felt they were too small. Ten of the 75 weightlifters had been raped as teenagers or adults, and most started or increased their weightlifting activities as a defense strategy. Seven of the 10 rape victims used anabolic steroids [07031].

**Steroid precursors (androstenedione and dehydroepiandrosterone)**

Steroid precursors include androstenedione and dehydroepiandrosterone (DHEA). These substances are closely related to testosterone. Due to poor surveillance, the prevalence of steroid precursor use by girls and women is difficult to determine. The NCAA’s study of substance use habits of college student-athletes found that 4.7 percent of men and women athletes surveyed had tried DHEA or androstenedione products at least once in the past year. The survey data, however, did not organize the percentages in terms of men and women. The CDC’s survey on youth risk behavior does not ask specifically about steroid precursors. One study of high school students found that androstenedione was the second most popular supplement, with 4 percent of students using it at least once in the past year. Again, the authors did not isolate a number for girls using androstenedione. It is also believed that these substances may have an androgenizing effect in female athletes. Androstenedione, produced in the adrenal glands and gonads, is more potent than DHEA, which is naturally produced in the adrenal cortex. The actual physiologic effects and effects on athletic performance have not been consistent. Several studies in women have shown increased serum androstenedione and testosterone after androstenedione supplementation. No trials have been published examining steroid precursors’ performance-enhancing effects in women. Further, studies in men have not consistently found an improvement in athletic performance with androstenedione or DHE. Steroid precursor use carries the same risks as testosterone use. Common adverse effects in women include virilization. There is also a risk of testing positive for testosterone or androstenedione [07086].

**Anabolic steroids in young females**

Women who take AAS can experience androgenic effects including changes in libido, male-pattern baldness, deepening of the voice, acne vulgaris, and other masculinizing effects in early use. Longer-term use causes clitoromegaly, changes in pubic hair growth, menstrual irregularities, and even breast reduction [06031].

Media reports have portrayed an alarming increase in apparent anabolic-androgenic steroid (AAS) use among American teenage girls; Congress even held hearings on the subject in June 2005. It was questioned whether AAS use among teenage girls was as widespread as claimed. It was reviewed four large national surveys and many smaller surveys examining
the prevalence of AAS use among teenage girls. Virtually all of these surveys used anonymous questionnaires. It was asked particularly whether the language of survey questions might generate false-positive responses among girls who misinterpreted the term "steroid." It was also reviewed data from other countries, together with results from the only recent study (to our knowledge) in which investigators personally interviewed female AAS users. The surveys produced remarkably disparate findings, with the lifetime prevalence of AAS use estimated as high as 7.3 percent among ninth-grade girls in one study, but only 0.1 percent among teenage girls in several others. Upon examining the surveys reporting an elevated prevalence, it appeared that most used questions that failed to distinguish between anabolic steroids, corticosteroids, and over-the-counter supplements that respondents might confuse with "steroids." Other features in the phrasing of certain questions also seemed likely to further bias results in favor of false-positive responses. It was concluded that many anonymous surveys, using imprecise questions, appear to have greatly overestimated the lifetime prevalence of AAS use among teenage girls; the true lifetime prevalence may well be as low as 0.1 percent. Future studies can test this impression by using a carefully phrased question regarding AAS use [06097].

**Estrogen antagonists**

Estrogen antagonists, such as tamoxifen, clomiphene, and anastrozole, have been used to block estrogen and increase testosterone effects. In the 1970s, the first reports of men using tamoxifen along with AAS occurred. Bodybuilders claimed that it decreased fat over muscle and produced a leaner appearance. An Internet-based survey of 500 bodybuilders found that 53 percent of AAS users were also using tamoxifen. This study included 494 men and 6 women. One case report and one survey have captured tamoxifen use for performance enhancement in women. All published reports have been in bodybuilders. In 2002, it was published a case report detailing a female competitive bodybuilder using tamoxifen based on a recommendation from another bodybuilder. She claimed it was easier to lose fat but noted side effects such as night sweats, hot flashes, and breast-mass loss. A recent survey of health club members to determine the prevalence of nontherapeutic medication use found that 22 percent had used tamoxifen. Seven percent of respondents to the survey were women. Tamoxifen use had increased from its previous levels. Tamoxifen's effect on athletic performance is unknown. Anecdotal reports of fat loss and leaner physique exist, but no studies have evaluated their validity. This medication involves multiple adverse effects for women, including endometrial cancer, thromboembolic events, teratogenic effects, ovarian cysts, bone-density loss, cataracts, hot flashes, and vaginal discharge [07086].

**Genetic influence**

In 1982, the International Olympic Committee accepted a T/E ratio greater than six as proof of testosterone doping, based on the log-normal distribution of the ratio established from the first population studies. A testosterone over epitestosterone (T/E) ratio exceeding 4.0 has later been considered as suspicious of testosterone administration, irrespectively of individual heterogeneous factors such as the athlete’s ethnicity. In antidoping laboratories, the urinary steroid profile usually encompasses the concentration levels of testosterone (T); its inactive epimer, epitestosterone (E); four testosterone metabolites, androsterone (A), etiocholanolone (Etio), 5α-androstane-3α,17β-diol (α-diol) and 5β-androstane-3α,17β-diol (β-diol); and a testosterone precursor, dehydroepiandrosterone (DHEA). The following cut-off concentration levels of endogenous steroids equivalent to the glucuronide: T>200 ng/ml, E>200 ng/ml, A>10 000 ng/ml, Etio>10 000 ng/ml and DHEA>100 ng/ml are considered as putative markers of androgen administration. In contrast to absolute steroid concentrations,
ratios such as T/E, A/Etio, A/T, α-diol/E and α-diol/β-diol are robust to circadian rhythm or changes in physiological conditions such as exercise workload for athletes. On the other hand, these parameters may be significantly altered according to the administered steroid and its application mode. However, a T/E higher than 4.0 no longer constitutes proof of testosterone misuse, but requires a subsequent confirmation analysis by gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS). GC/C/IRMS allows measurement of slight differences in $^{13}$C/$^{12}$C ratio of testosterone metabolites. A discrimination is feasible since exogenous testosterone or its precursors contain less $^{13}$C than their endogenous homologues. A deletion polymorphism in the UGT2B17 gene was demonstrated to account for a significant part of the interindividual variability in the T/E between Caucasians and Asians. The variability of urinary steroid profiles was examined in a widely heterogeneous cohort of professional soccer players. The steroid profile of 57 Africans, 32 Asians, 50 Caucasians and 32 Hispanics was determined by gas chromatography–mass spectrometry. Significant differences were observed between all ethnic groups. After estimation of the prevalence of the UGT2B17 deletion/deletion genotype (African: 22 %; Asian: 81 %; Caucasian: 10 %; Hispanic: 7 %), ethnic-specific thresholds were developed for a specificity of 99 percent for the T/E (African: 5.6; Asian: 3.8; Caucasian: 5.7; Hispanic: 5.8). Finally, another polymorphism could be hypothesised in Asians based on specific concentration ratio of 5α-/5β-androstane-3α,17β-diol in urine. These results demonstrate that a unique and non-specific threshold to evidence testosterone misuse is not fit for purpose. An athlete's endocrinological passport consisting of a longitudinal follow-up together with the ethnicity and/or the genotype would strongly enhance the detection of testosterone abuse. Finally, additional genotyping studies should be undertaken to determine whether the remaining unexplained disparities have an environmental or a genetic origin [09049].

**Doping tests and genetic confounders**

So far it is known of only genetic variations in three enzyme (UGT2B17, CYP17 and PDE7B) genes with a substantial influence on the T/E ratio. The major part of testosterone is excreted as the glucuronide but it was found a 100- or more -fold variation in excretion rate, both in a Caucasian and an Asian study group. A majority (75 %) of Asian subjects falls within the “low excretion” group compared with 9 percent among the Caucasians, and the widely different distribution into the two modes indicated a monogenic background of the excretion pattern. The conspicuous intra- and interethnic differences in testosterone excretion gave cause for concern about how to interpret the classical urinary T/E screening test as an indicator of exogenous administration of the hormone. The future test programme for testosterone ought to adopt a Bayesian inference technique for analysis of consecutive T/E samples in the individual, as has been applied in the detection of blood doping with the “blood pass” [12192].

In summary, large genetic variation in the disposition and effects of anabolic androgenic steroids is a reality that must be considered in the doping control strategy in sports as well as in society. Polymorphisms in three crucial enzyme genes have hitherto been shown to have an impact on the disposition of testosterone and the T/E ratio. Further genetic confounders in other genes cannot be excluded at present time. False negative and false positive results with the current principles for interpretation of the T/E screening test as described will lead to unnecessary and expensive follow-up analyses of many samples [12192].

**UDP-glucuronosyltransferase and UGT2B17 genotype**

Recently, it was demonstrated that genotype-based cutoff values may improve the sensitivity
and specificity of the test, this demonstrating that genetic variation in androgen disposition is of importance in those instances when androgen urinary excretion profile should be tested. A deletion polymorphism in the UGT2B17 gene can lead to misinterpretation of T/E ratio, this accounting for a significant part of ethnic interindividual variability. UGT2B17 genotype information is therefore crucial to the decision as to which initial cutoff ratio is to be employed for an individual as well as for enhancement of the sensitivity of the Bayesian analysis (a method of interpretation of probabilities). On the basis of these data, the proposition has been made that a Bayesian interpretation of consecutive tests in the same individual should be adopted to replace the epithestosterone ratio [12011].

The anabolic steroid testosterone can be used by athletes to enhance athletic performance and muscle growth. UDP-glucuronosyltransferase (UGT2B17) is the key enzyme involved in the glucuronidation of testosterone to testosterone glucuronide, which also serves as a marker for the testosterone/epitestosterone (T/E) ratio used to detect testosterone abuse in sport. Inhibitors of testosterone glucuronidation could have an impact on circulating testosterone levels, thus aiding performance, as well as potentially affecting the urinary T/E ratio and therefore masking testosterone abuse. Previous reports have revealed that non-steroidal, anti-inflammatory drugs, diclofenac and ibuprofen, inhibit the UGT2B17 enzyme. The aim of one study was to analyse dietary tea samples for inhibition of testosterone glucuronidation and, where inhibition is present, to identify the active compounds. Analysis of testosterone glucuronidation was conducted by performing UGT2B17 assays with detection of un-glucuronidated testosterone using high performance liquid chromatography. The results from this study showed that testosterone glucuronidation was inhibited by the green and white tea extracts, along with specific catechin compounds, notably: epicatechin, epigallocatechin gallate (EGCG) and catechin gallate. The IC50 inhibition value for EGCG was determined, using a Dixon plot, to be 64 μM, equalling the most active NSAID inhibitor diclofenac. Thus, common foodstuffs and their constituents, for the first time, have been identified as inhibitors of a key enzyme involved in testosterone glucuronidation. Whilst these common compounds are not substrates of the UGT2B17 enzyme, we showed that they inhibit testosterone glucuronidation which may have implications on current doping control in sport [12193].

The large variation in disposition known for most drugs is also true for anabolic androgenic steroids. Genetic factors are probably the single most important cause of this variation. Further, there are reasons to believe that there is a corresponding variation in efficacy of doping agents. Doped individuals employ a large variety of doping strategies in respect of choice of substance, dose, dose interval, duration of treatment and use of other drugs for enforcement of effects or correction of side effects. Metabolic steps up-stream and down-stream of testosterone are genetically variable and contribute substantially to the variation in disposition of testosterone, the most common doping agent in sports and in society. Large inter- and intra-ethnic variation in testosterone glucuronidation and excretion is described as well as the pitfalls in evaluation of testosterone doping test results. The hydrolysis and bioactivation of testosterone enanthate is also genetically variable yielding a 2-3 fold variation in excretion rate and serum concentration, thereby implicating a substantial variation in "efficacy" of testosterone. Given this situation it is logical to adopt the new findings in the doping control programme. The population based cut-off level for the testosterone:epitestosterone ratio should be replaced by a Bayesian interpretation of consecutive tests in the same individual. When combined with the above genetic information the sensitivity of the test is considerably improved. The combination of the three approaches should reduce the rate of falsely negative or positive results and the number of expensive follow-up tests, stipulated by the World Anti-Doping Agency [12192].
In the light of the continuously growing knowledge on the relevance of steroid conjugation (i.e. phase-II metabolism reactions), various new studies were initiated and reported concerning steroid glucuronides and sulfates, factors arguably confining their urinary concentrations, and the accurate and sensitive determination of these steroid conjugates for potential evaluation as a complement to the current steroid profiling approaches. It was investigated the utility of combining analytical results of 7 steroid glucuronides and 5 steroid sulfates for the detection of transdermal and oral administrations of testosterone and testosterone undecanoate, respectively. A total of 19 volunteers were subjected to genotyping concerning the insertion/deletion of the UGT2B17 gene yielding 7 ins/ins, 7 ins/del, and 5 del/del genotypes. All participants underwent a transdermal testosterone application (via patches providing 2.4 mg of testosterone/24 h) and, after washout, oral testosterone undecanoate administration (2 x 40 mg), and urine samples were collected over a period of 96 h. By means of LC-MS/MS, relevant steroid conjugates were quantified, corroborating the issue of common GC-MS-based steroid profile approaches that population-based reference ranges barely allow the identification of topical and oral testosterone administration. Employing an intra-individual profiling strategy, the administration of testosterone via patches was identified, particularly by means of the ratios of testosterone glucuronide (TG)/epitestosterone glucuronide (epiTG) as well as androsterone glucuronide (AG)/etiocholanolone glucuronide (EG). The ingestion of testosterone undecanoate was detectable predominantly by means of etiocholanolone sulfate (ES), especially in UGT2B17 del/del genotypes [13009].

UGT2B17 deletion genotypes are especially prevalent among Asian athletes, and the traceability of intramuscularly administered testosterone enanthate to female Japanese volunteers was therefore investigated with a cohort consisting of six del/del, three ins/del, and one ins/ins genotype. As expected, the T/epiT ratio of the del/del group did not exceed the limit of 4 at any time of the 16 days of the study period, thus no follow-up analyses by IRMS would have been triggered. Consequently, the authors suggested employing subject-based reference ranges and/or genotype-specific thresholds for steroid profile parameters such as the T/epiT ratio [13009].

Emphasis was put for instance on UDP-glucuronosyltransferase UGT2B17, a key enzyme in testosterone glucuronidation. In an in vitro experiment it was shown that UGT2B17 was be negatively influenced by catechins (epicatechin, epigallocatechin gallate, and catechin gallate) commonly found in dietary green and white teas. Since tea consumption can lead to pharmacologically relevant concentrations of these catechins, it is conceivable that steroid profiles can vary due to such licit dietary products; however, in vivo data remain to support this assumption and to assess the relevance for sports drug testing. Concerning the same key enzyme UGT2B17, the role of androgen sulfation was studied in volunteers with two, one, or no allele of the respective gene, who received a single oral dose of testosterone enanthate. While sulfates of urinary steroids were found to be inadequate for monitoring purposes in this scenario, the increased excretion of androsterone (A) glucuronide was considered helpful (especially when evaluated in relation to epitestosterone (EpiT) glucuronide), which is in agreement with earlier studies outlining the relevance of the A/EpiT ratio in steroid profiling. Deletion polymorphism concerning UGT2B17 is of great importance when interpreting steroid profile data; hence, the availability of a test assay for its determination from doping control urine sample was desirable and established in 2011. A total of 674 urine samples was phenotyped, corresponding T/EpiT ratios were determined and significant correlations between homozygote gene-deletion and low T/EpiT ratios confirmed [13012].

It was investigated the androgen receptor (AR) bioluminescence response in serum and urine before and after testosterone challenge in different genotypes of the UGT2B17
enzyme, which catalyses testosterone glucuronidation. The androgen receptor activity was determined using a yeast-based bioluminescence assay. The androgens were analysed using LC-MS/MS, and the individuals were genotyped for UGT2B17 deletion polymorphism using real-time polymerase chain reaction. The serum concentrations of testosterone and dihydrotestosterone (DHT) were markedly elevated on days 2 and 4 and were still above baseline on day 15 after a dose of 500 mg testosterone enanthate. The androgenic activity in serum increased in parallel and correlated with the hormone concentrations and remained above baseline on day 15. The urinary androgenic activity increased 4-5-fold and was closely related to the unconjugated testosterone and independent of the UGT2B17 genotype. The AR assay may serve as a complement to the urinary testosterone/epitestosterone (T/E) doping test, because this is profoundly influenced by the UGT2B17 deletion polymorphism. It may also be useful for detection of other illicit androgens in sports, or in the society, or for monitoring and diagnostics of androgen-related disorders [13217].

*Japan*

Ethnicity has been found to influence urinary testosterone glucuronide to epitestosterone glucuronide (T/E) ratios among athletes. Uridine diphospho-glucuronosyltransferase 2B17 (UGT2B17) is the most active enzyme in testosterone glucuronidation. UGT2B17 polymorphism analysis is rarely performed in Japanese athletes, and the influence of testosterone administration on steroid profiles and carbon isotope ratios, according to gene polymorphisms, in Asians remains unknown. The prevalence of UGT2B17 genotypes and urinary androgenic steroid profiles, classified according to UGT2B17 genotypes, was investigated in Japanese athletes (255 male and 256 female). Testosterone enanthate (100 mg) was administered intramuscularly to Japanese female volunteers (del/del: n=6, del/ins: n=3, ins/ins: n=1). The distribution rates of the UGT2B17 del/del genotype in Japanese male and female athletes were 75 percent and 60 percent, respectively. The ins/ins genotype was detected in only three male (1.2 %) and seven female (2.7 %) athletes. The prevalence of the UGT2B17 deletion genotype was extremely high in Japanese athletes. The T/E ratio in the del/del group was significantly lower than that in the other groups. After testosterone was administered to female volunteers, the T/E ratios for the del/del individuals failed to reach the positivity criterion of 4. By contrast, in all of the del/del subjects, the gas chromatography/combustion/isotope ratio mass spectrometry (GC-C-IRMS) analysis successfully fulfilled the positivity criterion. The overall result has demonstrated the limited effectiveness of population-based T/E ratios in screening tests for testosterone use. Subject-based steroid profiling with UGT2B17 genotyping will be an effective strategy for detecting testosterone misuse [12194, 13218].

*Genetic polymorphism*

Emphasis has been put on UDP-glucuronosyltransferase UGT2B17, a key enzyme in testosterone glucuronidation. In an in vitro experiment it was shown that UGT2B17 was negatively influenced by catechins (epicatechin, epigallocatechin gallate, and catechin gallate) commonly found in dietary green and white teas. Since tea consumption can lead to pharmacologically relevant concentrations of these catechins, it is conceivable that steroid profiles can vary due to such licit dietary products; however, in vivo data remain to support this assumption and to assess the relevance for sports drug testing. Concerning the same key enzyme UGT2B17, the role of androgen sulfation was studied in volunteers with two, one, or no allele of the respective gene, who received a single oral dose of testosterone enanthate. While sulfates of urinary steroids were found to be inadequate for monitoring purposes in this scenario, the increased excretion of androsterone (A) glucuronide was considered helpful (especially when evaluated in relation to epitestosterone (EpiT) glucuronide), which is in agreement with earlier studies outlining the relevance of the A/EpiT ratio in steroid profiling. Deletion polymorphism concerning UGT2B17 is of great importance.
when interpreting steroid profile data [12017].

Aiming at the identification of new, complementary biomarkers for endogenous steroid abuse, the utility of a steroidomic approach using UHPLC-HRMS was assessed. In a controlled elimination study with orally administered testosterone undecanoate (80 mg), urine samples were subjected to a holistic steroid analysis followed by chemometric/statistical data evaluation. Here, numerous glucuronidated or sulfated steroids, the deconjugated analogs, of which mostly constitute the established steroid profile, were found to support the discrimination of the groups having received either placebo or testosterone undecanoate. The study demonstrated the principle of modern analytical approaches commonly referred to as “-omics” strategies and its potential application to issues of doping controls; in order to consider the whole (holistic) picture of such approaches, complementary analyses (e.g. by means of GC-HRMS) might be required to strengthen the outcome and value [12017].

Urinary steroid profiling is used in doping controls to detect testosterone abuse. A testosterone over epitestosterone (T/E) ratio exceeding 4.0 is considered as suspicious of testosterone administration, irrespectively of individual heterogeneous factors such as the athlete's ethnicity. A deletion polymorphism in the UGT2B17 gene was demonstrated to account for a significant part of the inter-individual variability in the T/E between Caucasians and Asians. Now it was examined the variability of urinary steroid profiles in a widely heterogeneous cohort of professional soccer players. The steroid profile of 57 Africans, 32 Asians, 50 Caucasians and 32 Hispanics was determined by gas chromatography-mass spectrometry. Significant differences have been observed between all ethnic groups. After estimation of the prevalence of the UGT2B17 deletion/deletion genotype (African 22%; Asian 81%; Caucasian 10%; Hispanic 7%), ethnic-specific thresholds were developed for a specificity of 99 percent for the T/E (African 5.6; Asian 3.8; Caucasian 5.7; Hispanic 5.8). Finally, another polymorphism could be hypothesized in Asians based on specific concentrations ratio of 5α-/5β-androstan-3α,17β-diol in urine. These results demonstrate that a unique and nonspecific threshold to evidence testosterone misuse is not fit for purpose. An athlete’s endocrinological passport consisting of a longitudinal follow-up together with the ethnicity and/or the genotype would strongly enhance the detection of testosterone abuse. Finally, additional genotyping studies should be undertaken to determine if the remaining unexplained disparities have an environmental or a genetic origin [09050].

Genetic variation has a large impact on androgen disposition. This variation is of the utmost importance for the interpretation of doping test results and may modulate the effects of testosterone replacement therapy and testosterone doping [09051].

**Association with renal disease and gene polymorphism**

With prolonged use of anabolic androgenic steroids (AAS), occasional incidents of renal disorders have been observed. Independently, it has also been established that there are considerable inter-individual and inter-ethnic differences, in particular with reference to the uridine diphosphate-glucuronosyltransferase 2B17 (UGT2B17) gene, in metabolising these compounds. One report postulated the association of deletion polymorphism in the UGT2B17 gene with the occurrence of renal disorders on chronic exposure to AAS. The major deactivation and elimination pathway of AASs is through glucuronide conjugation, chiefly catalyzed by the UGT2B17 enzyme, followed by excretion in urine. Excretion of steroids is affected in individuals with a deletion mutation in the UGT2B17 gene. It was hypothesize that UGT2B17 deficient individuals are more vulnerable to developing renal disorders with prolonged use of AAS owing to increases in body mass index and possible direct toxic effects of steroids on the kidneys. Elevated serum levels of biologically active steroids due to inadequate elimination can lead to prolonged muscle build up. An increase in body mass
index may cause renal injuries due to sustained elevated glomerular pressure and flow rate. In the absence of controlled clinical trials in humans, observational studies can be carried out. Real time PCR with allelic discrimination should be employed to examine the prevalence of different UGT2B17 genotypes in patients with impaired renal function and AAS abuse. In individuals with the UGT2B17 deletion polymorphism, blood tests, biofluid analyses, urinalysis, and hair analyses following the administration of an anabolic steroid can be used to determine the fate of the substance once in the body. If the hypothesis is upheld, anabolic steroid users with a deletion mutation in the UGT2B17 gene may be exposed to an increased risk of developing renal disorders. In the current detecting – sanctioning anti-doping system, athletes motivated by the potential to evade detection owing to their unique genetic make-up could subject themselves to a serious health consequence. More research on AAS metabolism in the presence of UGT2B17 gene deletion is required. Benefit or harm evaluations in therapeutic use of anabolic steroids should also consider this potential link between UGT2B17 gene deletion polymorphism and renal disorders [10057].

Chemistry

Androgenic and anabolic steroids (AASs) are a class of chemical substances closely related to testosterone in molecular structure. They can be abused to enhance performances in human and equine athletes, and are banned by the sports authorities. To assist with method development for doping analyses of AASs, investigations were conducted to correlate their product ion profiles with the molecular structures. Although very similar in chemical structure, AASs generated noticeably different product ion profiles from collision-induced dissociation (CID). On the basis of both outlines of the product ion profiles and molecular structures, AASs studied were classified into six subclasses. In each subclass, the product ion profiles were identical or similar. However, the product ion profiles in one subclass were remarkably different from those in another. The classification reveals that the position and number of double bond(s) in conjugation with the 3-carbonyl group in the molecular structure of an AAS have significant effects on product ion profile. The presence or absence of the 19-methyl group in an AAS also has a remarkable influence on its product ion profile. A substitution in the A-, B- or D-ring of an AAS may cause a shift in mass value of the product ions. The correlation of product ion profiles with molecular structures of AASs has the implication that each AAS can be characterized by a combination of its [M + H]+ ion and product ion profile and as a result be identified with specificity. The classified product ion pattern may be useful in the identification of unknown AASs [10323].

Steroid hormones

Steroid hormones include the sex hormones, glucocorticoids, and mineralocorticoids. Within the family of sex hormones are the androgens, estrogens, and progestogens. All of the steroid hormones bind to their own specific receptor, which may be cytosolic or nuclear, to induce changes within a cell. All natural steroid hormones are synthesized from cholesterol in the adrenal glands and/or gonads. Some steroid hormones are further metabolized in the liver, peripheral and/or target tissues. As their precursor is cholesterol, they are hydrophobic in nature which allows them to pass easily through cell membranes. Once synthesized, the steroid hormones are carried in the blood stream bound to carrier proteins such as albumin, steroid hormone-binding globulin (SHBG) or corticosteroid-binding globulin to target tissues. The androgen produced in the highest concentration in the body is testosterone (T). This is a 19-C steroid that has androgenic and anabolic effects within the body. T is primarily produced in the gonads but a small amount is produced in the adrenal cortex or from the peripheral conversion of androstenedione. T production is much greater in males than in
females (5000-7000 microg/day vs 300 microg/day). In males, T is primarily produced by the Leydig cells in the testes whereas in females, the primary production of T occurs in the Theca cells of the ovaries. In both sexes, small amounts come from the adrenal cortex and the peripheral conversion of androstenedione. T acts in the body by acting directly through the AR or indirectly via metabolism to other sex steroids. T can be aromatized to estradiol (E2) which activates ER-alpha and/or ER-beta. Alternatively, T can be irreversibly converted to the more potent 5alpha-dihydrotestosterone (5alpha-DHT) by the enzyme 5alpha-reductase. T has many physiological actions in the body. It acts on muscles to stimulate growth and maintenance, it promotes bone development while inhibiting bone resorption, and it increases red blood cell and hemoglobin levels, augments libido and erectile function, enhances mood and cognition, and induces lipolysis. Low testosterone levels or deficit in androgen action induces frailty, sarcopenia, poor muscle quality, muscle weakness, hypertrophy of adipose tissue and impaired neurotransmission [13084].

**Testosterone and its modifications**

Testosterone is the most important androgen in the human body. The effects of androgens are most evident during puberty, as they elicit dramatic physiological changes in the male body, including the onset of secondary male characteristics, hair growth pattern, sebaceous gland activity and maturation of sperm and libido. These are considered the virilizing or “androgenic” effects. Daily testosterone synthesis ranges from 2.1 to 11.0 mg in individual males, with normal plasmatic levels of 300-1000 ng/dL, which progressively decline with age. Testosterone has several possible metabolic fates. First, it binds to the androgen receptor (AR) in target tissues to exert its effects. Second, it is reduced to 5alpha-dihydrotestosterone (5DHT), which also acts on the AR. Following a different path, testosterone may be aromatized to estradiol to exert estrogenic effects, typically water retention, breast tissue growth and an increase in body fat deposition. Along with the androgenic changes comes the “anabolic” effect. Anabolism is defined as any state in which nitrogen is differentially retained in lean body mass through the stimulation of protein synthesis and/or a reduction in protein breakdown. It includes growth promotion, protein and collagen synthesis and an increase in muscle size and bone metabolism. Characteristically, steroids that are more anabolic present weaker AR bindings, and those that are more androgenic strongly bind the AR, exerting a more potent effect. A “myotrophic-androgenic index”, based on the association between anabolic and androgenic bioassays in rats has been previously described. Since testosterone is the basic AAS, it has a 1:1 anabolic-androgenic ratio. Structural modifications have been made to the testosterone molecule in an attempt to maximize the anabolic effects and minimize the androgenic ones; however, all AASs are virilizing if administered for long enough, at high enough dosages. AASs therefore include synthetic derivatives of testosterone, and not only testosterone itself. The AAS structural base is the steran nucleus, consisting of three condensed cyclohexan rings, in nonlinear junction, and a cyclopentane ring. The anabolic effects are dose-dependent, and usually occur when supraphysiological testosterone levels (>1000 ng/dL) are found, which generally requires weekly doses of 300 mg or more. Traditionally, AASs are classified according to the route of administration and their carrier solvent and fall into two categories: oral and parenteral. Alkyl substitution prevents deactivation of the steroid by hepatic first-pass metabolism (necessitating hepatic monitoring), which promotes oral activity. They usually have short half-lives, making several daily doses necessary to maintain appropriate blood levels. This class includes the very common stanozolol and oxandrolone, as well as methyltestosterone and others. If the 17beta-hydroxyl group is esterified with an acid moiety it prevents rapid release from the oily vehicle. Roughly, the longer the chain length of the acid moiety, the more slowly the preparation is released into the blood stream. Once in the circulation, hydrolysis rapidly occurs yielding the active compound. They usually have a longer half-life and a slower absorption rate, bringing much less hepatic stress than the orally taken steroids. Pain at
injection sites is common, because of the oily base. There are several basic active compounds: testosterone, bound to esters such as undecanoate, cypionate, propionate and others; and 19-nortestosterone (or nandrolone), also bound to different esters. Nandrolone is extremely popular, owing to its high anabolic to androgenic ratio. In contrast to testosterone, nandrolone is converted to a less potent metabolite after 5alpha-reduction. This, in addition to nandrolone’s lesser affinity to AR, explains the higher myotrophic to androgenic ratio. Other group of compounds is headed by boldenone, bound to ester undecylenate; and trenbolone, bound to ester acetate [11028].

Two modifications made to the testosterone molecule alter the androgenic/anabolic profile, and thus the type of side effects seen from usage of the various AAS. Class A modifications are formulated by esterification of the 17-alpha-hydroxyl group, which increases the lipophilic properties, allowing a slow, delayed absorption as an injectable form. This is the most common form of modification because it allows the injection to be administered as infrequently as once every 2 to 6 weeks. This pharmacokinetic alteration also results in increased and unwanted androgenic effects. Class B modifications result from alkylation of the 17-alpha portion of the molecule, which decreases hepatic metabolism. This allows increased oral absorption and slower hepatic degradation. Slower clearance from the liver results in greater hepatic toxicity [06031].

**General metabolism**

The major elimination and deactivation pathway of AAS and their phase I metabolites is through glucuronide conjugation (phase II metabolism), mainly catalysed by the enzyme UGT2B17, followed by excretion in urine. However, inter-individual and inter-ethnic variations in the prevalence of deletion polymorphism in the gene coding of the UGT2B17 enzyme have been reported, which eventually influence the urinary excretion of AAS and potentially lead to false-negative doping results. It has also been reported that the glucuronidation activity of UGT2B17 and other UGTs towards AAS is inhibited by commonly used anti-inflammatory drugs like diclofenac and ibuprofen, in vitro. Common dietary substances such as red wine, white tea and green tea have also shown similar inhibitory effects in in vitro studies. Although the inhibitory effect is yet to be examined and reported in vivo, these in vitro results indicate that concomitant use of such over-the-counter medication or common dietary products with AAS may lead to impaired urinary excretion of AAS and their metabolites [12116].

Considering that such genetic and metabolic variations may limit the efficacy of urinalysis in testing doping, it can be suggested that urinalysis, if used as a stand-alone test, is susceptible to confounding doping results. Owing to the growing number of doping cases with AAS, there is an ever-increasing need to develop new methods to detect drug doping. The current anti-doping regime can be reinforced by employing additional biological samples like blood and hair analysed in tandem with urine. Since impaired glucuronidation leads to reduction in the urinary excretion rate of AAS, it can be assumed that the levels of unconjugated AAS and their phase I metabolites in the systemic circulation will be elevated and thus higher levels of AAS and their phase I metabolites will be available to get incorporated into hair and other body tissues. Hair analysis has been used in the past for detecting drug use as it predominantly favours the direct detection of parent AAS and determines a retrospective history of drug use. Thus, hair analysis and blood analysis can provide complementary information to urinalysis to prevent false doping results [12116].

**Effect of oxidizing adulterants on human urinary steroid profiles**

Steroid profiling is the most versatile and informative technique adapted by doping control laboratories for detection of steroid abuse. The absolute concentrations and ratios of
endogenous steroids including testosterone, epitestosterone, androsterone, etiocholanolone, 5alpha-androstane-3alpha,17beta-diol and 5beta-androstane-3alpha,17beta-diol constitute the significant characteristics of a steroid profile. In one study we report the influence of various oxidizing adulterants on the steroid profile of human urine. Gas chromatography-mass spectrometry analysis was carried out to develop the steroid profile of human male and female urine. Oxidants potassium nitrite, sodium hypochlorite, potassium permanganate, cerium ammonium nitrate, sodium metaperiodate, pyridinium chlorochromate, potassium dichromate and potassium perchlorate were reacted with urine at various concentrations and conditions and the effect of these oxidants on the steroid profile were analyzed. Most of the oxidizing chemicals led to significant changes in endogenous steroid profile parameters which were considered stable under normal conditions. These oxidizing chemicals can cause serious problems regarding the interpretation of steroid profiles and have the potential to act as masking agents that can complicate or prevent the detection of the steroid abuse [12117].

Steroids from musk deer

The administration of musk extract, that is, ingredients obtained by extraction of the liquid secreted from the preputial gland or resulting grains of the male musk deer (e.g. Moschus moschiferus), has been recommended in Traditional Chinese Medicine (TCM) applications and was listed in the Japanese pharmacopoeia for various indications requiring cardiovascular stimulation, anti-inflammatory medication or androgenic hormone therapy. Numerous steroidal components including cholesterol, 5alpha-androstane-3,17-dione, 5beta-androstane-3,17-dione, androsterone, etiocholanolone, epiandrosterone, 3beta-hydroxyandrost-5-en-17-one, androst-4-ene-3,17-dione and the corresponding urea adduct 3alpha-ureido-androst-4-en-17-one were characterised as natural ingredients of musk over several decades, implicating an issue concerning doping controls if used for the treatment of elite athletes. In the present study, the impact of musk extract administration on sports drug testing results of five females competing in an international sporting event is reported. In the course of routine doping controls, adverse analytical findings concerning the athletes' steroid profile, corroborated by isotope-ratio mass spectrometry (IRMS) data, were obtained. The athletes' medical advisors admitted the prescription of TCM-based musk pod preparations and provided musk pod samples for comparison purposes to clarify the antidoping rule violation. Steroid profiles, IRMS results, literature data and a musk sample obtained from a living musk deer of a local zoo conclusively demonstrated the use of musk pod extracts in all cases which, however, represented a doping offence as prohibited anabolic-androgenic steroids were administered [12120].

Physiology

Testosterone supplementation acts via numerous mechanisms as a highly potent anabolic agent to skeletal muscle. Although growth hormone (GH) strongly affects collagen synthesis and lipolysis, as well as increasing lean body mass, it is not anabolic toward the contractile (ie, myofibrillar) muscle tissue in healthy individuals. However, there is a persistent belief (both in scientific literature and among recreational weightlifters) that exercise-induced release of GH and testosterone underpins muscular hypertrophy with resistance training. This is a premature assumption because although pharmacological GH supplementation can increase muscle strength or size in individuals with clinical GH deficiency, there is no evidence that transient exercise-induced changes in GH have the same effects in individuals with normal GH levels. Exercise paradigms are designed based on the assumption (not necessarily evidenced-based mechanisms) that GH and testosterone facilitate anabolic processes that lead to skeletal muscle protein accretion and hypertrophy. Recent work
disputes this assumption. Instead, data indicate that exercise-induced hormonal elevations do not enhance intracellular markers of anabolic signaling or the acute postexercise elevation of myofibrillar protein synthesis. Furthermore, data from our training study demonstrate that exercise-induced increases in GH and testosterone availability are not necessary for and do not enhance strength and hypertrophy adaptations. Instead, our data lead us to conclude that local mechanisms that are intrinsic to the skeletal muscle tissue performing the resistive contractions (ie, weightlifting) are predominant in stimulating anabolism. Clarifying both the role of hormones in regulating muscle mass as well as the underlying basis for adaptation of skeletal muscle to resistance exercise will hopefully enhance and support the prescription of resistance exercise as an integral component of a healthy lifestyle [10444].

Dimethandroline (DMA: 7α,11β-dimethyl-19-nortestosterone) and 11β-methyl-19-nortestosterone (MNT) are potent androgens in development for hormonal therapy in men. As 5α-reduced androgens, such as 5α-dihydrotestosterone (DHT), may raise the risk of benign prostate hyperplasia, accelerate the development of prostate carcinoma, and increase male pattern baldness and acne, we investigated the role of 5α-reduction in the androgenic activity of DMA and MNT. The authentic 5α-reduced metabolites, 5α-dihydroDMA (5α-DHDMA) and 5α-dihydroMNT (5α-DHMNT), were prepared by chemical synthesis and compared in vitro and in vivo to the parent compounds. Both 5α-reduced androgens bind with high affinity to the rat androgen receptor (AR) and were potent inducers of transactivation of 3XHRE-LUC in CV-1 cells cotransfected with a human AR expression plasmid. To examine in vivo androgenic (stimulation of ventral prostate and seminal vesicle weights) and anabolic (stimulation of levator ani muscle weights) activity, 22-day-old castrate male rats were treated sc for 7 days with various doses of DMA, 5α-DHDMA, or testosterone (T) or MNT, 5α-DHMNT, or T and necropsied on day 8. 5α-DHDMA was at least threefold more potent than T in stimulating growth of the ventral prostate but only 30-40 percent as potent as DMA. 5α-DHMNT was four- to eightfold more potent than T, whereas MNT was approximately equipotent to T. To assess the possible role of 5α-reduction in ventral prostate and seminal vesicle growth, castrate immature rats were treated with maximally effective doses of T, DHT, DMA, MNT, or the related 19-norandrogen, 7α-methyl-19-nortestosterone (MENT), or vehicle, with or without dutasteride (DUT), an inhibitor of 5α-reductases types 1 and 2. In rats treated with T+DUT, serum T was significantly higher than in rats treated with T alone, and serum DHT was decreased to levels observed in castrate vehicle-treated rats. DUT significantly reduced both ventral prostate and seminal vesicle weights in T-treated rats, whereas there was no significant effect of DUT on weights of these accessory sex glands in rats treated with DMA, MNT, DHT, or MENT. These results indicate that inhibition of 5α-reductase activity in vivo does not affect the androgenic potency of DMA, MNT, or MENT [10445].

Over a period of 10 to 20 weeks, a supraphysiologic dose of testosterone administered to healthy young men can increase lean body mass, as well as muscle size and strength with or without exercise. These significant increases are dose dependent and only occur with doses of 300 mg per week and higher. The most profound effects are noted when supraphysiologic doses accompany a training program and are used in conjunction with a diet adequate in protein and calories. Testosterone-induced muscle hypertrophy and increases in muscle strength are the result of increases in the cross-sectional area of muscle fibers and myonuclear number. Research suggests that these anabolic effects are mediated by testosterone-influenced increases in muscle protein synthesis, creating a positive nitrogen balance. Androgen receptors in skeletal muscle regulate the transcription of the target genes that control the accumulation of DNA needed for muscle growth. Complementary effects include glucocorticoid antagonism, which minimizes the catabolic actions of corticosteroids released during the stress of athletic activity. Similarly, stimulation of the growth hormone
insulin-like growth factor-1 axis and enhanced collagen synthesis and bone mineral density are additional anabolic effects [07008].

Testosterone is produced in several areas within the human body. In men, most of it is synthesized in the Leydig cells of testes and in the adrenal glands; in women, testosterone is produced in the ovaries and adrenal glands, with a smaller fraction produced in other peripheral sites. Its synthesis involves a cholesterol precursor and a series of enzymatic reactions. Secretion is determined by a negative feedback mechanism that involves the anterior pituitary gland. It is here that luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are stored. Elevated levels of testosterone affect the hypothalamus and pituitary. At high levels of testosterone, LH tends to be reduced (affecting sperm and endogenous testosterone production). Studies by the World Health Organization examined the use of anabolic steroids as a form of male birth control, but the results were not promising [07007].

Mechanism of action

Testosterone is both an active hormone and a prohormone for the formation of the more active androgen, 5alpha-dihydrotestosterone (DHT) via 5alpha-reductase...The production of testosterone occurs predominantly (i.e. 95 %) in the Leydig cells of the testes and, to a lesser, extent in the adrenal glands. These creations of androgens from the adrenal cortex are insufficient to maintain male sexuality. Women also secrete small amounts of testosterone from the ovaries and adrenal glands including DHEA and androstenedione. Testosterone acts as an androgen either directly by binding to the androgen receptor or indirectly by conversion to DHT. This latter compound binds more avidly to the androgen receptor than testosterone. Dihydrotestosterone amplifies the action of androgen and conveys specific function to the androgen–androgen receptor complex. The conversion of testosterone to DHT is especially important for the appearance of virilization in female AAS users because high levels of 5alpha-reductase activity in the male accessory sex glands limits the effects of DHT. Activation of the intracellular, ligand-dependent androgen receptor complex by testosterone and AAS results in the production RNA, DNA, and the subsequent enhancement of protein synthesis, including increased amounts of actin and myosin in skeletal muscles. The androgen receptor belongs to the nuclear receptor family that contains a DNA-binding domain, a ligand-binding domain, and at least 2 transcriptional activation domains. The enzyme, aromatase controls the androgen-estrogen ratio by catalyzing the conversion of testosterone to estradiol in other tissues (e.g. adipose tissue and brain). Anabolic-androgenic steroids (e.g. methandienone, nandrolone, stanozolol) with the most potent anabolic effects also possess the relatively greatest androgenic effects. The interactions of AAS with the androgen receptors in various tissues vary between compounds in this group, and these variations account for differences in the anabolic andandrogenic effects of these compounds. The use of AAS increases skeletal muscle mass and strength when used in combination with intensive strength training and high-protein, high-caloriediets. Endogenous testosterone is responsible for sexual maturation at all stages of development throughout the life of males. Increased AAS plasma concentrations suppress gonadotropin-releasing hormone, endogenous testosterone secretion, luteinizing hormone, and follicle-stimulating hormone by a negative-feedback mechanism. Endogenous androgens stimulate RNA-polymerase, resulting in an increased production of proteins. These proteins are responsible for normal male sexual development, including the growth and maturation of the prostate, seminal vesicle, penis, and scrotum. During puberty, androgens cause a sudden increase in growth hand development of muscle along with redistribution of body fat and deepening of the voice.
Continued endogenous testosterone secretion produces increased hair (beard, and body hair), fusion of the epiphyses, termination of growth, and the maintenance of spermatogenesis. Testosterone also affects the formation of erythropoietin, the balance of calcium, and blood glucose concentrations [13002].

