Previous studies of bioactive molecules in platelet-rich plasma (PRP) have documented growth factor concentrations that promote tissue healing. However, the effects of leukocytes and inflammatory molecules in PRP have not been defined. The hypothesis for one study was that the concentration of growth factors and catabolic cytokines would be dependent on the cellular composition of PRP. Platelet-rich plasma was made from 11 human volunteers using 2 commercial systems: Arthrex ACP (Autologous Conditioned Plasma) Double Syringe System (PRP-1), which concentrates platelets and minimizes leukocytes, and Biomet GPS III Mini Platelet Concentrate System (PRP-2), which concentrates both platelets and leukocytes. Transforming growth factor-beta1 (TGF-beta1), platelet-derived growth factor-AB (PDGF-AB), matrix metalloproteinase-9 (MMP-9), and interleukin-1beta (IL-1beta) were measured with enzyme-linked immunosorbent assay (ELISA). The PRP-1 system consisted of concentrated platelets (1.99×) and diminished leukocytes (0.13×) compared with blood, while PRP-2 contained concentrated platelets (4.69×) and leukocytes (4.26×) compared with blood. Growth factors were significantly increased in PRP-2 compared with PRP-1. The PRP-1 system did not have a higher concentration of PDGF-AB compared with whole blood. Catabolic cytokines were significantly increased in PRP-2 compared with PRP-1. Significant, positive correlations were found between TGF-beta1 and platelets, PDGF-AB and platelets, MMP-9 and neutrophils, IL-1beta and neutrophils, and IL-1beta and monocytes. It was thus concluded that growth factor and catabolic cytokine concentrations were influenced by the cellular composition of PRP. Platelets increased anabolic signaling and, in contrast, leukocytes increased catabolic signaling molecules. Platelet-rich plasma products should be analyzed for content of platelets and leukocytes as both can influence the biologic effects of PRP. Depending on the clinical application, preparations of PRP should be considered based on their ability to concentrate platelets and leukocytes with sensitivity to pathologic conditions that will benefit most from increased platelet or reduced leukocyte concentration [11468].

The therapeutic use of autologous platelet-rich plasma constitutes a relatively new biotechnology that has been a breakthrough in the stimulation and acceleration of soft-tissue and bone healing. The efficiency of this process lies in the local and continuous delivery of a wide range of growth factors and proteins, mimicking the needs of the physiological wound healing and reparative tissue processes. Consequently, the application of platelet-rich plasma has been extended to many different fields, including orthopedics, sports medicine, dentistry, cosmetic and periodontal medicine and cosmetic, plastic and maxillofacial surgery. This article highlights the use of this technology and discusses some of the obstacles and challenges that need to be addressed to maintain progress in this field [06169].
Mechanical stimulation improves the repair of ruptured tendons. Injection of a platelet concentrate (platelet-rich plasma, PRP) can also improve repair in several animal models. In a rat Achilles tendon transection model, 1 postoperative injection resulted in increased strength after 4 weeks. Considering the short half-lives of factors released by platelets, this very late effect calls for an explanation. It was studied the effects of platelets on Achilles tendon regenerates in rats 3, 5 and 14 days after transection. The tendons were either unloaded by Botulinum toxin A (Botox) injections into the calf muscles, or mechanically stimulated in activity cages. No Botox injections and ordinary cages, respectively, served as controls. Repair was evaluated by tensile testing. At 14 days, unloading (with Botox) abolished any effect of the platelets and reduced the mechanical properties of the repair tissue to less than half of normal. Thus, some mechanical stimulation is a prerequisite for the effect of platelets at 14 days. Without Botox, both activity and platelets increased repair independently of each other. However, at 3 and 5 days, platelets improved the mechanical properties in Botox-treated rats. It was interpreted that platelets influence only the early phases of regeneration, but this allows mechanical stimulation to start driving neo-tendon development at an earlier time point, which kept it constantly ahead of the controls [06170].

Platelet-rich plasma (PRP) is an autologous blood product used to treat acute and chronic tendon, ligament, and muscle injuries in over 86,000 athletes in the United States annually. The World Anti-Doping Agency (WADA) banned intramuscular PRP injections in competitive athletes in 2010 because of concerns that it may increase performance-enhancing growth factors. The ban on PRP was removed in 2011 because of limited evidence for a systemic ergogenic effect of PRP, but the growth factors within PRP remain prohibited. One study aimed to quantify the effect of PRP injection on systemic growth factors with performance-enhancing effects and to identify molecular markers to detect treated athletes. Six ergogenic growth factors monitored by WADA-human growth hormone (hGH), insulin-like growth factor-1 (IGF-1), insulin-like growth factor binding protein-3 (IGFBP-3), basic fibroblast growth factor (bFGF or FGF-2), vascular endothelial growth factor (VEGF), and platelet-derived growth factor-BB (PDGF-BB) were measured in 25 patients before (baseline) and at 0.25, 3, 24, 48, 72, and 96 hours after intratendinous leukocyte-rich PRP injection. Eating and exercise were prohibited for 3 hours before testing. Growth factors were quantified by enzyme-linked immunosorbent assay, and the change relative to each patient's baseline was calculated. Relative to serum, PRP contained significantly more bFGF (226 vs 5 pg/mL), VEGF (1426 vs 236 pg/mL), and PDGF-BB (26,285 vs 392 pg/mL), but IGF-1 and hGH were not elevated. Serum levels increased significantly for IGF-1 at 24 and 48 hours, for bFGF at 72 and 96 hours, and for VEGF at 3, 24, 48, 72, and 96 hours after PRP injection. Additionally, VEGF was increased in all 25 patients after PRP treatment. It was concluded that serum IGF-1, VEGF, and bFGF levels are significantly elevated after PRP injection, supporting a possible ergogenic effect of PRP. An indirect marker for hGH doping, the product of IGFBP-3 × IGF-1, also significantly increased after PRP. Platelet-rich plasma appears to trigger an increase in circulating growth factors through activating biological pathways rather than by serving as a vehicle for the direct delivery of presynthesized growth factors. Elevated VEGF was observed in all patients after PRP, and ≥88 percent of patients had elevated VEGF at each time point from 3 to 96 hours after PRP, suggesting that VEGF may be a sensitive molecular marker to detect athletes recently treated with PRP. This is the first and only adequately powered study of the systemic effects of PRP. It was provided evidence that VEGF could serve as a useful molecular marker to detect athletes treated with PRP [12267].

Platelet rich plasma (PRP) is a powerful new biologic tool in sports medicine. PRP is a fraction of autologous whole blood containing and increased number of platelets and a wide variety of cytokines such as platelet derived growth factor (PDGF), vascular endothelial growth factor (VEGF) and transforming growth factor beta-1 (TGF-B1), fibroblast growth factor (FGF), Insulin-like growth factor-1 (IGF-1) among many others. Worldwide interest in
this biologic technology has recently risen sharply. Basic science and preclinical data support the use of PRP for a variety of sports related injuries and disorders. The published, peer reviewed, human data on PRP is limited. Although the scientific evaluation of clinical efficacy is in the early stages, elite and recreational athletes already use PRP in the treatment of sports related injuries. Many questions remain to be answered regarding the use of PRP including optimal formulation, including of leukocytes, dosage and rehabilitation protocols. In one review, a classification for platelet rich plasma is proposed and the in-vitro, preclinical and human investigations of PRP applications in sports medicine will be reviewed as well as a discussion of rehabilitation after a PRP procedure. The regulation of PRP by the World Anti-Doping Agency will also be discussed. PRP is a promising technology in sports medicine; however, it will require more vigorous study in order to better understand how to apply it most effectively [12268].

There is strong evidence that exercise affects platelet haemostasis factors, but this potential effect on growth factor concentrations in platelet-rich plasma (PRP) has never been studied. In addition, there is a paucity of studies focusing on the effects of activating agents used in conjunction with PRP. The first aim of this study was to evaluate the effect of exercise on platelet and platelet-derived growth factors (PDGF)-AB, hepatocyte growth factor (HGF), insulin-like growth factor-1 (IGF-1) and vascular endothelial growth factor (VEGF) concentrations in PRP. The second aim was to study the effect of the activating agent calcium chloride (CaCl₂) on growth factor concentration in relation to different exercise states. Ten healthy participants performed 1 h of submaximal exercise with blood being withdrawn immediately pre, post and 18 h following. PRP was prepared in each condition in both an activated CaCl₂ and non-activated form. Concentrations of PDGF-AB, HGF, IGF-1 and VEGF were evaluated using standard ELISA systems. Exercise had no significant effect on platelet concentration, but significantly suppressed both VEGF and PDGF-AB concentrations. Exercise state had no significant effect on IGF-1 or HGF concentration. Activation with CaCl₂ resulted in a significant increase in PDGF-AB and IGF-1 concentrations, unchanged VEGF and significantly reduced HGF concentrations. It was concluded that exercise significantly impacts on PDGFs in PRP with significantly reduced concentrations of VEGF and PDFG-AB. Furthermore, the activation of PRP with CaCl₂ results in a differentiated GF release from platelets. These relevant factors can potentially influence outcome in daily clinical practice and are recommended to be accounted for in future study design [13342].

Muscle strains are one of the most common injuries induced by sporting activities. According to the severity and location of the lesion different treatments can be delivered, including growth factor therapy through administration of autologous platelet-rich plasma (PRP) during the early period following the injury. PRP is easily obtained from centrifugation of the patient's own blood and contains high concentration of platelets, which release growth factors and cytokines by adding thrombin. This process improves tissue repair in cartilage, tendons, ligaments, muscles and bones by down-regulation of inflammatory mediators and synthesis of regenerative proteins. Furthermore, PRP has antimicrobial properties that may contribute to reduce pain⁸ and to prevent infections. PRP is administered by local injection or applied directly in the form of gel into the site of injury. Initially many PRP injections were done without imaging guidance by either palpating the site of tenderness or using a peppering technique to distribute the gel uniformly. The use of ultrasound (US)-guided injection has led to a more precise and direct visualisation of the exact site of the pathology and of the injected blood products in the region of lesion. Furthermore, sonography allows the position of the needle position to be adjusted in real time¹⁰-¹³. Considering these properties, local US-guided injection of PRP may improve the repair of tendons, muscles, ligaments, cartilage and bone injuries. The aim of one study was to demonstrate the efficacy of ultrasound-guided injection of platelet-rich plasma in muscle strains and the absence of
side effects. Fifty-three recreational athletes were enrolled in the study. The patients were recruited from the Emergency Room in the University Hospital at Parma according to a predefined protocol. Every patient was assessed by ultrasound imaging to evaluate the extent and degree of muscle injuries. Only grade II lesions were treated with three ultrasound-guided injections of autologous platelet-rich plasma every 7 days. Platelet concentrate was produced according to standard methods, with a 10 percent variability in platelet count. The platelet gel for clinical use was obtained by adding thrombin to the concentrates under standardised conditions. Outcomes assessed were: pain reduction, muscle function recovery and return to sports activity, ultrasound-imaging tissue healing, relapses, local infections, and any side effect during the treatment. In all cases muscle lesions healed fully on ultrasound-imaging, the pain disappeared, and muscle function recovery was documented with a return to sports activity. A single patient had a relapse 1 year after treatment. Platelet-rich plasma injected into the injury site is one of the most important factors rendering the treatment effective. To maximise its efficacy the preliminary ultrasound must be done accurately to localise the lesion and guide the needle into the corresponding lesion. According to the current results, which document full muscle recovery and no relapse except for one case, platelet-rich plasma ultrasound-guided injection represents a valid mini-invasive treatment for muscle injuries [13343].

Platelet-rich plasma (PRP) is an autologous blood product used to treat acute and chronic tendon, ligament, and muscle injuries in over 86,000 athletes in the United States annually. The World Anti-Doping Agency (WADA) banned intramuscular PRP injections in competitive athletes in 2010 because of concerns that it may increase performance-enhancing growth factors. The ban on PRP was removed in 2011 because of limited evidence for a systemic ergogenic effect of PRP, but the growth factors within PRP remain prohibited. To quantify the effect of PRP injection on systemic growth factors with performance-enhancing effects and to identify molecular markers to detect treated athletes six ergogenic growth factors monitored by WADA-human growth hormone (hGH), insulin-like growth factor-1 (IGF-1), insulin-like growth factor binding protein-3 (IGFBP-3), basic fibroblast growth factor (bFGF or FGF-2), vascular endothelial growth factor (VEGF), and platelet-derived growth factor-BB (PDGF-BB)-were measured in 25 patients before (baseline) and at 0.25, 3, 24, 48, 72, and 96 hours after intratendinous leukocyte-rich PRP injection. Eating and exercise were prohibited for 3 hours before testing. Growth factors were quantified by enzyme-linked immunosorbent assay, and the change relative to each patient's baseline was calculated. Relative to serum, PRP contained significantly more bFGF (226 vs 5 pg/mL), VEGF (1426 vs 236 pg/mL), and PDGF-BB (26,285 vs 392 pg/mL), but IGF-1 and hGH were not elevated. Serum levels increased significantly for IGF-1 at 24 and 48 hours, for bFGF at 72 and 96 hours, and for VEGF at 3, 24, 48, 72, and 96 hours after PRP injection. Additionally, VEGF was increased in all 25 patients after PRP treatment. It was concluded that serum IGF-1, VEGF, and bFGF levels are significantly elevated after PRP injection, supporting a possible ergogenic effect of PRP. An indirect marker for hGH doping, the product of IGFBP-3 × IGF-1, also significantly increased after PRP. Platelet-rich plasma appears to trigger an increase in circulating growth factors through activating biological pathways rather than by serving as a vehicle for the direct delivery of presynthesized growth factors. Elevated VEGF was observed in all patients after PRP, and ≥88 percent of patients had elevated VEGF at each time point from 3 to 96 hours after PRP, suggesting that VEGF may be a sensitive molecular marker to detect athletes recently treated with PRP. Thus, there are present evidence that PRP contains and may trigger systemic increases in substances currently banned in competitive athletes. Finally, it was provided evidence that VEGF could serve as a useful molecular marker to detect athletes treated with PRP [13344].

Platelet-rich plasma (PRP) is an autologous concentration of blood-derived human platelets in a small volume of plasma. The types of PRP vary according to the commercial preparation
system used, the platelet concentration, or the anticoagulant or activator used. Autologous conditioned plasma is an autologous concentration of human platelets in plasma 2 to 4 times greater than that which is found in blood at baseline. Platelets are important to the normal healing response of tissue by the local secretion of growth factors and recruitment of reparative cells in an area of injury. PRP is theorized to create an optimal healing environment in a region of tissue injury. This is a literature review of currently published studies using PRP in orthopedic injuries. It was performed a literature search in PubMed and Medline in April 2013 and concluded that given the number of variations of PRP available and the lack of high-level published studies, there is insufficient evidence to conclusively support its clinical use [13345].

Platelet-rich plasma (PRP) as a clinical treatment for bone, muscle, tendon, and cartilage injury has gained popularity in the field of orthopedic sports medicine. The use of a patient's own blood is an appealing aspect of PRP treatment, as the resulting plasma preparation is considered relatively benign in comparison with more common, potentially caustic treatments such as corticosteroids and anesthetics. Although appealing, the autologous nature of PRP introduces variability to plasma preparations, creating challenges for both the researcher and the clinician. Differences in patients at the time of blood draw result in plasma preparations that vary within as well as between patients. This variability is compounded by the multitude of protocols and devices available for procuring PRP. The variability of components and its effects on dosage should be considered in single or consecutive treatments of PRP [13346].

Platelet-rich plasma (PRP) has been advocated for the biological augmentation of tissue healing and regeneration through the local introduction of increased levels (above baseline) of platelets and their associated bioactive molecules. In theory, the increased levels of autologous growth factors and secretory proteins provided by the concentrated platelets may enhance the wound healing process, especially in degenerative tissues or biologically compromised individuals. Although PRP has been increasingly utilized in the treatment of a variety of sports-related injuries, improvements in healing and clinical outcomes have not been universally reported. One reason for this may be the fact that all PRP preparations are not the same. Variations in the volume of whole blood taken, the platelet recovery efficacy, the final volume of plasma in which the platelets are suspended, and the presence or absence of white blood cells, and the addition of exogenous thrombin to activate the platelets or calcium chloride to induce fibrin formation, can all affect the character and potential efficacy of the final PRP product. One article reviewed the basic principles involved in creating PRP and examine the potential basic scientific significance of the individual blood components contained in the various forms of PRP currently used in sports medicine [13347].

Platelets in PRP

Platelet rich plasma (PRP) therapies require blood to be processed prior to application, however, the full assessment of the output of platelet sequestration devices is lacking. In this study the products of the Autologous Fluid Concentrator (Circle BiologicsTM, Minneapolis, MN) and the Gravitational Platelet Separation System (GPS, Biomet, Warsaw, IN, USA) were evaluated in terms of platelet viability and PRP constituents. The AFC and GPS produced 6.4 mL and 6.3 mL of PRP, with platelet recovery of 46 and 60 percent producing fold increases of platelets of 4.19 and 5.19, respectively. Fibrinogen concentration was increased above baseline PPP produced with the AFC. pH was lower for both of the processed samples than for whole blood. White Blood Cell count was increased around 5 fold. Functional tests showed preserved viability with both devices. This represents essential
knowledge that every treating physician should have before they can confidently administer PRP therapy produced by any method. These are the first published results of platelet function for the GPS system and the first performance results of the AFC system. The PRP produced is classified according to broad classifications as Leukocyte-PRP (L-PRP) for both devices [13348].

A randomized study

Animal studies have shown that local application of platelet-rich plasma (PRP) stimulates tendon repair. Preliminary results from a retrospective case series have shown faster return to sports. Thirty patients were recruited consecutively to a randomized study. During surgery, tantalum beads were implanted in the Achilles tendon proximal and distal to the rupture. Before skin suture, randomization was performed, and 16 patients were injected with 10 mL PRP (10 times higher platelet concentration than peripheral blood) whereas 14 were not. With 3-dimensional radiographs (roentgen stereophotogrammetric analysis; RSA), the distance between the beads was measured at 7, 19, and 52 weeks while the patient resisted different dorsal flexion moments over the ankle joint, thereby estimating tendon strain per load. An estimate of elasticity modulus was calculated using callus dimensions from computed tomography. At 1 year, functional outcome was evaluated, including the heel raise index and Achilles Tendon Total Rupture Score. The primary effect variables were elasticity modulus at 7 weeks and heel raise index at 1 year. The mechanical variables showed a large degree of variation between patients that could not be explained by measuring error. No significant group differences in elasticity modulus could be shown. There was no significant difference in heel raise index. The Achilles Tendon Total Rupture Score was lower in the PRP group, suggesting a detrimental effect. There was a correlation between the elasticity modulus at 7 and 19 weeks and the heel raise index at 52 weeks. The results suggest that PRP is not useful for treatment of Achilles tendon ruptures. The variation in elasticity modulus provides biologically relevant information, although it is unclear how early biomechanics is connected to late clinical results [11159].

Rotator cuff

Long-standing rotator cuff tendon tearing is associated with retraction, loss of work capacity, irreversible fatty infiltration, and atrophy of the rotator cuff muscles. Although continuous musculotendinous relengthening can experimentally restore muscular architecture, restoration of atrophy and fatty infiltration is hitherto impossible. Continuous relengthening with pharmacological stimulation of muscle growth using an anabolic steroid or insulin-like growth factor (IGF) can reverse atrophy and fatty infiltration as well as improve the work capacity of chronically retracted rotator cuff muscles in sheep. Sixteen weeks after tenotomy of the infraspinatus (ISP) tendon, atrophy and fatty infiltration had developed in the retracted ISP muscle. The musculotendinous unit was continuously relengthened in 14 sheep during 6 weeks: Four sheep were treated without pharmacological stimulation, 4 with intramuscular administration of an anabolic steroid, and 6 with IGF before final repair and rehabilitation (12 weeks). Changes were documented by intraoperative measurements of muscle work capacity, histology, and computed tomography/magnetic resonance imaging. Musculotendinous relengthening by continuous traction resulted in gains of length ranging from 0.7 cm in the IGF group to 1.3 cm in the control group. Fatty infiltration progressed in all groups, and the muscle's cross-sectional area ranged from 71 to 74 percent of the contralateral side at sacrifice and did not show any differences between groups in weight, volume, histological composition, or work capability of the muscle. The contralateral muscles
in the anabolic steroid group, however, showed significantly higher (mean ± standard deviation) muscle work capacity of 10 ± 0.9 Nm than the contralateral muscles of the control group (6.8 ± 2.4 Nm). This was accompanied by an increased mean muscle fiber area as well as by an unusual gain in the animals' weight after injection of the anabolic steroid. Subcutaneous continuous relengthening of a chronically retracted musculotendinous unit is feasible and advances the retracted musculotendinous junction toward its original position. This does not change the muscle work capacity. Whereas anabolic steroids have been shown to be effective in preventing classic degenerative muscle changes after tendon tears, neither an anabolic steroid nor IGF contributes to regeneration of the muscle once degenerative changes are established. The findings demonstrate that muscle cells lose reactivity to an anabolic steroid and IGF once retraction has led to fatty infiltration and atrophy of the muscle. Retraction of the muscle after tendon tears must be avoided by early repair, particularly in an athlete, as no regeneration can be achieved by mechanical or pharmacological means at this time [12269].

Despite the theoretic basis and interest in using platelet-rich plasma (PRP) to improve the potential for rotator cuff healing, there remains ongoing controversy regarding its clinical efficacy. The objective of one systematic review was to identify and summarize the available evidence to compare the efficacy of arthroscopic rotator cuff repair in patients with full-thickness rotator cuff tears who were concomitantly treated with PRP. It was searched the Cochrane Central Register of Controlled Trials, Medline, Embase, and PubMed for eligible studies. Two reviewers selected studies for inclusion, assessed methodologic quality, and extracted data. Pooled analyses were performed using a random effects model to arrive at summary estimates of treatment effect with associated 95 percent confidence intervals. Five studies (2 randomized and 3 nonrandomized with comparative control groups) met the inclusion criteria, with a total of 261 patients. Methodologic quality was uniformly sound as assessed by the Detsky scale and Newcastle-Ottawa Scale. Quantitative synthesis of all 5 studies showed that there was no statistically significant difference in the overall rate of rotator cuff retear between patients treated with PRP and those treated without PRP (risk ratio, 0.77; 95% confidence interval 0.48 to 1.23). There were also no differences in the pooled Constant score; Simple Shoulder Test score; American Shoulder and Elbow Surgeons score; University of California, Los Angeles shoulder score; or Single Assessment Numeric Evaluation score. It was concluded that PRP does not have an effect on overall retear rates or shoulder-specific outcomes after arthroscopic rotator cuff repair. Additional well-designed randomized trials are needed to corroborate these findings [12270].

Tendopathies

Chronic degenerative tendinopathies are frequent and difficult to treat. Tendon healing and regeneration may be improved by injecting autologous growth factors obtained from the patient’s blood. Autologous growth factors can be injected with autologous whole blood or platelet-rich plasma (PRP). Electronic databases were searched for prospective clinical trials on treatment with autologous growth factors of patients with chronic tendinopathy. Chronic tendinopathy in this study included wrist extensors, flexors, plantar fasciopathy and patellar tendinopathy. Studies examining the treatment of other tendinopathies were not identified. The Physiotherapy Evidence Database score was used to examine the methodological quality of the assessment, and a qualitative analysis was performed with the levels of evidence. There are many proposed treatment options for chronic tendinopathy. Treatments in the form of injections with autologous whole blood or PRP are increasingly used in clinical practice. There are high expectations of these regenerative injections, and there is a clear need for effective conservative therapies. All studies showed that injections of autologous
growth factors (whole blood and PRP) in patients with chronic tendinopathy had a significant impact on improving pain and/or function over time. However, only three studies using autologous whole blood had a high methodological quality assessment, and none of them showed any benefit of an autologous growth factor injection when compared with a control group. At present, there is strong evidence that the use of injections with autologous whole blood should not be recommended. There were no high-quality studies found on PRP treatment. There is limited evidence to support the use of injections with PRP in the management of chronic tendinopathy. There is growing interest in the working mechanisms of autologous growth factors. The amount and mixture of growth factors produced using different cell separating systems are largely unknown and it is also uncertain whether platelet activation prior to injection is necessary. These variables should be taken into account when starting clinical studies. A good experimental model for studying tendinopathy would be helpful for basic research. Future clinical studies using a proper control group, randomization, blinded and validated disease-specific outcome measures for pain and function are needed [10133].

Tendinopathy is a failed healing response of the tendon. Despite an abundance of therapeutic options, very few randomized prospective, placebo-controlled trials have been carried out to assist physicians in choosing the best evidence-based management. Eccentric exercises have been proposed to promote collagen fiber cross-link formation within the tendon, thereby facilitating tendon remodeling. Overall results suggest a trend for a positive effect of eccentric exercises, with no reported adverse effects. Combining eccentric training and shock wave therapy produces higher success rates compared with eccentric loading alone or shock wave therapy alone. The use of injectable substances such as platelet-rich plasma, autologous blood, polidocanol, corticosteroids, and aprotinin in and around tendons is popular, but there is minimal clinical evidence to support their use. The aim of operative treatment is to excise fibrotic adhesions, remove areas of failed healing, and make multiple longitudinal incisions in the tendon to detect intratendinous lesions and to restore vascularity and possibly stimulate the remaining viable cells to initiate cell matrix response and healing. New operative procedures include endoscopy, electrocoagulation, and minimally invasive stripping. The aim of these techniques is to disrupt the abnormal neoinnervation to interfere with the pain sensation caused by tendinopathy. Randomized controlled trials are necessary to better clarify the best therapeutic options for the management of tendinopathy [10472].

The therapeutic use of platelet-rich plasma (PRP) is an autologous biotechnology that relies on the local delivery of a wide range of growth factors and cytokines with the aim of enhancing tissue healing. Understanding both tendon healing and PRP therapies is an area of research that is critically important in developing optimal formulations and protocols to achieve the intended therapeutic effects. It was summarise recent information on the mechanisms inherent to the earliest response to tendon injury. We then describe the positive effect of PRP therapies on tendon healing. Research on tendinopathy has produced several biological hypotheses based on histopathological, biochemical and clinical findings showing that cell apoptosis, angiofibroblastic features or abnormal biochemical adaptations underlie the condition. The article provided insights into early healing mechanisms and the influence of PRP therapies on inflammation, cell migration, angiogenesis and the proliferation and synthesis of extracellular matrix. The knowledge gained helps to better understand and optimize tendon therapies. The use of endogenous therapies has a positive effect on experimental tendon healing. However, several obstacles need to be addressed to optimise medical practice in this field [10473].

**Hamstrings**
Injury to the hamstring muscle complex (HMC) is extremely common in the athletic community. Anatomical and functional aspects of the HMC predispose it to injury, including the fact that the muscles cross two joints and undergo eccentric contraction during the gait cycle. Injury most commonly occurs at the muscle tendon junction but may occur anywhere between the origin and insertion. There is increasing interest in the use of growth factors to accelerate healing after muscle and tendon injury. Animal studies have demonstrated clear benefits in terms of accelerated healing. There are various methods of delivery of the growth factors, all involving the release of growth factors from platelets. These include plasma rich in platelets and autologous blood. Clinical studies in humans are very limited at this stage but are promising. At present the World Anti-Doping Authority bans the intramuscular administration of these agents [10134].

**The knee**

Platelet-rich plasma (PRP) is a natural concentrate of autologous blood growth factors experimented in different fields of medicine in order to test its potential to enhance tissue regeneration. The aim of one study was to explore this novel approach to treat degenerative lesions of articular cartilage of the knee. One hundred consecutive patients, affected by chronic degenerative condition of the knee, were treated with PRP intra-articular injections (115 knees treated). The procedure consisted of 150-ml of venous blood collected and twice centrifugated: 3 PRP units of 5 ml each were used for the injections. Patients were clinically prospectively evaluated before and at the end of the treatment, and at 6 and 12 months follow-up. IKDC, objective and subjective, and EQ VAS were used for clinical evaluation. Statistical analysis was performed to evaluate the significance of sex, age, grade of OA and BMI. A statistically significant improvement of all clinical scores was obtained from the basal evaluation to the end of the therapy and at 6-12 months follow-up. The results remained stable from the end of the therapy to 6 months follow up, whereas they became significantly worse at 12 months follow up, even if still significantly higher respect to the basal level. The preliminary results indicate that the treatment with PRP injections is safe and has the potential to reduce pain and improve knee function and quality of life in younger patients with low degree of articular degeneration [10135].

**Achilles tendon**

Non-insertional Achilles tendinopathy commonly impedes the functioning of active persons. Treatment methods vary, as do their results. The aim of one study was to evaluate the effectiveness of non-insertional Achilles tendinopathy treatment with autologous platelet-rich plasma (PRP). Autologous PRP was injected into the affected Achilles tendon of 14 prospectively selected patients (15 Achilles tendons). Before PRP administration, all patients were evaluated using the American Orthopedic Foot and Ankle Society (AOFAS) scale for the hind foot, and the Victorian Institute of Sport Assessment – Achilles (VISA-A) scale. Ultrasonography (US) and Power-Doppler ultrasonography (PDUS) of the area was also performed. Identical physical and imaging evaluations were performed at 6 weeks, and at 3, 6, and 18 months after injection. During follow up, a significant improvement was observed in the clinical and imaging results. The AOFAS scale improved significantly from a baseline median of 55 points to 96 points at 18 months, while the VISA-A scale improved from a baseline of 24 to 96 in the final evaluations. During the final evaluation, one subject experienced minor pain following prolonged daily activity, while another subject complained of pain following overloading activity. Local, accurate PRP administration improved
symptoms of non-insertional Achilles tendinopathy [10136].