**Chemical structure versus function**

Steroids are organic molecules with a tetracyclic ring system; all steroids with the exception of retinoic acid are derived from cholesterol. There are 4 major classes of natural steroid hormones (androgens, corticoids, estrogens, and progestogens) with testosterone being the principal male androgenic steroid. AASs are synthetic compounds similar in chemical structure to testosterone (molecular weight 288 g/mol). There are 3 major classes of AASs (oral, injectable-oil-based, and injectable-water-based) and at least 30 anabolic-androgenic steroid compounds. Abuse of other forms of AASs includes the use of buccal (Striant), sublingual (tetrahydrogestrinone), and transdermal (testosterone cream) preparations; these short-acting preparations are typically testosterone-based. The advantage of the buccal, sublingual, and transdermal preparations is the rapid clearance within 1 week after even large doses compared with 2-14 days for oral preparations and 4 weeks for water-soluble parenteral preparations. Non-steroidal selective androgen receptor modulators (SARMs) are experimental substances (e.g. bicyclic hydantoin, analogs of ary/propionamide, quinoline, tetrahydroquinoline) that may offer better dissociation of the biologic and anabolic effects of steroids; although these substances are not routinely available, the World Anti-Doping Agency (WADA) added these substances to the prohibited list in 2008. Up-to-date information on the list of banned substances is available on the WADA website (http://www.wada-ama.org/en/). Testosterone is the prototype for all AASs. Modification of testosterone during the synthesis of AASs involves the following three methods: alkylation of the 17beta-hydroxyl group, esterification at the 17alpha-position, or modification of the steroid nucleus to enhance anabolic properties. Although all currently available anabolic steroids have androgenic properties, the anabolic properties are greater for synthetic AASs than for testosterone. Some structural modifications improve bioavailability and prolong the duration of action, whereas other modifications reduce anabolic effects while enhancing androgenic effects. Esterification at the 17beta-hydroxy position increases lipophilic and androgenic properties while improving intramuscular bioavailability. In general, alkylation of the 17alpha-hydroxy position retards hepatic degradation and improves oral bioavailability, but these compounds typically are less potent than 17beta-esters. Weaker formulations of AASs are often marketed as prohormones in dietary supplements, particularly dehydroepiandrosterone (DHEA), 19-norandrostenediol, androstenedione, 19-norandrostenedione, 1-testosterone, and prostandol. The lack of the 17alpha-alkyl moiety results in extensive first-pass metabolism, and the anabolic effect of DHEA and androstenedione are limited by their weak binding to the androgen receptor despite some conversion to testosterone. The effect of these AASs is substantially greater on women than men because of the relatively larger increase in testosterone in the former. Tetrahydrogestrinone (THG;13-ethyl-17hydroxy-18,19-dinor-17alphapregn-4,9,11-trien-3-one), norbolethone, and madol (17alpha-methyl-5alpha-androst-2-en-17beta-ol) are designer anabolic steroids, which were synthesized to avoid detection during use. However, THG is a nonspecific androgen agonist that binds many steroid hormone receptors, particularly the glucocorticoid receptors [13002].

**Myotrophic action of androgens**

The myotrophic effects of androgens on muscle strength and mass are the main reason for their popularity among androgen users. Androgens also increase lean body mass, decrease fat mass, enhance performance, sustain intensive training periods, and can improve
appearance. The effects on lean body mass were shown by treating young men with a gonadotropin-releasing hormone (GnRH) analogue that suppressed endogenous T production. These men showed decreased rates of whole body protein synthesis, muscle strength and fat oxidation, together with an increased fat mass. When T was replaced through supplementation, there was a restoration of muscle size and strength with a concomitant reduction in fat mass. Androgens including T increase muscle fiber hypertrophy in human skeletal muscle by enhancing protein synthesis. This occurs via the activation of satellite cells and the promotion of myonuclear accretion when existing myonuclei become unable to sustain further enhancement of protein synthesis. The use of androgen therapy during aging is primarily to promote muscle strength by improving or maintaining muscle mass [13084].

Endogenous androgens

Cholesterol is the starting substance for formation of glucocorticoids, mineralocorticoids and sex steroids. Precursors of androgens are formed in the adrenals and biotransformed in the endocrine target organs, the gonads and the prostate gland. Dihydrotestosterone (DHT) is formed from testosterone in the prostate and is a more potent androgen than testosterone itself. Some of the testosterone precursors have weak androgenic effects such as dehydroepiandrosterone (DHEA) and androstenedione. They may be present in dietary products and abused per se. Most of the end products are eliminated via the kidneys after conjugation with glucuronic acid or sulphate groups by enzymes in the uridine glucuronosyl transferase (UGT) and sulphate transferase (SULT) super families, respectively. The UGT enzymes have different selectivities for the androgens and androgen metabolites. The specificity, the activity and the genetic variation of the various UGT enzymes is of particular interest in the conjugation and excretion of testosterone and epitestosterone as these steroids and their conjugates are quantified in the urine in conventional testosterone doping tests. Genetic variation in other steroid metabolizing enzymes may also influence the disposition of testosterone and other AAS [12192].

Androgen disposition and genetic variation

Genetic variation in genes involved in the synthesis, breakdown and elimination of androgens may affect the bioavailability of administrated AAS, and hence affect the degree of anabolic and toxic effects of doping. Moreover, genetic variation in the androgen receptor (AR) may modulate the pharmacodynamic effects of AAS. As a corollary, several of these polymorphisms may change the serum concentrations of AAS and excretion of AAS metabolites in the urine. Therefore, genetic variations are an important source of confounders in doping tests. Several functional polymorphisms in these genes known to alter the systemic load and excretion rate of androgens are discussed below in relation to doping and doping control [12192].

The metabolism of testosterone is revisited. Four previously unreported metabolites were detected in urine after hydrolysis with KOH using a liquid chromatography-tandem mass spectrometry method and precursor ion scan mode. The metabolites were characterized by a product ion scan obtained with accurate mass measurements. Androsta-4,6-dien-3,17-dione, androsta-1,4-dien-3,17-dione, 17-hydroxy-androsta-4,6-dien-3-one and 15-androsten-3,17-dione were proposed as feasible structures for these metabolites on the basis of the mass spectrometry data. The proposed structures were confirmed by analysis of synthetic reference compounds. Only 15-androsten-3,17-dione could not be confirmed, owing to the lack of a commercially available standard. That all four compounds are testosterone metabolites was confirmed by the qualitative analysis of several urine samples collected
before and after administration of testosterone undecanoate. The metabolite androsta-1,4-dien-3,17-dione has a structure analogous to that of the exogenous anabolic steroid boldenone. Specific transitions for boldenone and its metabolite 17β-hydroxy-5β-androst-1-en-3-one were also monitored. Both compounds were also detected after KOH treatment, suggesting that this metabolic pathway is involved in the endogenous detection of boldenone previously reported by several authors [10325].

**Metabolism – phase I enzymes**

Aldo-keto reductases (AKR1C) are divided into three families of which the AKR1C members AKR1C1, AKR1C2, AKR1C3, AKR1C4 and AKR1D1 have been shown to play an important role in steroid metabolism. Genetic variations in AKR1C genes may regulate the local concentration of steroid hormones. AKR1C3 is involved in the formation and inactivation of testosterone. Cytochromes P450 (CYPs) CYPs are the most important phase I enzymes in drug metabolism, accounting for the metabolism of more than 60 percent of all drugs. Several of the members of the CYP superfamily are also important catalysts in the metabolic network of steroids, e.g. CYP3A4 catalyzing 4-hydroxylation of testosterone. There is a large variation in the CYP3A4 activity between individuals, partly explained by polymorphisms in the CYP3A4 gene and partly by induction or inhibition by exogenous compounds and drugs. Several polymorphisms in this gene have been associated with altered serum concentrations of testosterone and oestrogens [12192].

Many anabolic steroids on the market are available as esters in order to achieve a retarded release. These pro-drugs need to be hydrolyzed prior to activation. It has been shown that PDE7B is involved in the hydrolysis of testosterone enanthate and nandrolone decanoate with implications for the serum concentrations and bioavailability of testosterone enanthate. It is conceivable that higher serum concentrations of testosterone convey an advantage in terms of strong androgenic influence on the organ receptors, thus being likely to improve the physical achievements [12192].

**Metabolism – phase II enzymes**

Uridine glucuronosyl transferases (UGTs) UGT enzymes are considered to be the main enzymes for inactivation and quantitative metabolic elimination of steroid hormones. UGT2B17 has been shown to be the main enzyme in testosterone glucuronidation activity in vitro and in vivo. It has been possible to demonstrate a large variation in the gene deletion both within, and between ethnic populations with important consequences for the interpretation of the T : E test. There is a large variation in urinary testosterone concentrations in UGT2B17 carriers, and this SNP may contribute to the variation in excretion within each UGT2B17 deletion polymorphism mode. UGT2B7 has also been identified as the main phase II enzyme involved in epitestosterone glucuronidation. Whether other SNPs in the UGT2B7 (or in other epitestosterone metabolizing enzyme genes) could explain the inter-individual variation in epitestosterone excretion needs to be investigated. Sulphotransferases (SULT) Even though glucuronides are the main conjugated metabolites of androgens, many steroids are also sulphated to different extent. For some steroids such as DHEA, sulphation is the major metabolic phase II pathway. As a matter of fact DHEA and DHEA sulphate are the most abundant androgen precursors in the circulation [12192].

Lately genetic polymorphisms in many transporter proteins have been shown to affect the outcome of drug treatment. The superfAMILY of organic anion transporting polypeptides (OATP), encoded by solute carrier organic anion transporter (SLCO) genes, mediates the uptake of various endogenous compounds including hormones. SLCO1B3 is involved in the uptake of several hormones including testosterone and SLCO2B1 mediates the transport of steroid conjugates, such as DHEA sulphate. Both these SLCOB genes are polymorphically expressed and have been shown to be functional, i.e. there is a correlation with the capacity
to transport hormones [12192].

**Steroid hormone binding globulin (SHBG)**

Steroid hormone binding globulin (SHBG) Testosterone and DHT bind with high affinity to SHBG, thereby regulating the concentration of bioactive testosterone. Several genetic polymorphisms have been characterized in the human SHBG gene. SHBG polymorphisms are associated with serum concentration of DHT and testosterone. Since genetic variation in the SHBG gene affects both the binding (and thereby bioavailability) and the urinary excretion of androgens, polymorphisms in SHBG may modulate both the effects of steroid doping and the analysis of illicit AAS [12192].

**Hydroxysteroid dehydrogenase**

The 3β-hydroxysteroid dehydrogenase/delta(5)-delta(4) isomerase (3β-HSD) and 1alpha-hydroxylase/17,20-lyase cytochrome P450 (P450c17) enzymes are important in determining the balance of the synthesis of different steroids such as progesterone (P4), glucocorticoids, androgens, and estrogens. How this is achieved is not a simple matter because each of the two enzymes utilizes more than one substrate and some substrates are shared in common between the two enzymes. The two synthetic pathways, delta(4) and delta(5), are interlinked such that it is difficult to predict how the synthesis of each steroid changes when any of the enzyme activities is varied. In addition, the P450c17 enzyme exhibits different substrate specificities among species, particularly with respect to the 17,20-lyase activity. The mathematical model developed in this study simulates the network of reactions catalyzed by 3β-HSD and P450c17 that characterizes steroid synthesis in human, non-human primate, ovine, and bovine species. In these species, P450c17 has negligible 17,20-lyase activity with the delta(4)-steroid 17alpha-hydroxy-progesterone (17OH-P4); therefore androstenedione (delta4) is synthesized efficiently only from dehydroepiandrosterone (DHEA) through the delta(5) pathway. The model helps to understand the interplay between fluxes through the delta(4) and delta(5) pathways in this network, and how this determines the response of steroid synthesis to the variation in 3beta-HSD activity or in the supply of the precursor substrate, pregnenolone (P5). The model simulations show that A4 synthesis can change paradoxically when 3beta-HSD activity is varied. A decrease in 3beta-HSD activity to a certain point can increase A4 synthesis by favouring metabolism through the delta(5) pathway, though further decrease in 3beta-HSD activity beyond that point eventually limits A4 synthesis. The model also showed that due to the competitive inhibition of the enzymes' activities by substrates and products, increasing the rate of P5 supply above a certain point can suppress the synthesis of A4, DHEA, and 17OH-P4, and consequently drive more P5 towards P4 synthesis [11568].

**Modulation of follistatin and myostatin propeptide**

The purpose of one pilot study was to investigate the impact of training, anabolic steroids and endogenous hormones on myostatin-interacting proteins in order to identify manipulations of myostatin signalling. To identify whether analysis of the myostatin interacting proteins follistatin and myostatin propeptide is suitable to detect the abuse of anabolic steroids, their serum concentrations were monitored in untrained males, bodybuilders using anabolic steroids and natural bodybuilders. In addition, we analysed follistatin and myostatin propeptide serum proteins in females during menstrual cycle. Our results showed increased follistatin concentrations in response to anabolic steroids. Furthermore, variations of sex steroid levels during the menstrual cycle had no impact on the expression of follistatin and myostatin propeptide. In addition, we identified gender differences
in the basal expression of the investigated proteins. In general, follistatin and myostatin propeptide concentrations were relatively stable within the same individual both in males and females. In conclusion, the current findings provide an insight into gender differences in myostatin-interacting proteins and their regulation in response to anabolic steroids and endogenous hormones. Therefore our data provide new aspects for the development of doping prevention strategies [13162].

**Chromosomal damage**

The aim of one study was to evaluate DNA damage (micronucleus) and cellular death (pyknosis, karyolysis and karyorrhexis) in exfoliated buccal mucosa cells from anabolic steroid users after 2 months of exposure. Two experimental groups consisting of 15 adult males who practise weight lifting and are anabolic steroid users or 15 adult males who practise weight lifting, but are non-anabolic steroid users, were recruited. In addition, 20 sedentary males, who do not practise any physical activity regularly, were matched by age with experimental groups. No significant statistical differences were noticed in individuals who practise physical activity only. On the other hand, an increase of micronucleated cells (MNCs) in anabolic steroid (decadurabulin and winstrol) users was observed. Regarding cytotoxic parameters, the same observation has occurred, that is, significant statistical differences were noticed in the group exposed to anabolic steroids when compared with other controls, as depicted by high frequencies of pyknosis, karyolysis and karyorrhexis. Taken together, the results suggest that genomic instability and cytotoxicity are induced by anabolic steroid administration in oral mucosa cells as assessed by the micronucleus test [10446].

**Androgen receptors**

The androgen receptor (AR) is expressed in many tissues and is activated through binding of testosterone and DHT. Activation of AR interacts with a broad variety of physiological processes. Therefore it is likely that genetic variation in AR may correlate with both anabolic effects and adverse side effects of androgen abuse. It has been speculated that these polymorphisms may affect the sensitivity to adverse psychic reactions such as aggression. Several polymorphisms have been described in the AR affecting the receptor affinity. In particular, a trinucleotide repeat (CAG) has been extensively studied and associated with disease risks, total fat free mass in men and acne, a common side effect of AAS abuse. In addition to their binding to AR, the testosterone metabolite 3alpha-androstanediol can bind to GABAA receptors, known to have an important role in the mediation of aggression [12192].

Nearly every cell in the human body has receptors for steroids, so that every organ system is susceptible to the effects of these molecules. Giving physiologic amounts of testosterone has no net effect on plasma levels because feedback inhibition shuts down endogenous production [07031].

The androgen receptor (AR) is a member of the steroid and nuclear receptor superfamily, and is a soluble protein that functions as an intracellular transcriptional factor. Structurally, AR contains three major functional domains, N-terminal domain (NTD), DNA-binding domain (DBD), and ligand binding domain (LBD). AR ligands regulate receptor function through binding to the LBD, which initiates sequential conformational changes of the receptor. Upon agonist binding, the receptor then undergoes dissociation from the chaperones, dimerization, phosphorylation, translocation to the nucleus, and binding to the androgen response element. Recruitment of other transcription coregulators and transcriptional machinery further ensures the transactivation of the AR-regulated gene expression upon agonist activation. AR
is mainly expressed in androgen target tissues, such as the prostate, skeletal muscle, liver, and central nervous system (CNS), with the highest expression level observed in the prostate, adrenal gland, and epididymis as determined by real-time PCR. AR can be activated by the binding of endogenous androgens, including testosterone and DHT. Physiologically, functional AR is responsible for male sexual differentiation in utero and for male pubertal changes. In adult males, androgen is mainly responsible for maintaining libido, spermatogenesis, muscle mass and strength, bone mineral density, and erythropoiesis. The actions of androgen in reproductive tissues, including prostate, seminal vesicle, testis, and accessory structures, are known as androgenic effects, while the nitrogen-retaining effects of androgen in muscle and bone are known as anabolic effects. Gonadal production of testosterone is under the feedback regulation of circulating testosterone through the hypothalamo-pituitary-gonadal axis [06049].

Androgen receptor (AR) is a member of the nuclear receptor (NR) superfamily of ligand-dependent transactivation factors. Androgens such as testosterone and 5alpha-dihydrotestosterone (DHT) act as agonists of AR. AR mediates various biological effects such as the development of male reproductive tissues, sexual development, and spermatogenesis. Since androgen declining with age contributes to age-related bone and muscle loss and increase in fat mass, the anabolic effect of androgen is attractive for the maintenance of health. Antagonists of AR (flutamide, bicalutamide, and nilutamide) are in use. AR is structurally characterized by an amino-terminal trans-activation domain (NTD/activation function 1, AF1), a DNA binding domain (DBD), and a ligand binding domain (LBD) including a carboxy-terminal transactivation domain (activation function 2, AF2). In the absence of a ligand, AR is localized in the cytoplasm, where it forms complexes with chaperones. Upon ligand binding, AR translocates into the nucleus. Following nuclear translocation, AR binds to androgen responsive elements (ARE) in the promoter regions of its target genes as a homodimer. Generally, the transcriptional activity of nuclear receptors is modulated by their interaction with cofactors such as coactivators and corepressors. The type of ligand that binds to the receptor determines which type of cofactor is chosen. In the case of agonists, AR interacts with coactivators dominantly over corepressors, and vice versa in the case of antagonists. Unlike other nuclear receptors, AR AF2 demonstrates weak transcriptional activity. However, ligand-dependent interaction between NTD and LBD/AF2 (which is termed as the N/C interaction) endows AR with synergistic transactivation potential) Thus, the N/C interaction is important for the ligand-dependent transactivation potential of AR [11062].

Androgens primarily exert their effects by binding to and activating a specific receptor, AR, which is expressed in most cells. The AR is a 110 kDa protein to which the natural androgens, T and DHT, bind with high affinity. In its inactivated state, AR is bound in the cytoplasm to heat shock proteins. When androgens bind to the AR via the ligand binding domain (LBD) of the AR, a conformational change is induced that promotes the dissociation of the heat shock proteins and AR subunits dimerize to form a homodimer. The dimerized AR complex translocates to the nucleus where it binds to androgen response elements (ARE) in the regulatory regions of androgen target genes. Binding of AR to the ARE occurs via the DNA binding domain (DBD). Regulatory cofactors interact with AR to promote DNA binding. Transcriptional activation by AR also involves cofactors that modify the chromatin structure and histone complexes in the DNA surrounding the ARE. This is important because the ARE can be located distantly from the transcription start site of androgen-regulated genes, therefore, cofactors that alter DNA shape and flexibility are needed for AR to augment transcription [13084].

**Androgen receptor polymorphism**
Muscle mass and strength, as well as aerobic fitness (VO$_{2\text{max}}$) are related to health and mortality. Muscle mass and strength is determined by environmental factors, principally endocrine, nutritional and mechanical loading, and by the genetic background. Gene polymorphisms, like those encoding for the insulin-like growth-factor-1 (IGF-1), type I collagen (COL1A1), ciliary neurotrophic factor (CNTF), interleukin-6 (IL-6), the vitamin D receptor (VDR), IGF-2, resistin (RETN) and androgen receptor (AR), have an influence on either muscle mass or strength. The AR gene is located to the X chromosome (q11.2–q12), and contains eight exons. The exon 1 contains a polyglutamine tract encoded by CAG repeats and a polyglycine tract (GGN) encoded by (GGT)$_3$(GGG(GGT)$_2$)GGC. Polymorphic tracts are close to the region encoding the transactivation-1 domain of the AR protein. The CAG and GGN polymorphisms of the androgen receptor (AR) gene are associated with the fat-free mass phenotype in healthy elders. However, it remains to be established if the AR polymorphism influences muscle mass and fitness in young adults. The polyglycine repeat length of AR ranges from 10 to 30. Short GGN repeats are associated with increased AR protein content in cell cultures that may in turn enhance the response to androgen stimulation. It remains unknown if a short GGN repeat number is associated to increased muscle mass or strength in humans. The exon-1 of the androgen receptor gene thus contains two repeat length polymorphisms which modify either the amount of AR protein inside the cell (GGN$_n$, polyglycine) or its transcriptional activity (CAG$_n$, polyglutamine). Shorter CAG and/or GGN repeats provide stronger androgen signalling and vice versa. To test the hypothesis that CAG and GGN repeat AR polymorphisms affect muscle mass and various variables of muscular strength and fitness traits, the length of CAG and GGN repeats was determined by PCR and fragment analysis and confirmed by DNA sequencing of selected samples in 282 men. Individuals were grouped as CAG short (CAG$_S$) if harbouring repeat lengths of ≤21 and CAG long (CAG$_L$) if CAG >21. GGN was considered short (GGN$_S$) or long (GGN$_L$) if GGN ≤23 or >23, respectively. No significant differences in lean body mass or fitness were observed between the CAG$_S$ and CAG$_L$ groups, or between GGN$_S$ and GGN$_L$ groups, but a trend for a correlation was found for the GGN repeat and lean mass of the extremities. In summary, the length of CAG and GGN repeat of the AR gene do not appear to influence lean mass or fitness in young men. Additional studies are required to test if men harbouring the combination CAG$_S$ and GGN$_S$ have more jumping capacity.

**Antagonists of the androgen receptor**

While the androgens of testicular origin (representing about 50% of total androgens in men over 50 years) can be completely eliminated by surgical or medical castration with GnRH (gonadotropin-releasing hormone) agonists or antagonists, the antiandrogens currently available as blockers of androgen binding to the androgen receptor (AR), namely bicalutamide (BICA), flutamide (FLU) and nilutamide have too weak affinity to completely neutralize the other 50 percent of androgens made locally from dehydroepiandrosterone (DHEA) in the prostate cancer tissue by the mechanisms of intracrinology. Series of steroid derivatives having pure and potent antagonistic activity on the human and rodent AR were synthesized. Assays of AR binding and activity in carcinoma mouse Shionogi and human LNCaP cells as well as in vivo bioavailability measurements and in vivo prostate weight assays in the rat were used. The chosen lead steroidal compound, namely EM-5854, has a 3.7-fold higher affinity than BICA for the human AR while EM-5855, an important metabolite
of EM-5854, has a 94-fold higher affinity for the human AR compared to BICA. EM-5854 and EM-5855 are 14 times more potent than BICA in inhibiting androgen (R1881)-stimulated prostatic specific antigen (PSA) secretion in human prostatic carcinoma LNCaP cells in vitro. MDV3100 has a potency comparable to bicalutamide in these assays. Depending upon the oral formulation, EM-5854 is 5- to 10-times more potent than BICA to inhibit dihydrotosterone (DHT)-stimulated ventral prostatic weight in vivo in the rat while MDV3100 has lower activity than BICA in this in vivo model. These data are supported by respective 40-fold and 105-fold higher potencies of EM-5854 and EM-5855 compared to BICA to inhibit cell proliferation in the androgen-sensitive Shionogi carcinoma cell model. Although the preclinical results data need evaluation in clinical trials in men, combination of the data obtained in vitro in human LNCaP cells as indicator of potency in the human prostate and the data on metabolism evaluated in vivo on ventral prostate weight in the rat, could suggest the possibility of a 70- to 140-fold higher potency of EM-5854 compared to bicalutamide (Casodex) for the treatment of prostate cancer in men [12115].

Physiological and clinical effects and side effects

The physiological direct effects of testosterone and AASs (AR-mediated) are well known. They include increases in renal erythropoiesis, lipolysis, protein synthesis, sebaceous secretion, hair growth and libido. However, the indirect effects should also be considered. These include antiglucocorticoid effects, which are mediated by testosterone occupation of cortisol receptors (which have a remarkable affinity with testosterone) and create an anti-catabolic effect. An increase in muscular activity is certainly the leading result of AAS use. It constitutes a complex phenomenon involving hypertrophy of skeletal muscle fibres that contain muscle cells and undifferentiated satellite cells. The latter become myoblasts that are incorporated into skeletal muscle cells, increasing the number of nuclei, and also the amount of cytoplasm, actin and myosin, making them larger and more potent. Notably, this phenomenon does not increase the number of fibres, only their size. Side effects of AASs are also well known. Their incidence is unclear, as the denominator of AAS use is not clear. Acne, alopecia and LUTS attributable to prostate enlargement are usually related to the strong androgenic 5DHT-effect. Erectile dysfunction and libido loss may also occur, especially after discontinuation, when endogenous testosterone levels are usually low. A sustained increase in testosterone levels during “cycles” leads to higher aromatization rates of testosterone, which accounts for the gynaecomastia typically found in steroid users. Hepatic effects are most often related to oral alkylated agents. They include the uncommon hepatic peliosis, cholestatic jaundice and hepatic neoplasms, such as focal nodular hyperplasia, which are all closely related to dose and duration of usage. Hepatocellular carcinoma and Wilm’s tumour are serious and rare side effects that are always related to long-term and heavy use. Interestingly, there are no reports linking AASs to prostate cancer or significant increases in PSA levels. The most severe consequences of long-term AAS use are associated with the cardiovascular system. Hypertension, arrhythmia, erythrocytosis and ventricular dysfunctions have been reported. Mortality risk among chronic users is estimated to be 4.6 times higher than among non-users. Cases of renal failure secondary to rhabdomyolysis and diffuse membranoproliferative glomerulonephritis in heavy users have been reported. Aggressive behaviour, depression, mood swings, altered libido, euphoria and even psychosis are some of the psychiatric patterns related to AAS. Overpharmacy may increase the risk of violent criminality. Withdrawal syndrome and dependency were also described, and the likelihood of psychiatric effects is greater where there is previous psychiatric history, or alcohol or drug abuse [11028].

The adverse endocrine effects of AASs are best understood if one first looks at the native effects of testosterone. Testosterone is responsible for the in utero masculinization of internal
genitalia, postnatal skeletal muscle development, and the development of male secondary sexual characteristics. In addition, testosterone is converted in peripheral tissues by 5-alpha-reductase to dihydrotestosterone (DHT), which contributes to fetal development of external genitalia, prostate, and seminal vesicles. DHT acts in the cell nucleus of target tissues, such as skin, male accessory glands, and the prostate, exerting predominantly androgenic, but also anabolic, effects. Testosterone is converted by the enzyme aromatase to estradiol and estrone, which are involved in the sexual differentiation of the brain, bone mass accretion, and fusion of the epiphyses at the conclusion of puberty, in addition to feminizing effects. Under normal physiologic circumstances, aromatase has a limited role; however, with high-dose AAS use, this role increases, and, therefore, so does the level of estrogens. An antiestrogen effect may be present as well with supraphysiologic doses of AASs. Excess AASs lead to a down-regulation of androgen receptors and AASs then compete with estrogens for the estrogen receptor. The net outcome of these two different pathways is difficult to predict. With this information, it is easier to understand the adverse outcomes of AAS use because many of the effects are amplifications of physiologic effects. Testosterone acts at the androgen receptor to increase protein synthesis; it also has effects through conversion to DHT and estrogens. At normal physiologic levels of testosterone, androgen receptors are saturated, and it is believed that some of the effects of AASs may be through one or more different mechanisms. Research has shown an antagonist effect at the glucocorticoid receptor at supraphysiologic levels that leads to an antianabolic effect.

Glucocorticoids influence glucose synthesis and protein catabolism. The stimulation of glucocorticoid receptors by glucocorticoids leads to increased protein breakdown in muscle. High-dose AASs may displace glucocorticoids from the glucocorticoid receptor and inhibit muscle protein breakdown that leads to an overall anabolic or muscle-building effect. By competing with glucocorticoids for the glucocorticoid receptor, AASs block the depressed protein synthesis that usually occurs during stressful training. AASs also exert some effect on the growth hormone (GH)-insulin-like growth factor (IGF)-1 axis. There seems to be an androgen-induced stimulation of GH secretion and a direct stimulation of hepatic IGF-1 synthesis. IGF-I stimulates skeletal muscle formation, and GH exhibits anabolic effects. AASs act on osteoblasts to stimulate proliferation and differentiation that may inhibit bone breakdown. There also may be some degree of “placebo effect” that allows AAS users to train harder and increase muscle mass as a result of the increased aggression, euphoria, and decreased fatigue and recovery time that many AAS users report [07058].

**Anticorticoid effects**
The supraphysiologic doses of AAS used by athletes reduce the catabolic effects of endogenous cortisol, which is increased during training, by competitive inhibition of cortisol binding to the glucocorticoid receptor. This helps to preserve muscle mass by inhibiting glucocorticoid stimulation of muscle glycogen breakdown and gluconeogenesis. AAS also increase 2, 3-diphosphoglycerate concentration which decreases hemoglobin-oxygen affinity, facilitating release of oxygen to the tissues [07002].

**Commonest AASs in use worldwide, according to main effect [11028]**

Commonly abused anabolic-androgenic steroids [07031]

**Oral preparations**

- Fluoxymesterone (Halotestin)
- Mesterolone (Proviron)
- Methandienone (Dianabol)
- Methyltestosterone (Virilon)
- Mibolerone (Cheque)
- Oxandrolone (Anavar, Oxandrin)
- Oxymetholone (Anadrol)
- Stanozolol (Winstrol)

**Intramuscular preparations**

- Boldenone undecylenate (Equipoise)
- Methenolone enanthate (Primobolan)
- Nandrolone decanoate (Deca Durabolin)
- Nandrolone phenylpropionate (Durabolin)
- Testosterone cypionate (Depotest)
- Testosterone enanthate (Andro-Estro)
- Testosterone propionate (Testex)
- Trenbolone acetate (Finajet)

**Molecular function**

Anabolic androgenic steroids, a class of steroid hormones related to testosterone, are natural ligands of androgen receptor (AR), a member of the nuclear receptor superfamily of ligand-activated transcription factors. AR binds specific DNA elements, known as androgen-response elements. Testosterone, the main male sexual hormone, binds AR directly and indirectly, through conversion into dihydrotestosterone (DHT), its more active metabolite. The effects of androgens can differ depending on the target cells and/or tissues. To gain insight into transcription activation mechanisms of AR, it was investigated AR protein signaling in human peripheral blood lymphocytes treated with supraphysiological doses of DHT. It was performed a comparative proteomic analysis and was identified about 30 differentially expressed proteins. At least five species contained a consensus androgen-response
elements sequence in the promoter region of related coding genes. The analysis also revealed that high doses of DHT activate the drug detoxification process, could stimulate an increase in cell motility and exert a prosurvival effect rather than an apoptotic one [10324]

**Physiological cellular effects of androgens**

Androgens promote anabolism in the musculoskeletal system while generally repressing adiposity, leading to lean body composition. Circulating androgens decline with age, contributing to frailty, osteoporosis, and obesity, however the mechanisms by which androgens modulate body composition are largely unknown. Here we demonstrate that aged castrated rats develop increased fat mass, reduced muscle mass and strength, and lower bone mass. Treatment with testosterone or 5alpha-dihydrotestosterone (DHT) reverses the effects on muscle and adipose tissues while only aromatizable T increased bone mass. During the first week, DHT transiently increased soleus muscle nuclear density and induced expression of insulin-like growth factor-1 (IGF-1) and its splice variant mechano growth factor (MGF) without early regulation of the myogenic factors MyoD, myogenin, MNF, or myostatin. A genome-wide microarray screen was also performed to identify potential pro-myogenic genes that respond to androgen receptor activation in vivo within 24 hours. Of 24,000 genes examined, 70 candidate genes were identified whose functions suggest initiation of remodeling and regeneration, including the type II muscle genes for myosin heavy chain II and parvalbumin and the chemokine MCP-1. Interestingly, Axin and Axin2, negative regulators of beta-catenin, were repressed, indicating modulation of the beta-catenin pathway. DHT increased total levels of beta-catenin protein, which accumulated in nuclei in vivo. Likewise, treatment of C2C12 myoblasts with both IGF-1Ea and MGF c-terminal peptide increased nuclear beta-catenin in vitro. Thus it was propose that androgenic anabolism involves downregulation of Axin, and induction of IGF-1, leading to nuclear accumulation of beta-catenin, a pro-myogenic, anti-adipogenic stem cell regulatory factor [09053].

**Episodical secretion**

Testosterone and cortisol respond to exercise stimuli and modulate adaptation. Episodic basal secretion of these hormones may modify the responsiveness of these hormones. It was attempted to identify episodic steroid secretion via frequent salivary sampling and investigate any interaction between ultradian rhythmicity and induced changes in testosterone. Salivary testosterone and cortisol concentrations of seven males (age 20-40 years) were measured every 10 min between 0800 and 1600 h on three consecutive days. On either the second or third day, three interventions designed to elicit a hormonal response were randomly assigned: sprint exercise (two 30-s maximal efforts on a cycle ergometer); boxing (two 30-s maximal punching efforts); and a violent video game (10 min of player vs. player combat). On the other days subjects were inactive. Testosterone data on non-intervention days suggested pulsatile secretion with a pulse interval of 47 ± 9 min (mean ± SD). The sprint intervention substantially affected hormones: it elicited a small transient elevation in testosterone (by a factor of 1.21; factor 90 % confidence limits x/ divided by 1.21) 10 min after exercise, and a moderate elevation in cortisol peaking 50 min post-exercise (factor 2.3; x/ divided by 2.6). The testosterone response correlated significantly with the change in testosterone concentration in the 10 min prior to the sprint and with a measure of randomness in testosterone fluctuations. Thus, the salivary testosterone response to exercise may be dependent on the underlying ultradian rhythm and aspects of its regulation. This interaction may have important implications for adaptation to exercise [10326].
Circadian rhythm

Diurnal variation of sports performance usually peaks in the late afternoon, coinciding with increased body temperature. This circadian pattern of performance may be explained by the effect of increased core temperature on peripheral mechanisms, as neural drive does not appear to exhibit nycthemeral variation. This typical diurnal regularity has been reported in a variety of physical activities spanning the energy systems, from Adenosine triphosphate-phosphocreatine (ATP-PC) to anaerobic and aerobic metabolism, and is evident across all muscle contractions (eccentric, isometric, concentric) in a large number of muscle groups. Increased nerve conduction velocity, joint suppleness, increased muscular blood flow, improvements of glycogenolysis and glycolysis, increased environmental temperature, and preferential meteorological conditions may all contribute to diurnal variation in physical performance. However, the diurnal variation in strength performance can be blunted by a repeated-morning resistance training protocol. Optimal adaptations to resistance training (muscle hypertrophy and strength increases) also seem to occur in the late afternoon, which is interesting, since cortisol and, particularly, testosterone (T) concentrations are higher in the morning. T has repeatedly been linked with resistance training adaptation, and higher concentrations appear preferential. This has been determined by suppression of endogenous production and exogenous supplementation. However, the cortisol (C)/T ratio may indicate the catabolic/anabolic environment of an organism due to their roles in protein degradation and protein synthesis, respectively. The morning elevated T level (seen as beneficial to achieve muscle hypertrophy) may be counteracted by the morning elevated C level and, therefore, protein degradation. Although T levels are higher in the morning, an increased resistance exercise-induced T response has been found in the late afternoon, suggesting greater responsiveness of the hypothalamo-pituitary-testicular axis then. Individual responsiveness has also been observed, with some participants experiencing greater hypertrophy and strength increases in response to strength protocols, whereas others respond preferentially to power, hypertrophy, or strength endurance protocols dependent on which protocol elicited the greatest T response. It appears that physical performance is dependent on a number of endogenous time-dependent factors, which may be masked or confounded by exogenous circadian factors. Strength performance without time-of-day-specific training seems to elicit the typical diurnal pattern, as does resistance training adaptations. The implications for this are athletes are advised to coincide training times with performance times, and individuals may experience greater hypertrophy and strength gains when resistance training protocols are designed dependent on individual T response [10054].

Testosterone and cortisol respond to exercise stimuli and modulate adaptation. Episodic basal secretion of these hormones may modify the responsiveness of these hormones. We sought to identify episodic steroid secretion via frequent salivary sampling and investigate any interaction between ultradian rhythmicity and induced changes in testosterone. Salivary testosterone and cortisol concentrations of seven males (age 20-40 years) were measured every 10 min between 0800 and 1600 h on three consecutive days. On either the second or third day, three interventions designed to elicit a hormonal response were randomly assigned: sprint exercise (two 30-s maximal efforts on a cycle ergometer); boxing (two 30-s maximal punching efforts); and a violent video game (10 min of player vs player combat). On the other days subjects were inactive. Testosterone data on non-intervention days suggested pulsatile secretion with a pulse interval of mean 47 ± 9 min. The sprint intervention substantially affected hormones: it elicited a small transient elevation in testosterone (by a factor of 1.21) 10 min after exercise, and a moderate elevation in cortisol peaking 50 min post-exercise (factor 2.3). The testosterone response correlated with the change in testosterone concentration in the 10 min prior to the sprint and with a measure of randomness in testosterone fluctuations. Thus, the salivary testosterone response to
exercise may be dependent on the underlying ultradian rhythm and aspects of its regulation. This interaction may have important implications for adaptation to exercise [10055].

Testosterone is the principal androgenic steroid produced by the testes. Testosterone is also a precursor to estrogen synthesis by the ovary in women. Steroids are hormones derived from cholesterol, and androgens promote the development and maintenance of male characteristics.. Many androgen actions in the body are mediated by binding to the androgen receptor, a nuclear receptor that modulates transcription of responsive genes. Whether of endogenous or exogenous origin in males and in females, excess testosterone creates an advantage in sports. While the anabolic effects of testosterone in hypogonadal males were well-accepted, early studies testing the effects of testosterone supplementation to eugonadal men were not well-controlled. More recent studies have shown that testosterone stimulates muscle mass and reduces body fat. Androgens likely also act on specific substrates in the brain to increase aggression and motivation for competition. Exogenous testosterone has been banned from Olympic competition since 1976, and was classified in the United States as a controlled substance by the Anabolic Steroid Control Act of 1990. Defining the upper limit for endogenous testosterone is complicated by the dynamic changes in testosterone across a number of temporal scales. On the shortest time-scale, testosterone production in the gonads follows the pulsatile release of luteinizing hormone. This introduces a level of unpredictability for estimating circulating androgen concentrations in any single biologic sample. Secondly, in both sexes, testosterone follows a diurnal rhythm with peak concentrations in the morning followed by progressive decline over the course of the day, rising again at night during sleep. In women, there is evidence that testosterone concentrations also vary as a function of the menstrual cycle, with peak testosterone concentrations in the peri-ovulatory window, and lower values in the early follicular and late luteal phases. On a somewhat longer time-scale, testosterone concentrations exhibit circannual variation and peak in the fall. Lastly, men's testosterone concentrations slowly decline over the lifespan while women face an abrupt decline in testosterone at menopause. Due to the dynamic regulation of endogenous testosterone production, including the acute effects of competition and exercise, testosterone concentrations may vary considerably within and among individuals. Accordingly, it has been difficult to establish a threshold separating endogenous testosterone from exogenous sources. Furthermore, disorders of sexual differentiation (DSD) can produce elevated concentrations of endogenous androgens, potentially creating a competitive advantage for female athletes with DSD. Due to variability in endogenous secretion, and similarities with exogenous testosterone, it has been challenging to establish allowable limits for testosterone in competition. Endogenous androgen production is dynamically regulated by both exercise and winning in competition. Furthermore, testosterone may promote athletic performance, not only through its long-term anabolic actions, but also through rapid effects on behavior [12100].

**Endogenous steroids**

The detection of misuse with naturally occurring steroids is a great challenge for doping control laboratories. Intake of natural anabolic steroids alters the steroid profile. Thus, screening for exogenous use of these steroids can be established by monitoring a range of endogenous steroids, which constitute the steroid profile, and evaluate their concentrations and ratios against reference ranges. Elevated values of the steroid profile constitute an atypical finding after which a confirmatory IRMS procedure is needed to unequivocally establish the exogenous origin of a natural steroid. However, the large inter-individual differences in urinary steroid concentrations and the recent availability of a whole range of natural steroids (e.g. dehydroepiandrosterone and androstenedione) which each exert a different effect on the monitored parameters in doping control complicate the interpretation of
the current steroid profile. The screening of an extended steroid profile can provide additional parameters to support the atypical findings and can give specific information upon the steroids which have been administered. The natural concentrations of 29 endogenous steroids and 11 ratios in a predominantly Caucasian population of athletes were determined. The upper reference values at 97.5 percent, 99 percent and 99.9 percent levels were assessed for male (n=2027) and female (n=1004) populations. Monitoring minor metabolites and evaluation of concentration ratios with respect to their natural abundances could improve the interpretation of the steroid profile in doping analysis [09052].

The detection of the administration of an androgen such as testosterone that could be present normally in human bodily fluids is based upon the methodical evaluation of key parameters of the urinary profile of steroids, precisely measured by GC/MS. Over the years, the markers of utilization were identified, the reference ranges of diagnostic metabolites and ratios were established in volunteers and in populations of athletes, and their stability in individual subjects were studied. The direct confirmation comes from the measurement of delta $^{13}$C values reflecting their synthetic origin, ruling out a potential physiological anomaly. Several factors may alter the individual GC/MS steroid profile besides the administration of a testosterone-related steroid, the nonexhaustive list ranging from the microbial degradation of the specimen, the utilization of inhibitors of 5alpha-reductase or other anabolic steroids, masking agents such as probenecid, to inebriating alcohol drinking. The limitation of the testing strategy comes from the potentially elevated rate of false negatives, since only the values exceeding those of the reference populations are picked up by the GC/MS screening analyses performed by the laboratories on blind samples, excluding individual particularities and subtle doping. Since the ranges of normal values are often described from samples collected in Western countries, extrapolating data to all athletes appears inefficient. Furthermore, with short half-life and topical formulations, the alterations of the steroid profile are less pronounced and disappear rapidly. GC/C/IRMS analyses are too delicate and fastidious to be considered for screening routine samples. An approach based upon the individual athlete's steroid profiling is necessary to pick up variations that would trigger further IRMS analysis and investigations [10090].

One review attempted to give a synopsis of the major aspects concerning the biochemistry of endogenous androgens, supplemented with several facets of physiology, particularly with respect to testosterone. Knowledge regarding the precursors and metabolism of endogenous testosterone is therefore fundamental to understanding many of the issues concerning doping with testosterone and its prohormones, including the detection of their administration. Further, adverse findings for nandrolone are frequent, but this steroid and 19-norandrosterone are also produced endogenously, an appealing hypothesis being that they are minor by-products of the aromatization of androgens. At sports tribunals pertaining to adverse analytical findings of natural androgen administration, experts often raise issues that concern some aspect of steroid biochemistry and physiology. Salient topics included within this review are the origins and interconversion of endogenous androgens, the biosynthesis of testosterone and epitestosterone, the mechanism of aromatization, the molecular biology of the androgen receptor, the hypothalamic-pituitary-testicular axis, disturbances to this axis by anabolic steroid administration, the transport (binding) of androgens in blood, and briefly the metabolism and excretion of androgens [10091].

Intake of natural anabolic steroids alters the steroid profile. Thus, screening for exogenous use of these steroids can be established by monitoring a range of endogenous steroids, which constitute the steroid profile, and evaluate their concentrations and ratios against reference ranges. Elevated values of the steroid profile constitute an atypical finding after which a confirmatory IRMS procedure is needed to unequivocally establish the exogenous origin of a natural steroid. However, the large inter-individual differences in urinary steroid
concentrations and the recent availability of a whole range of natural steroids (e.g., dehydroepiandrosterone and androstenedione) which each exert a different effect on the monitored parameters in doping control complicate the interpretation of the current steroid profile. The screening of an extended steroid profile can provide additional parameters to support the atypical findings and can give specific information upon the steroids which have been administered. The natural concentrations of 29 endogenous steroids and 11 ratios in a predominantly Caucasian population of athletes were determined. The upper reference values at 97.5 percent, 99 percent and 99.9 percent levels were assessed for male (n=2027) and female (n=1004) populations. Monitoring minor metabolites and evaluation of concentration ratios with respect to their natural abundances could improve the interpretation of the steroid profile in doping analysis [10092].