**Muscle injuries**

Muscle strains and contusions are extremely common in sport and account for significant time loss. The healing process can be slow, and reinjury is common. Recently there has been significant interest in the use of platelet-rich plasma (PRP) to enhance healing. There have been many attempts to speed muscle healing. Traditionally, ice, rest, anti-inflammatory medications and rehabilitation have been the mainstays of treatment. The use of non-steroidal anti-inflammatory drugs (NSAIDs) has been questioned. NSAIDs increase the expression of TGF-beta1 and decrease prostaglandin E2, which has a key role in the proliferation and differentiation of satellite cells. Recent studies have shown that NSAIDs likely tip the delicate balance of regeneration versus fibrosis toward fibrosis (scar). PRP has been shown to stimulate cell migration and myofibroblastic differentiation in vitro. Today serious questions remain as when and how to use PRP in muscle injury. A muscle is an actively healing, acutely inflammatory entity, and there remains potential to affect both the timing and the quality of repair adversely. PRP is heterogenous, and it may be that certain types of PRP are more effective than others. The timing, quantity and frequency of injections required are also in question. Given the pathophysiology of muscle healing, if PRP is used, the following can be considered [10137]:

- PRP should not be administered in the first 24 h after injury. Attempts should be made to limit the secondary injury using traditional means of controlling inflammation, namely compression, elevation and ice
- a leucocyte-poor product may mitigate the potentially adverse affects of neutrophils
- a product which includes a higher proportion of plasma may have increased levels of IGF-1 and potentially enhance healing and decrease fibrosis.

The muscle healing process is defined as a complex and dynamic process resulting in the restoration of anatomic continuity and function. This process is characterized by a cascade of events triggered by the tissue injury itself. It is widely accepted that growth factors play a central role in the healing processes by modulating the recruitment, duplication, activation, and differentiation of different cell types. This observation is the basis on which the use of platelet-rich plasma in several circumstances is founded; all of them requiring the activation or the modulation of the tissue repair process. There is an extensive documentation of in vitro and in vivo studies demonstrating the safety and efficacy of growth factors in the muscle healing process. Unfortunately, the precise biological efficacy and the lack of long-term side effects have not been clearly demonstrated. With regard to sports medicine, doping-related issues are still a matter of debate, especially regarding the treatment of muscle injuries. The purpose of one review was to examine the role of growth factors during muscle healing processes and to discuss the implications of platelet-rich plasma in its therapeutic applications. Sports medicine issues are also discussed particularly with regard to antidoping regulations [10471].
GROWTH HORMONE

Overviews

Human growth hormone (GH), but also GH related growth factors like the insulin-like growth factor-1 (IGF-1) are known to be abused in sports. Although the scientific evidence supporting a distinct effect of GH on performance in healthy trained subjects is limited, it has been repeatedly found with athletes or trainers, and the recent introduction of a first test to detect GH doping has led to a number of positive cases. Currently, there is no test for the detection of IGF-1 introduced worldwide, but confiscation of the drug from sports teams can be taken as indirect evidence for its abuse. The major biochemical difficulty for the detection of GH is that the recombinant form is identical in physicochemical properties to the endogenous GH secreted by the pituitary gland. Furthermore, the very short half-life of GH in circulation inherently shortens the window of opportunity where the drug can be detected. Two strategies have been followed for more than a decade to develop a test to detect the application of recombinant GH: the marker approach, which is based on the elevation of GH-dependent markers above the level seen under physiological conditions evoked by administration of recombinant GH, and the isoform approach, which is based on a change in the pattern of GH isoforms in circulation following the injection of recombinant GH [12205]. Since 2004, the isoform test for hGH abuse has been in use in routine doping controls and has undergone fine-tuning and continuous finishing to increase its sensitivity and thus broaden the window of opportunity for detection. In 2011, a controlled administration study with two preparations of recombinant hGH (Chinese and Swiss products, 0.1 IU/kg bodyweight) was conducted and the traceability of the drug (i.e. its influence on the circulating GH isoforms) was determined using the WADA approved analytical kits. Following a single injection, detection windows between 12 and 18 h were observed, while repeated hGH application (one injection/day over 14 days) allowed for hGH abuse detection up to 21 h after cessation. In a different study, the performance of two isoform-based growth hormone detection assays, namely the above mentioned WADA approved test and a 22 kDa/20 kDa isoform immunoassay, was compared. Volunteers received recombinant hGH s.c. at 0.026 mg/kg bodyweight once daily for seven consecutive days, and collected serum samples were analyzed on both platforms. The assays demonstrated good correlation concerning the detection of abnormal isoform concentrations in serum and exhibited comparable detection windows of up to 24 h [12017].

Recombinant human growth hormone (rhGH) has been on the list of forbidden substances since availability of its recombinant form improved in the early 1990s. Although its effectiveness in enhancing physical performance is still unproved, the compound is likely used for its potential anabolic effect on the muscle growth, and also in combination with other products (androgens, erythropoietin, etc.). The degree of similarity between the endogenous and the recombinant forms, the pulsatile secretion and marked interindividual variability makes detection of doping difficult. Two approaches proposed to overcome this problem are: the indirect method, which measures a combination of several factors in the biological cascade affected by administration of GH; and the direct method, which measures the difference between the circulating and the recombinant (represented by the unique 22 kD molecule) forms of GH. One article gave an overview of what is presently known about hGH in relation to sport. The main effects of exercise on hGH production and the use and effects of rhGH in athletes are discussed. Difficulties encountered by laboratories to prove misuse of this substance by both indirect and direct analyses are emphasised. The direct method currently seems to have the best reliability, even though the time window of detection is too
short. hGH doping is a major challenge in the fight against doping. The effect of exercise on hGH and its short half-life are still presenting difficulties during doping analysis. To date the most promising method appears to be the direct approach utilising immunoassays [06135].

Doping with growth hormone (GH) is banned; however, there is anecdotal evidence that it is widely abused. GH is reportedly often used in combination with anabolic steroids at high doses for several months. Development of a robust test for detecting GH has been challenging since recombinant human 22-kDa GH used in doping is indistinguishable analytically from endogenous GH and there are wide physiological fluctuations in circulating GH concentrations. One approach to GH testing is based on measurement of different circulating GH isoforms using immunoassays that differentiate between 22-kDa and other GH isoforms. Administration of 22-kDa GH results in a change in its abundance relative to other endogenous pituitary GH isoforms. The differential isoform method is, however, limited by its short time window of detection. A second approach that extends the time window of detection is based on detection of increased levels of circulating GH-responsive proteins, such as the insulin-like growth factor (IGF) axis and collagen peptides. As age and gender are the major determinants of variability for IGF-I and the collagen markers, a test based on these markers must take these factors into account. Extensive data now validate the GH-responsive marker approach, and implementation is largely dependent on establishing an assured supply of standardized assays. It was concluded that robust tests are available to detect GH and enforce the ban on its abuse in sports. Novel approaches that include gene expression and proteomic profiling must continue to be pursued to expand the repertoire of testing approaches available and to maintain deterrence of GH doping [11160].

Human growth hormone (GH) is widely abused by athletes; however, there is little evidence that GH improves physical performance. Replacement of GH in GH deficiency improves some aspects of exercise capacity. There is evidence for a protein anabolic effect of GH in healthy adults and for increased lean body mass following GH, although fluid retention likely contributes to this increase. The evidence suggests that muscle strength, power, and aerobic exercise capacity are not enhanced by GH administration, however GH may improve anaerobic exercise capacity. There are risks of adverse effects of long-term abuse of GH. Sustained abuse of GH may lead to a state mimicking acromegaly, a condition with increased morbidity and mortality [10138].

Although there is little evidence that GH improves performance in young healthy adults, randomized controlled studies carried out so far are inadequately designed to demonstrate this, not least because GH is often abused in combination with anabolic steroids and insulin. Some of the anabolic actions of GH are mediated through the generation of insulin-like growth factor-I (IGF-I), and it is believed that this is also being abused. Athletes are exposing themselves to potential harm by self-administering large doses of GH, IGF-I and insulin. The effects of excess GH are exemplified by acromegaly. IGF-I may mediate and cause some of these changes, but in addition, IGF-I may lead to profound hypoglycaemia, as indeed can insulin. Although GH is on the World Anti-doping Agency list of banned substances, the detection of abuse with GH is challenging. Two approaches have been developed to detect GH abuse. The first is based on an assessment of the effect of exogenous recombinant human GH on pituitary GH isoforms and the second is based on the measurement of markers of GH action. As a result, GH abuse can be detected with reasonable sensitivity and specificity. Testing for IGF-I and insulin is in its infancy, but the measurement of markers of GH action may also detect IGF-I usage, while urine mass spectroscopy has begun to identify the use of insulin analogues [08239].

There is little evidence that GH improves physical performance. Replacement of GH in GH deficiency improves some aspects of exercise capacity. There is evidence for a protein
anabolic effect of GH in healthy adults and for increased lean body mass following GH, although fluid retention likely contributes to this increase. The evidence suggests that muscle strength, power, and aerobic exercise capacity are not enhanced by GH administration, however GH may improve anaerobic exercise capacity. There are risks of adverse effects of long-term abuse of GH. Sustained abuse of GH may lead to a state mimicking acromegaly, a condition with increased morbidity and mortality [10139].

Human growth hormone (hGH) is a protein endogenously produced predominantly by the anterior pituitary gland. Native hGH and, especially, its recombinant analogue (rhGH), used to treat patients with hormone deficiency, are supposed to be abused by athletes searching its anabolic and lipolytic effects. Hence, hGH use has been prohibited for a long time by the sport authorities, but until recently, hGH abuse could not be detected. Two approaches have been followed when trying to develop methods for GH abuse detection. The direct method identifies an abnormal ratio between GH isoforms – a result of hGH exogenous administration. The time window to find a cheating athlete by this approach is limited by the excretion time of the hormone. The indirect approach measures serum biomarkers directly affected by GH intake (eg, markers of released liver growth factors and of bone and collagen turnover). In this approach, the retrospective power extends further. Alternative possibilities for cheating related to hGH could be the administration of recombinant growth factors themselves, the administration of hGH metabolic precursors such as ghrelin-like GH secretagogues, or the genetic manipulation of muscle growth-related genes (gene doping) [09194].

Human growth hormone (hGH) is seen as a doping risk in sport because of its possible anabolic and lipolytic effects. Due to its considered performance enhancing effects, human growth hormone (hGH) is abused as a doping agent in sport. Its misuse also carries potentially serious side effects to a person's health. Consequently, hGH and its releasing factors are prohibited in sport, as established in the Prohibited List which is updated and published yearly by the World Anti-Doping Agency (WADA). In 2008 significant progress has been made; there is one test for detecting HGH approved for use in anti-doping and a second detection method pending. This is a strong reflection of the ongoing research efforts in anti-doping and the progress being made by the Anti-Doping Organisations in reducing the risk that doping poses to sport [09192].

In order to fight the menace that hGH doping poses to the spirit of sport and to the health of athletes, the sport movement and the anti-doping authorities, initially led by the International Olympic Committee (IOC) and later by WADA, have put substantial efforts into developing tests for its detection. Currently, a primary analytical approach, the isoform differential immunoassay, has been implemented in WADA-accredited laboratories. In parallel, a second, indirect approach for the detection of hGH abuse, based on the quantification of hGH-associated biological markers, has been developed. The final aim is to combine both methodologies to improve the sensitivity and expand the time window to detect doping with hGH. In addition, novel analytical procedures, based on proteomic and genomic technologies as well as the use of mass spectrometry-based methods of detection, are being investigated for future application in hGH anti-doping tests [09193].

People have been attracted to the tales of giants able to perform extraordinary feats of strength, like Paul Bunyan, the mythical American lumberjack. HGH, or human growth hormone, has had the promise to achieve the dreams of some people to become a real-life Paul Bunyan. This, together with the fact that HGH can't be detected, has increased the popularity of this doping agent for athletes. Recently (2007) some high-profile athletes have been identified receiving HGH. The HGH came from a shady Florida warehouse under investigation for illegally distributing prescription medications. HGH has some definite and
proven medical benefits. It is currently approved medically in the United States for 2 primary indications, short-stature in children and growth hormone deficiency in adults. All of these HGH benefits, however, are in individuals with growth hormone deficiency. In people with normal GH levels, HGH does not improve athletic performance in terms of muscle strength, flexibility, and endurance. In fact, several placebo-controlled studies have been negative. A 4-week, double-blind Swedish study using 2 doses of HGH and placebo found no differences in subjects exercising on a bicycle in terms of power output and oxygen uptake. In another study, a single injection of HGH increased plasma lactate and reduced exercise performance. Indeed, in the classic HGH excess experiment in nature, acromegalic subjects have increased muscle mass but histologic evidence of myopathy with muscle weakness and pain. In addition to the lack of effectiveness for enhancing athletic performance, HGH has a downside. It can cause dose-related side effects including diabetes, carpal tunnel syndrome, fluid retention, joint stiffness, muscle pain, and high blood pressure. It turns out that, like Paul Bunyan, the athletic benefits of HGH is a myth [07141].

Circulating microRNAs (miRNAs) in plasma are being studied for use as biomarkers of specific diseases and as markers of administration of pharmaceutical agents. Administration of recombinant human growth hormone (rhGH) is prohibited by sporting authorities, but it continues to be used by athletes attempting to gain an unfair advantage in athletic competition. Current methods for detection of rhGH use rely on immunoassay technology and are limited by a short time-frame in which detection of rhGH is possible. It was hypothesized that administration of rhGH would alter expression of circulating miRNAs and that any changes could be detected. To identify potential miRNA targets, it was utilized miRNA microarrays for screening. Confirmatory testing used real-time reverse-transcriptase (RT) quantitative PCR (qPCR) assays of selected miRNAs in 35 plasma samples obtained from individuals with no known pituitary disorders, patients with excess GH production, and patients receiving therapeutic replacement doses of rhGH. It was identified and confirmed four miRNAs that were differentially expressed in all individuals using therapeutic replacement doses of rhGH when compared to individuals with naturally high levels of GH and normal controls. This study further develops the hypothesis that circulating miRNAs may be used as biomarkers for detection of doping in sports [13356].