By means of gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS) urinary steroids obtained from a reference population of 56 subjects were analyzed for their $^{13}$C/$^{12}$C-ratios. The analytes encompassed androsterone (A), etiocholanolone (E), 11beta-hydroxyetiocholanolone (OHE), 11beta-hydroxyandrosterone (OHA), and 5beta-pregnane-3alpha,20alpha-diol (PD). A and E represent androgen metabolites (AM). PD, OHE, and OHA have sources independent from androgen metabolism. The delta(13)C-values of the latter compounds may be compared to those of AM in order to detect doping with synthetic androgens and thus may serve as endogenous reference compounds (ERC). In order to allow for classification of conspicuous samples, reference ranges and limits were calculated for delta$^{13}$C-values of selected steroids and differences hereof (Delta$^{13}$C-values). When A is compared to ERCs, Delta$^{13}$C-values larger than 3 per thousand are very unlikely. A set of additional parameters was surveyed by a questionnaire. Several factors turned out to exert significant influence on the delta$^{13}$C-values of urinary steroids. These encompass the identity of the steroid itself, gender, oral contraception, travels, and physical activity [07059].

**Effect of smoking**

Cigarette tobacco smoke is a potent environmental contaminant known to adversely affect health including fertility and pregnancy. To examine the associations between second-hand cigarette tobacco-smoke exposure, or active smoking and serum concentrations of steroid hormones using tandem mass spectrometry. Healthy women (18-45 years) from the general community in the Metropolitan Washington, DC were recruited at the follicular stage of their menstrual cycle. Participants were assigned to one of three study groups: active smokers (n=107), passive smokers (n=86), or non-smokers (n=100). Classifications were based on a combination of self-reporting and serum cotinine concentrations. Serum androgens, estrogens, progestins, androstenedione, aldosterone, cortisol, corticosterone, dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), 11-deoxycorticisol and 25-hydroxy-vitamin D3 (25-OHvitD3) and cotinine were measured by isotope dilution tandem mass spectrometry (LC/MS/MS) (API-5000). Serum estrone, estradiol, and estriol concentrations were lower in active and passive smokers than in non-smokers. The three study groups differed significantly in serum concentrations of 16-OHE1, aldosterone and 25-OHVitD3, as well as in the ratios of many of the steroids. Pair-wise comparison of the groups demonstrated significant differences in hormone concentrations between smokers and non-smokers for aldosterone; passive smokers and non-smokers for aldosterone, progesterone and estriol. Moreover, for smokers and passive smokers, there were no significant differences in these hormone concentrations. It was concluded that smoke exposure was associated with lower than normal median steroid hormone concentrations. These processes may be instrumental in explaining some adverse effects of tobacco smoke on female health and fertility [11070].
Effects of dietary components on testosterone metabolism

The potential interference in testosterone metabolism through ingested substances has ramifications for:

- a range of pathologies such as prostate cancer
- medication contra-indications
- disruption to the endocrine system
- potential confounding effects on doping tests

Conjugation of anabolic steroids during phase II metabolism, mainly driven by UDP-glucuronosyltransferase (UGT) 2B7, 2B15, and 2B17, has been shown to be impaired in vitro by a range of compounds including xenobiotics and pharmaceuticals. Following early reports on the effects of a range of xenobiotics on UGT activity in vitro, the work was extended to reveal similar effects with common non-steroidal anti-inflammatory drugs. Notably, recent studies have evidenced inhibitory effects of the common foodstuffs green tea and red wine, along with their constituent flavonoids and catechins. This review amalgamates the existing evidence for the inhibitory effects of various pharmaceutical and dietary substances on the rate of UGT glucuronidation of testosterone; and evaluates the potential consequences for health linked to steroid levels, interaction with treatment drugs metabolized by the UGT enzyme and steroid abuse in sport [13209].

As a major route for excretion of exogenous and endogenous compounds, there is considerable interest in the roles of the UDP-glucuronosyltransferase (UGT) family, which has led to widespread investigations of their potential effects in health and disease. In particular, genetic and chemical modification of UGT activity relating to steroid metabolism has ramifications for a range of pathologies such as prostate cancer, medication contra-indications, disruption to the endocrine system, and potential confounding effects on doping tests in sport. Therefore, it is timely to review lifestyle factors that affect UGT activity. Variations in the activity of UGT isozymes occur as a result of gender and ethnic origins giving different levels of expression of UGT forms and altered ratios of testosterone/testosterone excreted in urine). In addition to genetic variations, from a steroid metabolism viewpoint, one current focus of investigation is on the regulation of specific UGT activity via induction or inhibition by exogenous compounds such as pharmaceuticals and dietary components. Several reports show induction of UGT activity by a range of compounds including phytochemicals and pharmaceuticals. Early studies reported the effects of drugs and dietary compounds on UGT activity in isolated microsomes or in rats without detailing the specific UGT isozymes involved. Liver microsomal glucuronidation of estradiol and estrone was inhibited by green and black teas, along with a constituent catechin [(-)-epigallocatechin gallate] and several flavonoids (kaempferol, quercetin, rutin, flavone, naringenin, hesperetin). Green tea polyphenols had a strong inhibitory effect of glucuronidation in vitro and showed a small increase in liver glucuronidation activity against estrone and estradiol was observed in vitro in rats with green tea as the sole fluid source. Consequent alterations in steroid metabolism have been debated to have a range of putative effects including varying responses to doping tests, inter-medication interactions, and susceptibility to developing cancer. From a treatment perspective, the roles of common compounds, including dietary components have been investigated as UGT inhibitors with a view to enhancing bioavailability of drugs. This approach to impairing metabolism and thus increasing the half-lives of drugs has been the subject of patent protection for a wide range of drugs (raloxifene, 2-methoxyestradiol, irinotecan, estradiol, labetalol, dilevalol, zidovudine,
and morphine) using numerous inhibitors from plant origin (epicatechin gallate, epigallocatechin gallate, octyl gallate, propyl gallate, quercetin, tannic acid, benzoin gum, capsaicin, dihydrocapsaicin, eugenol, gallocatechin gallate, geraniol, menthol, menthyl acetate, naringenin, allspice berry oil, N-vanillylnonanamide, clovebud oil, peppermint oil, silybinin, and silymarin) [13210].

Early reports demonstrated that a number of compounds interfere with the activity of UGT2B17 which is the major isozyme for clearance of anabolic steroids, having greater than double the activity of the next most active form UGT2A1. It has been reported that epitestosterone and two non-steroidal anti-inflammatory drugs (NSAID) act as competitive inhibitors against UGT2B17. Using human microsomes and recombinant enzymes they demonstrated that diclofenac and ibuprofen inhibited testosterone glucuronidation without having significant effects on epitestosterone glucuronidation. Similar inhibitory effects on testosterone glucuronidation were reported for both UGT2B15 and UGT2B17 isozymes in *in vitro* studies. The authors measured IC$_{50}$ values for diclofenac inhibition of testosterone glucuronidation by UGT2B15 and UGT2B17 of 25 microM and 65 microM respectively, at testosterone concentrations of 10 μM. The corresponding IC$_{50}$ values for ibuprofen were 121 μM and 1340 microM against UGT2B15 and UGT2B17 respectively. To date, no commensurate studies have been reported demonstrating an effect of pharmaceuticals on testosterone glucuronidation *in vivo*. A recent report showed only a slight modification but no significant effects of concomitant use of maximum recommended doses of ibuprofen or diclofenac with testosterone on the urinary ratios of testosterone/epitestosterone in individuals with either two, one, or no allele of the UGT2B17, and no effect when ibuprofen/diclofenac was administered prior to single dose of testosterone. Given the competitive nature of the inhibition, at least for diclofenac, the experiment was limited by restriction to maximum doses of the NSAID. Thus, doses of 50 mg × 3 per day of the single competitive inhibitor, although well reasoned, may not elicit an inhibitory effect given that ibuprofen can also elevate UGT enzyme activity *in vivo*. Although reports of *in vivo* studies are lacking to date, the potential effects of inhibiting major testosterone-metabolizing enzymes warrants further exploration, especially if common substances are considered where maximum dosage effects do not limit intake. From one standpoint, this effect could alter the results of a doping test which is based on the ratio of the glucuronidated testosterone and epitestosterone. Following these advances, researchers have recently explored the effects of dietary components on steroid metabolism [13210].

**Tea and cacao**

It was first reported the effects of dietary green and white teas on the activity of UGT2B17 toward testosterone glucuronidation. Using an high performance liquid chromatography (HPLC) assay, testosterone glucuronidation was monitored in the presence of tea extracts using human UGT2B17 supersomes. Under the conditions studied, green and white tea preparations inhibited the reaction by about 20 percent with a white tea powder inhibiting glucuronidation by 30 percent. HPLC analysis of the teas revealed key constituents such as epicatechin (EC) and epigallocatechin gallate (EGCG). Analysis via a Dixon plot revealed that EGCG was acting as a competitive inhibitor with an IC$_{50}$ value of 64 microM which equaled that found previously for diclofenac. At a concentration of 1 mM, EC inhibited testosterone (at 10 microM) glucuronidation by some 55 percent [13210].

Cacao also inhibits UGT2B17 but to a lesser extent (15 %). Under these conditions, at testosterone concentrations of 12 microg/mL, white and green tea preparations inhibited glucuronidation by 30 percent. Under the conditions studied, green and white tea preparations inhibited the reaction by about 20 percent with a white tea powder inhibiting glucuronidation by 30 percent. HPLC analysis of the teas revealed key constituents such as epicatechin (EC) and epigallocatechin gallate (EGCG). Analysis via a Dixon plot revealed that EGCG was acting as a competitive inhibitor with an IC$_{50}$ value of 64 microM which equaled that found previously for diclofenac. At a concentration of 1 mM, EC inhibited testosterone (at 10 microM) glucuronidation by some 55 percent [13210].
epigallocatechin gallate (78 %), and catechin gallate (90 %). Analysis of the tea and cacao samples by HPLC revealed catechins were present in these samples at lower levels in comparison to the tea samples. The cacao samples, whilst inhibiting testosterone glucuronidation, did so at a much lesser rate than the tea samples which could be linked with having lower levels of inhibiting catechin compounds at the same concentrations of the tea samples [13210].

Red wine
Red wine and its constituents were shown to inhibit testosterone glucuronidation by human UGT2B17 supersomes. Under the conditions studied, red wine inhibited glucuronidation by up to 70 percent over a 2-h period, with little effect arising from the alcohol content. Phenolic components were selected following HPLC analysis of the selected red wine and quercetin, caffeic acid, and gallic acid inhibited UGT2B17 testosterone glucuronidation by 72, 22, and 9 percent respectively, with concentrations of phenolic : testosterone of 100 : 250 microM. For the most active phenolic, reducing the quercetin concentration to 2 microM, maintained inhibition of 20 percent in spite of the 10-fold excess of testosterone [13201].

Testosterone plus an ornithine decarboxylase inhibitor

Because of its anabolic effects on muscle, testosterone is being explored as a function-promoting anabolic therapy for functional limitations associated with aging; however, concerns about testosterone's adverse effects on prostate have inspired efforts to develop strategies that selectively increase muscle mass while sparing the prostate. Testosterone's promyogenic effects are mediated through upregulation of follistatin. It was shown that the administration of recombinant follistatin (rFst) increased muscle mass in mice, but had no effect on prostate mass. Consistent with the results of rFst administration, follistatin transgenic mice with constitutively elevated follistatin levels displayed greater muscle mass than controls, but had similar prostate weights. To elucidate signaling pathways regulated differentially by testosterone and rFst in prostate and muscle, we performed microarray analysis of mRNAs from prostate and levator ani of castrated male mice treated with vehicle, testosterone, or rFst. Testosterone and rFst shared the regulation of many transcripts in levator ani; however, in prostate, 593 transcripts in several growth-promoting pathways were differentially expressed after testosterone treatment, while rFst showed a negligible effect with only 9 transcripts differentially expressed. Among pathways that were differentially responsive to testosterone in prostate, we identified ornithine decarboxylase (Odc1), an enzyme in polyamine biosynthesis, as a testosterone-responsive gene that is unresponsive to rFst. Accordingly, we administered testosterone with and without α-difluoromethylornithine (DFMO), an Odc1 inhibitor, to castrated mice. DFMO selectively blocked testosterone's effects on prostate, but did not affect testosterone's anabolic effects on muscle. Co-administration of testosterone and Odc1 inhibitor presents a novel therapeutic strategy for prostate-sparing anabolic therapy [13211].

Influence of alcohol on steroid metabolism

Besides the (mis)use of natural steroids, the impact of ethanol consumption on steroid profiles was subjected to further investigations. In a comprehensive study with 21 male and 15 female volunteers, alterations in steroid profile parameters were correlated with urinary ethanol-glucuronide and ethanol-sulfate concentrations, and threshold values of 48 microg/ml and 15.5 microg/ml for men and women, respectively, were suggested. When exceeded, an
influence on urinary steroid profiles due to ethanol-induced suppression of steroid biotransformation processes should be considered during data interpretation [13012].

Salivary hormones

Saliva contains cells and compounds, of local and non-local oral origin, namely inorganic, organic non-protein, protein/polypeptide, and lipid molecules. Moreover, some hormones, commonly assayed in plasma, such as steroids, are detectable in oral fluid and peptide/protein, and non-steroid hormones have been investigated. The sports practice environment and athletes’ availability, together with hormone molecule characteristics in saliva and physical exercise behavior effects, confirm this body fluid as an alternative to serum. One review focused on the relation between salivary steroids and psychophysiological stress and underlines how the measurement of salivary cortisol provides an approach of self-report psychological indicator and anxiety change in relation to exercise performance. The correlation between salivary and plasma steroid hormone (cortisol, testosterone, and dehydroepiandrosterone (DHEA)) levels, observed during exercise, has been considered, underlining how the type, duration, and intensity of the exercise influence the salivary steroid concentrations in the same way as serum-level variations. Training conditions have been considered in relation to the salivary hormonal response. One review focuses on studies related to salivary hormone measurements, mainly steroids, in physical exercise. Saliva use in physical disciplines, as a real alternative to serum, could be a future perspective [11068]

The combination of resistance and plyometric training, or complex training, may yield greater functional gains than either method alone. As steroid hormones respond to exercise stimuli and modulate the functional outcomes, it is possible that complex training creates an enhanced anabolic physiological milieu for adaptation. It was investigated acute responses of salivary testosterone and cortisol to complex exercise bouts. After a standardized warm-up, 16 semiprofessional rugby players performed 1 of 4 exercise bouts in a cross-over manner: power-power; power-strength; strength-power; or strength-strength. Each player completed each of the 4 bouts twice over a 4-week period in a balanced random order such that each player performed a total of 8 bouts. The power block consisted of 3 sets of 3 repetitions of jump squat exercise at 50 percent of 1-repetition maximum load. The strength block consisted of three sets of three repetitions of box squat exercise at a 3-repetition maximum load. There were 3-minute rest periods between sets and 4-minute rest periods between exercise blocks. Saliva was sampled before, during, and immediately after the exercise bout. The greatest overall hormonal responses were a small increase in testosterone (13 %; 90 % confidence limits ± 7 %) and a trivial increase in cortisol (27 %; ± 30 %) after the strength-power bout. A clear difference was observed between the strength-power and the power-power bouts immediately after exercise for testosterone (10 %; ± 8 %) and cortisol (29 %; ± 17 %). The preceding exercise block had little effect on subsequent strength and power performance. The hormonal response after the strength-power bout suggests that this exercise sequence provides an enhanced anabolic milieu for adaptation [11069].

Salivary testosterone

The aim of one study was to examine the acute response to plasma and salivary cortisol and testosterone to three training protocols. Ten trained endurance athletes participated in three experimental trials, such as interval training (INT), tempo run (TEMP) and bodyweight-only circuit training (CIR), on separate days. Blood and saliva samples were collected pre- and 0, 15, 30 and 60 min post-exercise. Peak post-exercise salivary cortisol was higher than pre-
exercise in all trials. After INT, salivary cortisol remained elevated above pre-exercise than 60 min post-exercise. Salivary testosterone also increased post-exercise in all trials. Plasma and salivary cortisol were correlated between individuals and within individuals. Plasma and salivary testosterone was also correlated between and within individuals.Peak cortisol and testosterone levels occurred simultaneously in plasma and saliva, but timing of post-exercise hormone peaks differed between trials and individuals. Further investigation is required to identify the mechanisms eliciting an increase in hormones in response to CIR. Furthermore, saliva is a valid alternative sampling technique for measurement of cortisol, although the complex, individual and situation dependent nature of the hormone response to acute exercise should be considered [13212].

Salivary testosterone (T) and cortisol (C) concentrations were monitored across a sports competition. Data were compared using two enzyme-immunoassay (EIA) methods and two sample preparations to determine their influence on hormone concentrations. A group of male athletes (n=19) provided a saliva sample the morning before and one day after (24h post) an international rugby union match. Following an extraction procedure, the samples were analysed for T and C concentrations using a commercial kit (CM(E)) and an in-house method (IH(E)). Raw samples (no extraction procedure) were also tested using the commercial kit (CM(R)). There were no significant changes in T and C levels from pre to post competition with each EIA method and sample preparation, but significant differences in T (IH(E)>CM(E)>CM(R)) and C (CM(R)>IH(E) and CM(E)) concentrations were seen when both samples were pooled. Bland-Altman analyses confirmed the presence of fixed and proportional bias. Strong and significant correlations were demonstrated between the IH(E) and CM(E) measures of salivary T and C. The T and C values from the raw and extracted samples were also strongly correlated. The measurement of salivary T and C concentrations across an international sports event was influenced by different EIA methods and sample preparations, but all measures were strongly correlated with some bias. Both T and C were unresponsive to the sports event, but within the group results large individual variation was seen [13213].

One study examined salivary cortisol and testosterone responses to two, different high-intensity, about 30-min cycles separated by 2 h rest before and after an 11-day intensified training period. Twelve recreationally active, healthy males completed the study. Saliva samples were collected before, immediately after and 30 min after both bouts with salivary cortisol and testosterone concentrations assessed. Compared with pre-training blunted exercise-induced salivary cortisol, testosterone and cortisol/testosterone responses to both bouts post-training were observed. Comparing pre- with post-training the absolute exercise-induced salivary cortisol, testosterone and cortisol/testosterone decreased from 11.1 to 3.1 and 7.0 to 4.4 nmol/L (cortisol), from 407 to 258 and from 473 to 274 pmol/L (testosterone) and from 12 to 4 and 7 to 5 (cortisol/testosterone) for the first and second bouts, respectively. No differences in the pre- and post-training rating of perceived exertion (RPE) and heart rate (HR) responses during the cycles or times to fatigue were found. Fatigue and Burnout scores were higher post- compared with pre-training. These high-intensity exercise bouts can detect altered hormonal responses following intensified training. This test could assess an athlete’s current hormonal status, reductions in salivary cortisol and testosterone responses suggestive of increased fatigue [13214].

In soccer
One study investigated the contribution of salivary testosterone concentration, years from peak height velocity (YPHV) and height by body mass interaction on jumping performance (counter movement jump; CMJ) and aerobic fitness (Yo-Yo intermittent endurance test, level 1) in young elite soccer players. Forty-five participants (age: 13 years; body mass: 49 kg, height: 156 cm) belonging to a top level Brazilian soccer club were evaluated at four time
points across a single semester. None of the assessed players had reached PHV. The data from the four evaluations were averaged and multiple linear regression analysis conducted. For CMJ, the model explained 43 percent of the variance; salivary testosterone concentration was the primary contributor and the YPHV contributed 10 percent of the variance. The model explained 29 percent of the variance in Yo-Yo. The salivary testosterone was the primary and single significant contributor. A significant difference was noted between high and low testosterone groups divided a posteriori to CMJ performance. These results suggest an important role for hormonal status in interpreting physical performance in preadolescent soccer players [13215].

Effects on cognitive functions

The illicit use of anabolic androgenic steroids (AAS) has gained popularity among adolescents in the last decade. However, although it is known that exposure to AAS impairs cognition in adult animal models, the cognitive effects during adolescence remain undetermined. An inhibitory avoidance task (IAT) was used to assess the effect of AAS (17alpha-methyltestosterone; 17alpha-meT, 7.5 mg/kg) in male and female periadolescent rats. A single injection of 17α-meT immediately before the footshock produced significant impairment of inhibitory avoidance learning in males but not females. Generalized anxiety, locomotion, and risk assessment behaviors (RAB) were not affected. The results show that exposure to a single pharmacological dose of 17alpha-meT during periadolescence exerts sex-specific cognitive effects without affecting anxiety. Thus, disruption of the hormonal milieu during this early developmental period might have negative impact on learning and memory [13114].

Effects of training

Performing strength exercise, whether acutely or in a training programme, leads to alterations at the hypothalamic-pituitary-testicular and hypothalamic-pituitary-adrenal axes. One way to evaluate these changes is by analysis of the excretion of steroid hormones in the urine. One study determined the variations in the urine profile of glucuroconjugated steroids after a single session of strength exercise and after a 4-week programme of strength training. The subjects were a group (n=20) of non-sportsman male university students who worked out 3 days a week, performing the exercises at 70-75 percent of one repetition maximum strength (1-RM). Four urine samples were collected per subject: (A) before and (B) after a standard session prior to initiating the training programme, and (C) before and (D) after the same standard session at the end of the study, and they were assayed by gas chromatography coupled to mass spectrometry. The concentrations of the different hormones were determined relatively to the urine creatinine level (ng steroid/mg creatinine) to correct for diuresis. After the exercise sessions, both before and after the training programme, there was a fall in the urine excretion of androgens and estrogens, but no statistically significant changes in the excretion of tetrahydrocortisol (THF) and tetrahydrocortisone (THE). The anabolic/catabolic hormones ratio also decreased after the acute session, although only androstenedione + dehydroepiandrosterone (DHEA)/THE + THF ratio had a significant decrease. After the training programme, there was a significant improvement in the strength of the muscle groups studied, and an increased urinary excretion of all the androgens with respect to the initial state of repose, with the difference being significant in the case of epitestosterone. The androsterone (A) + etiocholanolone (E)/THE + THF ratio increased significantly concerning the initial state. It was therefore concluded that subjects suffer variations of the urine profile with regard to the steroid
hormones before and after the acute strength sessions and after the training period. The alteration after the training programme seems to be due to the subjects' hypothalamic-hypophysis-testicular and hypothalamic-pituitary-adrenal axes adaptations, which enable them to increase physical strength [07060].

The purpose of one study was to examine the effects of an 8-week basic training with added strength training or endurance training on both the performance of a 3K-combat loaded run test and the acute neuromuscular and hormonal responses. All training groups significantly improved their run-test times: strength training by 12 percent, endurance training by 12 percent, and normal training by 10 percent. Significant acute decreases were observed in maximal isometric force of leg extensors in all subject groups following the run. Increases were observed in acute testosterone responses after the test in all groups both at pre- and post-training. However, endurance training and normal training demonstrated significantly lower acute post-training serum cortisol responses than strength training. In conclusion, the present results indicate that within a demanding basic training, the added training for endurance training and especially strength training may be compromised in their adaptation potential due to interference from the demands of basic training [10044].

Age-related skeletal muscle loss is thought to stem from suboptimal nutrition and resistance to anabolic stimuli. Impaired microcirculatory (nutritive) blood flow may contribute to anabolic resistance by reducing delivery of amino acids to skeletal muscle. In one study, it was employed contrast-enhanced ultrasound, microdialysis sampling of skeletal muscle interstitium, and stable isotope methodology, to assess hemodynamic and metabolic responses of older individuals to endurance type (walking) exercise during controlled amino acid provision. It was hypothesized that older individuals would exhibit reduced microcirculatory blood flow, interstitial amino acid concentrations, and amino acid transport when compared with younger controls. It was reported that aging induces anabolic resistance following endurance exercise, manifested as reduced (by 40 %) efficiency of muscle protein synthesis. Despite lower (by 40-45 %) microcirculatory flow in the older than in the younger participants, circulating and interstitial amino acid concentrations and phenylalanine transport into skeletal muscle were all equal or higher in older individuals than in the young, comprehensively refuting our hypothesis that amino acid availability limits postexercise anabolism in older individuals. The data point to alternative mediators of age-related anabolic resistance and importantly suggest correction of these impairments may reduce requirements for, and increase the efficacy of, dietary protein in older individuals [10447].

The objectives of one investigation were to study the inflammatory and performance responses after an acute bout of intense plyometric exercise during a prolonged recovery period. Participants were randomly assigned to either an experimental group (P, n=12) that performed intense plyometric exercises or a control group (C, n=12) that rested. The delayed onset of muscle soreness (DOMS), knee range of motion (KROM), creatine kinase (CK) and lactate dehydrogenase (LDH) activities, white blood cell count, C reactive protein (CRP), uric acid (UA), cortisol, testosterone, IL-6, IL-1b strength (isometric and isokinetic), and counter-movement (CMJ) and static (SJ) jumping performance were measured at rest, immediately postexercise and at 24, 48, 72, 96, and 120 hours of recovery. Lactate was measured at rest and postexercise. Strength remained unchanged throughout recovery, but CMJ and SJ declined significantly by 8-20 percent. The experimental group induced a marked rise in DOMS, CK, and LDH (peaked 24-48 hours postexercise) and a KROM decline. An acute-phase inflammatory response consisting of leukocytosis (postexercise and at 24 hours), an IL-6, IL-1b, CRP, and cortisol elevation (during the first 24 hours of recovery) and a delayed increase of UA (peaked at 48 hours) and testosterone (peaked at 72 hours) was observed in P. The results of this investigation indicate that performing an acute bout of intense
plyometric exercise may induce a short-term muscle damage and marked but transient inflammatory responses. Jumping performance seems to deteriorate for as long as 72 hours postexercise, whereas strength appears to remain unchanged. The acute-phase inflammatory response after a plyometric exercise protocol appears to follow the same pattern as in other exercise models. These results clearly indicate the need of sufficient recovery between successive plyometric exercise training sessions [10045].

One study aimed to develop a quantitative and in vivo magnetic resonance imaging (MRI) approach to investigate the muscle growth effects of anabolic steroids. A protocol of MRI acquisition on a standard clinical 1.5 T scanner and quantitative image analysis was established and employed to measure the individual muscle and organ volumes in the intact and castrated guinea pigs undergoing a 16-week treatment protocol by two well-documented anabolic steroids, testosterone and nandrolone, via implanted silastic capsules. High correlations between the in vivo MRI and postmortem dissection measurements were observed for shoulder muscle complex, masseter, temporalis, neck muscle complex, prostate gland and seminal vesicles, and testis. Furthermore, the longitudinal MRI measurements yielded adequate sensitivity to detect the restoration of growth to or towards normal in castrated guinea pigs by replacing circulating steroid levels to physiological or slightly higher levels, as expected. These results demonstrated that quantitative MRI using a standard clinical scanner provides accurate and sensitive measurement of individual muscles and organs, and this in vivo MRI protocol in conjunction with the castrated guinea pig model constitutes an effective platform to investigate the longitudinal and cross-sectional growth effects of other potential anabolic steroids. The quantitative MRI protocol developed can also be readily adapted for human studies on most clinical MRI scanner to investigate the anabolic steroid growth effects, or monitor the changes in individual muscle and organ volume and geometry following injury, strength training, neuromuscular disorders, and pharmacological or surgical interventions [08151].

The purpose of one study was to examine the changes in neuromuscular, perceptual and hormonal measures following professional rugby league matches during different length between-match microcycles. Twelve professional rugby league players from the same team were assessed for changes in countermovement jump (CMJ) performance (flight time and relative power), perceptual responses (fatigue, well-being and muscle soreness) and salivary hormone (testosterone and cortisol) levels during 5, 7 and 9 d between-match training microcycles. All training was prescribed by the club coaches and was monitored using the session-RPE method. Lower mean daily training load was completed on the 5 d compared with the 7 and 9 d microcycles. CMJ flight time and relative power, perception of fatigue, overall well-being and muscle soreness were significantly reduced in the 48 h following the match in each microcycle. Most CMJ variables returned to near baseline values following 4 d in each microcycle. Countermovement jump relative power was lower in the 7 d microcycle in comparison with the 9 d microcycle. There was significantly increased fatigue at 48 h in the 7 and 9 d microcycles but had returned to baseline in the 5 d microcycle. Salivary testosterone and cortisol did not change in response to the match. Neuromuscular performance and perception of fatigue are reduced for at least 48 h following a rugby league match but can be recovered to baseline levels within 4 d. These findings show that with appropriate training, it is possible to recover neuromuscular and perceptual measures within 4 d after a rugby league match [10330].

The combination of resistance and plyometric training, or complex training, may yield greater functional gains than either method alone. As steroid hormones respond to exercise stimuli and modulate the functional outcomes, it is possible that complex training creates an enhanced anabolic physiological milieu for adaptation. It was investigated acute responses of salivary testosterone and cortisol to complex exercise bouts. After a standardized warm-up,
16 semiprofessional rugby players performed 1 of 4 exercise bouts in a cross-over manner: power-power; power-strength; strength-power; or strength-strength. Each player completed each of the 4 bouts twice over a 4-week period in a balanced random order such that each player performed a total of 8 bouts. The power block consisted of 3 sets of 3 repetitions of jump squat exercise at 50 percent of 1-repetition maximum load. The strength block consisted of three sets of three repetitions of box squat exercise at a 3-repetition maximum load. There were 3-minute rest periods between sets and 4-minute rest periods between exercise blocks. Saliva was sampled before, during, and immediately after the exercise bout. The greatest overall hormonal responses were a small increase in testosterone (13 %; 90 % confidence limits ± 7 %) and a trivial increase in cortisol (27 %; ± 30 %) after the strength-power bout. A clear difference was observed between the strength-power and the power-power bouts immediately after exercise for testosterone (10 %; ± 8%) and cortisol (29 %; +/− 17%). The preceding exercise block had little effect on subsequent strength and power performance. The hormonal response after the strength-power bout suggests that this exercise sequence provides an enhanced anabolic milieu for adaptation [10331].

Appropriate physical activity is one of the bases of healthy lifestyle. In fact, physical exercise and playing sport may be associated with both improvements and injury to both general and reproductive health. A biologically normal testosterone secretion appears fundamental in males to guarantee both a physiological exercise adaptation and safe sport participation. The reproductive system is highly sensitive to the effects of exercise-related stress and the reproductive hormones may both increase and decrease after different acute or chronic exercises. Exercise and sport participation may positively or negatively influence andrological health status depending on the type, intensity and duration of performed physical activity and on individual health status. In addition, prohibited substances administration (e.g. androgenic-anabolic steroids, and so forth) in competitive and non-competitive athletes represents the main cause of iatrogenic andrological diseases. Preventing and treating andrological problems in active healthy and unhealthy individuals is as important as promoting a correct lifestyle. Physicians need to be educated on the relationships between the male reproductive system and sport participation and on the great role of the pre-participation physical examination in the prevention of andrological diseases [12121].

**Morphology versus performance after use of anabolic steroids**

It was hypothesized that treatment with testosterone (T) and recombinant human growth hormone (rhGH) would increase lean mass (LM) and muscle strength proportionally and in a linear manner over 16 weeks. This was a multicenter, randomized, controlled, double-masked investigation of T and rhGH supplementation in older (71 ± 4 years) community-dwelling men. Participants received transdermal T at either 5 or 10 g/day as well as rhGH at 0, 3.0 or 5.0 μg/kg/day for 16 weeks. Body composition was determined by dual-energy X-ray absorptiometry (DEXA) and muscle performance by composite one-repetition maximum (1-RM) strength and strength per unit of lean mass (muscle quality, MQ) for five major muscle groups (upper and lower body) at baseline, week 8 and 17. The average change in total LM at study week 8 compared with baseline was 1.50 ± 1.54 kg in the T only group and 2.64 ± 1.7 in the T + rhGH group and at week 17 was 1 in the T only group and 2.14 ± 1.96 kg in the T + rhGH group. 1-RM strength improved modestly in both groups combined (12.0 ± 23.9 %) at week 8 but at week 17 these changes were twofold greater. MQ did not significantly change from baseline to week 8 but increased for the entire cohort, T only, and T + rhGH groups by week 17. Despite sizeable increases in LM measurements at week 8, tests of muscle performance did not show substantive improvements at this time point [12195].

**Effects on training in males**
The acute response of free salivary testosterone and cortisol concentrations to four resistance exercise (RE) protocols in 23 elite men rugby players was investigated. It was hypothesized that hormonal responses would differ among individuals after four distinct RE protocols: four sets of 10 repetitions (reps) at 70 percent of 1 repetition maximum (1RM) with 2 minutes' rest between sets (4 x 10-70 %); three sets of five reps at 85 percent 1RM with 3 minutes' rest (3 x 5-85 %); five sets of 15 reps at 55 percent 1RM with 1 minute's rest (5 x 15-55 %); and three sets of five reps at 40 percent 1RM with 3 minutes' rest (3 x 5-40 %). Each athlete completed each of the four resistance exercise protocols in a random order on separate days. Testosterone and cortisol concentrations were measured before exercise, immediately after exercise, and 30 minutes post exercise. Each protocol consisted of four exercises: bench press, leg press, seated row, and squats. Pooled testosterone data did not change as a result of resistance exercise, whereas cortisol declined significantly. Individual athletes differed in their testosterone response to each of the protocols, a difference that was masked when examining the pooled group data. When individual data were retrospectively tabulated according to the protocol in which each athlete showed the highest testosterone response, a significant protocol-dependent testosterone increase for all individuals was revealed. Therefore, resistance exercise induced significant individual, protocol-dependent hormonal changes lasting up to 30 minutes after exercise. These individual responses may have important ramifications for modulating adaptation to resistance exercise and could explain the variability often observed in studies of hormonal response to resistance exercise [08152].

In aging men
Worldwide many aging males practice sports. A high prevalence of late-onset male hypogonadism has been observed in general population. Sport-participation influences the neuroendocrine system and may decrease serum testosterone. One preliminary study was designed to estimate the prevalence and the symptoms of undiagnosed testosterone deficiency in aging athletes. This observational survey was performed in 183 caucasian male athletes >50 years, in the setting of pre-participation screening. Pituitary-gonadal hormones and symptoms of hypogonadism were investigated. Serum total testosterone (TT), sex hormone binding globulin, luteinizing hormone (LH), follicle stimulating hormone (FSH), prolactin (PRL), free-T4, and thyroid stimulation hormone (TSH) were assayed, and free testosterone, bioactive testosterone, and the LH/TT ratio were calculated. The International Index of Erectile Dysfunction (IIEF-15) and the Center for Epidemiological Studies Depression Scale (CES-D) were administered. Hypogonadal athletes were compared with eugonadal athletes as controls. Prevalence and clinical symptoms of severe (TT < 8 nmol/L) or mild (TT between 8 and 12 nmol/L) testosterone deficiency were investigated. The mean sample age was 62 ± 8 years (range 50-75). Severe or mild testosterone deficiency was observed in 12 percent and 18 percent respectively, of overall athletes, with the highest prevalence in athletes >70 years (28 % and 25 %, respectively). Serum total testosterone did not correlate with age, training duration, or questionnaire scores. No differences were observed for nonspecific symptoms of hypogonadism, IIEF-15 and CES-D scores between eugonadal and severe hypogonadal athletes. It was concluded that independently of its etiology, a significant percentage of aging athletes had undiagnosed testosterone deficiency. In a relevant number of these cases, testosterone deficiency was not overtly symptomatic. Our results suggest that sport-participation per se can influence the symptoms of hypogonadism [10334].

Effects on training in females
The purpose of one investigation was to study the effects of an 11-week training period
performed by female weightlifters. Two weeks before this investigation, baseline measures for total testosterone, cortisol, and testosterone:cortisol ratio were collected. The 11-week training program consisted of the core exercises (i.e. clean, clean and jerk, and snatch) and other supplemental exercises (i.e. clean pull, snatch pull, squat, and front squat). Hormonal, isometric, and dynamic middle thigh pull force-time curve characteristics were assessed biweekly throughout the duration of the investigation, whereas volume load and training intensity were assessed weekly throughout the investigation. The testosterone:cortisol ratio of the baseline was significantly different from the ratio of weeks 1 and 9. When the week-to-week values were compared, week 1 was significantly different from week 3. A very strong correlation was found between the percentage change of the testosterone:cortisol ratio and volume load from weeks 1 to 11. Moderate to very strong correlations were noted between the percentage change in volume load and isometric peak force, peak force during the 30 percent isometric peak force trial, and peak force during the 100-kg trial during the 11 weeks of training. The primary finding of this study was that alterations in training volume load can result in concomitant changes in the anabolic-to-catabolic balance, as indicated by the testosterone:cortisol ratio, and the ability to generate maximal forces [08153].

Although androgens are produced in small amounts in women, androgens have direct and significant effects on many aspects of female physiology. Moreover, androgens are precursors to estrogens, which are the predominant female sex hormones. The measurement of androgens in blood is important in the diagnosis of both gonadal and adrenal functional disturbances, as well as monitoring subsequent treatments. The accuracy of such measurements is crucial in sports medicine and doping control. Therefore, the concentration of androgens in female subjects is frequently measured. Analysing such compounds with accuracy is especially difficult, costly and time consuming. Therefore, laboratories widely use direct radioimmunoassay kits, which are often insensitive and inaccurate. It is especially complicated to determine the level of androgens in women, as the concentration is much lower compared to the concentration found in males. Additionally, the amount of androgens in fluids tends to decrease with aging. Analyses of hormone concentrations are influenced by a myriad of factors. The factors influencing the outcome of these tests can be divided into in vivo preanalytical factors (e.g. aging, chronobiological rhythms, diet, menstrual cycle, physical exercise, etc.), in vitro preanalytical factors (e.g. specimen collection, equipment, transport, storage, etc.) and as mentioned before, analytical factors. To improve the value of these tests, the strongly influencing factors must be controlled. This can be accomplished using standardised assays and specimen collection procedures. In general, sufficient attention is not given to the preanalytical (biological) factors, especially in the measurement of androgens in females. Biological factors (non-pathological factors) that may influence the outcome of these tests in female subjects have so far received little attention [08154].

The aim of one study was to examine the effect of supra-maximal exercise on circulating concentrations of salivary testosterone, salivary cortisol, and salivary immunoglobulin A in female adolescents. Nineteen apparently healthy females aged 15-16 years participated in this study. All participants completed 6 × 8 s sprints, interspersed with 30 s recovery intervals on a cycle ergometer. Salivary testosterone, cortisol, and immunoglobulin A samples were taken before and 5 min after exercise. Experimental procedures continued over two mornings, at least 3 h after a light breakfast. Participants refrained from performing any strenuous physical activity for at least 24 h prior to the exercise test. None of the participants were engaged in a structured training programme. The group mean for peak power output was 562 ± 113 W. Female adolescents recruited for this study showed no changes in salivary testosterone, cortisol or immunoglobulin A following repeated bouts of supra-maximal cycling. To date, there has been a paucity of information concerning adolescents' hormonal and mucosal immune function responses to supra-maximal exercise. The data
provide further guidance with regard to physical activities and sports prescription for female adolescents. Further research, on a larger sample of females, is required to elucidate the physiological significance of these findings [10335].

In virtually all sports, participants "warm-up" prior to formal competition. Women athletes from a highly ranked varsity college volleyball team and, in a second study, a highly ranked varsity college tennis team gave saliva samples before warm-up, at mid-warm-up (volleyball) or after warm-up (tennis), and immediately after intercollegiate competition. For volleyball and tennis, warm-up was associated with a substantial elevation in saliva levels of testosterone which was carried over through the period of actual competition. Cortisol levels were relatively unchanged during warm-up, but typically rose during competition. Thus, as women prepare for athletic competition by warming up, testosterone levels rise in apparent anticipation of the coming contest and then remain high through the period of play. In volleyball and tennis, after-practice testosterone level was significantly higher than before-practice level, and practice session increases in testosterone (but not cortisol) were positively correlated with increases in testosterone during intercollegiate competition. When practice and competitive play share as yet undetermined key elements, individual differences in this endocrine response to "competition" appear stable across practice and intercollegiate competition [10336].

**Effects on stress**

After dominance-related encounters, testosterone levels increase in winners and decrease in losers. In humans, many exceptions have been described. It is possible that the complicated patterns in humans result from the methods limitations – measurement of hormone concentrations in simulated competitive events or sport instead in real-life situations. It was studied changes in hormonal levels and self-estimated attractivity in real situations, namely in students after written exams. It was observed that the testosterone and cortisol increased or decreased in relation to the number of wrong answers on the exam. The number of wrong answers was a better predictor of the hormonal changes (increase of both testosterone and cortisol in successful, decrease in unsuccessful students) than the self-estimated number of wrong answers or a subjectively opinionated impression from the exam. On the contrary, the concentration of hormones before the exam and self-estimated attractivity were better predictors of the subjective impression from the exam than the number of wrong answers. The results suggest that the students' subconsciousness, which directly influences the concentration of hormones, is able to objectively estimate results of an exam better than their consciousness [10337].

**Effects on muscles and tendons**

Combined androgenic-anabolic steroids (AAS) and overloading affects tendon collagen metabolism and ultrastructure and is often associated with a higher risk of injury. The aim of this prospective study was to investigate whether such effects would be reflected in the patellar tendon properties of individuals with a history of long-term resistance training and AAS abuse (RTS group), compared with trained (RT) and untrained (CTRL) nonsteroids users. Tendon cross-sectional area (CSA), stiffness, Young's modulus, and toe limit strain were measured in vivo, from synchronized ultrasonography and dynamometry data. The patellar tendon of RT and RTS subjects was much stiffer and larger than in the CTRL group. However, stiffness and modulus were higher in the RTS group (26 % and 30 %, respectively) than in the RT group. Conversely, tendon CSA was 15% (P < 0.05) larger in the RT group than in RTS, although differences disappeared when this variable was normalized to quadriceps maximal isometric torque. Yet maximal tendon stress was higher in RTS than in
RT (15 %), without any statistical difference in maximal strain and toe limit strain between groups. The present lack of difference in toe limit strain does not substantiate the hypothesis of changes in collagen crimp pattern associated with AAS abuse. However, these findings indicate that tendon adaptations from years of heavy resistance training are different in AAS users, suggesting differences in collagen remodeling. Some of these adaptations (e.g. higher stress) could be linked to a higher risk of tendon injury [13116].

Skeletal muscle regeneration efficiency declines with age for both men and women. This decline impacts on functional capabilities in the elderly and limits their ability to engage in regular physical activity and to maintain independence. Aging is associated with a decline in sex hormone production. Therefore, elucidating the effects of sex hormone substitution on skeletal muscle homeostasis and regeneration after injury or disuse is highly relevant for the aging population, where sarcopenia affects more than 30 percent of individuals over 60 years of age. While the anabolic effects of androgens are well known, the effects of estrogens on skeletal muscle anabolism have only been uncovered in recent times. Hence, the purpose of this review is to provide a mechanistic insight into the regulation of skeletal muscle regenerative processes by both androgens and estrogens. Animal studies using estrogen receptor (ER) antagonists and receptor subtype selective agonists have revealed that estrogens act through both genomic and non-genomic pathways to reduce leukocyte invasion and increase satellite cell numbers in regenerating skeletal muscle tissue. Although animal studies have been more conclusive than human studies in establishing a role for sex hormones in the attenuation of muscle damage, data from a number of recent well controlled human studies is presented to support the notion that hormonal therapies and exercise induce added positive effects on functional measures and lean tissue mass. Based on the fact that aging human skeletal muscle retains the ability to adapt to exercise with enhanced satellite cell activation, combining sex hormone therapies with exercise may induce additive effects on satellite cell accretion. There is evidence to suggest that there is a “window of opportunity” after the onset of a hypogonadal state such as menopause, to initiate a hormonal therapy in order to achieve maximal benefits for skeletal muscle health. Novel receptor subtype selective ligands and selective estrogen and androgen receptor modulators (SERMs, SARMs) promise to reduce health risks associated with classical hormonal therapies, whilst maintaining the positive effects on muscle repair. Dietary supplements containing compounds with structural similarity to estrogens (phytoestrogens) are increasingly used as alternatives to classical hormone-replacement therapies (HRT), but the effects on skeletal muscle are currently largely unknown. Research has started to investigate the combined effects of exercise and alternative HRTs, such as soy isoflavones, on skeletal muscle regenerative processes to provide safer and more efficient therapies to promote muscle regeneration and maintenance of muscle mass and strength in the aging population [13117].

Androgen-dependent impairment of myogenesis in muscular atrophy
Spinal and bulbar muscular atrophy (SBMA) is an inherited neuromuscular disease caused by expansion of a polyglutamine (polyQ) tract in the androgen receptor (AR). SBMA is triggered by the interaction between polyQ-AR and its natural ligands, testosterone and dihydrotestosterone (DHT). SBMA is characterized by the loss of lower motor neurons and skeletal muscle fasciculations, weakness, and atrophy. To test the hypothesis that the interaction between polyQ-AR and androgens exerts cell-autonomous toxicity in skeletal muscle, we characterized the process of myogenesis and polyQ-AR expression in DHT-treated satellite cells obtained from SBMA patients and age-matched healthy control subjects. Treatment with androgens increased the size and number of myonuclei in myotubes from control subjects, but not from SBMA patients. Myotubes from SBMA patients had a reduced number of nuclei, suggesting impaired myotube fusion and altered contractile structures. The lack of anabolic effects of androgens on myotubes from SBMA patients was
not due to defects in myoblast proliferation, differentiation or apoptosis. DHT treatment of myotubes from SBMA patients increased nuclear accumulation of polyQ-AR and decreased the expression of interleukin-4 (IL-4) when compared to myotubes from control subjects. Following DHT treatment, exposure of myotubes from SBMA patients with IL-4 treatment rescued myonuclear number and size to control levels. This supports the hypothesis that androgens alter the fusion process in SBMA myogenesis. In conclusion, these results provide evidence of an androgen-dependent impairment of myogenesis in SBMA that could contribute to disease pathogenesis [13118].

**Long-term effects on muscles**

Previous strength training with or without the use of anabolic steroids facilitates subsequent re-acquisition of muscle mass even after long intervening periods of inactivity. Based on in vivo and ex vivo microscopy we here propose a cellular memory mechanism residing in the muscle cells. Female mice were treated with testosterone propionate for 14 days, inducing a 66% increase in the number of myonuclei and a 77 percent increase in fibre cross-sectional area. Three weeks after removing the drug, fibre size was decreased to the same level as in sham treated animals, but the number of nuclei remained elevated for at least 3 months (>10 % of the mouse lifespan). At this time, when the myonuclei-rich muscles were exposed to overload-exercise for 6 days, the fibre cross-sectional area increased by 31 percent while control muscles did not grow significantly. It was suggested that the lasting, elevated number of myonuclei constitutes a cellular memory facilitating subsequent muscle overload hypertrophy. The findings might have consequences for the exclusion time of doping offenders. Since the ability to generate new myonuclei is impaired in the elderly our data also invites speculation that it might be beneficial to perform strength training when young in order to benefit in senescence [13119].

**Inhibitory actions on tendons**

One study investigated the structural changes in the rat calcaneal tendon (CT), superficial flexor tendon (SFT), and deep flexor tendon (DFT) in response to jump exercises and anabolic androgenic steroids (AAS). Animals were divided into four groups: sedentary, trained, AAS-treated sedentary rats, and AAS-treated trained animals. Training increased the volume density (Vv%) of blood vessels in all regions of the CT and DFT, cell Vv% in the peritendinous sheath of the proximal and distal regions of the SFT and proximal region of DFT, and cell Vv% in the tendon proper of the proximal and distal regions of the SFT and DFT. The combination of AAS and load exercises showed little increased blood vessel Vv% at the proximal region of the CT, intermediate region of the SFT, and all regions of the DFT as opposed to an increase in adipose cell Vv% in the CT proximal region. The AAS reduced the levels of hydroxyproline in the proximal region of the DFT and in the distal region of the STF. In conclusion, exercise promoted benefits to the adaptation of the tendons to overload. These effects were absent when load exercise was combined with AAS. The abusive consumption of AAS contributes to tendon inertness and rigidity, and increases the potential risk of injury [13120].

**Influence on immunological function**

The in vitro effect of testosterone on human neutrophil function was investigated. Blood neutrophils from healthy male subjects were isolated and treated with 10 nM, 0.1 and 10 microM testosterone for 24 h. As compared with untreated cells, the testosterone treatment produced a significant decrease of superoxide production as indicated by the measurement of extra- and intracellular superoxide content. An increment in the production of nitric oxide was observed at 0.1 and 10 microM testosterone concentrations, whereas no effect was found for 10 nM. Intracellular calcium mobilization was significantly increased at 10 nM,
whereas it was reduced at 10 microM testosterone. There was an increase in phagocytic capacity at 10 nM and a decrease of microbicidal activity in neutrophils treated with testosterone at 10 microM. Glutathione reductase activity was increased by testosterone treatment, whereas no effect was observed in other antioxidant enzyme activities. An increase in the content of thiol groups was observed at all testosterone concentrations. Lipid peroxidation in neutrophils evaluated by levels of TBARS was decreased at 10 nM and 0.1 microM testosterone. These results indicate the antioxidant properties of testosterone in neutrophils as suggested by reduction of superoxide anion production, and lipid peroxidation, and by the increase in nitric oxide production, glutathione reductase activity and the content of thiol groups. Therefore, the plasma levels of testosterone are important regulators of neutrophil function and so of the inflammatory response [10338].

Influence on endurance

Anabolic androgenic steroids (AAS) are doping agents that are mostly used for improvement of strength and muscle hypertrophy. In some sports, athletes reported that the intake of AAS is associated with a better recovery, a higher training load capacity and therefore an increase in physical and mental performances. The purpose of one study was to evaluate, the effect of multiple doses of AAS on different physiological parameters that could indirectly relate the physical state of athletes during a hard endurance training program. In a double blind settings, three groups (n = 9, 8 and 8) were orally administered placebo, testosterone undecanoate or 19-norandrostenedione, 12 times during 1 month. Serum biomarkers (creatine kinase, ASAT and urea), serum hormone profiles (testosterone, cortisol and LH) and urinary catecholamines (noradrenalin, adrenalin and dopamine) were evaluated during the treatment. Running performance was assessed before and after the intervention phase by means of a standardized treadmill test. None of the measured biochemical variables showed significant impact of AAS on physical stress level. Data from exercise testing on submaximal and maximal level did not reveal any performance differences between the three groups or their response to the treatment. In the present study, no effect of multiple oral doses of AAS on endurance performance or bioserum recovery markers was found [06095].

The purpose of the study was to investigate the influence of a 14-week swimming training program on psychological, hormonal, and performance parameters of elite women swimmers. Ten Olympic and international-level elite women swimmers were evaluated 4 times along the experiment (i.e. in T1, T2, T3, and T4). On the first day at 8:00 am, before the blood collecting at rest for the determination of hormonal parameters, the athletes had their psychological parameters assessed by the profile of mood-state questionnaire. At 3:00 am, the swimmers had their anaerobic threshold assessed. On the second day at 3:00 am, the athletes had their alactic anaerobic performance measured. Vigor score and testosterone levels were significantly lower in T4 compared with T3. In addition, the rate between the peak blood lactate concentration and the median velocity obtained in the alactic anaerobic performance test significantly increased in T4 compared with T3. For practical applications, the swimming coaches should not use a tapering with the present characteristics to avoid unexpected results [10046].

The purpose of one study was to explore the mechanisms for increased exercise performance in conditions of competition. Endurance trained subjects (n=14) performed incremental treadmill running to exhaustion in control laboratory conditions (non-competition) and in conditions of simulated competition to assess performance (running duration). Heart rate and respiration gases were monitored continuously through each exercise condition. Blood lactate, cortisol, growth hormone and testosterone concentrations were also determined at pre- (rest) and postexercise in each condition. Results indicated competition exercise performance was significantly increased as was peak VO$_2$ response versus non-
competition. No significant differences were found in peak measurements of minute ventilation, respiratory exchange ratio, ventilation threshold, post-exercise lactate, heart rate, or the ventilation equivalent for O2 between the exercise conditions. In both conditions growth hormone and testosterone concentrations increased significantly in response to exercise, whereas cortisol responses post-exercise were significantly elevated in the competition but not in the control condition. These findings support that in competitive situations the affective state (motivation) experienced by athletes can enhance performance in exercise events, and lead to an increased peak oxygen uptake. The magnitude of the improvement is of a substantial nature and of a level seen with some training programs. Competitive conditions also augment the cortisol response to exercise, suggesting that enhanced sympatho-adrenal system activation occur in such situations which may be one of the key "driving forces" to performance improvement [10047].

Effect of hydration
Exercise intensity powerfully influences testosterone, cortisol, and testosterone/cortisol ratio (T/C) responses to endurance exercise. Hydration state may also modulate these hormones, and therefore may alter the anabolic/catabolic balance in response to endurance exercise and training. This study examined the effect of running intensity on testosterone, cortisol, and T/C when exercise was initiated in a hypohydrated state. Nine male collegiate runners (age 20 years) completed four 10-min treadmill runs differing in pre-exercise hydration status (euhydrated, or hypohydrated by 5 % of body mass) and exercise intensity (70 % or 85 % VO2max). Body mass, urine osmolality, and urine-specific gravity documented fluid balance; blood samples drawn pre-, immediately post-, and 20 min post-exercise were analyzed for testosterone, cortisol, and T/C. Except for heart rate measured during the 70 percent VO2max trials, heart rate, VO2, and plasma lactate were similar between euhydrated and hypohydrated conditions for a given intensity, suggesting hypohydration did not measurably increase the physiological stress of the exercise bouts. Furthermore, hydration state had no measurable effect on testosterone concentrations before, during, or after exercise at either intensity. Regardless of exercise intensity, cortisol concentrations were greater during hypohydration than euhydration pre-exercise and 20 min post-exercise. Additionally, T/C was significantly lower 20 min post-exercise at 70 percent VO2max when subjects were initially hypohydrated (T/C = 0.056) versus euhydrated (T/C = 0.072). These findings suggest that depending on exercise intensity, T/C may be altered by hydration state, therefore influencing the balance between anabolism and catabolism in response to running exercise performed at typical training intensities [06096].

Influence on strength
Performing strength exercise, whether acutely or in a training programme, leads to alterations at the hypothalamic-pituitary-testicular and hypothalamic-pituitary-adrenal axes. One way to evaluate these changes is by analysis of the excretion of steroid hormones in the urine. One study determined the variations in the urine profile of glucuroconjugated steroids after a single session of strength exercise and after a 4-week programme of strength training. The subjects were a group (n=20) of non-sportsman male university students who worked out 3 days a week (Monday, Wednesday, and Friday), performing the exercises at 70-75 percent of one repetition maximum strength (1-RM). Four urine samples were collected per subject: (A) before and (B) after a standard session prior to initiating the training programme, and (C) before and (D) after the same standard session at the end of the study, and they were assayed by gas chromatography coupled to mass spectrometry. The concentrations of the different hormones were determined relatively to the urine creatinine level (ng steroid/mg creatinine) to correct for diuresis. After the exercise sessions, both before and after the training programme, there was a fall in the urine excretion of androgens and estrogens, but
no statistically significant changes in the excretion of tetrahydrocortisol (THF) and tetrahydrocortisone (THE). The anabolic/catabolic hormones ratio also decreased after the acute session, although only androstenodione + dehydroepiandrosterone (DHEA)/THE + THF ratio had a significant decrease. After the training programme, there was a significant improvement in the strength of the muscle groups studied, and an increased urinary excretion of all the androgens with respect to the initial state of repose, with the difference being significant in the case of epistosterone (Epit). The androsterone (A) + etiocholanolone (E)/THE + THF ratio increased significantly concerning the initial state. It was therefore conclude that subjects suffer variations of the urine profile with regard to the steroid hormones before and after the acute strength sessions and after the training period. The alteration after the training programme seems to be due to the subjects’ hypothalamic-hypophysis-testicular and hypothalamic-pituitary-adrenal axes adaptations, which enable them to increase physical strength [06094].

Previous studies with different results have suggested that total and bioavailable testosterone levels are modified by physical exercise. Such changes may be related to modifications in cortisol levels and could be reflected in some urine androgens. To determine how weight lifting training may affect serum and urinary androgens, it was measured total serum testosterone (T), cortisol, sex hormone binding globulin (SHBG) and urinary testosterone, epistosterone, androsterone, and etiocholanolone, in a group of 19 elite weight lifters after 20 weeks of training. SHBG increased significantly (from 28 ± 10 to 35 ± 8 nM) whereas T/SHBG decreased significantly (from 1.1 ± 0.4 to 0.9 ± 0.3). Serum total testosterone and cortisol did not change significantly. In urine, androsterone and etiocholanolone decreased significantly, whereas testosterone and epistosterone remained unchanged. Changes in T/SHBG were related positively with changes in urinary androgens, and changes in SHBG were negatively related with changes in urinary androgens. These results suggest that intense physical activity may have an influence on the elimination of androgenic hormones due mainly to changes in their transporting protein SHBG [10048].

One study assessed an enzyme-immunoassay (EIA) kit for measuring the salivary testosterone (T) and cortisol (C) concentrations of weightlifters. Saliva samples (n=64) were collected from male and female weightlifters during normal training procedures and analysed for T and C using a commercial EIA kit and a criterion radioimmunoassay (RIA) method. Significant correlations were demonstrated between the EIA and RIA measurements of salivary T and C concentrations. Further examination by sample and gender revealed similar relationships. The EIA concentrations of salivary T and C were found to be slightly greater (10-13 %) than the RIA values. Similar discrepancies were noted when gender comparisons were made, although the relative information on T (males > females) and C (males=females) were consistent for both assay methods. In conclusion, a commercially available EIA kit provided valid measures of the salivary T and C concentrations of male and female weightlifters. Factors to consider when using an enzyme-immunoassay kit include the hormone(s) of interest, the magnitude of the correlations, as well as the descriptive information gained (e. g. absolute, relative) and its uses within sport [10049].

In weightlifters

One study examined the relationships between salivary testosterone (Sal-T) and cortisol (Sal-C) concentrations and training performance in Olympic weightlifters. Four male and four female Olympic weightlifters each provided saliva samples before and after four workouts during a four-week training period. Training involved the same three exercises; snatch, clean and jerk, and front squat with the one repetition maximum (1RM) calculated for each exercise during each workout. Significant training improvements in 1RM performance (4.0-5.2 %) were noted during the snatch and clean and jerk exercises, along with the Olympic total lift.
For male participants only, the pre-workout concentrations of Sal T were significantly correlated with the snatch and clean and jerk 1RM, and the Olympic total lift. It was concluded that short period of training improved the 1RM performance of Olympic weightlifters in two exercises (snatch and clean and jerk) and the Olympic total. For male participants, their Sal-T concentrations before each workout was also related to 1RM performance during these exercises, thereby highlighting one possible short-term causative mechanism [10332].

One study examined the acute hormonal responses to a single high power resistance exercise training session. Four weight trained men participated as subjects in two randomly ordered sessions. During the lifting session, serum samples were collected pre- and 5 min post-exercise, and later analyzed for testosterone (Tes), cortisol (Cort), their ratio (Tes/Cort), and lactate (HLa). The lifting protocol was 10 x 5 speed squats at 70 percent of system mass (1 RM ± BW) with 2 min inter-set rest intervals. Mean power and velocity were determined for each repetition using an external dynamometer. On the control day, the procedures and times (1600-1900 hrs) were identical except the subjects did not lift. Tes and Cort were analyzed via EIA. Mean power and velocity was 1377 ± 10 W and 0.79 ± 0.01 m/s respectively for all repetitions, and did not decrease over the 10 sets. Although not significant, post-exercise testosterone exhibited a very large effect size. No changes were observed for either cortisol or the Tes/Cort ratio. Lactate significantly increased post-exercise. The exercise protocol resulted in no significant changes in Tes, Cort or the Tes/Cort ratio. The acute increase for Tes is in agreement with previous reports that high power activities can elicit a Tes response. High power resistance exercise protocols such as the one used in the present study produce acute increases of Tes. These results indicate that high power resistance exercise can contribute to an anabolic hormonal response with this type of training, and may partially explain the muscle hypertrophy observed in athletes who routinely employ high power resistance exercise [1033].

**Influence of sprint**

The purpose of this study was to investigate the effects of a 6-month sprint training program on plasma androgens and catecholamine (CA) concentrations in response to a 6 s sprint in adolescent boys [training group (TG), n=6; control group (CG), n=6]. A 6 s-sprint test was performed on a cycle ergometer before and after training (Pre-T and Post-T, respectively). Plasma total testosterone (TT), bioavailable testosterone (BT), and CA concentrations were measured at rest, after a warm-up, immediately after a 6 s-sprint, and during the recovery (i.e. 5 and 20 min). After training period, plasma TT concentrations increased significantly at the end of the sprint and during the recovery in the TG. No effects for sampling times and period were observed in BT levels. Plasma TT concentrations after 5 min of recovery were positively correlated with the corresponding values of plasma lactate (La) concentrations and with post-6 s-sprint plasma adrenaline (A) concentrations.. These results suggest that sprint training increases plasma TT concentrations in response to sprint exercise in adolescent boys. Plasma A and plasma La concentrations increases in response to sprint exercise could be involved in this elevation of plasma TT concentrations [10050].

**Influence of bodybuilders’ fasting periods**

The purpose of one study was to investigate simultaneous effects of energy balance, caloric intake, and the hormonal anabolic-catabolic balance in bodybuilders prior to competition. Fourteen male bodybuilders took part in an 11-week energy-restricted period to reduce body fat. The subjects were divided into the energy-restricted group (ERG) (n=7), who were preparing for the competition, or the control group (CG) (n=7) who continued to train regularly.
and did not change their dietary or training pattern. Participants were tested at 11 weeks (T1), 5 weeks (T2), and 3 days (T3) before competition for diet, body composition, and fasting hormonal assessment. Body mass and body fat percentage of ERG were significantly (p < 0.05) decreased during the study period. In ERG, insulinlike growth factor-1 (IGF-1) and insulin decreased significantly during the 11-week weight-reduction period. Testosterone was decreased only from week 11 to week 5 (from 20 ± 6 to 18 ± 7 nmol/L). Changes in IGF-1 concentration were significantly related to changes in insulin, fat mass, lean body mass, and body mass. Changes in insulin concentrations were significantly related to changes in fat mass, and lean body mass. These data indicate that severe energy restriction to extremely low body energy reserves decreases significantly the concentrations of 3 anabolic pathways despite high protein intake. Monitoring of insulin and IGF-1 concentration is suggested to prevent losses in muscle mass in energy-restricted conditions [10051].

**Flywheel ergometer workouts**

The purpose of one study was to compare blood lactate and hormonal responses with flywheel ergometer (FERG) leg presses for preliminary assessment of workouts best suited for future in-flight resistance exercise. Comprised of 10 repetition sets, the workouts entailed 3 sets of concentric and eccentric (CE3) actions, or concentric-only actions done for 3 (CO3) or 6 (CO6) sets. Methods employed included assessment of blood lactate concentrations (BLa) before and 5 minutes postexercise. Venous blood was also collected before and at 1 and 30 minutes postexercise to assess growth hormone, testosterone, cortisol concentrations. Results showed blood lactate concentrations had a time effect. Growth hormone concentration showed gender x workout, gender x time, and workout x time interactions, whereas testosterone had a 3-way interaction. Testosterone-cortisol ratio yielded a gender x time interaction. It was concluded that, because CO6 and CE3 yielded similar anabolic hormonal data but the latter had a lower cortisol 30 minutes postexercise, CE3 served as the best workout. Although the FERG was originally designed for microgravity, the effort put forth by current subjects was like that for workouts aimed at greater athletic performance and conditioning. Practical applications suggest that eccentric actions should be used for FERG workouts geared toward muscle mass and strength improvement [10052].

**Watching a previous victory**

Previous research indicates that testosterone concentrations are highly responsive to human competitive interactions and that winners have elevated testosterone concentrations relative to losers. Also, there is some evidence that simply observing others compete can have a similar effect on the endocrine system. Here, in two studies, it was examined the extent to which elite male hockey players would demonstrate an increase in testosterone concentrations after watching themselves engaged in a previous successful competitive interaction. Results indicated that watching a previous victory produced a significant increase in testosterone concentrations (42-44 % increase), whereas watching a previous defeat or a neutral video did not produce a significant change in testosterone (17 % and 6 %, respectively). Given that natural fluctuations in testosterone have been shown to influence future competitive and aggressive behaviours, the current studies may have important practical implications for individuals involved in competitive sports [10053].

**Effects of magnesium supplementation**

One study was performed to assess how 4 weeks of magnesium supplementation and exercise affect the free and total plasma testosterone levels of sportsmen practicing tae
Kwon do and sedentary controls at rest and after exhaustion. The testosterone levels were determined at four different periods: resting before supplementation, exhaustion before supplementation, resting after supplementation, and exhaustion after supplementation in three study groups, which are as follows: Group 1 - sedentary controls supplemented with 10 mg magnesium per kilogram body weight. Group 2 - tae kwon do athletes practicing 90-120 min/day supplemented with 10 mg magnesium per kilogram body weight. Group 3 - tae kwon do athletes practicing 90-120 min/day receiving no magnesium supplements. The free plasma testosterone levels increased at exhaustion before and after supplementation compared to resting levels. Exercise also increased testosterone levels relative to sedentary subjects. Similar increases were observed for total testosterone. The results show that supplementation with magnesium increases free and total testosterone values in sedentary and in athletes. The increases are higher in those who exercise than in sedentary individuals [10056].

Effects of training on salivary levels

The aims of one study were to identify the time-course of change of salivary testosterone (sT), cortisol (sC) and IgA (SIgA), mood state and performance capacity during a 2-week taper in judo athletes, and to examine the diurnal variation in these salivary markers. Eleven male judo athletes completed 5 weeks of training: 1 week of normal training (NORM), 2 weeks of intensified training (INT) and 2 weeks of exponential tapering (TAPER). Once per week subjects completed vertical and horizontal countermovement jump tests, a grip strength test, a Special Judo fitness test (SJFT), a multistage aerobic fitness test (MSFT), a 3x300-m run test and anthropometric measurement. Subjects also completed questionnaires to assess mood state and muscle soreness. Two daily saliva samples (at 07:00 and 19:00) were collected at the end of each week during NORM and INT and every day during TAPER. Increased morning sT, decreased evening sC, lower muscle soreness and enhanced mood state were evident by the early phases of TAPER. A significant 7 percent improvement in 3x300-m performance time, a 7 percent improvement in the vertical jump and increased morning and evening SIgA secretion rate were observed during the middle-late phases of TAPER. The higher values of salivary variables were observed in the morning. The study indicates that salivary hormones display diurnal variation. Furthermore, changes in hormonal responses, mood state and muscle soreness precede enhancements in performance and mucosal immunity, suggesting that judo athletes taper for at least a week prior to competition [12122].

Effects of androgens on IGF-1

The mechanism whereby anabolic androgens are associated with hypertrophy of skeletal muscle is incompletely understood but may involve an interaction with locally generated insulin-like growth factor (IGF) 1. The present investigation utilized a cell culture model of human skeletal muscle-derived cell maturation to test the hypothesis that androgens increase differentiation of human muscle precursor cells in vitro and to assess effects of androgen with or without IGF-1 on IGF-1 messenger RNA (mRNA) expression in human muscle precursor cells. Differentiation of muscle-derived cells was induced under standard low-serum conditions. Cultures were then exposed to androgen (testosterone, T) at 50, 100, and 500 nM or IGF-1 (10-50 ng/mL). Immunocytochemistry and real-time polymerase chain reaction (RT-PCR) were used to assess effects of androgens and IGF-1 after 3- (early) or 7-d (late) muscle differentiation, respectively; RT-PCR was used to quantify the effects on androgen receptor expression. Under low-serum conditions, 3-d exposure to androgens or IGF-1 or both resulted in no significant increase in cellular myogenic commitment. After 7-d exposure, however, T and IGF-1 were both found to increase fusion index with no
observable synergistic effect. T also increased IGF-1 mRNA generation, whereas exogenous IGF-1 reduced IGF-1 mRNA transcription relative to control. The T effect was reversible after treatment with flutamide, an androgen receptor antagonist. Both T and IGF-1 increase myogenic commitment after 7-d exposure to a differentiation medium. With T causing a concomitant increase in IGF-1 mRNA underpinning IGF-1 as a central mediator in the cellular pathways associated with muscle hypertrophy, including those affected by androgens. The novel system described has the potential for elucidating the pattern of growth factor effects associated with androgens in skeletal muscle [12123].

Interactions with opioids

Over the past decades, research on doping agents, such as anabolic androgenic steroids (AAS), has revealed that these compounds are often used in combination with other drugs of abuse. It seems that misuse of AAS probably involves more than a desire to enhance appearance or sports performance and studies have revealed that steroids are commonly connected with alcohol, opioids, tobacco, and psychotropic drugs. It was observed that AAS may interact with the endogenous opioids, excitatory amino acids, and dopaminergic pathways involved in the brain reward system. Furthermore, studies provide evidence that AAS may induce an imbalance in these signal systems leading to an increased sensitivity toward opioid narcotics and central stimulants. In fact, studies performed in various clinics have shown that individuals taking AAS are likely to get addicted to opioids like heroin [12124].

Induction of nitric acid

Accumulating evidence indicates that abuse of anabolic androgenic steroids may cause cardiovascular adverse side-effects, including endothelial dysfunction. The aim of the present study was to investigate the effects of supra-physiological doses of testosterone on the endothelial production of nitric oxide (NO) and oxidative stress in vitro and in vivo. Testosterone enanthate was administrated as of a single 500 mg dose to healthy volunteers (n=27). Gene expression was studied in human vascular endothelial cells exposed to testosterone. The in vivo results show that the urinary NO level and the antioxidative capacity were significantly decreased two days after testosterone administration. In agreement, our in vitro studies show that testosterone inhibits the gene expression of endothelial NO synthase (eNOS) after 48 hours. When the antioxidant seleno-L-methionine was added, the down-regulation of mRNA specific eNOS was partly abrogated. The mRNA expression of antioxidizing enzyme genes was significantly inhibited after eight hours and recovered 48 hours after testosterone treatment of endothelial cells. These results show that a supraphysiological dose of testosterone decreases the expression of eNOS and consequently the formation of NO, which could partly be explained by oxidative stress. These results indicate that supraphysiological doses of testosterone may induce endothelial dysfunction, which is of interest in relation to the cardiovascular adverse side-effects observed in anabolic androgenic steroid abusers [13207].

Lack of influence of NSAID

When focusing on steroid glucuronides as diagnostic parameters in doping controls, the influence of dietary components on relevant enzymes (i.e. UDP-glucuronosyltransferases) involved in the conjugation reactions in vivo must be considered. A variety of reports demonstrating glucuronide inhibiting properties of pharmaceuticals (e.g. non-steroidal anti-inflammatory drugs, NSAIDs) and ingredients of green tea or red wine were published, the majority of which however was done in vitro. It was therefore investigated the influence of
NSAIDs (ibuprofen and diclofenac) on the renal elimination of TG and epiTG in a controlled, randomized cross-over study with 23 male volunteers with two (n=8), one (n=7), or no (n=8) allele of the UGT2B17 gene, thus representing the above mentioned ins/ins, ins/del, and del/del genotype, respectively. Both the baseline T/epiT ratios as well as the T/epiT values following an intramuscular injection of 500 mg of testosterone enanthate were not significantly influenced by repeated maximum daily doses of the NSAIDs, which suggests that the commonly employed steroid profile approach is not compromised by NSAID applications [13009].

Testosterone is one of the most commonly abused anabolic androgenic steroids (AAS) within doping in sports and for enhancement of physical performance. In 2011 anabolic agents represented the most frequently reported adverse analytical findings and atypical findings (59%) by accredited doping laboratories. Among these, elevated testosterone/epitestosterone ratios represented 60 percent of the findings, although only 10 percent of these were adverse analytical findings. The UDP Glucuronosyl Transferase (UGT) enzymes are important in the pharmacokinetics, and conjugation, of a variety of drugs including non-steroidal anti-inflammatory drugs (NSAIDs) as well as anabolic androgenic steroids (AAS). Testosterone glucuronidation capacity is strongly associated with a deletion polymorphism in the UGT2B17 gene. As the use of high doses of NSAIDs has been observed in athletes there is a risk for a drug-drug interaction that may influence the doping tests for AAS. In vitro studies show inhibitory potential on UGT2B7, 2B15, and 2B17 enzymes by NSAIDs. To discriminate exogenous testosterone from testosterone of endogenous origin the urinary ratio of testosterone glucuronide (TG) to epitestosterone glucuronide (EG) (T/E ratio) is used. Based on population studies a normal T/E ratio would be around 1.0 and a T/E ratio above six was initially considered suspicious of doping. However, additional knowledge showed that Asian individuals excreted low amounts of TG, and as a result low T/E ratios increasing the risk of false negative doping test results. Due to these findings the T/E ratio was lowered to 4.0 in 2004. Testosterone is inactivated, and excreted in urine, mainly as glucuronide conjugates, the formation of which is catalyzed by UDP-glucuronosyltransferases (UGTs). These enzymes play a key role in the homeostasis of a number of endogenous molecules including steroid hormones. The UGT super family is subdivided into UGT1A, UGT2A, and UGT2B families based on sequence identity. The human UGT2B genes are clustered on chromosome 4q13-21.1 and encode seven functional enzymes: UGT2B4, B7, B10, B11, B15, B17, and B28. In vivo, UGT2B17 has been identified as the main enzyme in testosterone glucuronidation where a gene deletion in UGT2B17 was associated with low, or negligible, excretion of testosterone in urine. All subjects devoid of UGT2B17 had a T/E ratio below 0.4. This polymorphism was considerably more common in a Korean Asian than in a Swedish Caucasian population, with 67 and 9 percent deletion/deletion (del/del) homozygotes, respectively. The UGT enzymes are important in the pharmacokinetics, and conjugation, of a variety of drugs including non-steroidal anti-inflammatory drugs (NSAIDs). NSAIDs are a class of therapeutic agents used in the treatment of pain and inflammation and are commonly used by athletes. In fact, according to recent studies, inappropriate use of high doses and concomitant use of several different NSAIDs has been observed in athletes. Since steroids and NSAIDs are both inactivated by UGT enzymes there is a risk for a drug-drug interaction. In vitro studies show inhibitory potential on UGT2B7, 2B15 and 2B17 enzymes by NSAIDs. In the latter study both diclofenac and ibuprofen inhibited testosterone glucuronidation in liver microsomes, as well as recombinant UGT2B15 and UGT2B17 enzymes. However, epitestosterone glucuronidation activity in human liver microsomes was largely insensitive to ibuprofen and diclofenac. The aim of one study was to investigate if concomitant use of NSAIDs and a single dose of testosterone enanthate would affect the excretion rate of testosterone and epitestosterone glucuronide (TG and EG) as well as the T/E ratio, thereby affecting the outcome of the testosterone doping test. The study was designed as an open, randomized, cross-over study with subjects being their own control.
The 23 male healthy volunteers, with either two, one or no allele (ins/ins, ins/del, or del/del) of the UGT2B17 gene, received the maximum recommended dose of NSAID (Ibuprofen or Diclofenac) for 6 days. On day three, 500 mg of testosterone enanthate was administered. Spot urine samples were collected for 17 days. After a wash-out period of 4 months the volunteers received 500 mg testosterone enanthate only, with subsequent spot urine collection for 14 days. The glucuronides of testosterone and epitestosterone were quantified. NSAIDs did not affect the excretion of TG or EG before the administration of testosterone. The concomitant use of NSAIDs and testosterone slightly increased the TG excretion while the EG excretion was less suppressed compared to testosterone use only. The effects of the NSAIDs on the TG and EG excretion did not differ between the UGT2B17 genotype groups. In conclusion, the outcome of testosterone doping tests does not seem to be affected by the use of NSAIDs [13208].

Longitudinal steroid profiling

Another approach to detect testosterone use that is gaining widespread acceptance is longitudinal studies of urinary steroid concentrations. The concept is based on the observation that the T/E ratio for a single individual male typically varies by <30 percent, whereas between-individual variability is considerably larger. Individual T/E values from at least 3 test results are used to establish a baseline, and suspicious results that differ significantly from baseline are proof of synthetic testosterone use. Several statistical approaches have been used to detect outliers in longitudinal data. A Bayesian test using both population data and individual athlete test results appears to be superior to other statistical tests for detecting T/E ratio outliers. A Bayesian interpretation of T/E test results has been shown to produce 0 false-positive results for 43 true positives using a p-value of 0.1 percent. For the same data set, a population-based T/E cutoff of 4.0 resulted in 24 false positives and 34 true positives. Urine samples producing a test result significantly higher than baseline could then be submitted for GC/C/IRMS confirmation testing. This approach can be used to detect testosterone use in individuals with the UGT2B17 deletion polymorphism, possibly negating the need for genetic testing. Athlete-specific baseline T/E ratios, along with GC/C/IRMS testing on random and suspicious urine samples, were used at the Olympic Games 2008 to catch athletes that use synthetic testosterone and have low a T/E ratio. Longitudinal studies can also be applied to other urinary steroid metabolites to further enhance detection of synthetic steroid use [08016].

Long-time effects of anabolic steroids

To study the long-term impact of anabolic androgenic steroid (AAS) abuse on the cholesterol profile, and the potential to suppress endocrine activity in men working out at gym facilities a study of the relation between urinary biomarkers for testosterone and nandrolone abuse and the UGT2B17 genotype and time profile was performed. Subjects (n=56) were recruited through Anti-Doping Hot-Line. Serum levels of luteinizing hormone (LH), follicle-stimulating hormone (FSH), plasma levels of low density lipoprotein (LDL), high density lipoprotein (HDL) and urinary steroid profile were regularly measured for a period of up to one year after cessation of intramuscular AAS abuse. A sustained suppression of LH, and FSH was observed for several months. The nandrolone urinary biomarker 19-NA was detectable several months after the last nandrolone intake and was correlated to the levels of LH and FSH. Testosterone abuse on the other hand was detectable only for a few weeks, and some of the testosterone abusers did not test positive due to a genetic deletion polymorphism of the UGT2B17. Significantly increased levels of HDL and decreased levels of LDL were
observed for 6-months after cessation of AAS abuse. It was concluded that some individuals had a sustained suppression of LH and FSH for a period of 1 year whereas the cholesterol profile was normalized within 6 month. The long term consequences of these findings remain to be established [11570].

Effects of previous strength training can be long-lived, even after prolonged subsequent inactivity, and retraining is facilitated by a previous training episode. Traditionally, such "muscle memory" has been attributed to neural factors in the absence of any identified local memory mechanism in the muscle tissue. It was used in vivo imaging techniques to study live myonuclei belonging to distinct muscle fibers and observe that new myonuclei are added before any major increase in size during overload. The old and newly acquired nuclei are retained during severe atrophy caused by subsequent denervation lasting for a considerable period of the animal's lifespan. The myonuclei seem to be protected from the high apoptotic activity found in inactive muscle tissue. A hypertrophy episode leading to a lasting elevated number of myonuclei retarded disuse atrophy, and the nuclei could serve as a cell biological substrate for such memory. Because the ability to create myonuclei is impaired in the elderly, individuals may benefit from strength training at an early age, and because anabolic steroids facilitate more myonuclei, nuclear permanency may also have implications for exclusion periods after a doping offense [10306].

Anabolic androgenic steroids (AAS) use by adolescents is steadily increasing. Adolescence involves remodeling of steroid-sensitive neural circuits that mediate social behaviors, and previous studies using animal models document effects of AAS on male social behaviors. The present experiments tested whether AAS have persistent and more pronounced behavioral consequences when drug exposure occurs during adolescence as compared to exposure in adulthood. Male Syrian hamsters were injected daily for 14 days with either vehicle or an AAS cocktail containing testosterone cypionate (2 mg/kg), nandrolone decanoate (2 mg/kg), and boldenone undecylenate (1 mg/kg), either during adolescence (27-41 days of age) or adulthood (63-77 days of age). As adults, subjects were tested two or four weeks after the last injection for either sexual behavior with a receptive female or male-male agonistic behavior in a resident-intruder test. Compared with vehicle-treated males, AAS-treated males, regardless of age of treatment, displayed fewer long intromissions and a significant increase in latency to the first long intromission, indicative of reduced potential to reach sexual satiety. Increased aggression was observed in males exposed to AAS compared with males treated with vehicle, independently of age of AAS treatment. However, unlike hamsters exposed to AAS in adulthood, hamsters exposed to AAS during adolescence did not display any submissive or risk-assessment behaviors up to 4 weeks after discontinuation of AAS treatment. Thus, AAS have long-lasting effects on male sexual and agonistic behaviors, with AAS exposure during adolescence resulting in a more pronounced reduction in submissive behavior compared to AAS exposure in adulthood [09064].

Multi-parametric steroid profiling

Steroid profiling provides valuable information to detect doping with endogenous steroids. Apart from the traditionally monitored steroids, minor metabolites can play an important role to increase the specificity and efficiency of current detection methods. The applicability of several minor steroid metabolites was tested on administration studies with low doses of oral testosterone (T), T gel, dihydrotestosterone (DHT) gel and oral dehydroepiandrosterone (DHEA). The collected data for all monitored parameters were evaluated with the respective population based reference ranges. Besides the traditional markers T/E, T and DHT, minor metabolites 4-OH-Adion and 6α-OH-Adion were found as most sensitive metabolites to
detect oral T administration. The most sensitive metabolites for the detection of DHEA were identified as 16alpha-OH-DHEA and 7beta-OH-DHEA but longest detection up to three days (after oral administration of 50 mg) was obtained with non-specific 5beta-steroids and its ratios. Steroids applied as a gel had longer effects on the metabolism but were generally not detectable with universal decision criteria. It can be concluded that population based reference ranges show limited overall performance in detecting misuse of small doses of natural androgens. Although some minor metabolites provide additional information for the oral testosterone and DHEA formulations, the topical administered steroids could not be detected for all volunteers using universal reference limits. Application of other population based threshold limits did not lead to longer detection times [10307].

Steroid profiling is one of the most versatile and informative screening tools for the detection of steroid abuse in sports drug testing. Concentrations and ratios of various endogenously produced steroidal hormones, their precursors and metabolites including testosterone, epitestosterone, dihydrotestosterone (DHT), androsterone, etiocholanolone, dehydroepiandrosterone (DHEA), 5alpha-androstane-3alpha,17beta-diol, and 5beta-androstane-3alpha,17beta-diol as well as androstenedione, 6alpha-OH-androstenedione, 5beta-androstane-3alpha,17alpha-diol, 5alpha-androstane-3alpha,17alpha-diol, 3alpha,5-cyclo-5alpha-androstane-6beta-ol-17-one, 5alpha-androstenedione, and 5beta-androstenedione add up to a steroid profile that is highly sensitive to applications of endogenous as well as synthetic anabolic steroids, masking agents, and bacterial activity. Hence, the knowledge of factors that do influence the steroid profile pattern is a central aspect, and pharmaceutical (application of endogenous steroids and various pharmaceutical preparations), technical (hydrolysis, derivatization, matrix), and biological (bacterial activities, enzyme side activities) issues are reviewed [08184].

Prevalence of misuse

The prevalence of anabolic-androgenic steroids use has risen dramatically over the last two decades and filtered into all aspects of society. Support for AAS users has increased, but not by the medical profession, who will not accept that AAS use dependency is a psychiatric condition. Polypharmacy by self-prescription is prevalent in this sector. Most recently, AAS use has filtered through to "recreational street drug" users and is the largest growth of drugs in this subdivision. There is a degree of contentiousness in the scenario of anabolic-androgenic steroids drug use, both within and outside sport. AAS and associated doping agents are not illegal per se. Possession is not an offence, despite contravening sporting regulations and moral codes. Until AAS are classified in the same capacity as street drugs in the UK, where possession becomes a criminal offence, they will continue to attract those who want to win at any cost [08126].

Dependence

Anabolic-androgenic steroids (AAS) are widely used illicitly to gain muscle and lose body fat. Here it was reviewed the accumulating human and animal evidence showing that AAS may cause a distinct dependence syndrome, often associated with adverse psychiatric and medical effects. It was presented an illustrative case of AAS dependence, followed by a summary of the human and animal literature on this topic, based on publications known to us or obtained by searching the PubMed database. About 30 percent of AAS users appear to develop a dependence syndrome, characterized by chronic AAS use despite adverse effects on physical, psychosocial or occupational functioning. AAS dependence shares many features with classical drug dependence. For example, hamsters will self-administer AAS,
even to the point of death, and both humans and animals exhibit a well-documented AAS withdrawal syndrome, mediated by neuroendocrine and cortical neurotransmitter systems. AAS dependence may particularly involve opioidergic mechanisms. However, AAS differ from classical drugs in that they produce little immediate reward of acute intoxication, but instead a delayed effect of muscle gains. Thus standard diagnostic criteria for substance dependence, usually crafted for acutely intoxicating drugs, must be adapted slightly for cumulatively acting drugs such as AAS. It was concluded that AAS dependence is a valid diagnostic entity, and probably a growing public health problem. AAS dependence may share brain mechanisms with other forms of substance dependence, especially opioid dependence. Future studies are needed to characterize AAS dependence more clearly, identify risk factors for this syndrome and develop treatment strategies [09054].

Influence on reaction on pain

The purpose of one study was to investigate the effects of acute and chronic administration of anabolic-androgenic steroids (AAS) on nociception and morphine antinociception in acute pain models, as well as on chronic inflammatory nociception. In Experiment 1, adult, gonadally intact male rats were injected s.c. for 28 days with either 5mg/kg testosterone (T), dihydrotestosterone (DHT), stanozolol (STAN), or safflower oil vehicle (n=12-25/group). On day 28, rats in each group were tested on acute thermal and mechanical nociceptive assays, before and after morphine treatment. In Experiment 2, rats in each group (n=8-10/group) were injected with mineral oil or complete Freund's adjuvant (CFA) into one hindpaw after 28 days of AAS treatment, and then tested for thermal hyperalgesia, mechanical allodynia, inflammation and locomotor suppression intermittently for 28 days. Experiment 3 replicated nociceptive measurements in Experiments 1 and 2, but with a single AAS or vehicle injection occurring 3h prior to testing (n=10-12/group). While chronic AAS administration tended to decrease body weight gain and alter reproductive organ weights in the expected manner, it did not significantly alter acute nociception nor attenuate the development of various chronic pain indices after CFA administration. Morphine antinociceptive potency was significantly decreased by chronic DHT on the hotplate test only. Acute AAS administration also did not significantly alter acute or chronic nociception, or morphine antinociceptive potency. Comparisons between acute and chronic AAS administration suggest that steroid tolerance did not occur in rats treated with AAS chronically. Taken together, these data do not support the hypothesis that AAS exposure alters nociception or morphine antinociception in gonadally intact males [11071].