Beyond the discussion of supplemental GH to affect muscular adaptations, there is a consistent mistake made by athletes (and their coaches) that the natural robust exercise-induced rise in systemic GH concentrations after heavy weightlifting, is of value in augmenting skeletal muscular adaptations. There is firm evidence that refutes this “hormone hypothesis” for the support of gains in strength and lean mass after a programme of weightlifting in healthy adults. Indeed, future research will need to underpin whether there are benefits towards GH on the connective tissue and/or lipolysis. In general, the available evidence, largely derived from studies that administer rhGH, suggests that the use of peptide hormones to elevate systemic GH concentrations is unlikely to result in a competitive advantage in healthy adults. The mass availability to the athlete (via internet suppliers, nutrition stores, medical practitioners, etc) of synthetic peptides, combined with the lack of regulation of the supplement contents, underpins the important role of the sports scientist, coaches or medical practitioners in educating the athlete consumer that this doping practice is ineffective and with unknown side effects [13357].

Exercise depends on an adequate supply of nutrients and oxygen to the muscle fibers. Glucose for short-term high-intensity activity and free fatty acids (FFAs) for more prolonged activity are combusted to release kinetic energy. GH has a number of effects on protein anabolism and intermediate metabolism that may improve exercise performance through increased fuel and oxygen delivery to exercising muscle, increased muscle strength or any combination of these factors. In addition, it may improve cardiovascular function and
Thermoregulation. Athletes have been misusing growth hormone (GH) for its anabolic and metabolic effects since the early 1980s, at least a decade before endocrinologists began to treat adults with GH deficiency. Although there is an ongoing debate about whether GH is performance enhancing, recent studies suggest that GH improves strength and sprint capacity, particularly when combined with anabolic steroids. Prior to treatment, adults with GH deficiency lose lean tissue while accumulating fat, in particular visceral fat. Skeletal muscle mass and strength is reduced with a consequent impairment of physical performance, exercise capacity, and VO₂ max (aerobic capacity or the maximum ability to take in and use oxygen). Following treatment with recombinant human GH (rhGH), body composition normalizes and physical performance improves. It does not necessarily follow, however, that the administration of supraphysiological GH doses will lead to further performance advantage in healthy adults. Indeed the opposite is suggested by acromegaly, which is characterized by marked abnormalities in protein and carbohydrate metabolism, muscle weakness rather than excessive strength, and cardiomyopathy. A systematic review of 44 articles describing 27 studies reported that although GH administration was associated with increase in lean body mass and decrease in fat mass, it did not improve a number of measures of performance. The detection of GH misuse is challenging because it is an endogenous hormone. Two approaches have been developed to detect GH misuse; the first is based on the measurement of pituitary GH isoforms and the ratio of 22-kDa isoform to total GH. The second is based on the measurement of insulin like growth factor-I (IGF-I) and N-terminal propeptide of type III procollagen (P-III-NP) which increase in a dose-dependent manner in response to GH administration. Both methodologies have been approved by the World Anti-Doping Agency (WADA) and have led to the detection of a number of athletes misusing GH [13007].

Recombinant human growth hormone

Recombinant human growth hormone (rhGH), which is favoured due to its anabolic, lipolytic and post-trauma healing properties, is commonly abused in sport with the aim of improving performance. Substantial efforts have been made to develop tests for detection of doping with rhGH, but the challenge is a difficult one. Long-term efficacy of growth hormone in adults with growth hormone deficiency It is well known that GH stimulates lipolysis and lipid oxidation thereby reducing fat mass, while GH and insulinlike growth factor-I (IGF-I) increase protein synthesis and thus increase protein mass. Meanwhile, it has been shown that long-term treatment of GH deficient adults with GH, normalizes body composition by increasing lean body mass and decreasing fat mass. Exercise capacity is reduced in growth hormone deficiency (GHD) adults, while maximal oxygen consumption (VO₂ max), the aerobic capacity, is increased following GH replacement in subjects with adult GHD. However, it has not been shown that GH increases muscle strength in GHD patients. As primary impairment in the GH/IGF-I axis often leads to a high-risk cardiovascular profile which may partially be reversible during GH replacement. Benefits and harm arising from GH use in healthy subjects It has been reported that GH tends to increase whole body protein synthesis in some highly trained athletes, while in other athletes it does not. The use of rhGH in healthy adults causes a change in body composition with significant decrease in fat mass and significant increase in lean body mass. It has been suggested that hGH may be beneficial in stimulating the supporting connective tissues (strengthening of the matrix by increased tendon collagen synthesis). This may then accelerate healing of soft tissue injury and bone fractures. GH in sports is seldom used in high doses (in other words, several times higher than the daily production rate of GH). However, when high doses are involved, the many side-effects of GH abuse in sports are actually signs of acromegaly, such as swelling and arthralgias, providing ample evidence of the harmful effects of excessive GH. More serious
side-effects are diabetes and negative impact on heart function (increase in left ventricular mass and increased cardiac output). The results of most of the controlled studies in which supraphysiological dosages of hGH have been used are less impressive than the claims of those who misuse hGH, a substance whose abuse is prevalent in top-level sport. In order to detect GH abuse there are two approaches. One, the analytical method, relies on the measurement of molecular isoforms of GH, while the second relies on measurement of sensitive markers of biological activity of rhGH. A method was developed for detection of GH abuse (the GH-2000 project) based on the measurement of IGF-I and the amino-terminal pro-peptide of type III collagen (P-III-NP) by two commercial assays available for each analyte. By using this method, decision limits were developed to measure IGF-I and P-III-NP in elite athletes, thus enabling the introduction of a test for GH abuse based on the detection of GH biomarkers [12011].

**Epidemiology and demographic factors**

GH-responsive markers of the IGF system and of collagen turnover hold promise as the basis of a GH doping test. The purpose of one study was to determine the influence of age, gender, body mass index (BMI), ethnicity, and sporting type on GH-responsive serum markers in a large cohort of elite athletes from different ethnic backgrounds. The study was designed as a cross-sectional study. Participants: A total of 1103 elite athletes (699 males, 404 females), aged 22 years, from 12 countries and 10 major sporting categories participated in this study. Serum IGF-I, IGF binding protein-3 (IGFBP-3), acid labile subunit (ALS), and collagen markers [N-terminal propeptide of type I procollagen (PINP), C-terminal telopeptide of type I collagen (ICTP), N-terminal propeptide of type III procollagen (PIIINP)] were measured. There was a significant negative correlation between age and each of the GH-responsive markers. Serum IGF-I, IGFBP-3, and ALS were all lower, whereas the collagen markers PINP, ICTP, and PIIINP were higher in men than in women. Multiple regression analysis indicated that age, gender, BMI, and ethnicity accounted for 23-54 percent of total between-subject variability of the markers. Age and gender cumulatively accounted for 91 percent of the attributable variation of IGF-I and more than 80 percent for PINP, ICTP, and PIIINP. Gender exerted the greatest effect on ALS (48 %), and BMI accounted for less than 12 percent attributable variation for all markers. The influence of ethnicity was greatest for IGFBP-3 and ALS; however, for the other markers, it accounted for less than 6 percent attributable variation. Analysis of 995 athletes indicated that sporting type contributed 5-19 percent of attributable variation. It was concluded that age and gender were major determinants of variability of GH-responsive markers except for IGFBP-3 and ALS. Ethnicity is unlikely to confound the validity of a GH doping test based on IGF-I and these collagen markers [06136].

In order to verify the effects of the sporting season (entailing periods of training, competition, recovery, resting) on GH-dependent parameters in male and female athletes from different sporting disciplines, 47 male and female athletes (3 rowers, 5 swimmers, 7 alpine skiers, 3 soccer players, 7 middle distance runners, 14 sprinters, 4 triathletes, 1 road walker, 3 cyclists) were followed-up for a period of 6 months. Blood samples were taken every two months for the evaluation of IGF-I, N-terminal propeptide of type III procollagen (PIIINP) and C-terminal cross-linked telopeptide of type I collagen (ICTP). Abnormal IGF-I, PIIINP and ICTP levels were observed during the follow-up period in 7/100 (7 %), 9/100 (9 %) and 8/100 (8 %) samples of the male group, respectively, and in 9/88 (10 %), 1/88 (1 %) and 0/88 (0 %) samples of the female group, respectively. Abnormal levels appeared to be randomly distributed over the different periods of the sporting season and within male and female subjects, with the large majority of abnormal values being found in the younger athletes.
Taking into account all the tests done during the 6-month period (n=564), individual markers falling outside the normal range (for age) were observed in a small number of instances (34/564 tests done, 24/300 for males and 10/264 for females). When our method for the detection of exogenous recombinant GH (rhGH) administration, based on the concomitant determination of these three peripheral GH-dependent markers and on the attribution of specific scores, was applied in the same athlete at a given time point of the 6-month period, the prevalence of a positive score was extremely low (i.e. 3/188 samples or 1.6 %). Total positive scores were actually recorded in only three male athletes (2 swimmers and 1 skier, aged <21 yr) at one occasion during the 6-month period considered. In contrast, no total positive scores were found in female athletes (i.e. 0/88 samples). In conclusion, the concentrations of IGF-I, PIIINP and ICTP were stable and not significantly modified during 6 months of a sporting season (entailing periods of training, competition, recovery, resting) in athletes from different sporting disciplines. Therefore our method, based on the concomitant determination of three peripheral GH-dependent biomarkers appears safe, acceptable, relatively inexpensive and repeatable (in case of positive or suspected values) immediately or at different intervals of the sporting season. Further additional studies are requested to precise the cut-off values for narrower age-class subdivisions in both genders in order to improve the proposed method [06137].

**Adolescents**

The rationale for adolescent athletes taking rhGH, is that it should synergize with the physiologic (or doping) increases in testosterone to grow faster and to add additional lean body mass. It is understood that by becoming bigger and stronger the athlete will perform at a higher level. hGH is lipolytic in addition to being anabolic and thus may be considered for those in "physique" related sports such as body-building. In multiple surveys of adolescents who take anabolic agents, it is to "look good" as often as it is to augment athletic performance. As noted previously athletic performance is much more than just strength or endurance; for the athlete must produce, control and efficiently use the energy in a fashion that maximizes sport performance [10001].

Despite the paucity of data for performance enhancement, the "word on the street" is that this agent is quite actively being abused by athletes. It is unlikely that the athlete uses rhGH in isolation, thus making it quite difficult to define its exact role in athletic performance. There is however one very well controlled study that shows an effect on strength in a group of well defined abstinent steroid abusers (subject to strict drugs of abuse testing). There are no studies in child and adolescent athletes, but it may be that faster growth, weight gain and the salutary effects on body composition during adolescence could confer advantage to age-group athletes, for it has been shown at the elite level that the taller, heavier early adolescent athlete is represented out of proportion to his/her age-peers. Adolescents reach "near-adult" height later in the teen years with girls reaching this stature several years before boys; however, the adult body composition (muscle, bone and fat) and the regional distribution of body fat are not attained until early-to-middle third decade. If rhGH is effective to help one obtain these milestones early, perhaps there is some advantage; however this is quite theoretical [10001].

**Children**

There are many data for the short-term (years to more than a decade) in children with a number of conditions of childhood: GH deficiency, several genetic condition as well as "short-
normal" children. Two major data bases, the Kabi International Growth Study, now managed by Pfizer, Inc and the National Cooperative Growth Study produced and managed by Genentech, Inc show quite low incidences of scoliosis, slipped capital femoral epiphysis and rare instances of idiopathic intracranial hypertension, the one of greatest concern. Adults have noted more muscle and joint complaints than children. There is the long-term (theoretical) issue of neoplasia [10001].

The most notable effect in children and adolescents is linear growth. Growth hormone-deficient children and adolescents are likely to be 20 to 30 cm shorter than mid-parental target height if left untreated. Physiological stimuli to hGH release include: deep sleep, some amino acids and exercise. hGH is secreted in a pulsatile fashion every hour or two and has significant peaks approximately 90 min after the onset of deep sleep and within minutes of completing a bout of exercise. The main (iso)form of hGH is a 191 amino acid, 22 kD peptide with a significant amount of a 20 kD splice variant form. There are a multitude of post-translationally modified forms including those affected by metabolism and sulfation and phosphorylation. Several of the forms, predominantly the 22 kD and 20 kD forms interact with the hGH receptor, a dimeric member of the cytokine family of receptors at the cell surface to lead to the cellular actions of hGH. One of the main ones is to stimulate the hepatic synthesis of IGF-I (endocrine), but also to stimulate the paracrine and autocrine synthesis of IGF-I in various tissues, such as bone and muscle. In addition, it is lipolytic and can significantly alter body composition by directing muscle protein synthesis relative to fat. In fact, it is this action that has led to its use in animal husbandry with the "partitioning" of feed and "feed-efficiency" as the major outcomes [10001].

Native hGH and, especially, its recombinant analogue (rhGH), used to treat patients with hormone deficiency, are supposed to be abused by athletes searching its anabolic and lipolytic effects. Hence, hGH use has been prohibited for a long time by the sport authorities, but until recently, hGH abuse could not be detected. Two approaches have been followed when trying to develop methods for GH abuse detection. The direct method identifies an abnormal ratio between GH isoforms – a result of hGH exogenous administration. The time window to find a cheating athlete by this approach is limited by the excretion time of the hormone. The indirect approach measures serum biomarkers directly affected by GH intake (e.g. markers of released liver growth factors and of bone and collagen turnover). In this approach, the retrospective power extends further. Alternative possibilities for cheating related to hGH could be the administration of recombinant growth factors themselves, the administration of hGH metabolic precursors such as ghrelin-like GH secretagogues, or the genetic manipulation of muscle growth-related genes (gene doping). In parallel with the new types of abuse, which will surely emerge in the near future, the research and development for the improvement of the analytical detection of GH itself will continue [10141].

**Women**

*Prevalence*

Athletes use hGH, an endogenous hormone with an anabolic effect, to improve muscle mass and performance. The first documented use of hGH appeared in the early 1980s. A survey of adolescent boys and girls that grouped hGH use with DHEA and AAS use found that 0.2 percent of girls admitted to taking one of these substances at least once in the past year, while 0.1 percent used the supplement at least weekly. A 2001 NCAA survey found that 3.5 percent of college athletes had used hGH in the past year; however, separate data for men and women was not reported. hGH is secreted by the anterior pituitary gland. Its level peaks
during adolescence and decreases with age; production increases with exercise and decreases with starvation. hGH stimulates insulin-like growth factor (IGF-1) production in the liver. Both hGH and IGF-1 have effects of lipolysis and protein anabolism. Providing hGH to athletes was thought to have a protein-building, fat-burning effect. Athletes began using hGH instead of AAS because it was less detectable due to a shorter half-life. Athletes have also reported that hGH enhances performance, although scant scientific evidence supports its effectiveness. However, clinical trials are unable to administer the high doses that athletes may take — often in combination with the other supplements — in order to evaluate hGH efficacy. A 2002 review evaluated randomized, double-blind, placebo-controlled trials of exogenous hGH in trained adult athletes, with muscle strength or performance as outcome measures, finding few well-designed studies using performance-based outcomes in normal healthy athletes. Additionally, the studies did not consistently show any benefit in healthy athletes without growth hormone deficiencies. More recently, it was conducted a double-blind, placebo-controlled trial in 15 women and 15 men to evaluate hGH supplementation effects on endurance exercise capacity. Healthy active volunteers were given low hGH dose, high hGH dose, or placebo for 28 days, and maximal oxygen uptake during stationary cycling was measured. No effect was found in maximal oxygen uptake or maximum power output during exercise. Participants increased total body weight, but this was attributed to fluid retention, not muscle mass [07086].