Overview of detection of AAS abuse

AAS misuse can be conventionally detected by steroid profiling including precursors and metabolites as well the urinary testosterone/epitestosterone (T/E) ratio, of which normal levels are below or up to 4.0. Any sample displaying levels above this threshold should be quantitatively analyzed for confirmation by tandem gas chromatography/mass spectroscopy (GC/MS). Guidelines for confirmatory analysis by GC/MS and LC/MS/MS have been released by WADA. High-performance liquid chromatography-tandem mass spectrometry (LC/MS/MS), also employed in recent years in forensic toxicology, has been established as a powerful and reliable tool for quantitative confirmatory analysis of drugs used for doping. Epitestosterone administration is prohibited because it lowers the urinary testosterone/epitestosterone ratio, a marker of testosterone administration. However, use of a gas chromatography–combustion–isotope ratio mass spectrometry method resulted in quantification of the delta C values for urinary epitestosterone as high in controls and lower in
the epitestosterone group. A two-step derivatization procedure has recently been introduced to enhance performance of electrospay ionization liquid chromatography-mass spectroscopy in detecting ASS, these being compounds that notably possess limited ionization efficiency. Nevertheless, the newly initiated approach based on high resolution/high accuracy MS and ion mobility has the capacity to analyze the gas phase dissociation behaviour of several new drugs. The thus enabled cartography of fragmentation routes of new compounds may permit a more rapid identification of metabolites and “tailor-made” analogues developed for doping purposes. The detection of doping is moving away from checking for quantified exposure to prohibited substance towards biologic assays detecting an effect of prohibited substances. Cell-based biological assays comprise the future generation of assays which should be implemented by anti-doping laboratories to detect presence of androgenic anabolic steroids and other human AR ligands as well as assess the biological activity when the structure of the compound is not known. Another method, the metabolomics-based approach that was introduced as a high-tech strategy to determine the anabolic steroid urine profile in livestock production, is an illicit use of natural steroids and is moreover hard to prove since the metabolites are unknown. Despite the present lack of compelling data, metabolomics, involving study of the fingerprints of ASS metabolites, is likely to be added to the arsenal of anti-doping methods and control programs [12011].

Ratio between testosterone and epitestosterone

In addition to the development of secondary sex characteristics, testosterone (T) has anabolic effects including increases in muscle size and strength and increases in lean body mass. In the case of exogenous administration of testosterone, the ratio of testosterone to its isomer, epitestosterone (E), is elevated. WADA has set a standard for T/E ratios of 4.0 as indicative of possible exogenous testosterone administration. Typically, a sample that screens for a T/E ratio above that threshold is then subjected to quantitative confirmation by GC/MS. This methodology, however, can limited due to sensitivity issues as well as a limited number of qualifying ions that can be used for unambiguous identification. It was therefore developed a confirmation method which uses liquid/liquid extraction, followed by room temperature Girard P derivatization, and analysis using LC/MS-ToF. Analysis time is decreased. Sensitivity is increased, resulting in limits of detection of 2 and 0.5 ng/ml for testosterone and epitestosterone, respectively. The number of diagnostic qualifier ions is also increased allowing more confident identification of the analytes. Finally, while this method has been developed on a QToF instrument, it should be easily transferable to any tandem LC/MS/MS system [08181].

In an effort to control androgen use for enhanced sport performance, WADA screens biological samples for the presence of androgens, metabolites, and/or masking agents. Professional athletes are tested both during, and before, competition. There are a number of routine screening tests that are used to detect exogenous androgen administration, including measuring the testosterone to epitestosterone (T/E) ratio by GC-MS. Epitestosterone is a co-secreted product of T and normally is present in urine at levels similar to testosterone. If exogenous T is administered this will elevate the T level, but not the epitestosterone level. This test is complicated by the fact that the values of testosterone and epitestosterone vary greatly between individuals, and therefore, any sample that meets any one of the following criteria will be sent off for further analysis using Isotope Ratio Mass Spectrometry (IRMS): T/E value greater than or equal to 4, concentration of T or E greater than 200 ng/mL, concentration of androsterone or etiocholanolone greater than 10,000 ng/mL, or concentration of DHEA greater than 100 ng/mL [13084].
If a sample is submitted for further evaluation by IRMS, the $^{13}\text{C}/^{12}\text{C}$ ratio of the androgen will be measured. This is because commercially produced androgens will have higher $^{13}\text{C}$ levels compared with endogenous androgens. Synthetic androgen use is screened by GC-MS. This is possible because each synthetic androgen has a distinctive chemical structure on GC-MS that is readily identifiable and can be matched to a catalogue kept by WADA. Even trace amounts of synthetic androgen intake are detectable months after the last administration with GC/MS able to detect concentrations in the pg/ml range. The GC-MS screening tests are very sensitive and specific for known androgens on the WADA list. However, these screening tests cannot provide a complete detection of all androgens because they are unable to detect designer androgens [13084].

**Specific laboratory techniques for anabolic steroids**

The list of prohibited substances of the World Anti-Doping Agency (WADA) classifies the administration of several steroids in sports as doping. Their analysis is generally performed using urine specimen as matrix. Lots of the steroids are extensively metabolised in the human body. Thus, knowledge of urinary excretion is extremely important for the sensitive detection of steroid misuse in doping control. The methods routinely used in steroid screening mainly focus on substances, that are excreted unconjugated or as glucuronides. Common procedures include deconjugation using a beta-glucuronidase enzyme. Following extraction and concentration the analytes are submitted to LC-MS(/MS) analysis and/or GC-MS(/MS) analyses. Besides the classical steroids, more and more products appear on the market for "dietary supplements" containing steroids that have never been marketed as approved drugs, mostly without proper labelling of the contents. To cover the whole range of potential products comprehensive screening tools have to be utilised in addition to the classical methods. Endogenous steroids, e.g. testosterone, represent a special group of compounds. As classical chemical methodology is incapable of discriminating synthetic hormones from the biosynthesised congeners, the method of steroid profiling is used for screening purpose. Additionally, based on isotope signatures a discrimination of synthetic and natural hormones can be achieved [10339].

A simple, rapid and sensitive method was developed for determining the presence of seven anabolic steroids (boldenone, nandrolone, testosterone, methyltestosterone, epiandrosterone, androsterone, and atnozolol) in human urine. Glucuronide-conjugates of these compounds were hydrolyzed with beta-glucuronidase. The anabolic steroids were analyzed by on-line in-tube solid-phase microextraction (SPME) coupled with liquid chromatography-mass spectrometry (LC-MS). The steroids were separated within 14 min by high performance liquid chromatography using a Chromolith RP-18e column and 5 mM ammonium formate/methanol (35/65, v/v) as a mobile phase at a flow rate of 1.0 mL/min. Electrospray ionization conditions in the positive ion mode were optimized for the MS detection of these compounds. The optimum in-tube SPME conditions were 20 draw/eject cycles with a sample size of 40 microL using a Supel-Q PLOT capillary column for the extraction. The extracted compounds could be desorbed readily from the capillary column by flow of the mobile phase, and no carryover was observed. Using the in-tube SPME LC-MS with SIM mode detection, good linearity of the calibration curve ($r>0.995$) was obtained in the concentration range of 0.5-20 ng/mL, except for stanozolol. The detection limits ($S/N=3$) of anabolic steroids were in the range 9-182 pg/mL and the proposed method showed 20-33-fold higher sensitivity than the direct injection method. The within-day and between-day precisions were below 4.0 and 7.3 percent (n=5), respectively. This method was applied successfully to the analysis of urine samples without the interference peaks. The recovery rates of anabolic steroids spiked into urine samples were above 85 percent. This method is
useful to analyze the urinary levels of these compounds in anti-doping tests [10340].

Triple quadrupole (QqQ), time of flight (TOF) and quadrupole-time of flight (QTOF) analysers have been compared for the detection of anabolic steroids in human urine. Ten anabolic steroids were selected as model compounds based on their ionization and the presence of endogenous interferences. Both qualitative and quantitative analyses were evaluated. QqQ allowed for the detection of all analytes at the minimum required performance limit (MRPL) established by the World Anti-Doping Agency (between 2 and 10 ng/mL in urine). TOF and QTOF approaches were not sensitive enough to detect some of the analytes (3’-hydroxy-stanozolol or the metabolites of boldenone and formebolone) at the established MRPL. Although a suitable accuracy was obtained, the precision was unsatisfactory (RSD typically higher than 20 %) for quantitative purposes irrespective of the analyser used. The methods were applied to 30 real samples declared positives either for the misuse of boldenone, stanozolol and/or methandienone. Most of the compounds were detected by every technique, however QqQ was necessary for the detection of some metabolites in a few samples. Finally, the possibility to detect non-target steroids has been explored by the use of TOF and QTOF. The use of this approach revealed that the presence of boldenone and its metabolite in one sample was due to the intake of androsta-1,4,6-triene-3,17-dione. Additionally, the intake of methandienone was confirmed by the post-target detection of a long-term metabolite [11073].

In routine screening, hormone residues of all known growth promoting agents are detected by immuno assays or chromatographical methods in combination with mass spectrometry. To overcome the detection by these routine screening methods new xenobiotic growth promoters and new ways of application were developed, e.g. the combination of different agents in hormone cocktails are employed. To enable an efficient tracing of misused anabolic substances it is necessary to develop new screening technologies for a broad range of illegal drugs including newly designed xenobiotic anabolic agents. The use of omic technologies like, transcriptomics, proteomics or metabolomics is a promising approach to discover the misuse of anabolic hormones by indirectly detecting their physiological action. With the help of biostatistical tools it is possible to extract the quested information from the data sets retrieved from the omic technologies [09065].
A simple, low cost system for the backflushing of capillary gas chromatography (GC) columns has been investigated and integrated into a method for the detection of anabolic steroids in equine urine. The modification to the method was simple to make and quick to setup and optimize. The use of backflushing technology was found to offer significant benefits in terms of sample throughput and improved system robustness [10067].

A molecularly imprinted polymer (MIP), templated with methyltestosterone, had been synthesized for the cleanup of hydrolyzed urine samples for subsequent testosterone (T) quantification by LC-MS/MS. A concentration of 2 ng/mL testosterone could be quantified after a single step extraction on the MIP. The limit of detection and quantification with the criteria of a signal-to-noise ratio of 3 and 5 were 0.3 and 2 ng/mL, respectively. These values meet the conditions set by the World Anti-Doping Agency for the minimum required performance limits for doping controls, between 2 and 10 ng/mL. Epitestosterone (E) was also separated on this polymer and could be detected at concentrations down to 0.3 ng/mL. The quantification of T and E gives access to the determination of the T/E ratio, essential in doping analysis. Hence, the polymers can offer a more specific extraction procedure, resulting in increased sensitivity with limits of detection 10 times lower than the ones achieved by the standard SPE C(18) sorbents employed in official testing laboratories [10068].

Phase-II metabolism has a major contribution to androgen metabolism, converting the highly non-polar compounds to a more easily excreted form prior to their excretion in urine. In the human body the main phase-II metabolic reactions are glucuronidation and sulphonation. These reactions are catalysed by enzymes, which are categorised into families and further subfamilies based on their function and similarities of their amino-acid sequences. Due to inter-individual variation of the metabolising enzymes and their activities, the metabolic patterns of prohibited substances should be estimated for efficient doping control. In addition to target analytes the phase-II reactions have an effect on the selection of sample preparation procedure, chromatographic technique and ionisation method of the analysis routine. For method development and identification purposes adequate reference material is required, and to replace the laborious in vivo excretion studies, in vitro methodologies have been implemented to produce intact phase-II metabolites of androgens [10069].

A simple, rapid and sensitive method was developed for determining the presence of seven anabolic steroids (boldenone, nandrolone, testosterone, methyltestosterone, epiandrosterone, androsterone, and atnozolol) in human urine. Glucuronide-conjugates of these compounds were hydrolyzed with beta-glucuronidase. The anabolic steroids were analyzed by on-line in-tube solid-phase microextraction (SPME) coupled with liquid chromatography-mass spectrometry (LC-MS). The steroids were separated within 14 min by high performance liquid chromatography using a Chromolith RP-18e column and 5 mM ammonium formate/methanol (35/65, v/v) as a mobile phase at a flow rate of 1.0 mL/min. Electrospray ionization conditions in the positive ion mode were optimized for the MS detection of these compounds. The optimum in-tube SPME conditions were 20 draw/eject cycles with a sample size of 40 microL using a Supel-Q PLOT capillary column for the extraction. The extracted compounds could be desorbed readily from the capillary column by flow of the mobile phase, and no carryover was observed. Using the in-tube SPME LC-MS with SIM mode detection, good linearity of the calibration curve (r>0.995) was obtained in the concentration range of 0.5-20 ng/mL, except for stanozolol. The detection limits (S/N=3) of anabolic steroids were in the range 9-182 pg/mL and the proposed method showed 20-33-fold higher sensitivity than the direct injection method. This method was applied successfully to the analysis of urine samples without the interference peaks. The recovery rates of anabolic steroids spiked into urine samples were above 85 percent. This method is useful to
analyze the urinary levels of these compounds in anti-doping tests [10070].

One work presented the validation study of the comprehensive two-dimensional gas chromatography (GC x GC)-time-of-flight mass spectrometry method performance in the analysis of the key World Anti-Doping Agency (WADA) anabolic agents in doping control. The relative abundance ratio, retention time, identification and other method performance criteria have been tested in the GC x GC format to confirm that they comply with those set by WADA. Furthermore, tens of other components were identified with an average similarity of >920 (on the 0-999 scale), including 10 other endogenous sterols, and full mass spectra of 5,000+ compounds were retained. The testosterone/epitestosterone ratio was obtained from the same run. A new dimension in doping analysis has been implemented by addressing separation improvement. Instead of increasing the method sensitivity, which is accompanied by making the detector increasingly "blind" to the matrix (as represented by selected ion monitoring mode, high-resolution mass spectrometry (MS) and tandem MS), the method capabilities have been improved by adding a new "separation" dimension while retaining full mass spectral scan information. Apart from the requirement for the mass spectral domain that a minimum of three diagnostic ions with relative abundance of 5% or higher in the MS spectra, all other WADA criteria are satisfied by GC x GC operation. The minimum of three diagnostic ions arises from the need to add some degree of specificity to the acquired mass spectrometry data; however, under the proposed full MS scan method, the high MS similarity to the reference compounds offers more than the required three diagnostic ions for an unambiguous identification [10071].

Doping control screening based on the enhanced resolution of comprehensive two-dimensional gas chromatography hyphenated to time of flight mass spectrometer was investigated. The identification of anabolic agents (clenbuterol, norandrosterone, epimetendiol, two methyltestosterone metabolites and 3'-hydroxystanozolol) contained in a spiked urine sample (2 ng/ml) has been demonstrated. Special emphasis was given to 3'-hydroxystanozolol, mainly considering the difficulty in its detection. In contrast to conventional GC-MS approaches that must use single-ion monitoring, the GCxGC-TOFMS method enabled the identification of that metabolite through the deconvolution of the full mass spectrum and also resolved the co-eluted peaks of 3'-hydroxystanozolol and an endogenous Components [08166].

Current threshold levels of steroids do not allow for the detection of all endogenous steroid misuse due to great interindividual variations in urinary steroid concentrations. A method has been developed and validated to screen for traditionally monitored endogenous steroids in doping control as well as specific hydroxylated/oxygenated metabolites in order to enhance the detection capabilities for the misuse of endogenous steroids [08167].

The urinary metabolism of the irreversible aromatase inhibitor androsta-1,4,6-triene-3,17-dione was investigated. It is mainly excreted unchanged and as its 17beta-hydroxy analogue. For confirmation, 17beta-hydroxyandrosta-1,4,6-trien-3-one was synthesized and characterized by nuclear magnetic resonance (NMR) in addition to the parent compound. In addition, several reduced metabolites were detected in the post-administration urines, namely 17beta-hydroxyandrosta-1,4-dien-3-one (boldenone), 17beta-hydroxy-5beta-androst-1-en-3-one (boldenone metabolite), 17beta-hydroxyandrosta-4,6-dien-3-one, and androsta-4,6-diene-3,17-dione. The identification was performed by comparison of the metabolites with reference material utilizing gas chromatography/mass spectrometry (GC/MS) of the underivatized compounds and GC/MS and GC/tandem mass spectrometry (MS/MS) of their trimethylsilyl (TMS) derivatives. Alterations in the steroid profile were also observed, most obviously in the androsterone/testosterone ratio. Even if not explicitly listed, androsta-1,4,6-triene-3,17-dione is classified as a prohibited substance in sports by the World Anti-Doping
Agency (WADA) due to its aromatase-inhibiting properties. In 2006 three samples from human routine sports doping control tested positive for metabolites of androsta-1,4,6-triene-3,17-dione. The samples were initially found suspicious for the boldenone metabolite 17beta-hydroxy-5beta-androst-1-en-3-one. Since metabolites of androst-4-ene-3,6,17-trione were also present in the urine samples, it is presumed that these findings were due to the administration of a product like “Novedex Xtreme”, which could be easily obtained from the sport supplement market [08168].

The detection of steroids originating from synthetic precursors in relation to their chemically identical natural analogues has proven to be a significant challenge for doping control laboratories accredited by WADA. Endogenous steroid abuse may be confirmed by utilising the atomic specificity of gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS) that enables the precise measurement of differences in stable isotope ratios that arise as a result of fractionation patterns inherent in the source of steroids. A comprehensive carbon isotope ratio (delta^{13}C) profiling study (n=1262) of urinary ketosteroids is reported that demonstrates the inter-individual variation that can be expected from factors such as diet, ethnicity, gender and age within and between different populations (13 countries). This delta^{13}C distribution is shown by principal component analysis (PCA) to provide a statistical comparison to delta^{13}C values observed following administration of testosterone enanthate [08169].

The product Orastan-A from Gaspari Nutrition was analyzed for its steroid content. According to the labeling, it is supposed to contain "5a-androstano[2,3-c]furazan-17b-tetrahydropyranol ether", also called furazadrol-THP ether. The GC-MS analyses of the liberated steroids (after extraction from the capsule matrix and cleavage of the THP ether, TMS-derivative andunderivatized) revealed mass spectra of two components, both inconsistent with the labeling. Thus, the steroids were characterized by different analytical techniques such as mass spectrometry, nuclear magnetic resonance spectroscopy and X-ray crystal structure analysis. They were identified as 17beta-hydroxyandrostano[3,2-c]isoxazole and -[2,3-d]isoxazole [08170].

The use of natural and synthetic anabolic steroids in animal fattening has been prohibited in many countries because of their potential toxic effect on human health. One paper describes a newly developed gas chromatography-ion trap-mass spectrometry (GC-IT-MS) method for the quantitative determination of various residual anabolic steroids in meat. Anabolic steroid was derivatized with N-methyl-N-trimethylsilyltrifluoroacetamide prior to GC-IT-MS analysis. MS^2 was employed for quantitative measurement. In addition, 2d-estradiol was used as an internal standard. Quantitative determination was based on the ratio of peak area of steroid derivative to peak area of internal standard derivative. Good linearity of each compound, 0.03-1.0 mug/ml, was determined. Solvent extraction was used to extract residual anabolic compounds in meat samples and a solid phase extraction procedure was utilized for sample cleanup and pre-concentration. The limits of detection of anabolic compounds approximately ranged from 0.1 to 0.4 mug/kg. The detection limit was comparable with or better than reported methods and was below the minimum required performance limits established by the European Community (EC). The application of this newly developed method was demonstrated by analyzing various beef, pork, chicken and several animal internal organ samples from local markets [08171].

Carbon isotope ratio (CIR) analysis of urinary steroids using gas chromatography-combustion isotope ratio mass spectrometry (GCC-IRMS) is a recognized test to detect illicit doping with synthetic testosterone. There are currently no universally used steroid isotopic standards (SIS). It was adapted a protocol to prepare isotopically uniform steroids for use as a calibrant in GCC-IRMS that can be analyzed under the same conditions as used for
steroids extracted from urine. Two separate SIS containing a mixture of steroids were created and coded CU/USADA 33-1 and CU/USADA 34-1, containing acetates and native steroids, respectively. CU/USADA 33-1 contains 5alpha-androst-3beta-ol acetate (5alphaA-AC), 5alpha-androstan-3alpha-ol-17-one acetate (androsterone acetate, A-AC), 5beta-androstan-3alpha-ol-11, 17-dione acetate (11-ketoetiocholanolone acetate, 11k-AC) and 5alpha-cholestane (Cne). CU/USADA 34-1 contains 5beta-androstan-3alpha-ol-17-one (etiocholanolone), 5alpha-androstan-3alpha-ol-17-one (androsterone), and 5beta-pregnane-3alpha, 20alpha-diol (5betaP). Each mixture was prepared and dispensed into a set of about 100 ampoules using a protocol carefully designed to minimize isotopic fractionation and contamination. A natural gas reference material, NIST RM 8559, traceable to the international standard Vienna PeeDee Belemnite (VPDB) was used to calibrate the SIS. Absolute delta^{13}C(VPDB) and DeltaDelta^{13}C(VPDB) values from randomly selected ampoules from both SIS indicate uniformity of steroid isotopic composition within measurement reproducibility. This procedure for creation of isotopic steroid mixtures results in consistent standards with isotope ratios traceable to the relevant international reference material [08172].

The applicability of comprehensive two-dimensional gas chromatography (GCxGC) for sterol analysis was investigated by separation and identification of endogenous sterols in standards, and spiked in human urine. The modulation temperature was optimized to achieve the best separation and signal enhancement. The separation pattern of trimethylsilyl derivatives of sterols was compared on two complementary column sets. Whilst the BPX5/BPX50 column set offers better overall separation, BPX50/BPX5 provides better peak shape and sensitivity. The average match quality for 19 analysed sterols on the BPX50/BPX5 column set was 950/1000 when searched against the in-house library; only four were identified against the NIST05 library, at a match threshold of 800. The study shows that GCxGC-TOFMS yields high specificity for steroids derived from urine, with detection limits appropriate for use in doping control [08173].

Exogenous testosterone is known to decrease the urinary excretion rate of epitestosterone glucuronide due to suppression of the secretion of luteinizing hormone [08271-08273]. In one study the epitestosterone glucuronide levels decreased after a testosterone injection. There were large interindividual differences, but six days after the testosterone administration 92 percent of all subjects had epitestosterone glucuronide levels below 30 percent of baseline leading to even higher increases of T/E ratios [08011].

By means of gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS) urinary steroids obtained from a reference population of 56 subjects were analyzed for their C13/C12-ratios. Androsterone and etiocholanolone represent androgen metabolites, whereas 11beta-hydroxyetiocholanolone, 11beta-hydroxyandrosterone, and 5beta-pregnane-3alpha,20alpha-diol have sources independent from androgen metabolism. The deltaC13-values of the latter compounds may be compared to those of androgen metabolites in order to detect doping with synthetic androgens and thus may serve as endogenous reference compounds (ERC). In order to allow for classification of conspicuous samples, reference ranges and limits were calculated for deltaC13-values of selected steroids and differences hereof (DeltaC13-values). When androsterone is compared to ERCs, deltaC13-values larger than 3 per thousand are very unlikely. A set of additional parameters was surveyed by a questionnaire. Several factors turned out to exert significant influence on the deltaC13-values of urin ary steroids. These encompass the identity of the steroid itself, sex, oral contraception, travels, and physical activity [08174].

The detection of new anabolic steroid metabolites and new designer steroids in urine is a challenge in doping analysis. An approach based on precursor ion scanning for the detection
of unknown anabolic steroids and metabolites is proposed. The study of the MS/MS spectra of selected anabolic steroids revealed different fragmentation pathways at low and medium collision energy depending on the steroid structure. However, after analysis at high collision energy three common ions at m/z 105, m/z 91, and m/z 77 were found for all studied anabolic steroids. These ions can be explained by the fragmentation of the steroid structure and corresponded to the methyl tropylium, tropylium, and phenyl ions, respectively. Because of the theoretical low specificity of these ions, the simultaneous presence of all of them was used as a starting point to consider a substance as a possible anabolic steroid. Hence, the developed approach is based on the simultaneous acquisition of the precursor ion scan of m/z 105, 91, and 77. The specificity of this approach has been checked by the injection of several doping agents including beta-agonists, corticosteroids, beta-blockers, and diuretics. In general, only compounds with a steroidal structure showed a signal at all three selected m/z values although some exceptions have been found. The applicability of the method was tested for three different scenarios: the detection of steroid metabolites, the detection of unknown steroids, and the analysis of prohormones. In metabolic studies, several recently reported fluoxymesterone metabolites were also found using this method. For detection of unknown steroids, some negative urine samples were spiked with the designer steroid THG and 33 other anabolic steroids and treated as blind samples. Finally, the applicability of the developed approach for the analysis of dietary supplements was checked by the analysis of a prohormone where several impurities and/or degradation products were found [08175].

In recent years products containing 6alpha-methylandrost-4-ene-3,17-dione have appeared on the sport supplement market. Scientific studies have proven aromatase inhibition and anabolic and mild androgenic properties; however, no preparation has been approved for medical use up to now. In sports 6alpha-methylandrost-4-ene-3,17-dione has to be classified as a prohibited substance according to the regulations of WADA. For the detection of its misuse the metabolism was studied following the administration of two preparations obtained from the Internet (Formadrol and Methyl-1-Pro). Several metabolites as well as the parent compounds were synthesized and the structures of 3alpha-hydroxy-6alpha-methyl-5beta-androstan-17-one, 6alpha-methylandrost-4-ene-3,17-dione, and 5beta-dihydromedroxy-progesterone were confirmed by nuclear magnetic resonance (NMR) spectroscopy. The main metabolite, 3alpha-hydroxy-6alpha-methyl-5beta-androstan-17-one, was found to be excreted as glucuronide and was still detectable in microg/mL amounts until urine collection was terminated (after 25 h). Additionally, samples from routine human sports doping control had already tested positive for the presence of metabolites of 6alpha-methylandrost-4-ene-3,17-dione. Screening analysis can be easily performed by the existing screening procedure for anabolic steroids using 3alpha-hydroxy-6alpha-methyl-5beta-androstan-17-one as target substance (limit of detection <10 ng/mL). Its discrimination from the closely eluting drostanolone metabolite, 3alpha-hydroxy-2alpha-methyl-5alpha-androstan-17-one, is possible as the mono-TMS derivative [08176].

Nine anabolic steroids (andosterone, nandrolone, estradiol, testosterone propionate, nandrolone-17 propionate, dydrogesterone, testosterone, epitestosterone, boldenone) and alpha-cholestanone as internal standard were studied by gas chromatography coupled with mass spectrometry (GC/MS). Anabolic steroids can be derivatised into one or two forms, mainly for andosterone into A-monoTMS and A-diTMS. The aim of one study was to research the optimization conditions of the derivatisation process (maximum yield of silylation reaction) of each anabolic steroid into only one form. The interaction "temperature-reaction time" is significant and has a positive effect on the improvement of the effectiveness of the derivatisation. Considering the large amount of information, often not convergent, a global desirability function was applied for multi-responses optimization. Thus, the optimized temperature and the reaction time of silylation were 85 degrees C and 24 min, respectively. Several GC/MS analytical parameters were also studied: linearity (regression coefficient
upper than 0.99 for each compound, sensibility (range of concentration 0.05-0.30µg/ml).

Confirmatory experiments were applied to check the predicted values and to validate the model. The confirmatory assay responses are relatively close to the responses predicted. It was observed satisfactory resolutions by GC/MS and a run lower than 12 min [08177].

An isocratic HPLC method for the determination with screening purposes of anabolic androgenic steroids (fluoxymesterone, boldenone, nortestosterone, metandrostenedione, norethindrone, methyltestosterone and bolasterone), used as growth promoting agents, in finishing pig feed samples has been developed and validated. The separation was achieved by using a reversed-phase Chromolith RP-18e column at controlled temperature, UV-detection at 245nm and epitestosterone as internal standard. The method development involved optimization of different aqueous-organic mobile phases using methanol or acetonitrile as organic modifiers, flow-rate and temperature. The optimized method was applied to the analysis of anabolic steroids in finishing pig feed samples. The extraction efficiencies, decision limits (CCalpha) and detection capabilities (CCbeta) for these compounds were in the range 83-96 percent, 27-37 and 32-47 per microg/kg range, respectively. The within-laboratory reproducibility at 1, 1.5 and 2 CCbeta concentration levels were smaller than 13, 10 and 8 percent, respectively. Finally, the proposed method was successfully applied to nine different kinds of animal feed [08178].

An approach based on precursor ion scanning for the detection of unknown anabolic steroids and metabolites was proposed. The study of the MS/MS spectra of selected anabolic steroids revealed different fragmentation pathways at low and medium collision energy depending on the steroid structure. However, after analysis at high collision energy three common ions at m/z 105, m/z 91, and m/z 77 were found for all studied anabolic steroids. These ions can be explained by the fragmentation of the steroid structure and corresponded to the methyl tropylium, tropylium, and phenyl ions, respectively. Because of the theoretical low specificity of these ions, the simultaneous presence of all of them was used as a starting point to consider a substance as a possible anabolic steroid. Hence, the developed approach is based on the simultaneous acquisition of the precursor ion scan of m/z 105, 91, and 77. The specificity of this approach has been checked by the injection of several doping agents including beta-agonists, corticosteroids, beta-blockers, and diuretics. In general, only compounds with a steroidal structure showed a signal at all three selected m/z values although some exceptions have been found. The applicability of the method was tested for three different scenarios: the detection of steroid metabolites, the detection of unknown steroids, and the analysis of prohormones. In metabolic studies, several recently reported fluoxymesterone metabolites were also found using this method. For detection of unknown steroids, some negative urine samples were spiked with the designer steroid THG and 33 other anabolic steroids and treated as blind samples. Finally, the applicability of the developed approach for the analysis of dietary supplements was checked by the analysis of a prohormone where several impurities and/or degradation products were found [08179].

A GC-MS method for the determination of anabolic steroids used as growth promoting agents using SIM in piglet feed samples has been developed and validated, using testosterone as internal standard. The formation of volatile steroid derivatives was carried out by derivatization with N-methyl-N-(trimethylsilyl)trifluoroacetamide. The optimum separation was achieved using a Zebron ZB-5 column under a gradient temperature elution, allowing the separation of steroids in 18 min. The extraction efficiencies, CCalpha and CCbeta for these compounds were in the ranges 78-98 percent, 10-21 and 18-35 µg/kg, respectively. The repeatability and the within-laboratory reproducibility at 1, 1.5, and 2 CCbeta concentration levels were smaller than 8.2, 7.5, and 5.8 percent and 12.2, 9.5, and 7.5 percent, respectively. Accuracy was in the 99-103 percent range. The robustness was evaluated using the Youden robustness test. The proposed method was applied to the
One paper presents the development, optimization and validation of a methodology to determine nine key steroid hormones (viz. pregnenolone, progesterone, dehydroepiandrosterone, androstenedione, testosterone, dihydrotestosterone, estrone, 17alpha-estradiol and 17beta-estradiol) expressed in the steroidogenesis in biological fluids. The analytical method allows for the determination of steroid hormones in blood plasma and serum down to 0.08-0.16 ng/mL for estrogens, 0.20-0.36 ng/mL for androgens and 0.36-0.43 ng/mL for progestagens. These limits of detection were obtainable using a two-step solid-phase clean-up for fractionation and elimination of interfering lipids (fatty acids, phospholipids, glycerides and sterols) from the steroid hormones. The accuracy of the method was 50-112 percent in the range 0.10 to 2.00 ng/mL [11075].

Trimethylsilylation of anabolic agents and their metabolites is frequently achieved by using the derivatization mixture N-methyl-N-(trimethylsilyl)trifluoroacetamide (MSTFA)/NH4I/2-mercaptetoethanol. Nevertheless, artifacts were formed when this mixture was employed in the monitoring of exemestane and its main metabolite 17β-hydroxyexemestane prior to GC-MS analysis. These artifacts were identified as the N-methyltrifluoroacetamide (MTFA) and trimethylsiloxyethylmercapto products of the respective trimethylsilyl (TMS) derivatives. Furthermore, artifact formation was evaluated taking the structure (1,4-diene-3-keto-6-exomethylene) of the compounds into account. Although these artifacts are relevant for investigations regarding the derivatization process and may be of interest in many fields, they are detrimental to cope with the requirements of the World Anti-Doping Agency (WADA) in terms of the limits of detection (LODs) required. To overcome this issue, a method using an alternative derivatization was proposed: formation of methyloxime-TMS derivatives through double derivatization using O-methylhydroxylamine/pyridine and MSTFA/TMS imidazole after enzymatic hydrolysis and liquid-liquid extraction. Samples from an excretion study after administration of exemestane to healthy volunteers were analyzed by the proposed method and detection of both exemestane and its main metabolite was possible. This method showed excellent results for both analytes meeting the LODs required for antiestrogenic agents (50 ng/mL) established by WADA. The method was validated for the main metabolite, it was robust and cost-effective for qualitative and quantitative purposes, with LOD and LOQ of 10 ng/mL and 25 ng/mL, respectively [10449].
orally ingested DHEA is preferentially converted into sulphated metabolites and that the renal clearance of sulphated steroids is slow, only the $^{13}$C/$^{12}$C ratio of EpiA demonstrated the potential to prolong the detection time for DHEA misuse [10450].

The use of two separate derivatization procedures with the formation of oxime (hydroxyl ammonium pretreatment) and picolinoyl (mixed anhydride method) derivate of anabolic steroids following HPLC-MS/MS analysis was proposed. The main product ions of obtained derivatives for 21 anabolic steroids were evaluated and fragmentation pathways were compared. The analysis of MS/MS spectra for underivatized steroids versus oxime or picolinoyl derivatives showed that in case of analytes containing conjugated double bonds in sterane core all of the observed MS/MS spectra contained abundant product ions of diagnostic value. The implementation of derivatization procedures to such compounds is useful for upgrading sensitivity or selectivity of the evaluated method. On the other hand, MS/MS spectra of underivatized and oxime analytes without conjugated double bonds in sterane core produce spectra with large amounts of low abundant product ions. Picolinoyl derivatives formation leads to highly specific spectra with product ions of diagnostic value coupled with sensitive and selective analysis at the same time. The intra- and inter-group comparison analysis revealed that fragmentation pathways for underivatized steroids and correspondent oxime derivatives are similar. The obtained oxime and picolinoyl derivatives provided 10-15 times higher ESI response in the HPLC-ESI-MS-selected reaction monitoring (SRM) when compared to those of underivatized molecules in positive HPLC-ESI-MS mode. Due to the laborious sample preparation it was suggested to use the performed strategy for confirmation analysis purposes, metabolic studies or while the identification of new steroids or steroid-like substances [10452].

A relatively selective, chemically and physically robust SPME fiber was developed in a simple way with testosterone-imprinted polymer, and then directly coupled with gas chromatography-mass spectrometry (GC-MS) for selective extraction and analysis of anabolic steroids. The factors influencing polymerization (i.e. cross-linker, polymerization solvent, polymerization time) were optimized in detail and the polymer was characterized by scanning electron microscope, infrared spectrometer and thermogravimetric analyzer. Furthermore, the extraction performance of the MIP-coated SPME fibers such as extraction ability and selectivity was evaluated. Moreover, the interaction mode between target analytes and fiber coating was deducted. Finally, the method for extraction and determination of androstenedione, stanolone, androstenedione and methyltestosterone by the homemade MIP-coated SPME fibers with GC-MS was obtained. It was applied to the simultaneous analysis of four anabolic steroids in the spiked human urine with the satisfactory recoveries [10451].

Testing for the illicit use of AAS consists of measurement of synthetic testosterone and determining the ratio of testosterone to epitestosterone in the urine. A normal ratio in a man rarely exceeds 1.3 and only 1 in 1000 men will have a ratio of 4.12 [07002].

Steroids with large conjugated or cross-conjugated electron systems such as trenbolone and gestrinone or boldenone, respectively, have demonstrated marginal gas chromatographic properties under commonly employed derivatization and analytical conditions. These problems have resulted in relatively high detection limits using GC-MS approaches. However, their particular structures provide them with considerable proton affinities and so they are well suited to LC-MS/MS approaches. Consequently, anabolic steroids as well as glucocorticosteroids that are difficult to assay using GC have been analyzed using LC-MS/MS methods that yield detection limits matching the minimum required performance limits (MRPL) as defined by WADA. Also, the designer steroid tetrahydrogestrinone (THG), which bears the same steroidal nucleus as gestrinone, has been determined using LC-
MS/MS ever since it was discovered by Catlin et al. The fact that THG was not detected for several years illustrates a drawback of the doping control screening protocols usually used, which are based on target analysis. Known drugs and/or metabolic products are determined via precursor/product ion pair measurements, which provide the utmost sensitivity but reduce the analytical result to a limited number of compounds. Drugs that have unknown molecular weights and dissociation pathways under conventional collision-induced dissociation (CID) conditions are provided with a cloak of invisibility and remain undetected. Hence, complementary analyses have been suggested that are based on precursor ion scanning of the product ions that characterize particular steroid structures or that utilize androgen bioassays in concert with high resolution MS (HRMS), allowing broader views of urinary steroids. These proposals provide a deeper insight into potentially misused anabolic androgenic steroids, but they can still not ensure the determination of surreptitiously altered steroids prepared solely for doping purposes, as primarily metabolic reactions may reduce or even impede the effectiveness of these assays [07050].

A qualitative liquid chromatography-tandem mass spectrometry method for the analysis of 22 sporting federation-banned anabolic agents (or their metabolite markers) and anti-estrogens in urine that are refractory to analysis by gas chromatography-mass spectrometry is presented. In addition, a quantitative method built around World Anti-Doping Agency (WADA) guidelines for the confirmatory analysis of 19-norandrosterone, the primary metabolite of nandrolone with a WADA-specified minimum required performance limit of 1 ng/mL, is included. Hydrolysis of glucuronide conjugates, liquid-liquid extraction, no clean-up derivatization with Girard's Reagent P, and analysis by quadrupole-time-of-flight mass spectrometry provide sensitivity and selectivity well beyond that required by the WADA [07079].

Characteristic of the preceding WADA prohibited lists, anabolic agents (in particular anabolic-androgenic steroids, AAS) are most frequently reported concerning adverse analytical findings in doping control samples. Despite the well-documented health risks attributed to the abuse of AAS and the reoccurring case reports of AAS-associated fatalities, the attraction of anabolic agents seems to be unconfined among cheating athletes. Consequently numerous studies have been conducted to improve anti-doping efforts concerning this prime category of substances monitored in sports drug testing programs. Enhanced/expanded screening methods, improved steroid profiling approaches, new/complementary confirmation assays based on either conventional mass spectrometric methodologies or isotope-ratio mass spectrometry (IRMS) [13012].

Androgenic anabolic steroids (AAS) are prohibited in sports due to their anabolic effects. Doping control laboratories usually face the screening of AAS misuse by target methods based on MS detection. Although these methods allow for the sensitive and specific detection of targeted compounds and metabolites, the rest remain undetectable. This fact opens a door for cheaters, since different AAS can be synthesized in order to evade doping control tests. This situation was evidenced in 2003 with the discovery of the designer steroid tetrahydrogestrinone. One decade after this discovery, the detection of unknown AAS still remains one of the main analytical challenges in the doping control field. Although important steps have been made in order to minimize this analytical problem and different analytical strategies have been proposed, there are still some drawbacks related to each approach [13163].

Initial testing procedures
Gas chromatography-(tandem) mass spectrometry, GC-MS/(MS) has been the primary tool for analytical approaches aiming at steroidal agents (with few exemptions) for decades. Nevertheless, small but relevant modifications to established assays have been applied to
tweak methods and gain a competitive edge, for example in terms of sensitivity, robustness, or specificity. Employing conventional sample preparation and chromatography strategies as well as established target analytes, the use of the triple-quadrupole mass analyzer enabled LODs for clenbuterol at 0.01 ng/ml and for the steroidal agents between 0.2 and 1 ng/ml on a routine basis. In order to strengthen and expand the detection capabilities of initial testing procedures particularly regarding the extension of detection windows, in-depth investigations revealing potential long-term metabolites of anabolic agents are of great importance [13012].

**Sweeping-MEKC sample concentration technique**

A reliable, convenient, and sensitive on-line sweeping-MEKC sample concentration technique has been applied for the simultaneous separation of six steroids including two pairs of epimer with 10mM phosphate buffer (pH 7.0) that contains 80 mM sodium dodecyl sulfate (SDS), 14 mM beta-cyclodextrin (beta-CD), and 4 percent (v/v) methanol. The column length was 105 cm (effective length, 90 cm). Samples were hydrostatically injected for 600 s. The separation was performed at ambient temperature under an applied voltage of 25kV. The external standard calibration curves of the six steroidal hormones proved good linearity within the concentration range 0.025-1.0 μg/mL. The limit of detections of the on-line sweeping-MEKC with the ultraviolet detector at 220nm for estrone, alpha-estradiol, beta-estradiol, androstenedione, epitestosterone, and testosterone were 10, 24, 28, 53, 73, and 11 ng/mL and were 240, 125, 93, 47, 32, and 200 times more sensitive than MEKC, respectively. The Saccharomyces cerevisiae mediated simultaneous stereoselective reduction of estrone and androstenedione exhibited a 100 percent stereoselectivity toward beta-estradiol and testosterone. The accuracy and precision achieved for the spiking experiments of the sweeping-MEKC were 95-98 beta and less than 3.8 percent (RSD), respectively [11573].

**Bayesian based screening**

In elite sports, indirect testing of testosterone abuse is mainly based on the testosterone over epitestosterone (T/E) ratio. Since this marker is characterized by a small ratio of intra- to inter-individual variation, it is surprising that current anti-doping strategy uses a screening test based on a population-based limit. From a database of more than 15,000 steroid profiles obtained from routine controls, the collection of steroids profiles of 11 elite athletes followed during 2 years, and a longitudinal study involving 17 amateur athletes, 8 of which were orally administrated testosterone undecanoate pills, we selected 12 case studies to represent the possible scenarios to which the anti-doping laboratories are confronted. Various detection strategies at the disposal of the laboratories are employed and discussed, including isotope ratio mass spectrometry (IRMS) analysis and a Bayesian interpretation of the T/E-time profile. The weak sensitivity versus specificity relation of a population-based limit for the T/E ratio is outlined. As a result, it was propose a Bayesian screening test whose T/E threshold progressively evolves from a population basis to a subject basis as the number of individual test results increases. It was found that this screening test heightens drastically the capacity to detect testosterone abuse, at no additional financial and administrative expenses for anti-doping authorities [07080].

It was developed a test that compares sequential measurements of a biomarker against previous readings performed on the same individual. A probability mass function expresses prior information on interindividual variations of intraindividual parameters. Then, the model progressively integrates new readings to more accurately quantify the characteristics of the individual. This Bayesian framework generalizes the two main approaches currently used in forensic toxicology for the detection of abnormal values of a biomarker. The specificity is independent of the number n of previous test results, with a model that gradually evolves
from population-derived limits when \( n = 0 \) to individual-based cutoff thresholds when \( n \) is large. We applied this model to detect abnormal values in an athlete's steroid profile characterized by the testosterone over epitestosterone (T/E) marker. A cross-validation procedure was used for the estimation of prior densities as well as model validation. The heightened sensitivity/specificity relation obtained on a large data set shows that longitudinal monitoring of an athlete's steroid profile may be used efficiently to detect the abuse of testosterone and its precursors in sports. Mild assumptions make the model interesting for other areas of forensic toxicology [07081].

**Purity certified reference materials**

The need for certified reference materials (CRM) of anabolic-androgenic steroids reference materials was emphasized by the Beijing 2008 Olympic game as a tool to improve comparability, ensuring accuracy and traceability of analytical results for competing athletes. The China National Institute of Metrology responded to the state request by providing seven anabolic-androgenic steroids (AAS) reference materials for Beijing Olympic anti-doping. It was described the production of the series of AAS CRMs, according to ISO Guides 34 and 35, which comprises the material processing, homogeneity and stability assessment, CRMs' characterization including moisture content, trace metal content. The AAS' purity values were assigned with collaborative study involved eight laboratories applying high resolution liquid chromatography-diode array detector (HPLC-DAD). Homogeneity of the AAS CRMs were determined by an in-house validated liquid chromatographic methodology. Potential degradation during storage was also investigated and a shelf-life based on this value was established. The certified values of CRMs were 99.8, 99.8, 99.6, 99.7, 98.8, 96.3, and 99.7 percent for methyltestosterone, testosterone propionate, nandrolone, nandrolone 17-propionate, boldenone, trenbolone acetate and testosterone respectively. It was concluded that the certified values for all the studied AAS reference materials are traceable to the international system of units (SI). The CRMs developed were applied by 32 laboratory including sports organizations and analytical laboratories during the 2008 Olympic game for anti-doping control [12150].