Side effects

Adverse effects related to hGH range in severity. People with too much hGH develop acromegaly, an overgrowth of facial bones, tongue, nose, and jaw. These effects are thought to be nonreversible. Other effects include joint pain, muscle weakness, fluid retention, and carpal tunnel syndrome. More severe effects are impaired glucose regulation, cardiomyopathy, and hyperlipidemia. Overall, performance-enhancing benefits do not seem to outweigh risks [07086].

Physiology

The major isoform of growth hormone is made up of 191 amino acids stabilized by two disulfide bonds with a molecular weight of 22 kilodaltons. Hypothalamic secretion of human growth hormone-releasing hormone stimulates HGH release and somatostatin inhibits HGH release from the anterior pituitary. Recombinant HGH (rHGH) first became available for clinical use in 1983. rHGH has a short half life, approximately 15 minutes. It has been demonstrated that serum concentrations of growth hormone return to baseline approximately 8 to 16 hours after intramuscular injection and 11 to 20 hours after subcutaneous injection of rHGH. The usual therapeutic dose of recombinant HGH is 1-2 IU/day given either by intramuscular or subcutaneous injection at night. The doses used by athletes for performance enhancement are often 20 times the normal prescription doses and may cost from USD 3,000-5,000 [07002].

The diagnosis of growth hormone (GH) deficiency in children with short stature is complex, and in certain cases, might be very difficult. Most of the provocative tests used to evaluate GH deficiency use pharmacological agents. The artificial nature of the pharmacological tests and the possibility that these tests might not always reflect GH secretion under normal physiological conditions provides the impetus for a more physiologic test. Exercise is one of the important GH releasing physiological stimuli [09205].

The ability of the somatotroph cells in the anterior pituitary to synthesize and secrete the
polypeptide, hGH, is determined by a gene called the Prophet of Pit-1 (PROP1). When hGH is translated, 70-80 percent is secreted as a 191-amino-acid, 4-helix bundle protein, and 20-30 percent as a less abundant 176-amino-acid form. Hypothalamic-releasing and hypothalamic-inhibiting hormones acting via the hypophysial portal system control the secretion of hGH, which is secreted into the circulation. In healthy persons, the hGH level is usually <0.2 μg/L throughout most of the day. There are approximately 10-12 intermittent secretory bursts in a 24 hour period, mostly at night, when the level can rise to as much as 30 μg/L. hGH secretion declines at 14 percent per decade from the age of 20 years. hGH action is mediated by an hGH receptor, which is expressed mainly in the liver and is composed of dimers that change conformation when occupied by an hGH ligand. Cleavage of the hGH receptor provides a circulating hGH binding protein (GHBP), prolonging the half-life and mediating the transport of hGH [67]. Intracellular hGH signalling is decreased by suppressors of cytokine signaling. hGH induces the synthesis of peripheral insulin-like growth factor I (IGF-I) [ while endocrine, autocrine, and paracrine IGF-I induces cell proliferation and is thought to inhibit apoptosis [08240].

Growth hormone (GH) is secreted in a pulsatile pattern from the anterior pituitary, influenced by a variety of normal and pathophysiological conditions. Exogenous recombinant hGH is virtually indistinguishable from the predominant naturally occurring isoform and is cleared from the body within 24 hours. Although GH is on the World Anti-doping Agency list of banned substances, the detection of GH abuse remains challenging. This article gives an overview of the potential application of surface-enhanced laser desorption/ionization time-of-flight (SELDI-TOF) mass spectrometry to examine proteomic changes following GH administration, using both serum and white blood cell extracts as samples for analysis. Results to date indicate that proteomic changes observed following GH administration have the potential to yield novel biomarker sets for the detection of GH abuse [09206].

Human growth hormone (hGH) is a proteohormone secreted by the pituitary gland. It acts through binding to the hGH receptor, inducing either direct effects or initiating the production of insulin-like growth-factor I (IGF-I), the most important mediator of hGH effects. Growth hormone is primarily known to promote longitudinal growth in children and adolescents, but has also various important metabolic functions throughout adult life. Effects of hGH on the adult organism are well established from studies with recombinant growth hormone (rhGH) therapy in growth hormone deficient subjects. In this particular group of patients, replacement of hGH leads to increased lipolysis and lean body mass, decreased fat mass, improvements in VO_{2max}, and maximal power output. Although extrapolation from these findings to the situation in well trained healthy subjects is impossible, and controlled studies in healthy subjects are scarce, abuse of hGH seems to be popular among athletes trying to enhance physical performance. Detection of the application of rhGH is difficult, especially because the amino acid sequence of rhGH is identical to the major 22,000 Da isoform of hGH normally secreted by the pituitary. Furthermore, some physiological properties of hGH secretion also hindered the development of a doping test: secreted in a pulsatile manner, it has a very short half-life in circulation, which leads to highly variable serum levels. Concentration alone therefore cannot prove the exogenous administration of hGH. Two approaches have independently been developed for the detection of hGH doping: The so-called "marker approach" investigates changes in hGH-dependent parameters like IGF-I or components of bone and collagen metabolism, which are increased after hGH injection. In contrast, the so-called "isoform approach" directly analyses the spectrum of molecular isoforms in circulation: the pituitary gland secretes a spectrum of homo- and heterodimers and - multimers of a variable spectrum of hGH isoforms, whereas rhGH consists of the monomeric 22,000 Da isoform only. This isoform therefore becomes predominant after injection of rhGH. Specific immunoassays with preference for the one or the other isoform allow analysis of the relative abundance of the 22,000 Da isoform. Application of rhGH can
be proven when the ratio of this isoform relative to the others is increased above a certain threshold. Because the "marker method" and the "isoform method" have a different window of opportunity for detection, complementary use of both tests could be a way to increase the likelihood of detecting cheating athletes [10140].

One of its best-characterized effects of growth hormone is increasing levels of circulating insulin-like growth factor I (IGF-I), which is primarily of hepatic origin. It also induces synthesis of IGF-I in most non-hepatic tissues. The effects of GH in promoting postnatal body growth are IGF-I dependent, but IGF-I-independent functions are beginning to be elucidated. Although benefits of GH administration have been reported for those who suffer from GH deficiency, there is currently very little evidence to support an anabolic role for supraphysiological levels of systemic GH or IGF-I in skeletal muscle of healthy individuals. There may be other performance-enhancing effects of GH. In contrast, the hypertrophic effects of muscle-specific IGF-I infusion are well documented in animal models and muscle cell culture systems. Studies examining the molecular responses to hypertrophic stimuli in animals and humans frequently cite upregulation of IGF-I messenger RNA or immunoreactivity. The circulatory/systemic (endocrine) and local (autocrine and paracrine) effects of GH and IGF-I may have distinct effects on muscle mass regulation [08244].

Development of an assay for human GH was closely followed by the observation that plasma levels of GH increase soon after the beginning of exercise. Because of the known anabolic and lipolytic effects of GH and the observation that the exercise-associated increase in GH precedes an increase in circulating free fatty acids (FFAs), it was hypothesized that GH might play an important metabolic role during exercise. Further evidence for this notion came from the discovery in the 1980s that exercise capacity and muscle strength are impaired in GH-deficient (GHD) adults and improved by GH replacement. Reports of the use of GH by athletes as a performance-enhancing agent predated the introduction of recombinant human GH (rhGH) by at least 5 years, and there is an increasing body of evidence that GH abuse represents a significant problem in a number of sports including athletics, swimming, and cycling. The likelihood that attaining supraphysiological GH levels improves exercise performance should be considered in the context that although GH is clearly anabolic, there is no evidence that exercise capacity is enhanced by administration of GH to normal subjects, and in patients with long-standing endogenous GH excess (acromegaly), muscle strength is usually reduced. However, recent metabolic studies provide a plausible mechanistic explanation through which supraphysiological GH administration could lead to short- or medium-term improvements in exercise performance, and regular seizures of GH from athletes demonstrate an ongoing belief in sporting circles that GH is performance enhancing. Measures of exercise performance including maximal oxygen uptake and ventilatory threshold are impaired in adult GH deficiency and improved by GH replacement, probably through some combination of increased oxygen delivery to exercising muscle, increased fatty acid availability with glycogen sparing, increased muscle strength, improved body composition, and improved thermoregulation. In normal subjects, in addition to the long-term effects of GH/IGF-I status, there is evidence that the acute GH response to exercise is important in regulating substrate metabolism after exercise. Administration of supraphysiological doses of GH to athletes increases fatty acid availability and reduces oxidative protein loss, particularly during exercise, and increases lean body mass. Despite a lack of evidence that these metabolic effects translate to improved performance, GH abuse by athletes is widespread. Tests to detect GH abuse have been developed based on measurement in serum of 1) indirect markers of GH action, and 2) the relative proportions of the two major naturally occurring isoforms (20 and 22kDa) of GH. There is evidence that exercise performance and strength are improved by administration of GH and testosterone in combination to elderly subjects. The potential benefits of GH in these situations must be weighed against potential adverse effects [07142].

1069
The majority of studies reported to date have demonstrated increased maximum work rate and $\text{VO}_{2\text{max}}$ after GH replacement in subjects with both childhood- and adult-onset (AO) GH-deficient, although statistically significant improvements compared with placebo were not demonstrated in all of these studies. One study demonstrated no improvement after GH replacement, whereas another demonstrated no difference in the improvement in after exercise training in combination with GH replacement compared with after exercise training alone. Some of these studies may have been underpowered to detect between-group differences. The largest study to date addressing exercise performance in response to GH replacement included 55 patients with adult onset-GH-deficient in a placebo-controlled, crossover study in which GH therapy was individually dosed to obtain an IGF-I concentration within the normal range for age and gender. A highly significant effect of GH replacement to increase $\text{VO}_{2\text{max}}$ by approximately 6 percent was observed. The overall body of evidence therefore supports an effect of GH to improve maximum work rate, $\text{VO}_{2\text{max}}$, with changes in $\text{VO}_{2\text{max}}$ apparently accounted for by increased LBM [07142].

One study examined effects of prior sprint exercise on hormonal responses to subsequent resistance exercise with different recovery periods between exercise bouts. Nine men performed three types of exercise regimens: resistance exercise only (R), resistance exercise with prior sprint exercise and 60 min of rest (SR60), and resistance exercise with prior sprint exercise and 180 min of rest (SR180). Sprint exercises consisted of maximal sprint cycling (eight sets of 5-s sprints with 30-s rest periods between sets) with prior 10-min warm-up. Resistance exercise consisted of five exercises, each with three sets at a 10-repetition maximum with 1-min rest periods. Prior sprint exercise significantly increased blood lactate, glycerol, epinephrine, norepinephrine, growth hormone (GH), and free testosterone concentrations. Before the resistance exercise, free fatty acids concentration was higher in the SR180 trial than in the SR60 and R trials, whereas GH concentration was significantly higher in the SR60 trial. After the resistance exercise, no significant difference was found in responses of pH, epinephrine, norepinephrine, and free testosterone among trials. The SR180 trial showed a smaller GH response (peak value: $7.8 \pm 1.6$ ng/mL) than in the R trial ($12.8 \pm 3.7$ ng/mL), with no significant difference between trials. In the SR60 trial, GH response to resistance exercise was attenuated. Maximal strength and power measured immediately before the resistance exercise showed no difference among trials. These results indicate that GH response to resistance exercise was attenuated strongly when the exercise was preceded by sprint exercise and a shorter (60 min) recovery period [07143].

**Molecular and metabolic mechanisms**

Skeletal muscle is a target tissue of GH. Based on its anabolic properties, it is widely accepted that GH enhances muscle performance in sports and muscle function in the elderly. This paper critically reviews information on the effects of GH on muscle function covering structure, protein metabolism, the role of IGF1 mediation, bioenergetics and performance drawn from molecular, cellular and physiological studies on animals and humans. GH increases muscle strength by enhancing muscle mass without affecting contractile force or fibre composition type. GH stimulates whole-body protein accretion with protein synthesis occurring in muscular and extra-muscular sites. The energy required to power muscle function is derived from a continuum of anaerobic and aerobic sources. Molecular and functional studies provide evidence that GH stimulates the anaerobic and suppresses the aerobic energy system, in turn affecting power-based functional measures in a time-dependent manner. GH exerts complex multi-system effects on skeletal muscle function in part mediated by the IGF system [13364].
Promoters of secretion

The purpose of one study was to investigate the role of muscle metaboreflex on exercise-induced growth hormone (GH) secretion. In order to accumulate metabolites within exercised muscle with minimized central motor activity, electromyostimulation (EMS) was performed combined with blood flow restriction (BFR). Seven men performed one-legged isometric knee extension evoked by EMS (frequency, 20 Hz; pulse duration, 400 μs; on-off ratio, 3-1 s). Just before the exercise, proximal portion of either a stimulated thigh (ST) or a non-stimulated thigh (NT) was compressed at 150 mmHg with an air-pressure cuff for the purpose of BFR. The compression was kept throughout the exercise session, and was released 2 min after the end of the exercise. Two exercise sessions (ST(BFR), BFR for ST; NT(BFR), BFR for NT) were separated by 1 week. ST(BFR) was aimed to accumulate metabolites within exercised muscle, whereas NT(BFR) was aimed to match mechanical stress with ST(BFR) without accumulating metabolites. Blood samples for hormonal measurements were taken from the antecubital vein before and after the exercise. Blood lactate increased immediately after the exercise in the NT(BFR), whereas it increased after the cuff deflation in the ST(BFR), suggesting that locally produced metabolites were retained and accumulated within the exercised muscle in the ST(BFR). Although serum cortisol and plasma noradrenaline increased in a similar manner in two conditions, serum immunoreactive GH (irGH) increased only in the ST(BFR). These results suggest that muscle metaboreflex plays an important role in the exercise-induced GH secretion, at least in terms of irGH secretion [11470].

Influence of nutrition

Nocturnal endocrine responses to exercise performed in the evening and the potential role of nutrition are poorly understood. To gain novel insight, 10 healthy men ingested carbohydrate with (C+P) and without (C) protein in a randomized order and double-blind manner during 2 hr of interval cycling followed by resistance-type exercise and into early postexercise recovery. Blood samples were obtained hourly throughout 9 hr of postexercise overnight recovery for analysis of key hormones. Muscle samples were taken from the vastus lateralis before and after exercise and then again the next morning (7 a.m.) to calculate mixed-muscle protein fractional synthetic rate (FSR). Overnight plasma hormone concentrations were converted into overall responses (expressed as area under the concentration curve) and did not differ between treatments for either growth hormone (1,464 ± 257 vs 1,432 ± 164 pg/mL for 540 min) or total testosterone (18.3 ± 1.2 vs 17.9 ± 1.2 nmol/L for 540 min, C and C+P, respectively). In contrast, the overnight cortisol response was higher with C+P (102 ± 11 nmol/L for 540 min) than with C (81 ± 8 nmol/L for 540 min). Mixed-muscle FSR did not differ between C and C+P during overnight recovery and correlated significantly with the plasma total testosterone response. No correlations with FSR were apparent for the response of growth hormone cortisol or the ratio of testosterone to cortisol. In conclusion, protein ingestion during and shortly after exercise does not modulate the endocrine response or muscle protein synthesis during overnight recovery [11471].

Influence of testosterone on GH

Testosterone (T) supplementation increases skeletal muscle mass, circulating GH, IGF-I, and im IGF-I expression, but the role of GH and IGF-I in mediating T's effects on the skeletal muscle remains poorly understood. Here, it was shown that T administration increased body weight and the mass of the androgen-dependent levator ani muscle in hypophysectomized as well as castrated plus hypophysectomized adult male rats. T stimulated the proliferation of primary human skeletal muscle cells (hSKMCs) in vitro, an effect blocked by transfecting
hSKMCs with small interference RNA targeting human IGF-I receptor (IGF-IR). In differentiation conditions, T promoted the fusion of hSKMCs into larger myotubes, an effect attenuated by small interference RNA targeting human IGF-IR. Notably, MKR mice, which express a dominant negative form of the IGF-IR in skeletal muscle fibers, treated with a GnRH antagonist (acyline) to suppress endogenous T, responded to T administration by an attenuated increase in the levator ani muscle mass. In conclusion, circulating GH and IGF-I are not essential for mediating T's effects on an androgen-responsive skeletal muscle. IGF-I signaling plays an important role in mediating T's effects on skeletal muscle progenitor cell growth and differentiation in vitro. However, IGF-IR signaling in skeletal muscle fibers does not appear to be obligatory for mediating the anabolic effects of T on the mass of androgen-responsive skeletal muscles in mice [10475].

**Immunofunctional and traditional growth hormone**

The purpose of this study was to compare the growth hormone (GH) response, including the immunofunctional (IF) GH response, between an acute bout of aerobic and resistance exercise in the same subjects. Ten cross-trained males (24 years) performed both 30 min of continuous cycling at 70 percent of VO$_{2\text{max}}$, and intermittent free weight squatting at 70 percent of 1-RM, in a randomly assigned crossover design, separated by at least 1 week. Blood samples were collected at 10-min intervals for 2 h (30 min rest, 30 min exercise, 60 min recovery) and analyzed for total human and IF GH. After adjusting for the amount of work performed per minute of exercise, integrated GH AUC was significantly greater during the resistance session than the aerobic session as measured by both the total and IF GH assays. Peak GH concentrations were significantly greater during the resistance session than the aerobic session. A similar overall GH pattern was observed in response to both types of exercise, with peak values occurring at the end of exercise, regardless of the GH assay used. These data demonstrate that in young, cross-trained males, intermittent resistance exercise elicits a greater response of GH, including IF GH, compared to a continuous aerobic session, when controlling for the work performed per minute, intersubject variability, relative exercise intensity and session duration [07144].

**Effects on circulation**

The ability to perform exercise requires combustion of metabolic fuels, transforming chemical into kinetic and thermal energy. Glucose is the preferred fuel source for short-term high-intensity activity, whereas FFAs (derived from the circulation or from triglycerides stored in muscle or adipose tissue) become increasingly important during more prolonged activity. Oxygen delivery to muscles depends upon adequate ventilation and O$_2$ transport to hemoglobin, circulatory distribution by an adequate cardiac output (CO) and peripheral circulation, dilatation of the muscle capillary network, and extraction of O$_2$ by the muscle fibers with either storage in myoglobin or immediate combustion. GH could improve exercise performance through increased delivery of substrate and oxygen to exercising muscle, increased fat oxidation with glycogen sparing, increased muscle strength, or a combination of these variables. GH could also improve exercise performance through indirect mechanisms, including changes in body composition or more efficient thermoregulation. When pulmonary function – which does not appear to be impaired in GHD or improved by GH replacement – is adequate, delivery of O$_2$ to exercising muscle is dependent on the O$_2$-carrying capacity of the blood, CO, and regional blood flow. GH and IGF-I increase erythropoiesis in vitro, in animal models, and in growing children. It has been demonstrated reduced red cell mass and total blood volume in GHD adults, and normalization after GH replacement. Consistent with other studies, GH replacement also increased plasma volume, which by increasing preload, would be predicted to increase stroke volume (SV) and CO, the product of SV and heart rate.
Independent of effects on preload, GH could also increase cardiac contractility through an anabolic effect on the myocardium, mediated either directly or through increased IGF-I. Most, but not all studies using echocardiography or equilibrium radionuclide angiography have demonstrated reduced left ventricular (LV) mass and LV ejection fraction (EF) in GHD adults compared with normal subjects. Reports of the effects of GH replacement on cardiac structure and function are inconsistent, but a recent meta-analysis of placebo-controlled trials demonstrated a significant effect of GH replacement to increase left ventricular posterior wall thickness and SV. Of particular importance to this review is evidence from studies using radionuclide angiography that GH enhances the ability of LVEF to increase during exercise, which is necessary to provide adequate blood supply to exercising muscle. The effects of GH on SV and CO must be considered in relation to changes in systemic vascular resistance (SVR) and afterload. As described above, GH replacement increases SV, which in the absence of change in heart rate would be expected to increase mean arterial pressure. However, mean arterial pressure does not change or even decreases after GH replacement, and because it represents the product of CO and SVR, this observation can only be explained by a reduction in SVR. A mechanistic explanation for this effect is provided by a study that demonstrated increased production of nitric oxide, the key mediator of endothelial relaxation, after 3 months of GH replacement [07142].

**Fett-substrate metabolism**

It has been reported in 1965 that the exercise-induced increase in GH was followed by an increase in fatty acids and suggested that through its lipolytic effect GH could increase availability of fat as substrate during exercise. Under resting conditions, particularly when fasting, fatty acids are the predominant fuel used by skeletal muscle. Fat oxidation increases in relation to the intensity of exercise up to 65 percent of VO\(_{2\text{max}}\), when it accounts for approximately 50 percent of energy expenditure, but with increasing intensity of exercise, the reliance on glucose as fuel increases, and the relative oxidation of glucose in relation to fat increases. Whether fatty acid availability influences partitioning of substrate oxidation during exercise is unclear, some studies demonstrating increased fat oxidation and reduced muscle glycogen depletion when fatty acid availability is greater, and others demonstrating no effect. GH directly stimulates lipolysis through activation of adenyl cyclase followed by activation of cAMP-dependent protein kinase and phosphorylation and activation of hormone-sensitive lipase. Studies in fat cells and in animal models have shown that in addition to its direct lipolytic effect on adipose tissue (demonstrated by stimulation of basal lipolysis), GH also increases lipolysis indirectly by altering the effect of adipocytes to respond to lipolytic factors such as catecholamines. Already in 1959 it was also demonstrated that GH increased plasma FFA in human subjects, and that administration of GH enhanced forearm muscle uptake and oxidation of FFA and increased the release of FFA from adipose tissue. GH, administered as a bolus or by infusion, increases circulating levels of glycerol and FFA in GHD and normal subjects after a lag time of 2-3 hours. Small pulses of GH designed to mimic physiological pulses have been shown to induce a dose-dependent stimulation of lipid oxidation and increase circulating levels of FFA and glycerol. Using microdialysis techniques, it has been shown that a physiological GH pulse stimulates lipolysis in both abdominal and femoral adipose tissue, although to a greater degree in abdominal tissue [07142].

In normal subjects, the onset of exercise leads to a 3-fold increase in the rate of lipolysis and a rapid increase in uptake of FFAs into skeletal muscle. The rate of disappearance of FFA from the circulation, which during exercise is largely into skeletal muscle, was also reduced after GH withdrawal. One experimental protocol resulted in an increment in circulating GH levels during exercise that was indistinguishable from that seen in healthy normal subjects. Under resting conditions, there was no effect of GH, whereas during and after 45 min of
exercise at lactate threshold there was a greater increment in fatty acid turnover after GH administration. GH clearly increases whole-body fat oxidation under resting conditions, and an increase in maximal fat oxidation during exercise has also been demonstrated in GH-deficient adults after 6 and 12 months of GH replacement. There are also findings suggesting that under resting conditions (when the biopsies were taken) increased fat oxidation in response to GH occurs in tissues other than skeletal muscle. It is possible that different effects would occur during exercise [07142].

*Glucose-substrate metabolism*

There is less information available concerning the effects of GH-deficiency and GH replacement on glucose kinetics during exercise. Under resting conditions, GH administration results in increased hepatic glucose production, reduced glucose uptake into skeletal muscle, and increased insulin secretion. There is increasing evidence that this effect may occur secondary to the lipolytic effect of GH. In summary, therefore, there is strong evidence that GH replacement increases lipolysis, FFA availability, and uptake from the circulation more markedly during exercise compared with resting conditions. There is also preliminary evidence that GH replacement increases whole-body fat oxidation during exercise, although it is not known whether this effect occurs in skeletal muscle or in other tissues. The effects of GH replacement on glucose metabolism during exercise appear to be less marked 07[142].

*Effects on muscle mass and strength.*

There is an extensive body of literature from in vitro and animal models concerning the cellular mechanisms through which GH and IGF-I exert anabolic effects on skeletal muscle. Studies in human subjects have provided information regarding the immediate and short-term effects on gene transcription through which these processes occur. GH-induced tyrosine phosphorylation (indicating activation) of STAT5, consistent with a direct effect of GH in skeletal muscle, mediated through the Janus kinase/signal transducer and activator of transcription (JAK-STAT) signaling pathway. This finding is consistent with previous observations from regional amino acid balance studies that showed an acute effect of GH to promote protein synthesis in forearm muscle. The physiological importance of the anabolic effect of GH is apparent in GHD adults. Briefly, lean body mass (LBM) is reduced in GH-deficient adults by approximately 7-8 percent compared with age- and gender-matched normal subjects, representing similar reductions in extracellular water and body cell mass, the metabolically active component of LBM. Skeletal muscle comprises the majority of body cell mass, and studies using computed tomography and magnetic resonance imaging scanning have demonstrated a reduction in cross-sectional skeletal muscle area in GH-deficient adults that is proportional to the reduction in LBM estimated by measurement of total body potassium. Reduced muscle mass in GHD subjects is associated with reduced isometric muscle strength, whereas some but not all studies have also demonstrated reduced isokinetic strength. It remains uncertain whether reduced strength is entirely accounted for by the reduction in muscle mass or whether there is also intrinsic muscle weakness associated with GHD. In contrast to the protein anabolic effect of GH replacement, which occurs within days to weeks of initiation of treatment, the overall body of evidence suggests that long-term but not short-term GH replacement increases and normalizes muscle strength. It was carried out an extensive series of strength tests at the beginning and end of 6 months of GH replacement. Strength increased in most of the nine muscle groups that were studied, but it only reached statistical significance in one of the groups. This study and two other studies of GH replacement, lasting 12 weeks and 6 months, respectively, may not have been adequately powered to demonstrate a statistically significant effect. After 2 years of treatment with a mean daily dose of 0.62 ± 0.03 mg of GH, isometric and isokinetic
strength in GH-deficient men increased into the normal range, although a reduction was seen in muscle endurance. A later study confirmed that these effects persisted after 5 years of treatment. Like many of the clinical features of GHD, the effect of GH replacement was most pronounced in subjects in whom strength was most abnormal at baseline [07142].

**Body fat, extracellular water, and thermoregulation**

In addition to reduced muscle mass, other abnormalities of body composition and the ability to dissipate excess heat in GH-deficient individuals could contribute to impaired exercise performance. Total body and centrally distributed fat are increased in proportion to the duration of GHD, whereas extracellular water is reduced. The ability to carry out weight-bearing exercise is influenced by the quantity of body fat, which represents a mechanical limitation to exercise. The effect of reduced extracellular water on exercise capacity is less clear but might also be important. Sweating is essential for maintenance of body temperature during exercise, and thus impaired thermoregulation during exercise may also contribute to reduced exercise capacity in GHD. Using pilocarpine iontophoresis, it has been demonstrated that the sweat secretion rate is significantly lower in GHD adults than in appropriately matched control subjects and is increased during GH replacement. Despite GH replacement, sweat secretion rates were reduced, body heat storage was increased, and therefore there was a greater increase in core temperature during exercise in GHD subjects. Interestingly, five of 10 GHD patients stopped exercise prematurely because of subjective discomfort and signs of heat exhaustion [07142].

**Interactions with thyroid hormones and sex steroids**

Interactions between the GH/IGF-I axis and thyroid hormones and sex steroids may also be important. Thyroid hormone replacement in the hypopituitary patient cannot be titrated against serum TSH, the most sensitive index of tissue activity of thyroid hormones, and thus subtle degrees of over- and underreplacement with thyroid hormones likely occur in hypopituitarism. GH, through increased 5′-deiodinase activity, increases conversion of T₄ to metabolically active T₃, and it has been suggested that this effect might underlie some of the metabolic changes observed with GH replacement. Untreated testosterone deficiency in males is associated with reduced LBM, increased body fat, and reduced exercise capacity, whereas orally administered estrogen reduces fat oxidation and increases body fat in normal women. When administered together, testosterone and GH exert a combined effect on protein anabolism and body composition, and there is increasing evidence that androgen deficiency might also contribute to the phenotype of hypopituitary women [07142].

**Hypothalamo-pituitary-adrenal (HPA) axis**

Activation of the hypothalamo-pituitary-adrenal (HPA) axis and of the growth hormone/insulin-like growth factor-1 (GH/IGF-1) axis represents a physiological response to the energetic, metabolic, vascular, and sometimes neurophysiologic or psychological needs of exercise. Long-lasting increased and (or) decreased secretion of cortisol (the end-product of the HPA axis) or of GH is detrimental to health. This suggests that the activity of these hormonal axes is finely tuned toward homeostasia, tolerating limited prolonged homeostatic disruption. However, the relationships between exercise training and cortisol and GH secretion are full of odd and controversial ideas. In one review, the relationships between HPA axis adaptation to exercise training or disadaptation with overtraining was discussed, with an emphasis on the limitation on the current measures used to profile hormonal activity. Knowledge of these relationships between cortisol and GH responses to exercise is an important tool to fight against doping with glucocorticoids and GH, and their health-damaging
consequences [07145].