**Steroid profiling**

Steroid profile analyses represent an important resource of information concerning both the administration of natural (endogenous) steroids as well as those of xenobiotic origin. Steroid profiling has been utilized in sports drug testing for more than three decades and still much effort is invested in elaborating and improving this valuable tool, particularly to increase its screening efficiency and to allow for consideration of more recently clarified (genetically or pharmacologically induced) variations influencing the steroid profile interpretation [13009].

GC-MS/(MS)-based methods with electron ionization (EI) are still preferred over alternative options to produce steroid profile data; nevertheless, the utility of chemical ionization (CI) in combination with comprehensive 2-dimensional GC (GCxGC) and a fast-scanning quadrupole-MS was evaluated and found to be competitive with commonly used GC-MS benchtop systems concerning steroid quantification. The advantage of this approach was mentioned to be the superior GCxGC separation of analytes with full-scan EI-MS data recording, which supports the detection of presumably unknown anabolic agents. Here, the employed model steroids were measured mainly underivatized or acetylated, which is common to IRMS analyses but (yet) seldom to generic steroid screening assays [13012].

**Alkaline hydrolysis of steroid metabolites**
The alkaline hydrolysis (as opposed to commonly employed enzymatic deconjugation) of steroid metabolites has recently revealed additional analytes serving as potential markers for the abuse of natural steroids. The utility of these markers concerning the detection of orally administered testosterone undecanoate (120 mg) or dehydroepiandrosterone (DHEA) as well as transdermally applied dihydrotestosterone (DHT) or testosterone (T) was presented. Prolonged detection windows for testosterone undecanoate administration were recognized particularly when employing androsta-1,4-dien-3,17-dione (ADION) as one variable of the monitored steroid metabolite ratios. In cases of transdermal DHT and oral DHEA application, no advantage over established steroid profile ratios was observed; however, the detection of trandermal administered T was substantially improved when the ratio of ADION and androst-15-en-3,17-dione (15-AD) was monitored [13012].

Stacking method of repetitive large volume sample injection

In one research, a novel stacking capillary electrophoresis method, repetitive large volume sample injection and sweeping MEKC (rLVSI-sweeping MEKC) were developed to analyze the presence of three androgenic steroids considered as sport doping drugs, testosterone (T), epitestosterone (E) and epitestosterone glucuronide (EG) in urine. This method provides better sensitivity enhancement than the traditional large volume sample stacking-sweeping strategies due to sensitivity enhancement by repetitive injections. This multiple sampling method enhances sensitivity of monitoring of urine samples by UV detection (254 nm).

Firstly, the phosphate buffer was filled into an uncoated fused silica capillary and the samples were injected into the capillary at 10 psi for 20s, and then stacked at -10 kV for 1 min using phosphate buffer containing SDS. The above injecting and stacking steps were repeated five times. Finally, separation was performed at -20 kV, using phosphate buffer containing methanol, SDS and (2-hydroxypropyl)-beta-cyclodextrin. Method validation showed that calibration plots were linear over a range of 5-200 ng/mL for T, 20-200 ng/mL for E and 0.5-500 ng/mL for EG. The limits of detection were 1.0 ng/mL for T, 5.0 ng/mL for E and 200.0 pg/mL for EG. When evaluating precision and accuracy, values of RSD and RE in intra-day (n=3) and inter-day (n=5) analysis were found to be less than 10.0 percent.

Compared with the simple LVSS-sweeping, which is also a stacking strategy, this method further improves sensitivity up to 25 folds (about 2500 folds with MEKC without preconcentration). This method was applied to monitor 10 athletes' urine, and did not detect any analyte. The novel stacking method was feasible for monitoring of doping by sportsmen [12156].

The presence of microorganisms in urine samples, under favourable conditions of storage and transportation, may alter the concentration of steroid hormones, thus altering the correct evaluation of the urinary steroid profile in doping control analysis. According to the rules of the World Anti-Doping Agency (WADA technical document TD2004 EAAS), a testosterone deconjugation higher than 5 percent and the presence of 5alpha-androstane-3,17-dione and 5beta-androstane-3,17-dione in the deconjugated fraction, are reliable indicators of urine degradation. The determination of these markers would require an additional quantitative analysis since the steroids screening analysis, in anti-doping laboratories, is performed in the total (free+conjugated) fraction. The aim of this work is therefore to establish reliable threshold values for some representative compounds (namely 5alpha-androstane-3,17-dione and 5beta-androstane-3,17-dione) in the total fraction in order to predict directly at the screening stage the potential microbial degradation of the urine samples. Preliminary evidence on the most suitable degradation indexes has been obtained by measuring the urinary concentration of testosterone, epitestosterone, 5alpha-androstane-3,17-dione and 5beta-androstane-3,17-dione by gas chromatography-mass spectrometric every day for 15 days in the deconjugated, glucuronide and total fraction of 10 pools of urines from 60 healthy
subjects, stored under different pH and temperature conditions, and isolating the samples with one or more markers of degradation according to the WADA technical document TD2004EAAS. The threshold values for 5α-androstane-3,17-dione and 5beta-androstane-3,17-dione were therefore obtained correlating the testosterone deconjugation rate with the urinary concentrations of 5alpha-androstane-3,17-dione and 5beta-androstane-3,17-dione in the total fraction. The threshold values suggested as indexes of urine degradation in the total fraction were: 10 ng/mL for 5α-androstane-3,17-dione and 20 ng/mL for 5beta-androstane-3,17-dione. The validity of this approach was confirmed by the analysis of routine samples for more than five months (i.e. on a total of more than 4000 urine samples): samples with a concentration of total 5α-androstane-3,17-dione and 5β-androstane-3,17-dione higher than the threshold values showed a percentage of free testosterone higher than 5 of its total amount; whereas free testosterone in a percentage higher than 5 of its total amount was not detected in urines with a concentration of total 5alpha-androstane-3,17-dione and 5beta-androstane-3,17-dione lower than the threshold values [11072].

Minimum package of anabolic steroids in urine

One method comprises the screening of two groups of anabolic compounds, the stilbenes and several steroids. All compounds, inclusive their metabolites when possible, for which gas chromatography-mass spectrometry (GC-MS) currently is the preferred analytical technique, are included. Two different derivatives are prepared. One group, including the stilbenes, is detected as HFB derivative (Method 1), the second group is detected as TMS derivative (Method 2). The method is used to perform a qualitative and semi-quantitative analysis of a minimum package of anabolic steroids to be included in National Residue Control Plans based on Council Directive 96/23 and complies with the current Minimum Required Performance Limits. The method has been validated according to Commission Decision 2002/657/EC. The CCalpha and CCbeta values are based on the detection of the most abundant ion. Results of validation experiments are presented. The method is flexible and due to the non-specific sample clean-up more and new anabolic compounds can be easily added in order to new monitoring requirements [06098].

ELISA

A multianalyte enzyme-linked immunosorbent assay (ELISA) has been developed for the simultaneous detection of anabolic androgenic steroids (AAS) in human serum. The multiplexed method was developed according to a planar strategy in which the analytes are identified by their location in the microtiter plate. In the immunochemical procedure established here, human serum samples are mixed with a cocktail of antibodies and added to the distinct sections of a microplate biofunctionalized with different haptenized biomolecules. The cocktail of antibodies consists of a mixture of polyclonal antibodies raised against stanozolol (ST), boldenone (B), and tetrahydrogestrinone (THG). The whole immunochemical analytical procedure takes around 2 h including sample preparation, and many samples can be processed simultaneously to screen for the presence of the three AAS in a single run. Using this ELISA, ST, B, and THG can be detected and quantified individually. When used as a screening method, due to the cross-reactivity profiles of the immunoreagents used, the presence of up to 11 AAS can be detected simultaneously. The detectabilities achieved by this method in human serum are below the MRPLs (minimum required performance limits) proposed by WADA (World Anti-Doping Agency) and reference laboratories of the European Community [12151].

Liquid chromatography

Liquid chromatography electrospray ionization tandem mass spectrometry (LC-ESI-MS/MS)
method for simultaneous and direct detection of 12 glucuronide-conjugated anabolic androgenic steroid (AAS) metabolites in human urine was described. The compounds selected were the main metabolites detected in human urine after dosing of the most widely abused AAS in sports, e.g. methandienone, methenolone, methyltestosterone, nandrolone and testosterone, and certain deuterium-labeled analogs of these metabolites. Sample preparation and the LC-ESI-MS/MS method were optimized, validated, and the overall process was implemented and the results between seven laboratories were compared. All the metabolites were extracted simultaneously by solid-phase extraction (SPE) and analyzed by LC-ESI-MS/MS with positive ionization mode and multiple reaction monitoring (MRM). Recovery of the SPE for the anabolic androgenic steroid glucuronides was 89-100 percent and ten out of twelve compounds had detection limits in the range of 1-10 ng/ml in urine. The results for inter/intraday repeatability were satisfactory and the interlaboratory comparison with authentic urine samples demonstrated the ease of method transfer from one instrument setup to another. When equivalent triple quadrupole analyzers were employed the overall performance was independent from instrument manufacturer, electrospray ionisation (ESI) or atmospheric pressure chemical ionization (APCI) and liquid chromatoohraphic (LC) column, whereas major differences were encountered when changing from one analyzer type to another, especially in the analysis of those AAS glucuronides ionized mainly as adducts [08182].

Gas chromatography-triple quadrupole mass spectrometry

A rapid, sensitive and robust gas chromatography-triple quadrupole mass spectrometry method was developed for the determination of seven anabolic agents in human urine. The selection of analytes includes the main metabolites of all anabolics with higher sensitivity requirements. After optimizing the fragmentation conditions for each compound, a validation procedure for qualitative analysis was performed. The selectivity of the method showed that no interfering peaks were observed at the retention time of the compound. Adequate intermediate precision, below 14 percent, was observed for all of the compounds at the lower concentration tested. The concentrations assayed were in accordance with the performance limits required by the World Anti-Doping Agency (WADA). Unlike a previously published GC/QqQ method, detection of 17alpha-methyl-5beta-androstane-3alpha,17beta-diol (the main metabolites of methyltestosterone) at 2 ng/mL was accomplished under routine conditions. The qualitative method was applied to the analysis of 1367 samples in the span of 2 weeks, as part of the doping control of the XVI Pan American Games which took place in Mexico (14th-30th October, 2011). The high sensitivity was maintained during the analysis of all analytical batches, proving for the first time the excellent ruggedness of GC/QqQ methods [12152].

Liquid chromatography-tandem mass spectrometry method (LC-MS/MS)

The liquid chromatography-tandem mass spectrometry method (LC-MS/MS) was developed and validated to detect androgenic steroids: trenbolone, nortestosterone, boldenone, methylboldenone, testosterone, methyltestosterone, 17beta-1-testosterone and their metabolites in bovine urine. Sample preparation before LC-MS/MS analysis involved an enzymatic hydrolysis with glucuronidase AS-HP, isolation of free hormones from urine on C(18) SPE column and purification of the extract using liquid-liquid extraction with n-pentane and SPE NH(2) column. For the chromatographic separation of steroids, the Poroshell 120-EC C18 column (150 x 2.1 mm, 2.7 microm) was used. Mass spectrometric measurement was achieved using the API 4000 triple quadrupole instrument with a Turbolon-Spray source operating in positive electrospray ionization mode. The procedure was validated according to the Decision 2002/657/EC. Recovery ranged from 77 to 119 percent for all examined
compounds. The repeatability was below 20 percent and reproducibility did not exceed the 25 percent. The linearity was good for all analytes in the whole range of tested concentrations, as proved by the correlation coefficients greater than 0.99. The application of an innovative Poroshell column allowed for very good chromatographic separation of steroids with a much shorter time of analysis [12153].

A fast and sensitive LC-MS/MS method for the quantitative analysis of seven steroid hormones in 150 microL of human serum was developed and validated. The following compounds were included: 17alpha-hydroxyprogrenolone, 17alpha-hydroxyprogesterone, androstenedione, dehydroepiandrosterone, testosterone, pregnenolone, and progesterone. Individual stable isotope-labeled analogues were used as internal standards. Sample preparation was performed by liquid-liquid extraction, followed by oxime derivatization to improve the ionization efficiency of the analytes. In contrast to the common derivatization-based methods, the reaction was incorporated into the sample preparation process and the only additional step due to the derivatization was a short heating of the autosampler vials before the sample injection. Chromatographic separation was achieved on a reversed-phase column using a methanol-water gradient. For the analyte detection, a triple quadrupole instrument with electrospray ionization was used. Total run time was 7.0 min and the lower limits of quantification were in the range of 0.03-0.34 nM (0.01-0.10 ng/mL), depending on the analyte. The method was validated using human serum samples from both sexes and applied for the serum steroid profiling of endometriosis patients [11572].

A specific and sensitive multi-method based on liquid chromatography-tandem mass spectrometry using atmospheric pressure chemical ionization (LC-APCI-MS/MS) has been developed for the determination of 20 anabolic steroids in muscle tissue (diethylstilbestrol, beta-estradiol, ethynylestradiol, alpha/beta-boldenone, alpha/beta-nortestosterone, methyltestosterone, beta-trenbolone, triamcinolone acetonide, dexamethasone, flumethasone, alpha/beta-zearalenol, alpha/beta-zearalanol, zearalenone, melengestrol acetate, megestrol acetate and medroxyprogesterone acetate). The procedure involved hydrolysis, extraction with tert-butyl methyl ether, defattening and final clean-up with solid phase extraction (SPE) on Oasis HLB and Amino cartridges. The analytes were analyzed by reversed-phase LC-MS/MS, in positive and negative multiple reaction monitoring (MRM) mode, acquiring two diagnostic product ions from each of the chosen precursor ions for the unambiguous confirmation of the hormones. The method was validated at the validation level of 0.5ng/g. The accuracy and precision of the method were satisfactory. The decision limits CC-alpha ranged from 0.03 to 0.14ng/g while the detection capabilities CC-beta ranged from 0.05 to 0.24ng/g. The developed method is sensitive and useful for detection, quantification and confirmation of these anabolic steroids in muscle tissue and can be used for residue control programs [09067].

Liquid chromatography/electrospray ion trap mass spectrometry
A fast and selective LC/MS/MS method for the screening of four anabolic steroids in human urine has been developed and validated. Liquid-liquid extraction with diethyl ether was applied after enzymatic hydrolysis. Analyses were performed on an ion trap mass spectrometer equipped with electrospray ionisation. MS/MS was applied for all compounds. The analytical run time was 11 min. The LOD for all compounds varied between 1 and 10 ng/mL. Left-over A samples, which were declared positive by GC/MS for the presence of 3'-hydroxystanozolol, were assessed using the described method [06099].

Ultra high performance liquid chromatography tandem mass spectrometry
The use of doping agents, once restricted to professional athletes, has nowadays become a problem of public health, since it also concerns young people and non-competing amateurs in different sports. The use is also diffused in social life for improving physical appearance
and enhancing performance and even dietary supplements assumed to improve performance often contain anabolic steroids. While decades ago the so-called "classical doping agents" (like stimulants and narcotics) were used, to-day anabolic steroids are more widely diffused. Anabolic steroids are synthetic substances prepared by introducing modifications in the molecular structure of testosterone, the main natural androgenic anabolic steroid that forms in testes interstitial cells. Over the years, always new doping substances are synthesized and, as a consequence, the list of prohibited compounds is continuously updated and new suitable analytical methods for their detection and determination in biological matrices are continuously required. In doping control analysis the knowledge of steroid metabolism pathway in human body is of primary importance and the analytical methods must permit the simultaneous detection and determination not only of the forbidden precursor agents but also of their metabolites. In addition, the potential presence and amount in the biological samples of species that can interfere in the analysis should be evaluated. Also the several anabolic steroids, specifically designed to circumvent doping control, put on the market have been incorporated in the list of the prohibited substances of the World Anti-Doping Agency (WADA). In WADA list steroids figure in three main classes, namely anabolic steroids, corticosteroids and substances with anti-estrogenic properties. It must be strongly reminded that assumption of doping agents not only leads to athletes the possible failing of doping tests but causes important health risk and WADA prohibited list establishes criteria to highlight the alteration of the natural steroid profile caused by exogenous administration. Doping control analyses are generally performed in urine, a matrix that provides a prolonged detection time window, and less often in blood, serum, plasma, hair, saliva, and nails. To identify the chemical structures of anabolic steroids the use of mass spectrometry detection is very advantageous. Gas chromatography-mass spectrometry (GC-MS) techniques allowed for the development of comprehensive screening methods. GC-MS methods are sensitive and robust but present the disadvantages of time-consuming sample pretreatment, that is often based on hydrolysis and derivatisation reactions. Liquid chromatography-mass spectrometry (LC-MS) methods have been successfully used to identify and determinate steroids in different matrices, as well as to study their metabolisms. Nowadays, automatic rapid ultra high performance liquid chromatography (UHPLC) tandem mass spectrometry has become the technique of choice for steroid analysis. Due to its generally higher speed, sensitivity, reproducibility and specificity with respect to HPLC, it can be used to simultaneously separate and determinate multi component steroid mixtures. The technique is of huge interest to separate conjugates anabolic androgenic steroids, as it allows efficiency enhancement due to the small particle (sub-2μm) column packing, which provides high peak capacity within analysis times even 5-10 fold shorter than conventional HPLC methods. Modern multiplex instruments can analyze thousands of samples per month so that, notwithstanding the generally high instrumental costs, the cost of the individual assay is affordable. In addition, the improved specificity and resolution offered by time-of-flight or quadrupole time-of-flight mass spectrometry allow their application in doping control analysis or in steroid profiling for accurate and sensitive full mass range acquisition. Aim of one review was to consider, compare and discuss the applications of the UHPLC/MS methods present in literature for the identification and determination of forbidden steroids and their metabolites in human biological matrices [13004].

**Ligand and structure-based virtual screening**

Parallel ligand- and structure-based virtual screenings of 269 steroids with anabolic activity evaluated in vivo were performed. The quantitative structure-activity relationship (QSAR) model expressed by selected descriptors as the octanol-water partition coefficient, the molar volume and the quantum mechanical calculated charge values on atoms C1, C2, C5, C9, C10, C14 and C17 of the steroid skeleton, expresses structural features of anabolic steroids (AS) contributing to the transport and steroid-receptor interaction. On the other hand,
computational simulations of a candidate ligand binding to a receptor study (a "docking" procedure) predict the association of these AS with the human androgen receptor (AR). Fourteen compounds were identified as lead; the most potent was the 7alpha-methylestr-4-en-3, 17-dione. It was concluded that a good anabolic activity requires hydrogen bonding interactions between both Arg752 and Gln711 residues in the cycles A with O3 atom of the steroid and either Asn705 and Thr877 residues in the cycles D of steroid with O17 atom [13171].

3-Oxo-steroidal agents

Focusing on 3-oxo-steroidal agents (methyltestosterone, nandrolone, boldenone, trenbolone, fluoxymesterone, mesterolone, and bolasterone), a MALDI-MS-based protocol was presented, reporting on the detection of the intact steroids as extracted from spiked urine at 2 ng/mL. Using a proprietary derivatization reagent with hydrazine-based chemistry, substantial sensitivity was accomplished enabling the above mentioned detection limits of the assay; however, as in the aforementioned study on CE and AAS, the target analytes (i.e. the intact drugs) were not an appropriate choice of compounds to provide proof-of-concept for a potential doping control method. Besides the fact that steroid analysis in sports drug testing necessitates an extraordinary comprehensive picture of xenobiotic and natural/endogenous steroids and their metabolites, which is not yet achievable by the MALDI-MS approach, the method would benefit from demonstrating the capability of the developed reagent to convert 17-oxo groups. Aiming at the facilitated data interpretation, the same group presented a software supporting the library-assisted identification of steroidal agents measured by means of MALDI-MS/(MS) [13009].

Stable isotope dilution liquid chromatography electrospray ionization

Prostate cancer is the most frequently diagnosed form of cancer in males in the United States. The disease is androgen driven and the use of orchietomy or chemical castration, known as androgen deprivation therapy (ADT) has been employed for the treatment of advanced prostate cancer for over 70 years. Agents such as GnRH agonists and non-steroidal androgen receptor antagonists are routinely used in the clinic, but eventually relapse occurs due to the emergence of castration-resistant prostate cancer. With the appreciation that androgen signaling still persists in these patients and the development of new therapies such as abiraterone and enzalutamide that further suppresses androgen synthesis or signaling, there is a renewed need for sensitive and specific methods to quantify androgen precursor and metabolite levels to assess drug efficacy. It was described the development, validation and application of a stable isotope dilution liquid chromatography electrospray ionization selected reaction monitoring mass spectrometry (SID-LC/ESI/SRM/MS) method for quantification of serum keto-androgens and their sulfate and glucuronide conjugates using Girard-T oxime derivatives. The method is robust down to 0.2-4 pg on column, depending on the androgen metabolite quantified, and can also quantify dehydroepiandrosterone sulfate (DHEA-S) in only 1 microL of serum. The clinical utility of this method was demonstrated by analyzing serum androgens from patients enrolled in a clinical trial assessing combinations of pharmacological agents to maximally suppress gonadal and adrenal androgens (Targeted Androgen Pathway Suppression, TAPS clinical trial). The method was validated by correlating the results obtained with a hydroxylamine derivatization procedure coupled with tandem mass spectrometry using selected reaction monitoring that was conducted in an independent laboratory [13173].

Microflow tile technology and LC-MS/MS
A novel microfluidic chromatography device coupled with tandem mass spectrometry (LC-MS/MS) was utilized for the multiplex analysis of 5 steroids (testosterone, dihydrotestosterone, progesterone, cortisol, cortisone) in human serum. The use of microfluidics allowed for reduction of the chromatographic flow rate to 3 microl/min with overall method run times comparable to standard flow LC-MS/MS methods reported in the literature, corresponding to a 150 fold decrease in solvent consumption. Furthermore, a simple sample preparation protocol was employed requiring injection of only 0.5 microl of sample, corresponding to a 100-400 fold increase in on-column sensitivity as compared to published standard flow assays. The measured LOQ for both testosterone and progesterone was 0.4 ng/mL, representing an improvement over reported literature values obtained by standard flow methods employing comparable sample preparation and large injection volumes. The LOQs for cortisol (1.9 ng/mL), cortisone (0.3ng/mL), and dihydrotestosterone (1.4 ng/mL) were all within a biologically relevant range. A comparison of clinical serum samples was performed for the analysis of testosterone using this microfluidic LC-MS/MS assay and the Beckman Access II automated antibody-based measurement system. The immunoassay results were systematically higher due to matrix interference which was easily resolved with the increased chromatographic resolution obtained in the microflow LC-MS/MS assay [13174].

**Effects of sample storage condition steroid hormones in saliva**

Measurement of steroid hormones in saliva is increasingly common in elite sport settings. However, this environment may enforce handling and storage practices that introduce error in measurement of hormone concentrations. It was assessed the influence of storage temperature and duration on reproducibility of salivary steroid levels. Nine healthy adults provided morning and afternoon saliva samples on two separate occasions. Each sample was divided into identical saliva aliquots which were stored long-term (i.e. 28 and 84 days) at -80°C or -20°C (testing day 1), and short-term (i.e. 1, 3, 7 and 14 days) at 4°C or 20°C (testing day 2). Samples were analyzed for cortisol, testosterone and estradiol using ELISA. In non-freezer conditions, there was a decrease from baseline to 7 days in testosterone (-26 ± 15 %) and estradiol (-58 ± 17 %) but not cortisol concentrations. This decrease was larger in samples stored at room temperature than in the refrigerator. There were small but significant changes in measured concentrations of all hormones after 28 and/or 84 days of storage in freezer conditions, but these were generally within 12 percent of baseline concentrations, and may be partly explained by inter-assay variability. Whole saliva samples to be analyzed for cortisol, testosterone and estradiol should be frozen at -20°C or below within 24 h of collection, and analyzed within 28 days. Storage of samples for measurement of testosterone and estradiol at temperatures above -20°C can introduce large error variance to measured concentrations [13175].

**IRMS**

Nowadays, the importance of IRMS in sports drug testing is substantial and, as recently concluded, its relevance is continuously growing and new instrumental options allow for enhanced detection assays. In doping controls, IRMS is currently applied mainly to the analysis of natural/endogenous anabolic-androgenic steroids and its metabolites; however, additional candidates such as cortisone or 5-aminoimidazole-4-carboxamide-ribonucleoside (AICAR) have been subject of recent research projects and are conceivable future target analytes. IRMS represents a comparably complex and challenging analytical methodology that necessitates thorough consideration of information indicating the need for an IRMS-based analysis of a doping control sample and factors influencing the analytical result as well as its interpretation [13009].
Gas chromatography coupled to IRMS

The administration of anabolic steroids is one of the most important issues in doping control and is detectable through a change in the carbon isotopic composition of testosterone and/or its metabolites. Gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS), however, remains a very laborious and expensive technique and substantial amounts of urine are needed to meet the sensitivity requirements of the IRMS. This can be problematic because only a limited amount of urine is available for anti-doping analysis on a broad spectrum of substances. In this work we introduce a new type of injection that increases the sensitivity of GC-C-IRMS by a factor of 13 and reduces the limit of detection, simply by using solvent vent injections instead of splitless injection. This drastically reduces the amount of urine required. On top of that, by only changing the injection technique, the detection parameters of the IRMS are not affected and there is no loss in linearity [12154].

The application of a comprehensive gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS)-based method for stable carbon isotopes of endogenous urinary steroids was presented. The key element in sample preparation is the consecutive cleanup with high-performance liquid chromatography (HPLC) of underivatized and acetylated steroids, which allows the isolation of ten analytes (11beta-hydroxyandrosterone, 5alpha-androst-16-en-3beta-ol, pregnanediol, androsterone, etiocholanolone, testosterone, epitestosterone, 5alpha-androstane-3alpha,17beta-diol, 5beta-androstane-3alpha,17beta-diol and dehydroepiandrosterone) from a single urine specimen. These steroids are of particular importance to doping controls as they enable the sensitive and retrospective detection of steroid abuse by athletes. Depending on the biological background, the determination limit for all steroids ranges from 5 to 10 ng/mL for a 10 mL specimen. The method is validated by means of linear mixing models for each steroid, which covers repeatability and reproducibility. Specificity was further demonstrated by gas chromatography/mass spectrometry (GC/MS) for each analyte, and no influence of the sample preparation or the quantity of analyte on carbon isotope ratios was observed. In order to determine naturally occurring $^{13}$C/$^{12}$C ratios of all implemented steroids, a reference population (n=61) subjects was measured to enable the calculation of reference limits for all relevant steroidal delta values [08183].

An alternative calibration procedure for the gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS) measurements of the World Antidoping Agency (WADA) accredited laboratories is presented. To alleviate the need for externally calibrated CO$_2$ gas for GC-C-IRMS analysis of urinary steroid metabolites, calibration using an external standard mixture solution of steroids with certified isotopic composition was investigated. The reference steroids of the calibration mixture and routine samples underwent identical instrumental processes. The calibration standards bracketed the entire range of the relevant delta$^{13}$C values for the endogenous and exogenous steroids as well as their chromatographic retention times. The certified delta$^{13}$C values of the reference calibrators were plotted in relation to measured m/z $^{13}$CO$_2$/$^{12}$CO$_2$ (i.e. R(45/44)) mass spectrometric signals of each calibrator. delta$^{13}$C values of the sample steroids were calculated from the least squares fit through the calibration curve. The effect of the external calibration on delta$^{13}$C values, using the same calibration standards and set of urine samples but different brands of GC-C-IRMS instruments, was assessed by an interlaboratory study in the WADA Accredited Laboratories of Sydney, Australia and Athens, Greece. Relative correspondence between the laboratories for determination of androsterone, etiocholanolone, 5beta-androstane-3alpha,17beta-diacetate, and pregnanediacetate means were SD(delta$^{13}$C) 0.012, 0.058, -0.034, and -0.040 percent, respectively. These data demonstrate that accurate intralaboratory external
calibration with certified steroids provided by United States Antidoping Agency (USADA) and without external CO$_2$ calibration is feasible and directly applicable to the WADA Accredited Laboratories for the harmonization of the GC-C-IRMS measurements [11076].

An alternative calibration procedure for the gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS) measurements of the World Antidoping Agency (WADA) Accredited Laboratories is presented. To alleviate the need for externally calibrated CO$_2$ gas for GC-C-IRMS analysis of urinary steroid metabolites, calibration using an external standard mixture solution of steroids with certified isotopic composition was investigated. The reference steroids of the calibration mixture and routine samples underwent identical instrumental processes. The calibration standards bracketed the entire range of the relevant $\delta^{13}C$ values for the endogenous and exogenous steroids as well as their chromatographic retention times. The certified $\delta^{13}C$ values of the reference calibrators were plotted in relation to measured $m/z$ $^{13}CO_2/^{12}CO_2$ mass spectrometric signals of each calibrator. $\delta^{13}C$ values of the sample steroids were calculated from the least squares fit through the calibration curve. The effect of the external calibration on $\delta^{13}C$ values, using the same calibration standards and set of urine samples but different brands of GC-C-IRMS instruments, was assessed by an interlaboratory study in the WADA Accredited Laboratories of Sydney, Australia and Athens, Greece. Relative correspondence between the laboratories for determination of androsterone, etiocholanolone, 5beta-androstan-3alpha,17beta-diacetate, and pregnanediacetate means were SD($\delta^{13}C$) 0.12‰, 0.58‰, -0.34‰, and 0.40‰, respectively. These data demonstrate that accurate intralaboratory external calibration with certified steroids provided by United States Antidoping Agency (USADA) and without external CO$_2$ calibration is feasible and directly applicable to the WADA Accredited Laboratories for the harmonization of the GC-C-IRMS measurements [11432].

**Gas chromatography-combustion-isotope ratio mass spectrometry**

The administration of anabolic steroids is one of the most important issues in doping control and is detectable through a change in the carbon isotopic composition of testosterone and/or its metabolites. Gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS), however, remains a very laborious and expensive technique and substantial amounts of urine are needed to meet the sensitivity requirements of the IRMS. This can be problematic because only a limited amount of urine is available for anti-doping analysis on a broad spectrum of substances. In this work we introduce a new type of injection that increases the sensitivity of GC-C-IRMS by a factor of 13 and reduces the limit of detection, simply by using solvent vent injections instead of splitless injection. This drastically reduces the amount of urine required. On top of that, by only changing the injection technique, the detection parameters of the IRMS are not affected and there is no loss in linearity [13170].

The analysis of urinary metabolites of testosterone-related steroids through the measurement of their carbon isotopic signature ($\delta^{13}C$) by gas chromatography combustion/mass spectrometry (GC/C/IRMS) is a confirmation method employed in doping control analyses. Stringent analytical conditions are essential to an accurate and precise analysis as well as the proper selection of the metabolites, which forms the basis of the refined method presented in one paper. In a simplified approach, following enzymatic hydrolysis and extraction from a relatively low volume of urine sample, a one-step high-performance liquid chromatography (HPLC) purification was developed for seven diagnostic urinary metabolites (TS) including testosterone itself, dehydroepiandrosterone, 5alpha- and 5beta-androstenediol, epitestosterone, androsterone, etiocholanolone and two endogenous reference compounds (ERC), 5beta-pregnanediol and 5alpha-androst-16-en-3beta-ol. These steroids were pooled in three fractions and analyzed as such. With regards to the GC/C/IRMS analysis, a multi-level isotopic calibration using the 'identical treatment' principle
was created. The proposed isotopic calibration yielded results for purified reference steroids with a precision ≤0.15 and accuracy of ≤0.030 percent (between-assay, n=26). Compared to other common endogenous reference compounds, those selected in this study had delta^{13}C values close to the target metabolites which, along with the proposed isotopic calibration, produced narrow reference intervals within ±0.3 percent for most diagnostic TS-ERC pairs, in compliance with the requirements of the World Anti-Doping Agency. These carefully controlled analytical conditions are compatible with routine operations, affording accurate and precise results for the more diagnostically relevant metabolites such as testosterone itself and the 5alpha- and 5beta-androstanediols. The values of the TS-ERC pairs measured in reference populations are described and the results from the routine testing of several hundreds of athletes' samples are discussed. Robust, this technique permitted the detection of adverse findings that would have been missed had these low level metabolites not been analyzed [13172].

**Gas chromatographic/time-of-flight mass-spectrometric**

The method of high sensitive gas chromatographic/time-of-flight mass-spectrometric (GC/TOF-MS) analysis of steroids was developed. Low-resolution TOF-MS instrument (with fast spectral acquisition rate) was used. This method is based on the formation of the silyl derivatives of steroids; exchange of the reagent mixture (pyridine and N,O-bis(trimethylsilyl)trifluoroacetamide (BSTFA)) for tert-butylmethylether; offline large sample volume injection of this solution based on sorption concentration of the respective derivatives from the vapour-gas mixture flow formed from the solution and inert gas flows; and entire analytes solvent-free concentrate transfer into the injector of the gas chromatograph. Detection limits for 100 microL sample solution volume were 0.5-2 pg/µL (depending on the component). Application of TOF-MS model 'TruTOFcoupled with gas chromatograph and ChromaTOF software (Leco, St Joseph, MO, USA) allowed extraction of the full mass spectra and resolving coeluted peaks. Due to use of the proposed method (10 microL sample aliquot) and GC/TOF-MS, two times more steroid-like compounds were registered in the urine extract in comparison with the injection of 1 microL of the same sample solution [11074].

**Carbon isotope ratio (CIR)**

Carbon isotope ratio (CIR) analysis has been routinely and successfully used in sports drug testing for many years to uncover the misuse of endogenous steroids. One limitation of the method is the availability of steroid preparations exhibiting CIRs equal to endogenous steroids. To overcome this problem, hydrogen isotope ratios (HIR) of endogenous urinary steroids were investigated as a potential complement; results obtained from a reference population of 67 individuals are presented herein. An established sample preparation method was modified and improved to enable separate measurements of each analyte of interest where possible. From the fraction of glucuronidated steroids; pregnanediol, 16-androstenol, 11-ketoetiocholanolone, androsterone (A), etiocholanolone (E), dehydroepiandrosterone (D), 5alpha- and 5beta-androstanediol, testosterone and epitestosterone were included. In addition, sulfate conjugates of A, E, D, epiaandrosterone and 17alpa- and 17beta-androstanediol were considered and analyzed after acidic solvolysis. The obtained results enabled the calculation of the first reference-population-based thresholds for HIR of urinary steroids that can readily be applied to routine doping control samples. Proof-of-concept was accomplished by investigating urine specimens collected after a single oral application of testosterone-undecanoate. The HIR of most testosterone metabolites were found to be significantly influenced by the exogenous steroid beyond the established threshold values. Additionally, one regular doping control sample with an extraordinary testosterone/
epitestosterone ratio of 100 without suspicious CIR was subjected to the complementary methodology of HIR analysis. The HIR data eventually provided evidence for the exogenous origin of urinary testosterone metabolites. Despite further investigations on HIR being advisable to corroborate the presented reference-population-based thresholds, the developed method proved to be a new tool supporting modern sports drug testing procedures [12155].

Isotope ratio mass spectrometry (IRMS) testing is performed to determine if an atypical steroid profile is due to administration of an endogenous steroid. Androsterone (Andro) and etiocholanolone (Etio), and/or the androstanediols (5alpha- and 5beta-androstane-3alpha,17beta-diol) are typically analyzed by IRMS to determine the $^{13}$C/$^{12}$C ratio. The ratios of these target compounds are compared to the $^{13}$C/$^{12}$C ratio of an endogenous reference compound (ERC) such as 5beta-pregnane-3alpha,20alpha-diol (Pdiol). Concentrations of Andro and Etio are high so $^{13}$C/$^{12}$C ratios can easily be measured in most urine samples. Despite the potentially improved sensitivity of the androstanediols for detecting the use of some testosterone formulations, additional processing steps are often required that increase labour costs and turnaround times. Since this can be problematic when performing large numbers of IRMS measurements, we established thresholds for Andro and Etio that can be used to determine the need for additional androstanediol testing. Using these criteria, 105 out of 2639 urine samples exceeded the Andro and/or Etio thresholds, with 52 of these samples being positive based on Andro and Etio IRMS testing alone. The remaining 53 urine samples had androstanediol IRMS testing performed and 3 samples were positive based on the androstanediol results. A similar strategy was used to establish a threshold for Pdiol to identify athletes with relatively $^{13}$C-depleted values so that an alternative ERC can be used to confirm or establish a true endogenous reference value. Adoption of a similar strategy by other laboratories can significantly reduce IRMS sample processing and analysis times, thereby increasing testing capacity [13095].

Carbon isotope ratio combined with hydrogen isotope ratio

Carbon isotope ratio (CIR) analysis has been routinely and successfully applied to doping control analysis for many years to uncover the misuse of endogenous steroids such as testosterone. Over the years, several challenges and limitations of this approach became apparent, e.g., the influence of inadequate chromatographic separation on CIR values or the emergence of steroid preparations comprising identical CIRs as endogenous steroids. While the latter has been addressed recently by the implementation of hydrogen isotope ratio (HIR), an improved sample preparation for CIR avoiding co-eluting compounds is presented herein together with newly established reference values of those endogenous steroids being relevant for doping controls. From the fraction of glucuronidated steroids 5beta-pregnane-3alpha,20alpha-diol, 5alpha-androst-16-en-3alpha-ol, 3alpha-Hydroxy-5beta-androstane-11,17-dione, 3alpha-hydroxy-5alpha-androstan-17-one (ANDRO), 3alpha-hydroxy-5beta-androstan-17-one (ETIO), 3beta-hydroxy-androst-5-en-17-one (DHEA), 5alpha- and 5beta-androstane-3alpha,17beta-diol (5aDIOL and 5bDIOL), 17beta-hydroxy-androst-4-en-3-one and 17alpha-hydroxy-androst-4-en-3-one were included. In addition, sulfate conjugates of ANDRO, ETIO, DHEA, 3beta-hydroxy-5alpha-androstan-17-one plus 17alpha- and androst-5-ene-3beta,17beta-diol were considered and analyzed after acidic solvolysis. The results obtained for the reference population encompassing 67 males and females confirmed earlier findings regarding factors influencing endogenous CIR. Variations in sample preparation influenced CIR measurements especially for 5alphiDIOL and 5betaDIOL, the most valuable steroidal analytes for the detection of testosterone misuse. Earlier investigations on the HIR of the same reference population enabled the evaluation of combined measurements of CIR and HIR and its usefulness regarding both steroid metabolism studies and doping control analysis. The combination of both stable isotopes would allow for lower reference limits
providing the same statistical power and certainty to distinguish between the endogenous or exogenous origin of a urinary steroid [13165].

**Capillary electrophoresis**

One report described a rapid, simple, and highly selective approach to perform testosterone competitive immunoassay by capillary electrophoresis (CE) and LIF detection. The method involves using synthesized fluorescence-labeled testosterone as a tracer to compete with testosterone. Two polyclonal antibodies arised and their respective tracers have been optimized and a system is used for the quantification of testosterone by CE-based immunoassay. The method is developed with a wide working range of 3.70-2000 ng/mL and a limit of detection at 1.11 ng/mL. Tests for normal and positive urine samples show that this method has the potential to be applied in testosterone doping control [08185].

**Prediction of metabolic pattern of new derivatives of AAS**

The aim of one work was to develop a flexible in vitro synthesis procedure, which can be applied in order to study and predict the metabolic patterns of new derivatives of anabolic androgenic steroids with respect to most prominent target compounds for doping control purposes. Microsomal and S9 fraction of human liver preparations were used as a source of metabolising enzymes and the co-substrates of the synthesis mixture were selected to favour phase-I metabolic reactions and glucuronidation as phase-II conjugation reactions. Model compounds within the study were 4,9,11-trien-3-one steroids, structural derivatives of gestrinone and trenbolone, which both are included in the list of prohibited compounds in sports by the World Anti-Doping Agency (WADA). The correlation between in vitro metabolism of human microsomes and in vivo excretion studies in human was compared with gestrinone and subsequently, the applicability of the in vitro model for prediction of AAS metabolic pathways for new doping agents was evaluated. All the AAS examined within this study were successfully metabolised using the developed in vitro model, hydroxylation, reduction and glucuronide conjugation being the most prominent reaction pathways. Hydroxylated and glucuronide-conjugated metabolites of in vivo experiment with gestrinone were the same metabolites formed in the enzyme-driven process, thus showing good in vitro-in vivo correlation. Liquid chromatographic-mass spectrometric and tandem mass spectrometric methods were developed, relying on the positive polarity of electrospray ionisation, which also allowed the direct detection of intact glucuronide-conjugated AAS metabolites. Due to charge delocalisation and high proton affinity, the developed method was proven effective in the analysis of anabolic steroids metabolites bearing extensive conjugated double bond systems in their structures [08187].

**Mass spectometry**

The metabolism of two anabolic steroids – oxymetholone and desoxymethyltestosterone – was reinvestigated to identify new targets potentially valuable for the antidoping analysis. Excretion urine samples from the laboratory reference collection were used in this study. Following fractionation of the urinary extract by means of high performance liquid chromatography (HPLC), each fraction was subjected to gas chromatography-mass spectrometry (GC-MS) and gas chromatography-tandem mass spectrometry (GC-MS/MS) analysis after trimethylsilylation. About 20 metabolites were found for desoxymethyltestosterone and more than 40 for oxymetholone, with many of them being isomeric compounds. In addition to the well-known reduced and hydroxylated metabolites, 18-nor-17,17-dimethyl and 18-nor-17-hydroxymethyl-17-methyl steroids were also identified. Having evaluated all the metabolites in terms of how long they could be detected, it was suggested
that 18-nor-2epsilon,17beta-hydroxymethyl-17alpha-methyl-5alpha-androst-13-en-3alpha-ol is an important marker of oxymetholone abuse. In case of desoxymethyltestosterone, better detectability could be achieved if 18-nor-17,17-dimethyl-5alpha-androst-13-en-2epsilon, 3alpha-diol is monitored. These novel metabolites could be detected using GC-MS/MS at least for 14 days after administration of these anabolic steroids compared to 5-7 days for previously reported metabolites [12157].

Mass spectrometric identification of anabolic androgenic steroids challenges standard doping-control methods. To reveal a doping offence the presence of prohibited anabolic androgenic steroids at trace levels in the picogram-per-millilitre range must be confirmed as reliable. Human urine samples containing epitrenbolone, metandienone metabolite (17beta-hydroxymethyl-17alpha-methyl-18-norandrost-1,4,13-trien-3-one), stanozolol, 16beta-hydroxystanozolol and 4beta-hydroxystanozolol were analysed using LC-FAIMS-MS/MS. These substances are prohibited in sport according to World Anti-Doping Agency (WADA) regulations. Glucuronides were hydrolysed and prepared by liquid-liquid extraction. Excellent recovery and precision were obtained for all compounds. Linear calibration results for epitrenbolone and metandienone metabolite were obtained and concentration information could be determined in the ranges of reliable response between 750-1200 and 100-600 pg/mL, respectively. Limits of detection were estimated at 25 pg/mL (stanozolol), 50 pg/mL (metandienone metabolite, 16beta-hydroxystanozolol), 100 pg/mL (4beta-hydroxystanozolol) and 500 pg/mL (epitrenbolone). The assay was applied to doping-control samples. For all analytes, LC-FAIMS-MS/MS resulted in excellent interference removal, which effectively extends the post-dose detection time [09068].