**Growth hormones secretagogues**

The administration of growth-promoting agents such as human growth hormone as well as compounds with respective secretagogue activity is prohibited in sports according to the regulations of the World Anti-Doping Agency. Acetylcholine esterase inhibitors have been demonstrated to stimulate growth-hormone secretion in elderly humans, and new orally active drugs have been developed to provide alternatives to therapeutic injections of growth-hormone preparations. Preventive anti-doping strategies include method development for emerging drugs and potentially misused compounds. Hence, the mass spectrometric dissociation behavior of three acetylcholine esterase inhibitors (donepezil, galantamine and rivastigmine) and a structural analogue to the growth-hormone secretagogue SM-130686 were studied using high-resolution/high-accuracy orbitrap mass spectrometry. These data provided substantial information for screening procedures, complementing common methods of sports drug testing. Using liquid-liquid extraction and subsequent liquid chromatography/tandem mass spectrometry (LC/MS/MS) analysis, the four target analytes were determined at urinary concentrations of 15-20 ng/mL, recoveries ranged from 55-97 percent, and assay precisions were calculated at 5.2-15.8 percent (intraday) and 10.2-21.6 percent (interday) for all compounds. The applicability of the developed assay to authentic urine specimens was tested using two administration study urine samples after application of Reminyl (galantamine) and Aricept (donepezil). In both cases, the administered drug and the respective desmethylated metabolites were detected [06138].

**The GH-IGF-I axis and exercise in normal subjects**

It has been demonstrated that plasma levels of GH increase during exercise, and it was later shown that exercise is the most potent physiological stimulus to GH release. GH levels start to increase 10 to 20 min after the onset of exercise, peak either at the end or shortly after exercise, and remain elevated for up to 2 h after exercise. The neuroendocrine pathways through which GH secretion is regulated during exercise are complex and poorly understood, but there is evidence that adrenergic, cholinergic, and opioid pathways are involved. The magnitude of the GH response to exercise is influenced by age, gender, body composition, physical fitness, and the intensity, nature and duration of exercise. The impact of these variables has been more clearly defined in a recent series of meticulously carried out studies using ultrasensitive chemiluminescence GH assays and deconvolution analysis of GH secretion. A linear dose-response relationship between exercise intensity and the GH secretory response has been demonstrated, with escalating GH release across the range (25 to 175 % of lactate threshold) of exercise intensities. Later studies from the same laboratory demonstrated that GH secretion correlates positively with duration of exercise when intensity is constant, is augmented by repetitive bouts of exercise, but is not influenced by the time of day that exercise was performed. It has also been demonstrated that GH secretion rates under resting conditions were greater in women; but during exercise, although absolute GH secretion rates were also increased, the increment from baseline was similar in men and women and did not correlate with sex hormones. The GH response to exercise, like 24-hr GH secretion rates, declines with aging, and it has been demonstrated that even in early middle age (mean age, 42 years), the GH response to exhaustive exercise is greatly attenuated compared with younger (mean age, 21 years) subjects. It is, however, difficult to separate inherent effects of aging from changes in body composition, because body fat increases with aging and GH secretory rates are reduced in overweight subjects. In a study designed to separate out the effects of aging, body composition, and physical fitness, the GH response was found to be determined by age and physical fitness (VO\textsubscript{2max}) but not by body.
fat, implying that maintenance of physical fitness with increased aging is more important in determining GH release than avoidance of increased adiposity. However, training programs that improve physical fitness do not appear to increase the GH response to exercise. The physiological mechanisms through which GH secretion increases during exercise are not known, but changes in body temperature, blood lactate levels, and pH have all been postulated [07142].

Exercise exerts acute effects on other components of the GH/IGF-I axis. GH-binding protein, total IGF-I, IGF binding protein (IGFBP)-3, and acid-labile subunit increase slightly during exercise, whereas IGFBP-1 increases after exercise, and free IGF-I does not appear to change during or after exercise. These observations are not altered after adjustment for changes in hydration status during exercise. IGF-I, IGFBP-3, and acid-labile subunit circulate as a ternary complex, and the observation that all three components increase in parallel with no change in free IGF-I suggests that these effects occur due to mobilization of preformed intact complexes. Consistent with this, IGFBP-3 proteolysis has been shown not to increase during or after strenuous rowing exercise. The physiological relevance of these effects is not known, but it has been postulated that the modest increase in IGF-I might enhance postexercise reparative processes, or that increased IGFBP-1 might protect against delayed onset hypoglycemia. Twenty-four-hour GH secretion rates and plasma IGF-I levels correlate positively with VO_{2max} and leisure time physical activity whereas long-term exercise training approximately doubles integrated GH concentrations in women when measured on nonexercising days. Levels of IGFBP-3 and total and free IGF-I increase after training, increased IGF-I levels becoming detectable within 2 week of commencing training and remaining above baseline for at least 6 months. These long-term effects of exercise on the GH-IGF-I axis might also contribute to some of the effects of training, including increased muscle mass and increased CO, although evidence for this is currently lacking [07142].

**Supraphysiological GH and exercise performance**

Administration of supraphysiological GH to normal subjects under resting conditions increases insulin secretion, lipolysis, fatty acid availability, and fat oxidation, and reduces glucose uptake into skeletal muscle. More recently, the effects of administration of supraphysiological GH on intermediate metabolism during exercise have also been addressed. It was demonstrated that plasma levels of glucose, glycerol, FFA, and lactate were greater during moderate to high-intensity exercise in trained men after administration of a single dose of rhGH, 2.5 mg sc, 4 h before exercise. It was also studied glycerol and glucose turnover using stable isotope techniques in endurance-trained athletes before and during 4 wk of rhGH (0.06 mg/kg/d) administration. rhGH increased lipolysis and plasma levels of FFA at rest and during and after submaximal exercise. rhGH did not influence glucose turnover at rest but increased rates of glucose production and uptake during and after exercise. Taken together, the findings of available studies demonstrate that GH enhances lipolysis during exercise under both postabsorptive and postprandial conditions and that the lipolytic effect of GH during and after exercise does not depend on increased circulating levels of GH during exercise. Despite increased fatty acid availability, there is no effect of GH on fat oxidation during or after exercise. A number of small studies have addressed the effect of supraphysiological GH administration to normal or trained subjects on protein metabolism with some conflicting findings. Observations vary between studies of athletic and nonathletic subjects, and between those of whole-body protein turnover and muscle protein synthesis. It is apparent that studies of protein metabolism in the resting state may fail to recognize important changes occurring during or after exercise. rhGH administration has been consistently shown to increase LBM in young normal or trained subjects, but it is not known how much of this increase is secondary to protein accretion and
how much to increased total body water (TBW) secondary to the antinatriuretic effect of GH. There is evidence, therefore, that supraphysiological GH administration to trained subjects results in conservation of protein and that this effect is particularly marked during exercise. However, protein anabolic processes are influenced by fatty acid availability, and therefore it is possible that these effects are secondary to the lipolytic effect of supraphysiological GH. Although findings suggest that long-term GH excess (acromegaly) is likely to be detrimental to exercise performance, it should be noted that clinical features of acromegaly are usually present for some years before diagnosis, and that biochemical GH excess precedes the appearance of clinical signs [07142].

GH was recommended in “The Underground Steroid Handbook” in 1983 as “a new and exiting anabolic agent” approximately 7 years before any publication suggesting that this effect occurred in adults appeared in the scientific literature. Ben Johnson was disqualified from the gold medal position in the 100 m in the 1988 Olympic Games and subsequently admitted under oath to having self-administered GH as well as anabolic steroids. Although it is clear that GH abuse by athletes is widespread there is no evidence of its efficacy. The most plausible mechanisms by which administration of supraphysiological doses of GH could improve exercise performance are through increased muscle mass and strength and through increased fatty acid availability resulting in glycogen sparing and increased endurance. Only two studies, with seven and eight subjects, respectively, receiving GH, have investigated the effect of GH on strength in young normal or trained subjects. Neither demonstrated any significant improvement, although the studies were of short duration and almost certainly lacked statistical power to detect a meaningful difference. There is also no evidence that GH improves endurance. However, to put these unimpressive scientific findings into context, anabolic steroids were widely abused for more than 40 years before they were definitively shown to increase strength, and the pattern of GH abuse by athletes may differ considerably from controlled clinical trials. In particular, there is evidence of an additive effect between testosterone and GH, and trials of their combined administration to athletes have not yet been reported. Furthermore, the marginal changes that differentiate winning from losing in high-level sport are unlikely to be detected in classical clinical trials, which are usually statistically powered to distinguish much larger differences. Athletes and coaches, who meticulously monitor their own performance, can detect much smaller changes with different interventions that could not be identified in small or medium-sized clinical trials. This has been demonstrated in secret doctoral theses pertaining to the sports doping program of the German Democratic Republic, which became available in the early 1990s after German reunification. In these papers, it is clearly shown that the principal method used by doctors and coaches to evaluate the effects of anabolic steroids was by comparing performance targets in individual athletes when taking and not taking different agents [07142].

Influence of training on GH response

One study examined the effects of short-term physical training on the acute hormonal response (i.e., growth hormone [GH], total and free IGF-I, and IGFBP-1, -2, and -3) to resistance exercise (RE) in women. Forty-six women (20 years) were randomly assigned to an endurance training (E), resistance training (R), combined training (R+E), or control (C) group for 8 weeks. Subjects completed a standardized bout of resistance exercise (six sets of back squats at 10-RM) before and after training. Blood samples were obtained at rest (PRE), after the third set, immediately post-exercise (POST), and at 15 min and 30 min after exercise. Acute RE significantly increased serum GH, total IGF-I, IGFBP-1, IGFBP-2, and IGFBP-3 concentrations and decreased free IGF-I concentrations. Following 8 weeks of training, total IGF-I concentrations were significantly increased and IGFBP-1 concentrations were significantly decreased during exercise in groups that participated in resistance training;
no significant changes were seen following E or C. It was concluded that participation in resistance training increased total IGF-I and reduced IGFBP-1 concentrations during acute resistance exercise, indicating exercise mode-specific adaptations in the circulating IGF-I system [12208].

Influence of carbohydrates and proteins

Endocrine responses to repeated exercise have hardly been investigated and no data are available regarding the mediating influence of nutrition. On three occasions, participants ran for 90 min at 70 percent \(\text{VO}_{2\text{max}}\) (R1) before a second exhaustive treadmill run at the same intensity (R2). During the intervening 4 h recovery, participants ingested either: 0.8 g sucrose/kg/h with 0.3 g/kg/h whey protein isolate (CHO-PRO); (ii) 0.8 g sucrose/kg/h (CHO) or; (iii) 1.1 g sucrose/kg/h (CHO-CHO). The latter two solutions therefore matched the former for carbohydrate or for available energy, respectively. Serum growth hormone concentrations increased from 1.7 ± 0.9 micr g/L to 16.7 ± 7.8 micro g/L during R1 considered across all treatments. Concentrations were similar immediately after R2 irrespective of whether CHO or CHO-CHO was ingested, whereas ingestion of CHO-PRO produced an augmented response. Growth hormone binding protein concentrations were unaffected by R1 but increased similarly across all treatments during R2, as was the case for plasma total testosterone. There was an overall treatment effect for serum cortisol, with no specific differences at any given time-point but lower concentrations immediately after R2 with CHO-PRO than CHO or CHO-CHO. Thus, ingesting carbohydrate with added whey protein isolate during short-term recovery from 90 minutes of treadmill running increases the growth hormone response to a second exhaustive exercise bout of similar duration [12209].

Influence on glucose homeostasis

It has been demonstrated that AAS use, specifically growth hormone, can affect glucose homeostasis through increasing cellular insulin resistance and reducing glucose uptake. Excess growth hormone has been shown to cause symptoms of acromegaly which predisposes up to 40 percent of patients to diabetes. As trenbolone acetate is not indicated for human use and athletes are known to use supraphysiologic doses of this underground, performance enhancing drug, the correlation of the timing of events and the use of this veterinary growth hormone likely exacerbated an underlying condition or caused this new onset diabetes. A 33-year-old male presented to the emergency department with complaints of polydipsia, polyuria, nausea, headaches, blurry vision and malaise. Lab work revealed a serum glucose level of 1166 mg/dl (64.8 mmol/L). The patient admitted to completing a cycle of androgenic anabolic steroids (AASs) for bodybuilding. His regimen consisted of supraphysiologic intramuscular injections of a bovine growth hormone, trenbolone acetate and testosterone. The patient received intravenous fluids and insulin to restore metabolic balance. Previously healthy with a non-contributory family history, he was diagnosed with new onset diabetes. AAS have the potential to induce or exacerbate diabetic conditions due to decreased glucose tolerance and increased insulin resistance [12210].

Influence on cardiovascular system

Growth hormone (GH) exerts its effects through insulin-like growth factor-1, and although ubiquitous in human tissues, it has a significant role in cardiovascular function. In recent years, there has been a great deal of interest in GH as an etiologic factor in many cardiovascular disease states. Acromegaly, a state of endogenous GH excess, results in myocardial hypertrophy and decreased cardiac performance with increased cardiovascular mortality. Additional insight into the role of excess GH on the cardiovascular system has
been gained from data collected in athletes doping with GH. Likewise, GH deficiency is associated with increased mortality, possibly from the associated increase in atherosclerosis, lipid abnormalities, and endothelial dysfunction. However, further research is required to clarify the benefit of GH treatment in both deficient states and in heart failure patients [12211].

**Effect on IGFBP-4 and -5**

It was studied the effects on insulin-like growth factor binding proteins (IGFBP)-4 and -5 after one month's treatment with supraphysiological doses of growth hormone (GH) in healthy, active young adults with a normal GH-IGF-I axis. Furthermore, the possible use of IGFBP-4 and IGFBP-5 as markers of GH doping is discussed. Thirty healthy, physically active volunteers (15 men and 15 women), mean age 26 years (range 18-35), participated in this randomized, double-blind, placebo-controlled, parallel study with three groups (n=10; 5 men and 5 women in each group). The groups comprised the following: placebo, GH 0.1IU/kg/day (0.033mg/kg/day) and GH 0.2IU/kg/day (0.067mg/kg/day). Baseline levels of IGFBP-4 were higher (+20 %), while IGFBP-5 levels were lower (-37 %) in women than in men. IGFBP-5 levels were positively correlated to age, but no significant correlation was found for IGFBP-4. In the pooled group with active GH treatment (n=20), both IGFBP-4 and IGFBP-5 levels were significantly increased versus the placebo group from day 14 until end of treatment: day 28, IGFBP-4 (+40 %) and IGFBP-5 (+61 %). After inclusion of serum IGF-I as a covariate in the linear regression analysis, the associations between GH treatment and the IGFBP-4 and IGFBP-5 levels were not significant. The study shows that the levels of IGFBP-4 and IGFBP-5 are affected by supraphysiological GH treatment given to young, healthy, physically active adults of both genders. The present study, including relatively few subjects, does not support that IGFBP-4 and IGFBP-5 can be used as IGF-I independent markers in a forthcoming method for detecting GH doping, although, further studies are needed to investigate the potential use of IGFBP-4 and IGFBP-5 as markers of GH doping [07146].