Regularly new anabolic steroids appear on the black market. In most cases these substances are marketed on websites or are confiscated during inspections. 1,(5alpha)-Androstene-17beta-ol-3-one, also known as 1-testosterone, is one of these substances presented to body-builders as a nutritional supplement or a pro-hormone. 1-Testosterone closely resembles the natural hormone testosterone except for a 1,2-double bound instead of a 4,5-double bound. 1-Androstene-3beta,17beta-diol is transformed into 1-testosterone after oral administration. 1-Testosterone, 1-androstene-3beta,17beta-diol and some other related “new” anabolic steroids were studied with gas chromatography coupled to mass spectrometry (GC-MS) and Liquid chromatography coupled to tandem mass spectrometry (LC-MS2) methods. Similarities in spectra to known analytes, which may lead to pitfalls in the interpretation of the derivatised analytes, are discussed [06100].

Electrospray ionization tandem mass spectrometry

Anabolic steroids are structurally similar compounds, and their product-ion spectra obtained by tandem mass spectrometry under electrospray ionization conditions are quite difficult to interpret because of poly-ring structures and lack of a charge-retaining center in their chemical structures. In the present study, the fragmentation of nine anabolic steroids of interest to the racing industry was investigated by using triple quadrupole mass spectrometer, Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer, and a linear ion trap instrument. With the aid of an expert system software (Mass Frontier version 3.0), accurate mass measurements, and multiple stage tandem mass spectrometric (MS(n)) experiments, fragmentation pathways were elucidated for boldenone, methandrostenolone, tetrahydrogestrinone (THG), trenbolone, normethandrolone and mibolerone. Small differences in the chemical structures of the steroids, such as an additional double-bond or a methyl group, result in significantly different fragmentation pathways. The fragmentation pathways proposed in this paper allow interpretation of major product ions of other anabolic steroids reported by other researchers in a recent publication. The proposed fragmentation
pathways are helpful for characterization of new steroids. The approach used in this study for elucidation of the fragmentation pathways is helpful in interpretation of complicated product-ion spectra of other compounds, drugs and their metabolites [06101].

**GCxGC-TOFMS**

The application of comprehensive two-dimensional gas chromatography coupled to time-of-flight mass spectrometry (GCxGC-TOFMS) for the analysis of six anabolic agents (AAs) in doping control is investigated in this work. A non-polar-polar column configuration with 0.2microm film thickness second dimension (2D) column was employed, offering much better spread of the components on 2D when compared to the alternative 0.1microm 2D column. The proposed method was tested on the "key" AA that the World Anti-Doping Agency (WADA) had listed at the low ng/mL levels ( clenbuterol, 19-norandrostosterone, epimethendiol, 17alpha-methyl-5alpha-androstane-3alpha,17beta-diol, 17alpha-methyl-5beta-androstane 3alpha,17beta-diol and 3'-OH-stanozolol). The compounds were spiked in a blank urine extract obtained by solid-phase extraction, hydrolysis and liquid-liquid extraction; prior to analysis they were converted to the corresponding trimethylsilyl (TMS) derivatives. The limit of detection (LOD) was below or equal to the minimum required performance limit (MRPL) of 2ng/mL defined by WADA, and the correlation coefficient was in the range from 0.995 to 0.999. The method allows choosing an ion from the full mass spectra which shows the least interference from the matrix and/or the best sensitivity; this can only be done if full scan mass spectral data are available. The advantage of GCxGC over classical one-dimensional GC (1D GC), in terms of separation efficiency and sensitivity, is demonstrated on a positive urine control sample at a concentration of 5ng/mL. The obtained similarity to the in-house created TOFMS spectra library at this level of concentration was in the range from 822 to 932 (on the scale from 0 to 999). Since full mass spectral information are recorded, the method allows the retro-search of non-target compounds or new “designer steroids”, which cannot be detected with established GC-MS methods that use (SIM) mode [09066].

**UHPLC-HRMS**

Aiming at the identification of new, complementary biomarkers for endogenous steroid abuse, the utility of a steroidomic approach using UHPLC-HRMS was assessed. In a controlled elimination study with orally administered testosterone undecanoate (80 mg), urine samples were subjected to a holistic steroid analysis followed by chemometric/statistical data evaluation. Here, numerous glucuronidated or sulfated steroids, the deconjugated analogs, of which mostly constitute the established steroid profile, were found to support the discrimination of the groups having received either placebo or testosterone undecanoate. The study demonstrated the principle of modern analytical approaches commonly referred to as “-omics” strategies and its potential application to issues of doping controls; in order to consider the whole (holistic) picture of such approaches, complementary analyses (e.g. by means of GC-HRMS) might be required to strengthen the outcome and value [13012].

**Single-stage-Orbitrap-MS**

A prominent trend which has been observed in recent years in the analysis of veterinary drugs and growth-promoting agents is the shift from target-oriented procedures, mainly based on liquid chromatography coupled to triple-quadrupole mass spectrometry (LC-QqQ-MS), towards accurate mass full scan MS (such as time of flight (ToF) and Fourier Transform (FT) Orbitrap MS). In this study the applicability of high resolution single-stage-Orbitrap-MS for confirmatory analysis of growth-promoting agents in meat was compared to that of a QqQ-MS. Validation according to CD 2002/657/EC demonstrated that steroid analysis based
on Orbitrap MS, operating at a resolution of 50,000 FWHM, is indeed capable to compete with QqQ-MS in terms of selectivity/specificity, while providing excellent linearity (for most compounds >0.99) but somewhat inferior sensitivity. Indeed, CCalphas reached from 0.04 to 0.88 microg/kg for the 34 anabolic steroids upon MS/MS detection, while upon Orbitrap MS detection a range of 0.07-2.50 microg/kg was observed. Using QqQ-MS adequate precision was obtained since relative standard deviations, associated with the repeatability and intralaboratory reproducibility, were below 20%. In the case of Orbitrap MS, for some compounds (i.e. some estrogens) this threshold was exceeded and thus poor precision was observed, which is possibly caused by the lack in sensitivity. Overall, it may be concluded that Orbitrap-MS offers an adequate performance in terms of linearity and precision but lacks in sensitivity for some of the compounds [13166].

**Full-capillary sample injection combined with a sweeping CE stacking method**

One study describes an on-line stacking CE approach by sweeping with whole capillary sample filling for analyzing five anabolic androgenic steroids in urine samples. The five anabolic steroids for detection were androstenedione, testosterone, epitestosterone, boldenone, and clostebol. Anabolic androgenic steroids are abused in sport doping because they can promote muscle growth. Therefore, a sensitive detection method is imperatively required for monitoring the urine samples of athletes. In this research, an interesting and reliable stacking capillary electrophoresis method was established for analysis of anabolic steroids in urine. After liquid-liquid extraction by n-hexane, the supernatant was dried and reconstituted with 30 mM phosphate buffer (pH 5.00) and loaded into the capillary by hydrodynamic injection (10 psi, 99.9 s). The stacking and separation were simultaneously accomplished at -20 kV in phosphate buffer (30 mM, pH 5.0) containing 100 mM sodium dodecyl sulfate and 40 % methanol. During the method validation, calibration curves were linear over a range of 50-1,000 ng/mL for the five analytes. In the evaluation of precision and accuracy for this method, the absolute values of the RSD and the RE in the intra-day (n=3) and inter-day (n=5) analyses were all less than 6.6 percent. The limit of detection for the five analytes was 30 ng/mL. Compared with simple MECK, this stacking method possessed a 108- to 175-fold increase in sensitivity. This simple and sensitive stacking method could be used as a powerful tool for monitoring the illegal use of doping [13167].

**Oxidizing adulterants’ effect on the steroid profile of human urine**

Steroid profiling is the most versatile and informative technique adapted by doping control laboratories for detection of steroid abuse. The absolute concentrations and ratios of endogenous steroids including testosterone, epitestosterone, androsterone, etiocholanolone, 5alpha-androstane-3alpha,17beta-diol and 5beta-androstane-3alpha,17beta-diol constitute the significant characteristics of a steroid profile. In the present study we report the influence of various oxidizing adulterants on the steroid profile of human urine. Gas chromatography-mass spectrometry analysis was carried out to develop the steroid profile of human male and female urine. Oxidants potassium nitrite, sodium hypochlorite, potassium permanganate, cerium ammonium nitrate, sodium metaperiodate, pyridinium chlorochromate, potassium dichromate and potassium perchlorate were reacted with urine at various concentrations and conditions and the effect of these oxidants on the steroid profile were analyzed. Most of the oxidizing chemicals led to significant changes in endogenous steroid profile parameters which were considered stable under normal conditions. These oxidizing chemicals can cause serious problems regarding the interpretation of steroid profiles and have the potential to act as masking agents that can complicate or prevent the detection of the steroid abuse [13168].

**Electrospray ionization tandem mass spectrometry (ESI-MS/MS)**
Electrospray ionization tandem mass spectrometry (ESI-MS/MS) was used to investigate the effect of different substitutions introduced during metabolism on fragmentation patterns of four anabolic steroids including methyltestosterone, methandrostenolone, cis-androsterone and adrenosterone, along with their metabolites. Collision-induced dissociation (CID) analysis was performed to correlate the major product ions of 19 steroids with structural features. The analysis is done to portray metabolic alteration, such as incorporation or reduction of double bonds, hydroxylations, and/or oxidation of hydroxyl moieties to keto functional group on steroidal skeleton which leads to drastically changed product ion spectra from the respective classes of steroids, therefore, making them difficult to identify. The comparative ESI-MS/MS study also revealed some characteristic peaks to differentiate different steroidal metabolites and can be useful for the unambiguous identification of anabolic steroids in biological fluid. Moreover, LC-ESI-MS/MS analysis of fermented extract of methyltestosterone, obtained by Macrophomina phaseolina was also investigated [13169].

Glucuronocojugated metabolites

In humans, conjugation with glucuronic acid is the most important phase II metabolic reaction of steroidal compounds. Glucuronocojugated metabolites have been conventionally studied by using beta-glucuronidase enzymes to release the phase I metabolites. It is well-known that hydrolysis with beta-glucuronidase presents some limitations that may result in the underestimation of some conjugates. The aim of the present work was to develop and to evaluate liquid chromatography-tandem mass spectrometry (LC-MS/MS) scan methods for the open detection of steroid glucuronides in urine samples. The mass spectrometric behavior of thirteen representative steroid glucuronides, used as model compounds, was studied. Characteristic ionization and collision induced dissociation behaviors were observed depending on the steroid glucuronide structure. Neutral loss (NL of 176, 194, 211, and 229 Da) and precursor ion (PI of m/z 141, 159, and 177, in positive mode and m/z 75, 85, and 113, in negative mode) scan methods were evaluated. The NL scan method was chosen for the open detection of glucuronocojugated steroids due to its sensitivity and the structural information provided by this method. The application of the NL scan method to urine samples collected after testosterone (T) undecanoate administration revealed the presence of two T metabolites which remain conjugated as glucuronides after an enzymatic hydrolysis of the urine. 3alpha,6beta-Dihydroxy-5alpha-androstan-17-one (6beta-hydroxyandrostosterone) glucuronide and 3alpha,6beta-dihydroxy-5beta-androstan-17-one (6beta-hydroxyetiocholanolone) glucuronide were established as the structures for these metabolites, by comparing the structure of the steroids released after chemical hydrolysis with reference materials. An increase of 50-300-fold of these metabolites after oral administration of T undecanoate was observed, proving that their determination can be useful in the doping control field. Moreover, these results exemplify that significant information might be missed, unless direct methods for the determination of steroid glucuronides are employed [13164].

Relative retention times

A quantitative structure-retention relationship (QSRR) study has been performed to correlate relative retention times (RRTs) of trimethylsilylated (TMS) anabolic androgenic steroids (AAS) with their molecular characteristics, encoded by the respective descriptors, for the prediction of RRTs of novel molecules, using gas chromatography time-of-flight mass spectrometry (GC-TOF-MS). The elucidation of similarities and dissimilarities among the data structures was carried out using principal component analysis (PCA). Successful models were established using multiple linear regression (MLR) and partial least squares (PLS) techniques as a function of topological, three-dimensional (3D) and physicochemical descriptors. The models are useful for the estimation of RRTs of designer steroids for which
Variability in the $^{13}\text{C}/^{12}\text{C}$ ratios

The determination of the carbon isotope ratio in androgen metabolites has been previously shown to be a reliable, direct method to detect testosterone misuse in the context of antidoping testing. Here, the variability in the $^{13}\text{C}/^{12}\text{C}$ ratios in urinary steroids in a widely heterogeneous cohort of professional soccer players residing in different countries (Argentina, Italy, Japan, South Africa, Switzerland and Uganda) was examined. Carbon isotope ratios of selected androgens in urine specimens were determined using gas chromatography/combustion/isotope ratio mass spectrometry (GC-C-IRMS). Urinary steroids in Italian and Swiss populations were found to be enriched in $^{13}\text{C}$ relative to other groups, reflecting higher consumption of C3 plants in these two countries. Importantly, detection criteria based on the difference in the carbon isotope ratio of androsterone and pregnanediol for each population were found to be well below the established threshold value for positive cases. The results obtained with the tested diet groups highlight the importance of adapting the criteria if one wishes to increase the sensitivity of exogenous testosterone detection. In addition, confirmatory tests might be rendered more efficient by combining isotope ratio mass spectrometry with refined interpretation criteria for positivity and subject-based profiling of steroids [09070].

Principal components analysis

Principal components analysis was applied to anabolic androgenic steroids molecules referred in the WADA list of prohibited substances, resulting to their classification into six distinct groups related to structure features where metabolic alterations usually occur. The metabolites of the steroids participating to these six groups were treated using the Excel(c) classification filters showing that common metabolism routes are derived for each of the above principal components analysis classes, leading to the proposed metabolism schemes of the study. This rule-based approach is proposed for the prediction of the metabolism of unknown, chemically modified steroids, otherwise named as designer steroids. The metabolites of three known, in the literature, anabolic androgenic steroids are estimated using the proposed metabolism schemes, confirming that their use could be a useful tool for the prediction of metabolic pathways of unknown anabolic androgenic steroids [09071].

Androgen receptors assay

Anabolic androgenic steroids (AAS) share the activation of the androgen receptor (AR) as common mechanism of action. The mammalian androgen responsive reporter gene assay (AR CALUX bioassay), measuring compounds interacting with the AR can be used for the analysis of AAS without the necessity of knowing their chemical structure beforehand, whereas current chemical-analytical approaches may have difficulty in detecting compounds with unknown structures, such as designer steroids. One study demonstrated that AAS prohibited in sports and potential designer AAS can be detected with this AR reporter gene assay, but that also additional steroid activities of AAS could be found using additional mammalian bioassays for other types of steroid hormones. Mixtures of AAS were found to behave additively in the AR reporter gene assay showing that it is possible to use this method for complex mixtures as are found in doping control samples, including mixtures that are a result of multi drug use. To test if mammalian reporter gene assays could be used for the detection of AAS in urine samples, background steroidal activities were measured. AAS-spiked urine samples, mimicking doping positive samples, showed significantly higher androgenic activities than unspiked samples. GC-MS analysis of endogenous androgens and AR reporter gene assay analysis of urine samples showed how a combined chemical-
analytical and bioassay approach can be used to identify samples containing AAS. The results indicate that the AR reporter gene assay, in addition to chemical-analytical methods, can be a valuable tool for the analysis of AAS for doping control purposes [09072].

The utility of androgen receptor-based bioassays to probe for the presence of AAS and other non-steroidal anabolic agents in dietary products (with and without additional mass spectrometric measurement) has been demonstrated with various applications and reports in the past. One of the main advantages of this approach is the assay’s capability to indicate the presence of one or more substances able to bind to the androgen receptor, even if the structures and compositions of the substrates are unknown to the analyst. Moreover, the bioassay will provide information on the sum of androgen receptor activation. Hence, if two or more anabolic agents are present at low concentration, their detection is facilitated compared to methods that are designed to measure each analyte individually. Once suspicious bioassay results are obtained, products can be scrutinized for known as well as possibly unknown anabolic agents as recently shown in a study using a combined bioaffinity mass spectrometry methodology employing a competitive inhibition binding assay interfaced to a UHPLC-MS/MS system. In terms of doping controls, particularly the first-mentioned feature of measuring the combined androgen receptor binding of multiple analytes was evaluated as a potential means to tackle the issue of testosterone doping. The androgenic activity in urine as well as serum was measured prior to and after intramuscular testosterone enanthate administration, demonstrating that the readout of the bioassay was elevated independent from UGT2B17 ins/ins, ins/del, and del/del genotypes, suggesting that this approach might complement traditional steroid profile measurements [13009].

Although the specificity and unambiguous nature of mass spectrometry-based methods is undisputed, the search for complementary approaches, especially for initial test methods, is unbound. Here the utility of effect-based test methods such as those utilizing bioassays with androgen-receptors have been extensively reviewed. These assays can indicate the presence of agents stimulating the human androgen receptor without detailed knowledge of the substrate; however, proof of the misuse of anabolic agents remains to be provided, most likely by structural identification of the banned substance, for example, by mass spectrometry. In addition, immunological methodologies have been proposed to support the detection of AAS from human serum in a recent communication. By means of three different polyclonal antibodies (raised against boldenone, stanozolol, and tetrahydrogestrinone) and their respective cross reactivities, a total of 11 AAS is described to be detectable in less than 3 h. The authors highlight the sensitivity of the assay as being in agreement with WADAs MRPL; however, for serum samples no MRPL is given as to AAS concentrations and urine specimens have to be taken into account where metabolic processes and other potential [13012].

Receptor binding (competitive) assays
Receptor binding assays are based on the binding affinity of a ligand for its receptor. For this assay, purified receptor is immobilized on a column or suspended in a homogenate and to this, radiolabeled testosterone of known concentration is added. For the test, the suspect molecule is added to the radiolabeled testosterone, and it is measured whether the unknown molecule displaces the binding of the testosterone. If there is displacement then the unknown molecule has AR binding affinity. This type of assay only measures binding to AR and therefore is not able to differentiate between agonist and antagonist activity, or if any activity per se. Receptor binding assays require the use of radiolabelling, which presents a hazard if used as a routine screening test. These assays can be developed as high-throughput and are relatively easy to perform. To date, they have been used in a number of applications, including screening animal feed for growth hormones and screening for potential endocrine
disrupting chemicals (EDCs). They can also be used to investigate the potential potency of anabolic steroids by assessing the ability to bind to AR [13084].

**Androgen bioassays**

Androgen bioassays used for detection differ from the techniques described above because they mimic AR function and are not dependent on chemical structure. There are a number of different bioassays ranging from those based on whole animals to those based on mammalian or yeast cells. The Hershberger assay is an example of an *in vivo* androgen bioassay. The endpoint of this assay is a measured increase in the weight of androgen-dependent tissues. It is based on orchidectomised animals that produce little endogenous sex steroid hormones. These animals are treated with the test compound. If the test compound is androgenic, it will promote growth of androgen-dependent tissues. As this is an *in vivo* assay, metabolism of test molecules can also be tested by analyzing metabolites present in the blood stream and/or urine. As metabolism occurs upon treatment, this assay cannot be used to screen for activation or inactivation of androgens but it does allow the dissection of anabolic and androgenic effects of the test molecule or its metabolites. An assay based in animals is not feasible for routine sports doping screening in WADA laboratories. This has led to the development of *in vitro* cell-based androgen bioassays to screen for androgenic compounds. *In vitro* cell-based bioassays are widely used to detect androgenic molecules. They were first developed to test environmental pollutants (endocrine disrupting chemicals, EDCs) for their ability to alter normal hormonal function. Many substances including detergents (nonylphenol and other alkylphenols), plastics (bisphenol A), pesticides, insecticides, and even pharmaceutical wastes such as birth control tablets (ethinylestradiol) are now classified as EDCs. In vitro yeast androgen bioassays can be used in combination with other detection methods such as ultra high performance liquid chromatography combined with time-of-flight-tandem mass spectrometry (UHPLC/TOFMS) or liquid chromatography screening method. Moreover, bioassays can detect androgens in samples where LC-MS/MS could not, highlighting that bioassays have a valuable role in the fight against doping [13084].

**Cell-based androgen bioassays**

Cell proliferation assays can be used to measure the hormonal activity of a suspected agonist (or antagonist) in a sample because hormones, via their specific receptors, stimulate cell growth. In these assays, radioactive-labeled nucleotides are included in the culture media that become incorporated into DNA as cells proliferate. The radiolabel that incorporates into cells is a direct measurement of cell proliferation. These assays can measure both agonist and antagonist activity, as an agonist for the receptor of interest can stimulate cell growth, whereas an antagonist will block cell growth in the presence of an agonist. To date, this type of bioassay has not been extensively used to screen for androgens, however, it is the basis of the E-screen, which uses the human breast-cancer cell line (MCF-7) to screen for xenoestrogens. This assay is relatively simple to perform and is amenable to high-throughput readouts. However, results can be confounded by cell expression of other receptors (such as AR and glucocorticoid receptor) that induce non-specific cell proliferation. The assay relies on cell growth and, therefore, it can take days to produce results. Thus, it is not really feasible for use in sport doping laboratories [13084].

**Sensitivities of various androgen bioassays.**

The detection of prohormones or an understanding of potential metabolism of test extracts is central for the analysis of nutritional sport supplements. Mammalian cell lines may be limited in their metabolic capacity, compared to *in vivo* metabolism. To address this, a liver tissue metabolism step has been combined with the yeast AR/ARE/EGFP-based bioassay. In this two-step assay, test extracts are first incubated with a bovine liver S9 fraction, the extract
recovered, and then exposed to the yeast AR bioassay. As the liver tissue is whole, it is expected that this ex vivo approach will mimic the in vivo capacity for enzymatic conversions of steroids and therefore detect both prohormones and/or strong androgenic metabolites. In another example of introducing a pre-metabolism step prior to testing with a yeast AR bioassay to allow for prohormone or androgen metabolite detection, samples were pretreated with a *Helix pomatia* enzyme mix to activate inactive hormone conjugates including sulphates, glucuronides and glycosides. This example was in the setting of feed supplementation, rather than nutraceutical supplements, however, it is possible that a similar approach could be used to detect such conjugates if they were components of nutraceuticals [13084].

### Protein assays

The purpose of one study was to develop a rapid and sensitive method utilizing the state-of-the-art protein arrays technique to detect urinary anabolic steroids (ASs) in athletes. Three experiments were designed to investigate the feasibility of the protein arrays for ASs testing. Firstly, androgen receptor (AR) and estrogen receptor (ER) protein arrays were prepared on polysaccharide-coated slides to investigate whether they can bind to ASs (affinity tests). Secondly, in comparison to adrenergic receptor (the receptor of beta-blockers) and opioid receptor (the receptor of narcotic analgesics) arrays, AR and ER protein arrays were used to test whether they can determine the ASs positive urine sample specifically (specific binding tests). At last protein arrays were used to estimate qualitatively the ASs in positive urine samples (qualitative tests). From the results of the affinity tests the shape of the dose-dependence curve suggested a positive cooperative binding of ASs with the protein arrays. The AR and ER protein arrays showed affinities for fluorescence labelled testosterone and estradiol that were similar to those of literatures (0.65 vs 0.89 nM, 5.96 vs 10.3 nM, respectively). Based on the data, the sensitivity of testing can reach 0.1 nM that was much better than the World Anti-Doping Code (WADA) standard. Specific binding tests showed that the prohibited substance in positive urine samples belonged to the anabolic estrogenic inhibitor of ASs. From the results of the affinity tests the shape of the dose-dependence curve suggested a positive cooperative binding of ASs with the protein arrays. The total time of the test process for ASs in urine needed less than 1 h. In summary, the present study showed that the protein arrays method provided a highly sensitive and rapid alternative to screen urine samples for the detection of the misuse of ASs in athletes and was suitable for testing in both weekly training sessions as well as large-scale competition events [06102].

### Enzyme-immunoassay kit

One study assessed an enzyme-immunoassay (EIA) kit for measuring the salivary testosterone and cortisol concentrations of weightlifters. Saliva samples (*n*=64) were collected from male and female weightlifters during normal training procedures and analysed for testosterone and cortisol using a commercial EIA kit and a criterion radioimmunoassay (RIA) method. Significant correlations were demonstrated between the EIA and RIA measurements of salivary testosterone and cortisol concentrations. Further examination by sample and gender revealed similar relationships. The EIA concentrations of salivary testosterone and cortisol were found to be slightly greater (10-13 %) than the RIA values. Similar discrepancies were noted when gender comparisons were made, although the relative information on testosterone (males > females) and cortisol (males=females) were consistent for both assay methods. In conclusion, a commercially available EIA kit provided valid measures of the salivary testosterone and cortisol concentrations of male and female weightlifters. Factors to consider when using an EIA kit include the hormone(s) of interest,
the magnitude of the correlations, as well as the descriptive information gained (e.g. absolute, relative) and its uses within sport [10341].

**Triptorelin test**

In a case report a 34-year-old man had a single dose (100 mug) of triptorelin (triptorelin test). Within 1 month, the patient's serum testosterone was in the normal range, and he reported a return to normal energy and libido. The World Anti-Doping Code has proved to be a very powerful and effective tool in the harmonization of antidoping efforts worldwide, but it is insufficient to combat this illegal phenomenon. To tackle the serious side effects caused by doping we believe that it is necessary to increase monitoring and adopt severe sanctions, particularly with regard to Internet sites [10074].

**Serum inhibin B as a potential marker of testosterone doping**

The aim of one study was to explore effectors of the pituitary-testicular axis suitable as potential biochemical markers to screen for testosterone doping. A pilot study with male bodybuilding athletes with a self-reported history of testosterone doping (repeated intramuscular administration of testosterone preparations, last injection 8 weeks or less ago) were compared with an equal sized control group matched for sex, age, and body mass index. Fifteen healthy young men of white background were tested for inhibin B, testosterone, luteinizing hormone (LH), follicle-stimulating hormone (FSH). Although the levels of testosterone, LH, and FSH did not differ between the 2 groups, the serum concentrations of inhibin B in individuals with a history of testosterone doping were exclusively at or below the lower limit of the normal range for adult men (100-400 pg/mL). Inhibin B was significantly lower in those men who used testosterone for weight lifting (76 ± 36 ng/L) than in controls (182 ± 35 ng/L). It was concluded that a low concentration of serum inhibin B may reflect the application of exogenous testosterone and appears to be a potential marker associated with anabolic androgenic steroid doping [10075].

**Two-dimensional gas chromatography**

This work presents the validation study of the comprehensive two-dimensional gas chromatography (GC x GC)-time-of-flight mass spectrometry method performance in the analysis of the key World Anti-Doping Agency anabolic agents in doping control. The relative abundance ratio, retention time, identification and other method performance criteria have been tested in the GC x GC format to confirm that they comply with those set by WADA. Furthermore, tens of other components were identified with an average similarity of >920 (on the 0-999 scale), including 10 other endogenous sterols, and full mass spectra of 5,000+ compounds were retained. The testosterone/epitestosterone ratio was obtained from the same run. A new dimension in doping analysis has been implemented by addressing separation improvement. Instead of increasing the method sensitivity, which is accompanied by making the detector increasingly "blind" to the matrix (as represented by selected ion monitoring mode, high-resolution mass spectrometry (MS) and tandem MS), the method capabilities have been improved by adding a new "separation" dimension while retaining full mass spectral scan information. Apart from the requirement for the mass spectral domain that a minimum of three diagnostic ions with relative abundance of 5 percent or higher in the MS spectra, all other WADA criteria are satisfied by GC x GC operation. The minimum of three diagnostic ions arises from the need to add some degree of specificity to the acquired mass spectrometry data; however, under the proposed full MS scan method, the high MS similarity to the reference compounds offers more than the required three diagnostic ions for an unambiguous identification. This should be viewed as an extension of the present criteria.
Effective detection of the abuse of androgenic-anabolic steroids in human and animal sports often requires knowledge of the drug's metabolism in order to target appropriate urinary metabolites. "Designer" steroids are problematic since it is difficult to obtain ethical approval for in vivo metabolism studies due to a lack of a toxicological profile. In one study, the in vitro metabolism of estra-4,9-diene-3,17-dione is reported for the first time. This is also the first study comparing the metabolism of a designer steroid in the three major species subject to sport's doping control; namely the equine, canine and human. In order to allow the retrospective analysis of sample testing data, the use of a high-resolution (HR) accurate-mass Thermo LTQ-Orbitrap LC-MS instrument was employed for metabolite identification of underivatised sample extracts. The full scan HR-LC-MS Orbitrap data was complimented by several further experiments targeted at elucidating more detailed structural information for the most abundant metabolites. These included; HR-LC-MS/MS of the underivatised metabolites, functional group selective chemical derivatisation followed by full scan HR-LC-MS, enzyme inhibition experiments and full scan electron ionization GC-MS analysis of methoxynamine-trimethylsilyl derivatives. The major metabolite detected in all species, and therefore the most suitable candidate for screening of estra-4,9-diene-3,17-dione abuse, was proposed to be an isomer of 17-hydroxy-estra-4,9-dien-3-one. Less significant metabolic pathways in all species included hydroxylation and reduction followed by hydroxylation. Reductive metabolism in the canine was less significant than in the other two species, while the equine was unique in producing a di-reduced metabolite (proposed to be an isomer of estra-4,9-diene-3,17-diol) and also relatively large quantities of d-ring hydroxy and hydroxy-reduced metabolites [10077].

Adequate detection of designer steroids in the urine of athletes is still a challenge in doping control analysis and requires knowledge of steroid metabolism. In one study we investigated whether uPA(+/+)-SCID mice carrying functional primary human hepatocytes in their liver would provide a suitable alternative small animal model for the investigation of human steroid metabolism in vivo. A quantitative method based on liquid chromatography-tandem mass spectrometry (LC-MS/MS) was developed and validated for the urinary detection of 7 known methandienone metabolites. Application of this method to urine samples from humanized mice after methandienone administration allowed for comparison with data from in vivo human samples and with reported methandienone data from in vitro hepatocyte cultures. The LC-MS/MS method validation in mouse and human urine indicated good linearity, precision, and recovery. Using this method it was quantified 6 of 7 known human methandienone metabolites in the urine of chimeric mice, whereas in control nonchimeric mice we detected only 2 metabolites. These results correlated very well with methandienone metabolism in humans. In addition, it was detected 4 isomers of methandienone metabolites in both human and chimeric mouse urine. One of these isomers has never been reported before. The results of this proof-of-concept study indicate that the human liver-uPA(+/-)-SCID mouse appears to be a suitable small animal model for the investigation of human-type metabolism of anabolic steroids and possibly also for other types of drugs and medications [09073].

**Molecularly imprinted polymer filaments (MIPFs)**

An online system that can perform dynamic microextraction, on-coating derivatization and desorption, and subsequent GC-MS analysis with a large-volume injection was developed. A derivatization cell as the conjunction of the online system was developed for the online extraction and derivatization. To evaluate the feasibility of the online system,
methyltestosterone molecularly imprinted polymer filaments (MIPFs) were prepared for the selective online extraction of five androgenic steroids, namely, methyltestosterone, testosterone, epitestosterone, nandrolone, and metandienone. Under the optimized conditions, the detection limits of testosterone and epitestosterone were 0.09 and 0.12 μg/L, respectively, which were under the minimum required performance limits between 2 and 10 μg/L from the World Anti-Doping Agency. The detection limits of the other three androgenic steroids were varied from 0.04 to 0.18 microg/L. Finally, the MIPFs-GC-MS method was applied for the determination of androgenic steroids in urine, and satisfactory recovery (78-97 %) and reproducibility (3.2-8.9 %) were obtained. The proposed online coupling system offers an attractive alternative for hyphenation to GC instruments and could also be extended to other adsorptive materials [13176].

An online system that can perform dynamic microextraction, on-coating derivatization and desorption, and subsequent GC-MS analysis with a large-volume injection was developed. A derivatization cell as the conjunction of the online system was developed for the online extraction and derivatization. To evaluate the feasibility of the online system, methyltestosterone molecularly imprinted polymer filaments (MIPFs) were prepared for the selective online extraction of five androgenic steroids, namely, methyltestosterone, testosterone, epitestosterone, nandrolone, and metandienone. Under the optimized conditions, the detection limits of testosterone and epitestosterone were 0.09 and 0.12 microg/L, respectively, which were under the minimum required performance limits between 2 and 10 microg/L from the World Anti-Doping Agency. The detection limits of the other three androgenic steroids were varied from 0.04 to 0.18 microg/L. Finally, the MIPFs-GC-MS method was applied for the determination of androgenic steroids in urine, and satisfactory recovery (78.0-96.9 %) and reproducibility (3.2-8.9 %) were obtained. The proposed online coupling system offers an attractive alternative for hyphenation to GC instruments and could also be extended to other adsorptive materials [13177].

**Urinary steroids**

One work presented a novel database search engine – MLibrary – designed to assist the user in the detection and identification of androgenic anabolic steroids (AAS) and its metabolites by matrix assisted laser desorption/ionization (MALDI) and mass spectrometry-based strategies. The detection of the AAS in the samples was accomplished by searching the mass spectrometric (MS) spectra against the library developed to identify possible positives and by comparison of the tandem mass spectrometric (MS/MS) spectra produced after fragmentation of the possible positives with a complete set of spectra that have previously been assigned to the software. The urinary screening for anabolic agents plays a major role in anti-doping laboratories as they represent the most abused drug class in sports. With the help of the MLibrary software application, the use of MALDI techniques for doping control is simplified and the time for evaluation and interpretation of the results is reduced. To do so, the search engine takes as input several MALDI-TOF-MS and MALDI-TOF-MS/MS spectra. It aids the researcher in an automatic mode by identifying possible positives in a single MS analysis and then confirming their presence in tandem MS analysis by comparing the experimental tandem mass spectrometric data with the database. Furthermore, the search engine can, potentially, be further expanded to other compounds in addition to AASs. The applicability of the MLibrary tool is shown through the analysis of spiked urine samples [13178].

**In saliva**

To validate the testosterone (T) and cortisol (C) concentration measures in saliva in
response to short high-intensity exercise 9 healthy males provided matching saliva and plasma samples before and after a 30-second Wingate cycle test. Saliva was assayed for T (Sal-T) and C (Sal-C) concentrations, and plasma for total T and total C, sex hormone-binding globulin, corticosteroid-binding globulin (CBG) and albumin concentrations. The plasma free and bioavailable hormones were calculated. The Sal-T and plasma T correlations were weak to moderate when examined between individuals (pooled data for all participants), but these relationships improved within individuals (data for each participant on average). The Sal-C and plasma C correlations were strong both between individuals and within individuals. The peak relative increases in Sal-T (35 ± 9 %) and Sal-C (63 ± 29 %) concentrations exceeded the plasma total and/or free hormones, but not the bioavailable hormones. Albumin and CBG also increased with exercise, along with blood lactate. It was concluded that the Sal-T and Sal-C concentration measures were validated in response to short high-intensity exercise, especially for individuals. The hormonal changes in saliva were also more sensitive to exercise (i.e. greater relative responses) than the plasma total and/or free hormones, potentially arising from changes in the binding proteins and blood lactate. These findings support the use of saliva as a medium for steroid determination in sport [10072].

In hair

The measurement of anabolic steroid levels in human hair is possible in order to distinguish between pharmaceutical steroids and natural steroids. It was now presented the first investigation into the physiological concentrations of anabolic steroids in human hair in Chinese subjects. A gas chromatography-tandem mass spectrometry (GC/MS/MS) method was developed for the simultaneous identification and quantitation of five endogenous anabolic steroids (testosterone, epitestosterone, androsterone, etiocholanolone and dehydroepiandrosterone) in hair. After basic hydrolysis, hair samples were extracted with diethyl ether, derivatized and then detected using GC/MS/MS in the multiple-reaction monitoring mode. The one precursor/two product ion transitions for each anabolic steroid were monitored. The limits of detection for the five endogenous anabolic steroids were in the 0.1-0.2 pg/mg range. Within-day and between-day precisions were less than 20 percent. This method was applied to the analysis of testosterone, epitestosterone, androsterone, etiocholanolone, and dehydroepiandrosterone in human hair. Full-length hair samples were taken at the skin surface from the vertex of 39 males, 30 females and 11 children from China. None of the subjects were professional athletes. Testosterone and dehydroepiandrosterone were detected in all the hair segments. The physiological concentrations of testosterone were in the range 0.8-24.2 pg/mg, 0.1-16.8 pg/mg and 0.2-11.5 pg/mg in males, females and children, respectively, however, the mean values of dehydroepiandrosterone were much higher than the concentrations of testosterone. These data are suitable reference values and are the basis for the interpretation of results from investigations into the abuse of endogenous anabolic steroids [09074].

A simple and sensitive gas chromatography/tandem mass spectrometry (GC/MS/MS) method is described for the detection of anabolic steroids, usually found in keratin matrix at very low concentrations. Hair samples from seven athletes who spontaneously reported their abuse of anabolic steroids, and in a single case cocaine, were analyzed for methyltestosterone, nandrolone, boldenone, fluoxymesterone, cocaine and its metabolite benzoylecgonine. Anabolic steroids were determinate by digestion of hair samples in 1 m NaOH for 15 min at 95 degrees C. After cooling, samples were purificated by solid-phase and liquid-liquid extraction, then anabolic steroids were converted to their trimethylsilyl derivative and finally analyzed by GC/MS/MS. For detection of cocaine and benzoylecgonine, hair samples were extracted with methanol in an ultrasonic bath for 2 h at 56 degrees C then overnight in a thermostatic bath at the same temperature. After the
incubation, methanol was evaporated to dryness, and benzoylecgonine was converted to its trimethylsilyl derivative prior of GC/MS/MS analysis. Results obtained are in agreement with the athletes' reports, confirming that hair is a valid biological matrix to establish long-term intake of drugs [07082].

New highly sensitive, specific, reliable, reproducible and robust LC-MS/MS methods were developed to detect the anabolic steroids, nandrolone and stanozolol, in human hair for the first time. Hair samples from 180 participants (108 males, 72 females, 62 % athletes) were screened using ELISA which revealed 16 athletes as positive for stanozolol and 3 for nandrolone. Positive samples were confirmed on LC-MS/MS in selective reaction monitoring (SRM) mode. The assays for stanozolol and nandrolone showed good linearity in the range 1-400 pg/mg and 5-400 pg/mg, respectively. The methods were validated for LLOD, interday precision, intraday precision, specificity, extraction recovery and accuracy. The assays were capable of detecting 0.5pg stanozolol and 3.0 pg nandrolone per mg of hair, when approximately 20 mg of hair were processed. Analysis using LC-MS/MS confirmed 11 athletes' positive for stanozolol (5.0 pg/mg to 86.3 pg/mg) and 1 for nandrolone (14.0 pg/mg) thus avoiding false results from ELISA screening. The results obtained demonstrate the application of these hair analysis methods to detect both steroids at low concentrations, hence reducing the amount of hair required significantly. The new methods complement urinalysis or blood testing and facilitate improved doping testing regimes. Hair analysis benefits from non-invasiveness, negligible risk of infection and facile sample storage and collection, whilst reducing risks of tampering and cross-contamination. Owing to the wide detection window, this approach may also offer an alternative approach for out-of-competition testing [10073].

New highly sensitive, specific, reliable, reproducible and robust LC-MS/MS methods were developed to detect the anabolic steroids, nandrolone and stanozolol, in human hair for the first time. Hair samples from 180 participants (108 males, 72 females, 62 % athletes) were screened using ELISA which revealed 16 athletes as positive for stanozolol and 3 for nandrolone. Positive samples were confirmed on LC-MS/MS in selective reaction monitoring (SRM) mode. The assays for stanozolol and nandrolone showed good linearity in the range 1-400 pg/mg and 5-400 pg/mg, respectively. The methods were validated for LLOD, interday precision, intraday precision, specificity, extraction recovery and accuracy. The assays were capable of detecting 0.5pg stanozolol and 3.0 pg nandrolone per mg of hair, when approximately 20 mg of hair were processed. Analysis using LC-MS/MS confirmed 11 athletes' positive for stanozolol (5.0 pg/mg to 86.3 pg/mg) and 1 for nandrolone (14.0 pg/mg) thus avoiding false results from ELISA screening. The results obtained demonstrate the application of these hair analysis methods to detect both steroids at low concentrations, hence reducing the amount of hair required significantly. The new methods complement urinalysis or blood testing and facilitate improved doping testing regimes. Hair analysis benefits from non-invasiveness, negligible risk of infection and facile sample storage and collection, whilst reducing risks of tampering and cross-contamination. Owing to the wide detection window, this approach may also offer an alternative approach for out-of-competition testing [10453].

A method for the screening of various anabolic steroids and their esters in human hair, based on liquid-chromatography-high resolution mass spectrometry using an Exactive benchtop Orbitrap mass spectrometer, has been set up and validated. This method involved methanolic incubation of 30 mg of hair and analysis of the relevant extract in HPLC using a C18 column. The mass detector, with nominal resolving power of 100,000, operated in full scan mode in APCI under positive ionization mode. Analytes were identified by exact mass, correspondence of isotopic cluster and retention times. The limits of detection obtained varied from 10 to 50 pg/mg, and limits of quantitation were 0.5 ng/mg for all compounds. The
method was linear for all analytes in the ranges from the LOQ to 6 ng/mg, giving correlation coefficients >0.99 for all analytes. Also accuracy (intended as %E) and repeatability (%CV) were always lower than 15 percent. Specificity was assessed by analysing ten blank samples and fifteen samples from polidrug abusers. This method was applied to a real-life case, resulting in the identification of testosterone undecanoate in the hair of a suspect. The analyte identity was confirmed by the analysis of its in-source fragmentation and comparison to a certified standard. Thanks to the scan acquisition, this method also enables retrospective re-analysis of the acquired datafile in case a further analyte needs to be screened [13179].

**Faecal analyses**

Faeces, which could be a potential alternative medium for doping control, have been used for the detection of 1,4-androstadiene-3,17-dione administration to horses. Semi-quantitative analyses of 1,4-androstadiene-3,17-dione, testosterone, 17alpha- and 17beta-boldenone have been conducted in pre- and post-administration faeces, and in controls (untreated stallions, geldings and mares). Sample preparation comprised diethyl ether extraction, lipid removal, HPLC purification and derivatisation. 1,4-Androstadiene-3,17-dione, testosterone, 17alpha- and 17beta-boldenone were analysed by GC-EI/MS/MS. Quantitative limits of detection were 0.1 ng/g for 1,4-androstadiene-3,17-dione, and 0.025 ng/g for testosterone, 17alpha- and 17beta-testosterone. In post-administration samples from geldings and mares, peak levels of 1,4-androstadiene-3,17-dione, 17alpha-, 17beta-boldenone and testosterone were attained 24 h after administration. In untreated geldings and mares (in dioestrus), 17alpha- and 17beta-boldenone and testosterone were not detected. Faeces from females in oestrus had detectable levels of boldenone isomers and testosterone. 1,4-Androstadiene-3,17-dione was undetectable in faeces collected from untreated horses, but the presence of this androgen was recently reported in faeces from untreated swine and it would therefore be advisable to check for its possible presence in a larger number of individual faecal samples [08191].

**In food**

Anabolic steroids are banned from use in food-producing animals in the European Union (Council Directive 96/22/EC). To control the zero-tolerance concept, an LC-MS/MS method for the screening and confirmation of most of the relevant natural and synthetic estrogenic and androgenic steroids in bovine and porcine blood plasma was developed and validated. The method permits confirmation and quantification of all analytes above a concentration of 0.65 microg/L. The validation was carried out according to Commission Decision 2002/657/EC, Chapter 3.1.3 "Alternative Validation", by applying a matrix-comprehensive in-house validation concept. Decision limit CCalpha, detection capability CCbeta, recovery, repeatability, within-laboratory reproducibility and the uncertainty of measurement were calculated. Furthermore, a factorial effect analysis was carried out to identify factors that have a significant influence on the method. Factors considered to be relevant for the method in routine analysis (e.g. operator, storage duration of the extracts before measurement and different cartridge lots) were systematically varied on two levels [13182].

**In egg**

A cheap, reliable and practical high-performance liquid chromatography-tandem mass spectrometric method was developed for the simultaneous determination of seven anabolic steroids in eggs, including trenbolone, boldenone, nandrolone, stanozolol, methandienone, testosterone and methyl testosterone. The analytes were extracted from the egg samples using methanol. The extracts were subjected to the removal of fat by freezing-lipid filtration
and then further purified by liquid-liquid extraction using tert-butyl methyl ether. The analytes were separated on a Luna C18 column by a gradient elution program with 0.1% formic acid and acetonitrile. This method was validated over 1.00-100 ng/g for all steroids of interest. The correlation coefficients (r) for each calibration curve are higher than 0.99 within the experimental concentration range. The decision limits of the steroids in eggs ranged from 0.20 to 0.44 ng/g, and the detection capabilities were below 1.03 ng/g. The average recoveries were between 66.3 and 82.8% in eggs at three spiked levels of 1.00, 1.50 and 2.00 ng/g for each analyte. The between-day and within-day relative standard deviations were in the range of 2.4-11 percent. High matrix suppression effects were observed for all compounds of interest [13183].

**Musk extracts**

The relevance of IRMS analyses in sports drug testing was highlighted in a recent case report concerning the administration of musk pod extracts to female elite athletes. Numerous steroidal components relevant to doping controls and steroid profiling were influenced by the preparation commonly used in traditional Chinese medicine (TCM) regimens and triggered GC/C/IRMS analyses that confirmed the non-human origin of the urinary steroid metabolites. In a follow-up study, the diversity of musk preparations concerning steroid content and respective CIR was demonstrated. Four batches of musk grains were purchased including two specimens from wild musk deer and two from domesticized musk deer, outlining substantial differences in both amounts of steroids and isotopic signatures. In administration studies with two preparations (100 mg of musk grains) however no significant change in urinary steroid profiles and CIR were found [13009].

Musk is widely used as a traditional drug in Asia for the treatment of stroke, tumour, and cardiopathy with an oral dosage of 0.03-0.1 g per day. Because of the potential anabolic effect, musk preparations have been included in the list of medical products containing prohibited substances employed for doping. The application of musk pod formulation was regarded as the reason of some adverse analytical findings in the 2011 FIFA Women's World Cup. In order to investigate the influence of musk administration on the doping test, we executed a chemical analysis and excretion study. The gas chromatography/mass spectrometry (GC-MS) analysis demonstrated the diversity of steroid concentrations in musk samples. Furthermore, the delta-13C-values of steroids from wild deer musk showed more depleted than those of domestic deer musk by gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS) analysis. Because the steroids from some musk had delta-13C-values in the range of naturally produced steroids in human body, the possible abuse of this kind of musk is very hard to be detected by isotope ratio mass spectrometry (IRMS) in doping control. Musk grains from wild and domestic deer were administrated for the excretion study respectively. Spot urine samples were collected from two male volunteers before and after 100 mg musk grains administration. The profiles and carbon isotope ratios of urinary steroids were determined by GC-MS and GC/C/IRMS. The ingestion of either wild or domestic deer musk did not lead to the adverse analytical finding of doping control in the single dosage of 100 mg [13184].

Musk is the dried secretion from the preputial follicles of the male musk deer, which are located in a small sac (resulting from an infolding of the skin) in close proximity to the preputial orifice. This sac (or pod), which contains the brownish musk, comprises a small canal debouching close to the preputial orifice that allows the controlled release of the unctuous product by the animal. Upon removal of moisture, the material converts into small, dark, reddish-brown musk grains. In comprehensive studies, the lipid constituents of musk were elucidated and numerous steroidal components were characterized. The administration
of musk extract, that is, ingredients obtained by extraction of the liquid secreted from the preputial gland or resulting grains of the male musk deer (e.g. Moschus moschiferus), has been recommended in traditional chinese medicine (TCM) applications and was listed in the Japanese pharmacopoeia for various indications requiring cardiovascular stimulation, anti-inflammatory medication or androgenic hormone therapy. Numerous steroidal components including cholesterol, 5alpha-androstane-3,17-dione, 5beta-androstane-3,17-dione, androsterone, etiocholanolone, epiandrosterone, 3beta-hydroxy-androst-5-en-17-one, androst-4-ene-3,17-dione and the corresponding urea adduct 3alpha-ureido-androst-4-en-17-one were characterised as natural ingredients of musk over several decades, implicating an issue concerning doping controls if used for the treatment of elite athletes. In the present study, the impact of musk extract administration on sports drug testing results of five females competing in an international sporting event is reported. In the course of routine doping controls, adverse analytical findings concerning the athletes’ steroid profile, corroborated by isotope-ratio mass spectrometry (IRMS) data, were obtained. The athletes’ medical advisors admitted the prescription of TCM-based musk pod preparations and provided musk pod samples for comparison purposes to clarify the antidoping rule violation. Steroid profiles, IRMS results, literature data and a musk sample obtained from a living musk deer of a local zoo conclusively demonstrated the use of musk pod extracts in all cases which, however, represented a doping offence as prohibited anabolic-androgenic steroids were administered [13185].

A user-friendly library

One work presents a novel database search engine - MLibrary - designed to assist the user in the detection and identification of androgenic anabolic steroids (AAS) and its metabolites by matrix assisted laser desorption/ionization (MALDI) and mass spectrometry-based strategies. The detection of the AAS in the samples was accomplished by searching the mass spectrometric (MS) spectra against the library developed to identify possible positives and by comparison of the tandem mass spectrometric (MS/MS) spectra produced after fragmentation of the possible positives with a complete set of spectra that have previously been assigned to the software. The urinary screening for anabolic agents plays a major role in anti-doping laboratories as they represent the most abused drug class in sports. With the help of the MLibrary software application, the use of MALDI techniques for doping control is simplified and the time for evaluation and interpretation of the results is reduced. To do so, the search engine takes as input several MALDI-TOF-MS and MALDI-TOF-MS/MS spectra. It aids the researcher in an automatic mode by identifying possible positives in a single MS analysis and then confirming their presence in tandem MS analysis by comparing the experimental tandem mass spectrometric data with the database. Furthermore, the search engine can, potentially, be further expanded to other compounds in addition to AASs. The applicability of the MLibrary tool is shown through the analysis of spiked urine samples [13180].

Reference values from South America

The urinary steroid profile has been used in clinical endocrinology for the early detection of enzyme deficiencies. In the field of doping, its evaluation in urine samples is used to diagnose the abuse of substances prohibited in sport. This profile is influenced by sex, age, exercise, diet, and ethnicity, among others; laboratories own reference ranges might compensate for ethnic differences among population and inter-laboratory biases. One paper shows the reference ranges obtained in the Antidoping Laboratory of Havana for the following steroid profile parameters: ten androgens (testosterone, epitestosterone, androsterone, etiocholanolone, 5alpha-androst-3alpha,17beta-diol, 5beta-androstan-
3alpha,17beta-diol, dehydroepiandrosterone, epiandrosterone, 11beta-hydroxyandrostenedione and 11beta-hydroxyetiocholanolone), three estrogens (estradiol, estriol and estrone), two pregnanes (pregnanediol and pregnanetriol) and two corticosteroids (cortisol and tetrahydrocortisol). The urine samples (male: n=2454 and female: n=1181) and data obtained are representative of population from Latin-American countries like Cuba, Venezuela, Mexico, Dominican Republic, Guatemala and Chile. Urine samples were prepared by solid-phase extraction followed by enzymatic hydrolysis and liquid-liquid extraction with an organic solvent in basic conditions. Trimethylsilyl derivatives were analyzed by gas chromatography coupled to mass spectrometry. Reference ranges were established for each sex, allowing the determination of abnormal profiles as a first diagnostic tool for the detection of the abuse of androgenic anabolic steroids. The comparison with the Caucasian population confirms that the urinary steroid profile is influenced by ethnicity [13181].

**Experimental**

**Contextual interaction**

Seasonal changes in steroid hormones are known to have a major impact on social behavior, but often are quite sensitive to environmental context. In the bi-directionally sex changing fish, Lythrypnus dalli, stable harem groups exhibit baseline levels of interaction. Status instability follows immediately after male removal, causing transiently elevated agonistic interactions and increase in brain and systemic levels of a potent fish androgen, 11-ketotestosterone (KT). Coupling KT implants with a socially inhibitory environment for protogynous sex change induces rapid transition to male morphology, but no significant change in social behavior and status, which could result from systemically administered steroids not effectively penetrating into brain or other tissues. Here, it was first determined the degree to which exogenously administered steroids affect the steroid load within tissues. Second, it was examined whether coupling a social environment permissive to sex change would influence KT effects on agonistic behavior. It was implanted cholesterol (Chol, control) or KT in the dominant individual (alpha) undergoing sex change (on d0) and determined the effects on behavior and the degree to which administered steroids altered the steroid load within tissues. During the period of social instability, there were rapid (within 2h), but transient effects of KT on agonistic behavior in alphas, and secondary effects on betas. On d3 and d5, all KT, but no Chol, treated females had male typical genital papillae. Despite elevated brain and systemic KT 5days after implant, overall rates of aggressive behavior remained unaffected. These data highlight the importance of social context in mediating complex hormone-behavior relationships [13186].

**Prepuberal induction**

Few data are available on adolescent users because most behavioral studies on anabolic-androgenic steroids (AAS) abuse have been performed in adults. Studies evaluating the impact of long-term effects of AAS abuse on the prepubertal phase are even more uncommon. Accordingly, this study was developed to test the hypothesis that changes induced by the use of AAS during the adolescent phase may be noted in the adult phase even when the AAS treatment cycle is discontinued. Therefore, not only behavioral changes but also possible autonomic and electrolyte disorders were evaluated. For this purpose, we used male prepubertal, 26-day-old (P26) Wistar rats that were treated with vehicle (control, n=10) or testosterone propionate (TP; 5 mg/kg intramuscular (IM) injection, AAS, n=10) five times per week for 5 weeks, totaling 25 applications during the treatment. Aggression tests were performed at the end of the cycle (P54-56), whereas open-field tests (OFTs), elevated plus maze (EPM) behavioral tests and measurements of heart rate variability (HRV), fluid intake and pathology were conducted in the adult phase (P87-92). The AAS group showed
greater aggressiveness in the pubertal phase and higher levels of horizontal and vertical exploration and anxiety-related behavior in the adult phase than the control group. HRV tests showed an increase in sympathetic autonomic modulation, and hydroelectrolytic assessment showed lower basal intake levels of hypertonic saline than the control group, without statistically significant changes in the basal intake of water. These data together suggest that the use of AAS during the prepubertal phase induces behavioral, autonomic and hydroelectrolytic changes that manifest in the adult phase even when treatment is discontinued in late adolescence in rats [13187].

Markers for anabolic steroids

The screening of testosterone misuse in the doping control field is normally performed by the measurement of the ratio between the concentrations of testosterone and epitestosterone excreted as glucuronides (T/E). Despite the satisfactory results obtained with this approach, the measurement of T/E presents some limitations like the long-term detection of oral testosterone administration. Recently, several testosterone metabolites released after basic treatment of the urine have been reported (androsta-1,4-dien-3,17-dione, androsta-4,6-dien-3,17-dione, 17beta-hydroxy-androsta-4,6-dien-3-one and 15-androsten-3,17-dione). In one work, the usefulness of these metabolites for the detection of oral testosterone misuse were evaluated and compared with the conventional T/E measurement. For this purpose, 173 urine samples collected from healthy volunteers were analysed in order to obtain reference concentrations for the four metabolites released after alkaline treatment. On the other hand, urine samples collected from five volunteers before and after testosterone undecanoate administration were also analysed. Concentrations of androsta-4,6-dien-3,17-dione and 17beta-hydroxy-androsta-4,6-dien-3-one showed a similar behaviour as the T/E, allowing the detection of the misuse for several hours after administration. More promising results were obtained by quantifying androsta-1,4-dien-3,17-dione and 15-androsten-3,17-dione. The time in which the concentrations of these analytes could be differentiated from the basal level was between 3 and 6 times longer than the obtained with T/E, as a result, an improvement in the detection of testosterone abuse can be achieved. Moreover, several ratios between these compounds were evaluated. Some of them improved the detection of testosterone misuse when comparing with T/E. The best results were obtained with those ratios involving androsta-1,4-dien-3,17-dione [11576].

The aim of one study was to explore effectors of the pituitary-testicular axis suitable as potential biochemical markers to screen for testosterone doping. It was a pilot study with male bodybuilding athletes with a self-reported history of testosterone doping (repeated intramuscular administration of testosterone preparations, last injection 8 weeks or less ago) compared with an equal sized control group matched for sex, age, and body mass index. Fifteen healthy young men of white background had inhibin B, testosterone, luteinizing hormone (LH), follicle-stimulating hormone (FSH) tested. Although the levels of testosterone, LH, and FSH did not differ between the 2 groups, the serum concentrations of inhibin B in individuals with a history of testosterone doping were exclusively at or below the lower limit of the normal range for adult men (100-400 pg/mL). Inhibin B was significantly lower in those men who used testosterone for weight lifting. It was concluded that low concentration of serum inhibin B may reflect the application of exogenous testosterone and appears to be a potential marker associated with anabolic androgenic steroid doping [10095].

AICAR

Influencing the endurance in elite sports is one of the key points in modern sports science. Recently, a new class of prohibited substances reached in the focus of doping control
laboratories and their misuse was classified as gene doping. The adenosine monophosphate activated protein kinase activator 5-amino-4-imidazolecarboxamide ribonucleoside (AICAR) was found to significantly enhance the endurance even in sedentary mice after treatment. Due to endogenous production of AICAR in healthy humans, considerable amounts were present in the circulation and, thus, were excreted into urine. Considering these facts, the present study was initiated to fix reference values of renally cleared AICAR in elite athletes. Therefore a quantitative analytical method by means of isotope-dilution liquid chromatography (analytical column: C6-phenyl) coupled to tandem mass spectrometry, after a sample preparation consisting of a gentle dilution of native urine, was developed. Doping control samples of 499 athletes were analysed, and AICAR concentrations in urine were determined. The mean AICAR value for all samples was 2,186 ng/mL with a standard deviation of 1,655 ng/mL. Concentrations were found to differ depending on gender, type of sport and type of sample collection (in competition/out of competition). The method was fully validated for quantitative purposes considering the parameters linearity, inter- (12 %, 7 % and 10 %) and intraday precision (14 %, 9 % and 12 %) at low, mid and high concentration, robustness, accuracy (approx. 100 %), limit of quantification (100 ng/mL), stability and ion suppression effects, employing an in-house synthesised 13C5-labelled AICAR as internal standard [10096].

Activity on carboanhydrases

The in vitro effects of the anabolic compounds, zeranol, 17beta-estradiol, diethylstilbestrol (DES), and trenbolone, on the activity of purified human carbonic anhydrase I and II were evaluated. In vitro carboanhydrase enzyme activity was determined colorimetrically using the CO2 hydration method of Maren. IC50 values of the compounds that caused inhibition were determined by means of activity percentage diagrams. The IC50 concentrations of zeranol, 17beta-estradiol, DES and trenbolone on human carbonic anhydrase I were 94, 55, 10, 898 microM and for human carboanhydrase II 89, 159, 439 and 101 microM, respectively [11110].

Purchase over the Internet

A case of hypogonadotropic hypogonadism due to the chronic abuse of anabolic steroids purchased over the Internet was reported. It was described the clinical symptoms, androgen normalization, levels of serum testosterone, follicle-stimulating hormone, and luteinizing hormone, and after withdrawal, within 1 month, the patient's serum testosterone was in the normal range, and he reported a return to normal energy and libido [10454].

Anabolic steroid use and condom use

Previous research has revealed a significant bivariate relationship between anabolic-androgenic steroid (AAS) use and reduced condom use among adolescent boys. However, to date, no known studies have explored the psychological mechanisms that may explain this relationship. Thus, the current study sought to examine two possible mediators in the association between AAS and condom use: depressive symptoms and substance use. Data were extracted from a nationally representative sample of US adolescents. Participants were 3,780 U.S. high school boys who responded to self-report items assessing a number of health behaviors, including symptoms of depression, substance use, AAS use, and use of condoms during their most recent act of intercourse. Both depression and substance use
were significant mediators in the relationship between AAS and condom use. However, when these effects were contrasted, the indirect effect of substance use was significantly stronger in magnitude than the effect of depression. Although AAS use was associated with sexual risk behaviors among adolescent boys, significant variance in this relationship was accounted for by elevated levels of depression and substance use, with substance use demonstrating a particularly salient pathway [13161].

Case reports

Most users of anabolic androgenic steroids (AAS) are male, but the prevalence of such use appears to be increasing in females. It was presented a sudden unexpected death in a female fitness athlete with a possible connection to use of doping agents [08192].

It was presented a case of a 19-year-old male athlete with protein C deficiency who developed proximal deep venous thrombosis and pulmonary embolism while abusing anabolic-androgenic steroids. Anabolic-androgenic steroids have been reported to have anticoagulatory and profibrinolytic effects in patients with protein C deficiency. Despite these antithrombotic effects, the patient developed repeated venous thromboembolism during treatment with low-molecular-weight heparin. The net effect of anabolic-androgenic steroids on the haemostatic system may change from antithrombotic to prothrombotic in male abusers of anabolic steroids with protein C deficiency [08193].

An increase in the use of anabolic and amino acid supplements has been linked to a diverse array of pathologies. It was reported multi-organ damage resulting from the abuse and uncontrolled use of anabolic steroid supplements, mainly testosterone. A 24-year-old white man presented with abdominal pain concomitant with nausea and vomiting. Laboratory analysis revealed hypercalcemia, elevated liver enzymes and high levels of amylase, lipase and creatine protein kinase [08194].

Experimental

GABA type A receptors

Anabolic androgenic steroids (AAS) can promote detrimental effects on social behaviors for which GABA type A (GABA_A) receptor-mediated circuits in the forebrain play a critical role. While all AAS bind to androgen receptors (AR), they may also be aromatized to estrogens and thus potentially impart effects via estrogen receptors (ER). Chronic exposure of wild-type male mice to a combination of chemically distinct AAS increased action potential frequency, selective GABA_A receptor subunit mRNAs, and GABAergic synaptic current decay in the medial preoptic area. Experiments performed with pharmacological agents and in AR-deficient mutant mice suggest that the AAS-dependent enhancement of GABAergic transmission in wild-type mice is AR-mediated. In AR-deficient mice, the AAS elicited dramatically different effects, decreasing AP frequency, spontaneous IPSC amplitude and frequency and the expression of selective GABA_A receptor subunit mRNAs. Surprisingly, in the absence of AR signaling, the data indicate that the AAS do not act as ER agonists, but rather suggest a novel in vivo action in which the AAS inhibit aromatase and impair endogenous ER signaling. These results show that the AAS have the capacity to alter neuronal function in the forebrain via multiple steroid signaling mechanisms and suggest that effects of these steroids in the brain will depend not only on the balance of AR- versus ER-mediated regulation for different target genes, but also on the ability of these drugs to alter
steroid metabolism and thus the endogenous steroid milieu [09075].

**Effect of subcutaneous testosterone on emotionality**

The androgenic steroid testosterone is well known for its function in reproduction, sexual differentiation and sexual behavior. A growing number of human and animal studies suggest a modulatory role of testosterone in the regulation of emotionality and associated psychiatric disorders, including depressive-like disorders. However, most of the studies have been carried out in subjects deficient in androgenic steroid levels. Here, it was tested potential beneficial effects of subcutaneously applied testosterone on emotionality and depressive-like behavior in healthy male rats. For this purpose, male Wistar rats (3-4 months) received either vehicle or testosterone (1.0, 2.0, 4.0mg/kg) subcutaneously and were tested for potential effects on motor activity and anxiety-like behavior in a novel open field and elevated plus-maze. The forced swim test was used for assessing potential beneficial effects of testosterone on depressive-like behavior. The results show, that, while subcutaneous application of testosterone failed to influence spontaneous motor activity as well as anxiety-like behavior in the open field, a trend for an increase in the time spent on the open arms in the elevated plus-maze with the highest dose was found. Furthermore, in the forced swim test, testosterone application induced a dose-dependent reduction of immobility behaviour, indicating antidepressant-like action of testosterone in healthy animals [09076].

**Effect of testosterone in castrated guinea pigs**

Anabolic steroids are widely used to increase skeletal muscle mass and improve physical performance. Some dietary supplements also include potent steroid precursors or active steroid analogs such as nandrolone. One previous study reported the anabolic steroid effects on skeletal muscle mass in a castrated guinea pig model with muscle measured using a highly quantitative magnetic resonance imaging (MRI) protocol. The aim of one study was to apply this animal model and in vivo MRI protocol to evaluate the growth effects of four widely used over-the-counter testosterone and nandrolone precursors: 4-androstene-3 17-dione (androstenedione), 4-androstene-3beta 17beta-diol (4-androsdiol), 19-nor-4-androstene-3beta-17beta-diol (bolandiol) and 19-nor-4-androstene-3 17-dione (19-norandrostenedione). The results showed that providing precursor to castrated male guinea pigs led to plasma steroid levels sufficient to maintain normal skeletal muscle growth. The anabolic growth effects of these specific precursors on individual and total muscle volumes, sexual organs, and total adipose tissue over a 10-week treatment period, in comparison with those in the respective positive control testosterone and nandrolone groups, were documented quantitatively by MRI [09077].

**Apoptosis and NOS2 (nitric-oxide synthase 2)**

Anabolic-androgenic steroids (AAS) are synthetic derivatives of testosterone (T) predominantly taken as drugs of abuse. Using in vivo treatment of adult male rats we investigated the effects of testosterone enanthate (TE) a widely abused AAS, on apoptosis of Leydig cells. Increased T and decreased luteinizing hormone levels in serum and decreased intra-testicular T values were found in 2 and 10 weeks treated groups. Two weeks of TE-treatment stimulated the expression of inducible nitric oxide synthase (NOS2) followed by increased NO production, decreased mitochondrial membrane potential and increased prevalence of Leydig cell apoptosis. This was prevented by in vivo administration of androgen receptor blocker. The induced NOS2 level and apoptosis returned to control levels after 10 weeks of TE-treatment but testes contained fewer Leydig cells. Overall, AAS in addition to reduced steroidogenesis induce transient increase of Leydig cells apoptotic rate
through mechanism associated with androgen receptor, most likely involving NOS2 induction [12158].

Androgen-induced cardiac autonomic dysfunction

One study aimed to evaluate the combined effects of exercise and antagonists of the angiotensin II and aldosterone receptors on cardiac autonomic regulation and ventricular repolarization in rats chronically treated with nandrolone decanoate (ND), a synthetic androgen. Thirty male Wistar rats were divided into six groups: sedentary, trained, ND-treated, trained and ND-treated, trained and treated with both ND and spironolactone, and trained and treated with both ND and losartan. ND (10 mg/kg weekly) and the antagonists (20 mg/kg daily) of the angiotensin II AT(1) (losartan) and aldosterone (spironolactone) receptors were administered for 8 weeks. Exercise training was performed using a treadmill five times each week for 8 weeks. Following this 8-week training and treatment period, electrocardiogram recordings were obtained to determine the time and frequency domains of heart rate variability (HRV) and corrected QT interval (QTc). Nandrolone decanoate treatment increased the QTc interval and reduced the parasympathetic indexes of HRV (RMSSD, pNN5 and high-frequency power) in sedentary and trained rats. The ratio between low- and high-frequency power (LF/HF) was higher in ND-treated groups. Both losartan and spironolactone treatments prevented the effects of ND on the QTc interval and the HRV parameters (RMSSD, pNN5, high-frequency power, and the LF/HF ratio). The results show that chronic treatment with a high dose of ND induces cardiac parasympathetic dysfunction and disturbances in ventricular repolarization in both sedentary and exercised rats. Furthermore, inhibiting the renin-angiotensin-aldosterone system using losartan, or spironolactone, prevented these deleterious effects [12159].

Interaction of testosterone with cocaine

Abuse of cocaine and androgenic-anabolic steroids (AASs) has become a serious public health problem. Despite reports of an increase in the incidence of simultaneous abuse of these substances, potential toxic interactions between cocaine and AASs are poorly known. In one study, it was investigated the effects of either single or combined administration of testosterone and cocaine for one or 10 consecutive days on autonomic (arterial pressure, heart rate and tail cutaneous temperature) and neuroendocrine (plasma corticosterone) responses induced by acute restraint stress in rats. Combined administration of testosterone and cocaine for 10 days reduced the increase in heart rate and plasma corticosterone level, as well as the fall in tail skin temperature induced by restraint stress. Furthermore, repeated administration of cocaine inhibited the increase in arterial pressure observed during restraint, and this effect was not affected by coadministration of testosterone. Ten-day combined administration of testosterone and cocaine increased basal values of arterial pressure. Moreover, chronic administration of testosterone induced rest bradycardia and elevated basal level of plasma corticosterone. One-day single or combined administration of the drugs did not affect any parameter investigated. In conclusion, the present study demonstrated that combined administration of testosterone and cocaine changed the autonomic and neuroendocrine responses to acute restraint stress. These findings suggest that interaction between AASs and cocaine may affect the ability to cope with stressful events [12160].
SIDE EFFECTS OF TESTOSTERONE AND OTHER ANABOLIC STEROIDS

Overviews

Depending on duration and dosage of administration, AAS can cause various adverse effects marked by virilization and hirsutism in women, deepening of voice (permanent) as well as testicular atrophy (reversible) and gynaecomastia in men. Furthermore, ASS abuse in adolescence may induce premature epiphyseal fusion resulting in stunted growth. Also, via both genomic and non-genomic pathways, AAS can trigger aggressive behaviour and hostility as well as mood disturbances such as depression and hypomania. However, the development of side-effects induced by supraphysiological doses of AAS correlate, at least as regards the psychiatric symptoms, to the dose and duration of abuse. Considerable changes of lipid profile result in decrease in HDL and increase in LDL concentration, as well as diabetes mellitus, arterial hypertension and cardiac morbidity have been associated with AAS abuse. The most typical cardiac abnormality is left ventricular hypertrophy with fibrosis, while rare cardiovascular substrate is eosinophilic myocarditis. Nevertheless, the cause–effect relationship between AAS abusers and cardiac death has not been conclusively established, though ventricular arrhythmias and congestive heart failure have often been reported, and thrombotic complications (intracardial thrombosis, stroke, venous thromboembolism, cerebral venous sinus thrombosis) have been markedly associated with AAS abusers [12011].

Anabolic steroids have been linked to many adverse health effects, including cardiomyopathy, cerebrovascular events, hypertension, aggression, prostatic hypertrophy, and cholestatic liver injury. In one study, 96 percent of users of anabolic steroids reported at least one side effect. However, the absolute risks have not been fully evaluated. Users typically take them in “cycles” that vary in length (often 8-12 weeks) to minimise side effects, with a similar amount of time “off cycle” [12025].

Anabolic-androgenic steroids (AAS) administration has been shown to be associated with cardiovascular side effects, urogenital problems, that is, gynecomastia, impotency, hepatotoxicity, hepatocellular carcinoma, and neuropsychiatric disorders, that is, aggressiveness and depression. Cardiovascular adverse effects of AAS abuse have been reported sporadically as case reports of hypertension, myocardial infarction (MI) and stroke, dysrhythmia, cardiomyopathy, and sudden cardiac death in body builders with long-term AAS abuse in the recent years. Case reports on hard atherosclerotic endpoints (sudden cardiac death, MI or stroke) comprise young AAS abusers without preexistent cardiac risk factors, suggesting that a high AAS dose imposes additional independent risk to conventional cardiovascular risk factors. It has been reported a more than four times higher incidence of early death in professional athletes abusing AAS compared to the age- and sex-matched general population, in a 12-years prospective observation. In addition to the potential risk associated with AAS abuse, it is notable that therapeutic treatment with AAS in hypogonadic men has recently been shown to be linked with a higher cardiovascular event rate. This important finding underscores that there is a delicate balance between benefits and risks related to AAS use as a treatment option for patients suffering from androgen deficiency. Adding up clinical AAS use and illegal AAS abuse rates represent a new wave of AAS-associated cardiovascular adverse consequences, in which early diagnosis can reduce health burden. The wave of now middle-aged ex-AAS abusers and the increasing group of the elderly AAS users necessitates more detailed documentation of the underlying pathophysiology to enhance insight into the delicate balance between benefit and harm. Owing to the obvious ethical reasons, prospective double-blinded human studies are not
easily justified. Accordingly, retrospective case-control studies of cohorts and prospectively follow-up of such cohorts seem to be the most feasible strategy for human studies to obtain more conclusive epidemiologic data [12125].

There are limited data on the short-term complication of AAS use with most data involving case reports. The long-term health effects of chronic AAS abuse are not well defined because of the difficulty in studying illicit drug use and the highly-variable dosages involved with AAS abuse. Clinical and laboratory studies indicate that the administration of AASs causes physiologic changes, primarily in the liver, reproductive system, and serum lipids. The use of AAS produces an unfavorable change in the blood lipid profile (i.e. elevated low-density lipoprotein, reduced high-density lipoprotein) with potentially increased risk of coronary heart disease; although conflicting, some data suggest left ventricular hypertrophy may persist after cessation of AAS use as a result of elevated blood pressure during use. Other potential adverse effects include glucose intolerance (i.e. increased peripheral insulin resistance), hyperinsulinism, behavioral and mood changes, cerebrovascular accidents, prostate abnormalities, edema, and immune dysfunction. Most physiologic changes associated with AAS use are reversible within several months of the cessation of AAS use [13003].

**Short-term side effects**

The attraction of anabolic agents apparently continues to be unconfined among cheating athletes and recreational sportsmen and women despite numerous comprehensive and new reports on health risks attributed to the abuse of AAS, ranging from acne fulminans over cardiovascular issues to increased risk of breast and Leydig cell cancer as well as psychic disorders and dependence [13009].

Most of the adverse effects following the use of AASs result from the enhancement of normal physiologic response to testosterone by either direct receptor agonist activity or suppression of steroid biosynthesis. In general, toxic effects associated with AAS abuse involve the following:

- anabolic side effects
- enhanced androgenic effects
- estrogenic side effects
- antiandrogenic effects from the suppression of the hypothalamus-pituitary-adrenal/gonadal axes
- hepatotoxicity
- neuropsychiatric effects

Methodological issues limit the determination of the toxic effects of illicit AAS use including the extraordinary doses and types of AAS used by athletes compared with medical use, reporting bias of self-reports, the paucity of well-documented pathologic findings, and the lack of well-defined postmortem markers of AAS use. Most medical data on the toxic effects of AAS abuse involve case reports rather than epidemiologic studies. Pathologic abnormalities from AAS abuse are best-documented in the cardiovascular system, reproductive system, liver, and serum lipids. Animal studies suggest that AAS can cause dysplasia of collagen fibrils and decreased tensile strength, and potentially the use of these drugs could cause disruption of connective tissue [13003].

**Anesthesia risk**
A strong tendency toward body enhancement and body forming in western industrial societies makes it more likely for each anesthesiologist to get involved in the care of bodybuilders. These patients quite frequently consume androgenic anabolic steroids, human growth hormone and other drugs or substances which are believed to accelerate muscle gain. Cardiovascular, hepatic, psychiatric, hormonal and infectious side effects or complications are common and rarely monitored by health care professionals. The anesthesia risk is not exactly known but seems to be determined mainly by cardiovascular events like myocardial ischemia and dysrhythmias [08143].

**Different effects of different anabolic steroids**

All synthetic AAS are derived from testosterone. They have a carbon skeleton with 4 fused rings; most have 19 carbons. Modifications include hydroxylation at the C10 position to increase receptor binding affinity (e.g. nandrolone) esterification to slow release into circulation (e.g. testosterone cypionate), or alkylation at the C17 position to permit moral delivery by reducing first-pass metabolism in the liver (e.g. oxymetholone). AAS can be converted to highly-androgenic or estrogenic metabolites. For testosterone, dihydroteosterone is the principle androgenic product; estradiol is the major estrogenic metabolite. Non-aromatizable AAS (e.g. drostanolone) have fewer estrogenic side-effects such as gynecomastia. Non-reducible AAS (e.g. oxandrolone) have fewer androgenic side-effects such as acne, baldness, and prostatic hypertrophy because they have lower binding affinity for the androgen receptor. For athletes subject to drug testing, a key drawback of synthetic AAS is that their use is easily detected, since their metabolites are not normally present. An extended precompetition wash-out period is necessary to avoid a positive test. This varies with the route of administration and the half-life of the individual AAS. However, long-acting AAS such as nandrolone can be detected for at least 6 months. By contrast, the urinary metabolites of exogenous and endogenous testosterone are virtually identical. Many athletes take long-acting testosterone esters such as testosterone propionate. Although esterification prolongs the half-life in circulation, the active steroid is still testosterone [12100].

Doping is becoming an everyday problem in sports medicine. Its main feature is its universality: it concerns all sports, even the most unexpected, from cycling to billiards; all countries are affected with certain continental preferences with regards to the substances used; it is seen in all levels of competition, both in amateurs and professionals. Doping is observed early on, even in childhood. Many substances are used and they are increasingly available: all bodily functions are targeted: cerebral, metabolic, cardiovascular, respiratory, haematological and, in the near future, genetic. Detection of doping is difficult and unpredictable in a legislative environment which is gradually improving. The different modes of action of the doping substances often target the cardiovascular system, especially with regards to their potential complications: hypertension, arrhythmias, thrombosis, coronary artery and peripheral artery diseases and also cardiomyopathies. Every cardiologist should therefore be aware of the problem, even outside the context of sport, as it may impact on daily cardiological practice [06065].

**Toxicokinetics**

Most of the data on the kinetics of testosterone and AASs is derived from the pharmacokinetics of these compounds in animals or in hypogonadal males receiving therapeutic doses of AASs. There are few data on the toxicokinetics of AASs in individuals abusing AASs at doses up to 10-100 times the therapeutic dose. Despite the rapid
absorption of testosterone, the systemic bioavailability of oral testosterone is low as a result of extensive first-pass hepatic metabolism. Structural modifications of testosterone produce synthetic testosterone derivatives (anabolic-androgenic steroids), which increase bioavailability and prolong the duration of action. Alkylation of the 17-alpha position of testosterone produces oral AAS, whereas esterification of the 17-beta position results in injectable AAS (e.g. lipid-soluble cypionate or enanthat). The duration of action of these esters depends on the rate of absorption from the site of administration as determined by the chain length of the acid moiety and the formulation. Hydrolysis of these esters in vivo prolongs the duration of action compared with testosterone. Anabolic androgenic steroids can diffuse across the skin and mucous membranes, allowing other delivery modes including transdermal patches, nasal sprays, and buccal tablets. Following oral administration of 120 mg testosterone undecanoate, volunteer studies in dicate that plasma concentrations of testosterone are detectable for about 1-6 h after administration using gas chromatography–tandem massspectrometry. There are dramatic individual variations (i.e.10-fold) in the peak total plasma testosterone concentrations. In a study of 61 eugonadal men receiving long-acting gonadotropin-releasing hormone agonist to suppress endogenous testosterone secretion, the mean nadir testosterone concentrations ranged from 2.53 to 23.7 ng/mL following weekly injections of testosterone enanthate doses of 25-600 mg for 20 weeks [13003].

Anabolic-androgenic steroids are bound in the plasma to sex-hormone-binding globulins. Although testosterone is highly protein bound (i.e. 98 %) in plasma, the binding of AAS to sex-hormone-binding globulins is highly variable base done animal studies. The metabolism of endogenous testosterone involves the conversion to the estrogenic compound, estradiol, via steroid aromatase and the androgenic compound, 5alpha-dihydrotestosterone, via 5alpha–steroid-reductase. Comparatively, the biotransformation of AASs is quite complex. The initial and rateliming step in testosterone metabolism is reduction of the C4-C5 double bond on the A-ring with 5alpha-reductase and 5beta-reductase. Hydroxylation of testosterone by CYP450 isoenzymes results in the formation of a variety of minor urinary metabolites of testosterone. Single-dose human excretion studies indicate that 6-beta-hydroxylation is also a minor pathway for the biotransformation of boldenone (17beta-hydroxyandrost-1,4-dien-3-one) and 17alpha-methyl-testosterone. However, 6beta-hydroxylation of the B-ring is the major metabolic pathway for 4-chloro-1,2-dehydro-17alpha-methyltestosterone, methandienone, and fluoxymesterone because the presence of a C1-C2 double bond in the former 2steroids and the C9 alpha-fluorine atom in the latter compound blocks A-ring reduction. Metabolic changes (e.g. 12-hydroxylation) of AASs at the C-ring are minor. D-ring metabolism by the enzymatic oxidation of 17beta-hydroxysteroid-dehydrogenase to form the corresponding 17-ketosteroid is a major metabolic pathway for testosterone and all AAS swith secondary 17beta-hydroxy groups (e.g. boldenone, clostebol, drostanolone, mesterolone, methenolone, nandrolone, norclostebol, and stenbolone). The main urinary metabolites of testosterone are androstanone (3alpha-hydroxy-5alpha-androstan-17-one), etiocholanolone (3alpha-hydroxy-5beta-androstan-17-one), epiandrosterone (3beta-hydroxy-5alpha-androstan-17-one), 5alpha-androstane-3alpha, 17beta-diol, and 5beta-androstane-3alpha,17beta-diol [13003].

In individuals without AAS use, only small amounts (i.e. about 1 %) of endogenous testosterone appear unchanged in the urine. Phase II conjugation reactions couple AASs and associated metabolite swith glucuronic acid or sulfate before excretion in the urine. The vast majority (i.e. about 90 %) of the absorbed dose of testosterone appears in the urine as glucuronide or sulfate conjugates. In a study of 8 hypogonadal males, the terminal elimination half-lives of 500 mg and 1000 mg intramuscular doses of testosterone undecanoate were 18.3 and 2.3 days and 23.7 and 2.7 days, respectively. The mean residence times were 21.7 and 1.1 days and 23.0 and 0.8 days, respectively. Not all anabolic
steroids undergo phase II reactions. Unconjugated AASs in human urine include oxandrolone, fluoxymesterone, 4-chloro-1,2-dehydro-17alpha-methyltestosterone, and formebolone, along with metabolites of oxandrolone, methandienone, and stanozolol. There is very limited (i.e., about 5%) enterohepatic recirculation of testosterone. Anabolic-androgenic steroids readily cross the placenta [13003].

**Impurities in illicit samples of anabolic steroids**

There are few data on the purity of illicit samples of AASs as a result of the lack of regulation. Consequently, there are no assurances that the chronic AAS abuser knows the dose or type of AAS. The difficulty determining doses used by AAS abusers limits the ability of studies to elucidate the effect of AAS abuse. Frequently, illicit samples of AASs do not contain declared ingredients or concentrations of ingredients. Analysis of 70 products confiscated from illegal sources demonstrated 17 (35%) of the 48 steroidal compounds did not contain labeled ingredients as measured by liquid chromatography-tandem mass-spectrometry, gas chromatography mass-spectrometry with nitrogen-phosphorus detection, gel-electrophoresis, and immunological tests. Visual inspection did not distinguish original products from counterfeits [13003].

**Anabolic steroids’ impact on the cardiovascular system**

**Overview**

The use of doping substances and methods is extensive not only among elite athletes, but also among amateur and recreational athletes. Many types of drugs are used by athletes to enhance performance, to reduce anxiety, to increase muscle mass, to reduce weight or to mask the use of other drugs during testing. However, the abuse of doping substances and methods has been associated with the occurrence of numerous health side-effects. The adverse effects depend on the type of the consumed drug, as well as the amount and duration of intake and the sensitivity of the body, since there is a large inter-individual variability in responses to a drug. Usually the doses used in sports are much higher than those used for therapeutic purposes and the use of several drugs in combination is frequent, leading to higher risk of side-effects. Among biomedical side-effects of doping, the cardiovascular ones are the most deleterious. Myocardial infarction, hyperlipidemia, hypertension, thrombosis, arrhythmogenesis, heart failure and sudden cardiac death have been noted following drug abuse. This paper reviews the literature on the adverse cardiovascular effects after abuse of prohibited substances and methods in athletes, aiming to inform physicians, trainers and athletes and to discourage individuals from using drugs during sports [06063].

The intake of anabolic-androgenic steroids (AAS) leads to an increase in skeletal muscle mass and is prohibited as a doping measure in sport. AAS abuse is not limited to competitive athletes. It is also prevalent in subjects who do body building or resistance training for cosmetic reasons only. Out of the numerous and partly serious side effects, the cardiovascular ones maybe most important. An increase in left ventricular muscle mass is well documented, and some researchers have even reported concentric hypertrophy. By contrast, resistance training without AAS intake does not lead to increased ventricular wall thickness. AAS do not affect the systolic function of the left ventricle, whereas diastolic function might be impaired. Different ultrastructural myocardial alterations have been documented in animal studies. In addition, AAS can induce arterial hypertension. Blood clotting and fibrinolysis are negatively affected, and several case studies of thrombi exist in
young strength athletes. Changes in the concentration of blood lipoproteins, particularly a reduction in vessel-protective HDL cholesterol, can lead to early atherosclerosis. Many case reports exist about cardiac deaths in seemingly healthy subjects-most often body builders and other strength athletes. In fatal and nonfatal myocardial infarctions patent coronary arteries were proven frequently. Besides the prothrombotic effects of AAS, an impaired endothelial function and vasospasms are discussed hypothetically as pathomechanisms. Also, cardiomyopathies can occur due to AAS abuse. On the basis of the described possible cardiovascular side effects, it can be concluded that in cases of sudden cardiac deaths in young athletes, a misuse of AS should be excluded [06064].

Scientific data on the cardiac and metabolic complications of AAS abuse are divergent and often conflicting. A total of 49 studies describing 1,467 athletes were reviewed to investigate the cardiovascular effects of the abuse of AAS. Although studies were typically small and retrospective, some associated AAS abuse with unfavorable effects. Otherwise healthy young athletes abusing AAS may show elevated levels of low-density lipoprotein and low levels of high-density lipoprotein. Although data are conflicting, AAS have also been linked with elevated systolic and diastolic blood pressure and with left ventricular hypertrophy that may persist after AAS cessation. Finally, in small case studies, AAS abuse has been linked with acute myocardial infarction and fatal ventricular arrhythmias. In conclusion, recognition of these adverse effects may improve the education of athletes and increase vigilance when evaluating young athletes with cardiovascular abnormalities [10305].

Abuse of anabolic androgenic steroids (AAS) has been linked to a variety of different cardiovascular side effects. In case reports, acute myocardial infarction is the most common event presented, but other adverse cardiovascular effects such as left ventricular hypertrophy, reduced left ventricular function, arterial thrombosis, pulmonary embolism and several cases of sudden cardiac death have also been reported. However, to date there are no prospective, randomized, interventional studies on the long-term cardiovascular effects of abuse of AAS. In one review it was studied the relevant literature regarding several risk factors for cardiovascular disease where the effects of AAS have been scrutinized:

- echocardiographic studies show that supraphysiologic doses of AAS lead to both morphologic and functional changes of the heart. These include a tendency to produce myocardial hypertrophy, a possible increase of heart chamber diameters, unequivocal alterations of diastolic function and ventricular relaxation, and most likely a subclinically compromised left ventricular contractile function
- AAS induce a mild, but transient increase of blood pressure. However, the clinical significance of this effect remains modest
- AAS confer an enhanced pro-thrombotic state, most prominently through an activation of platelet aggregability. The concomitant effects on the humoral coagulation cascade are more complex and include activation of both pro-coagulatory and fibrinolytic pathways