**Influence of alcohol**

Alcohol decreases spontaneous growth hormone (GH) secretion, but the mechanism is unclear. The aim of this study was to test whether administration of alcohol (study 1) or a N-methyl d-aspartate (NMDA) receptor antagonist (study 2) attenuates the GH response to pharmacological dopaminergic stimulation. The 2-session repeated measures design was conducted at an endocrine laboratory. Twenty healthy Caucasian males aged 35 years without a history of alcohol use disorders were tested using the apomorphine (APO) challenge test. In study 1, it was injected APO (0.01 mg/kg s.c.) 1 hour after oral administration of 1 g/kg ethanol and placebo, respectively. In study 2, the APO challenge was conducted after 0.3 mg/kg dextromethorphan (DXM) and placebo. The main outcome measures were the peak serum GH concentration and area under the time/concentration curve up to 120 minutes after APO. Compared with placebo, alcohol significantly decreased the APO-induced GH release (mean and SEM peak GH concentration 20 ± 3 vs 6 ± 2 ng/mL). Dextromethorphan did not change APO-induced GH response. It was concluded that a single intermediate alcohol dose markedly reduces GH response to dopaminergic stimulation. Although alcohol is thought to stimulate dopaminergic function in certain pathways, but not necessarily in the hypothalamus, our results are in line with the alcohol effect on baseline GH secretion. Growth hormone suppression appears not to be mediated by ethanol's NMDA-antagonistic properties [07147].

**Effects on other variables**
A double blind placebo controlled study of one month's GH administration to 102 healthy non-competing but trained subjects. Blood levels of nine markers of GH action were measured throughout the study and for 56 days after cessation of GH administration. Blood samples were also taken from 813 elite athletes both in and out of competition. GH caused a significant change in the nine measured blood markers. Men were more sensitive to the effects of GH than women. IGF-I and N-terminal extension peptide of procollagen type III were selected to construct formulae which gave optimal discrimination between the GH and placebo groups. Adjustments were made to account for the fall in IGF-I and P-III-P with age and the altered distribution seen in elite athletes. Using a cut-off specificity of 1:10,000 these formulae would allow the detection of up to 86 percent of men and 60 percent of women abusing GH at the doses used in this study. This will provide the basis of a robust and enforceable test identifying those who are already cheating and provide a deterrent to those who may be tempted to do so [07148].

Effects on respiration

To determine whether 6 days recombinant human growth hormone (rhGH) administration, in an abstinent anabolic-androgenic steroid (AAS) using group had any respiratory, endurance exercise and biochemical effects compared with an abstinent AAS control group male subjects (n=48) were randomly divided, using a single blind procedure into two groups. Anthropometry, respiratory muscle function and endurance exercise were investigated. Respiratory measurements examined, were forced expiratory volume in one second, forced vital capacity, maximum inspiratory pressure and maximum expiratory pressure. Endurance exercise was assessed by measuring peak oxygen uptake (VO$_{2peak}$). Biochemical analysis included; haemoglobin, packed cell volume, glucose, sodium, urea, creatinine, total protein, albumin, testosterone and insulin like growth factor-I (IGF-I). Forced expiratory volume in one second/forced vital capacity, maximum inspiratory pressure, maximum expiratory pressure, and IGF-I significantly increased compared with the control group. Body mass index, fat free mass index, peak oxygen uptake, maximum inspiratory pressure, maximum expiratory pressure, IGF-I and serum sodium significantly increased, whilst body fat, total protein and albumin, significantly decreased within the GH group. The findings of the study indicated that short-term high dose rhGH increased aerobic performance and respiratory muscle strength in former AAS users [07149].

Side effects

The side effects associated with GH administration in GH deficiency are well-documented and may affect any athlete receiving GH; however, as anecdotal evidence suggests that many athletes are taking much higher doses than those used therapeutically, it is possible that features of acromegaly may become apparent with prolonged use. Additional long-term effects may include fluid retention, which may lead to ankle swelling, hypertension, headache, diabetes, and cardiomyopathy. There is also a potential for increased risk of certain cancers; including colorectal, thyroid, breast, and prostate cancer. Cadaveric GH, with its attendant risk of the prion-induced Creutzfeldt-Jakob disease, is still available in the black market [13007].

Clinical use

GH replacement is an effective and rational therapy for adult men and women with known pituitary disease or risk factors for hypopituitarism; for example, severe head trauma or
pituitary irradiation, provided that GHD is proven. Only at-risk adults should be tested, and 
adults with childhood GHD should be retested before prescribing GH for adult needs. A 
neuroendocrine review should be considered in all cases of TBI and SAH. The AACE,
Endocrine Society, and GRS have issued detailed GHD treatment guidelines. Diagnostic 
evaluations should follow these guidelines, and physicians should stay abreast of changing 
information about testing cut-points and the use of IGF-1 as a marker for GHD. The pros and 
cons of GH treatment must be discussed with each patient, after which GH doses should be 
individualized and titrated to maximum efficacy with minimal side effects. Off-label use of GH 
therapy as an anti-aging treatment or sports enhancement is clearly at odds with current 
guidelines and should not be prescribed under any circumstances. GH replacement therapy 
has been shown to improve the clinical features of GHD in adults, although there have yet 
been no studies on endpoints such as cardiovascular events, fractures, and death. When 
used in an approved and ethical fashion for the defined population, this treatment can 
enhance the health and well-being of the many patients who suffer from the complications of 
GHD [09200].

In recent years there have been rapid developments in the use of growth factors for 
accelerated healing of injury. Growth factors have been used in maxillo-facial and plastic 
surgery with success and the technology is now being developed for orthopaedics and sports 
medicine applications. Growth factors mediate the biological processes necessary for repair 
of soft tissues such as muscle, tendon and ligament following acute traumatic or overuse 
injury, and animal studies have demonstrated clear benefits in terms of accelerated healing. 
There are various ways of delivering higher doses of growth factors to injured tissue, but 
each has in common a reliance on release of growth factors from blood platelets. Platelets 
contain growth factors in their alpha-granules (insulin-like growth factor-1, basic fibroblast 
growth factor, platelet-derived growth factor, epidermal growth factor, vascular endothelial 
growth factor, transforming growth factor-beta1 and these are released upon injection at the 
site of an injury. Three commonly utilised techniques are known as platelet-rich plasma, 
autologous blood injections and autologous conditioned serum. Each of these techniques 
has been studied clinically in humans to a very limited degree so far, but results are 
promising in terms of earlier return to play following muscle and particularly tendon injury. 
The use of growth factors in sports medicine is restricted under the terms of the World Anti-
Doping Agency (WADA) anti-doping code, particularly because of concerns regarding the 
insulin-like growth factor-1 content of such preparations, and the potential for abuse as 
performance-enhancing agents. The basic science and clinical trials related to the 
technology are reviewed, and the use of such agents in relation to the WADA code is 
discussed [07150].

Delivery methods

In recent years there have been rapid developments in the use of growth factors for 
accelerated healing of injury. Growth factors have been used in maxillo-facial and plastic 
surgery with success and the technology is now being developed for orthopaedics and sports 
medicine applications. Growth factors mediate the biological processes necessary for repair 
of soft tissues such as muscle, tendon and ligament following acute traumatic or overuse 
injury, and animal studies have demonstrated clear benefits in terms of accelerated healing.

The use of growth factors in sports medicine is restricted under the terms of the World Anti-Doping Agency (WADA) anti-doping code, particularly because of concerns regarding the insulin-like growth factor-1 content of such preparations, and the potential for abuse as performance-enhancing agents. The basic science and clinical trials related to the technology were reviewed, and the use of such agents in relation to the WADA code is discussed.[07151]

Use in weightlifters

In a study of performance-enhancing substance use among 231 experienced young male weightlifters, it was found that 27 (12%) reported illicit use of human growth hormone (HGH) or its bioactive derivative, insulin-like growth factor-1. All of these 27 men also reported use of anabolic-androgenic steroids (AAS) and 22 (81%) met criteria for current or past AAS dependence. Fifteen (56%) also reported current or past dependence on opioids, cocaine, and/or ecstasy. These findings suggest that among young male weightlifters, illicit HGH use has become a common form of substance abuse, frequently associated with both AAS dependence and classical substance dependence[11164].

Biomarkers for use (other than IGF-1)

The detection of recombinant human growth hormone (rhGH) is difficult due to its short half-life; therefore, novel and robust biomarkers of rhGH abuse are needed. In one study, serum samples derived from subjects treated with rhGH in a randomized, double blind, placebo-controlled crossover study were analyzed by 2-DE coupled with MS. Eight healthy male subjects aged 23 ± 1 years were injected with rhGH (2 mg/day) or saline for 7 days with serum samples drawn at days 0, 3, and 8. Protein intensities were quantified and analyzed for differences between rhGH and placebo treatments. Proteins that showed significant changes were identified and confirmed by Western blotting. These included specific isoforms of alpha-1 antitrypsin and transthyretin that increased; and inter-alpha-trypsin inhibitor heavy chain H4, apolipoprotein A-1, and hemoglobin beta chain that decreased. These proteins represent novel biomarkers of short-term rhGH exposure and may lead to a new method for detecting rhGH doping[11165].

GH generates the expression of both circulating and peripheral IGF-I. The GH induced circulating IGF-I, IGF binding protein (IGFBP3) and acid labile subunit (ALS) are predominantly liver derived. GH also increases bone and collagen turnover markers, with type 3 procollagen (P-III-P) being the specific marker. The biological variability of IGF-I and P-III-P has been studied longitudinally in a placebo controlled double blind manner (project GH-2000), and subsequently in project GH 2004 in amateur athletes, and longitudinally in Italian elite athletes. Some have proposed the use of these biological markers of GH action as the athlete's "passport" whereby each athlete acts as his or her own control. Another complementary GH-related biomarker is mannan-binding lectin (MBL), which is reported to increase, with a clear concentration of up to 700 %, following recombinant GH (rGH) administration while exhibiting a slow recovery time. The influence of co-administration of testosterone on the level of GH markers shows that IGF-I levels are not affected; however, the levels of P-III-P are increased[12011].
Aiming for a complementary (pre-)screening tool, the utility of DNA aptamers in an immunoassay-like scenario was reported. In a study comparing the affinity of aptamers to recombinant and natural hGH, the formation of non-covalent dimers of recombinant hGH (bridged by the aptamer DNA) was shown. The homodimeric structure was not found when applying the aptamer assay to natural hGH. A phenomenon which was suggested to provide a means to indicate the presence of non-natural hGH in doping control samples [12016].

There is growing concern about the use of recombinant human growth hormone (rhGH) by individuals taking part in competitive sports. Although rhGH is banned by the international organizations, the detection of GH doping is difficult. It was postulated that rhGH will suppress endogenous GH production, which can be assessed by the measurement of mRNA for GH and growth hormone-releasing hormone (GHRH). In order to prove this concept, it was undertaken a pilot study to examine whether circulating nucleic acids are useful in the detection of endogenous GH production. In acromegalic patients, median mRNA concentration for GHRH (corrected for beta-actin mRNA) was 30.7 times lower than in Control. There was a significant correlation between serum IGF-1 score and mRNA for GHRH. In acromegalic patients, mRNA for GH was significantly higher than in controls. As GH production is known to decline with age, it was also examined mRNA for GH and GHRH according to age subgroups. Both markers were significantly lower in the older age group (>50 years) compared to the younger age group (<34 years). These results show that mRNA for GH and GHRH can be detected in the peripheral circulation [08249].

A family of small peptides has reached the focus of doping controls representing a comparably new strategy for cheating sportsmen. These growth hormone releasing peptides (GHRP) are orally active and induce an increased production of endogenous growth hormone (GH). While the established test for exogenous GH fails, the misuse of these prohibited substances remains unrecognized. The present study provides data for the efficient extraction of a variety of known drug candidates (GHRP-1, GHRP-2, GHRP-4, GHRP-5, GHRP-6, alexamorelin, ipamorelin, and hexarelin) from human urine with subsequent mass spectrometric detection after liquid chromatographic separation. The used method potentially enables the retrospective evaluation of the acquired data for unknown metabolites by means of a non-targeted approach with high-resolution/high-accuracy full-scan mass spectrometry with additional higher collision energy dissociation experiments. This is of great importance due to the currently unknown metabolism of most of the targets and, thus, the method is focused on the intact peptidic drugs. Only the already characterised major metabolite of GHRP-2 (D: -Ala-D: -2-naphthylAla-L: -Ala, as well as its stable isotope-labelled analogue) was synthesised and implemented in the detection assay. Method validation for qualitative purpose was performed with respect to specificity, precision (<20 %), intermediate precision (<20 %), recovery (47-95 %), limit of detection (0.2-1 ng/mL), linearity, ion suppression and stability. Two stable isotope-labelled internal standards were used (deuterium-labelled GHRP-4 and GHRP-2 metabolite). The proof-of-principle was obtained by the analysis of excretion study urine samples obtained from a single oral administration of 10 mg of GHRP-2. Here, the known metabolite was detectable over 20 h after administration while the intact drug was not observed [11161].

A method to perform absolute quantification of two biomarkers (IGF-1 and IGFBP-3) of growth hormone abuse has been developed. Isotope dilution is used with synthetically labelled peptides as internal standards. Peptide selection and multiple reaction monitoring design are discussed. A simple sample preparation based on the reduction and alkylation of cysteine residues followed by tryptic digestion provides a sufficient digestion of proteins. Serum samples fortified with increasing amounts of target proteins are analysed by liquid chromatography-tandem mass spectrometry (LC-MS/MS) on a triple quadrupole mass spectrometer. Specificity is ensured by the selection of sequences with no homology in
BLAST, as well as retention time deviation check, and ion ratio monitoring. Linearity is studied in terms of calibration curves. These curves for IGFBP-3 and IGF-1 are generated with mean slopes of 0.055 and 0.065, intercepts of 0.107 and -0.011, and with coefficients of correlation of 0.95 and 0.98, respectively. These curves result from the addition of proteins to the serum. Risks of variations related to potential matrix effects are therefore reduced, as well as probable variations related to the digestion steps. The working concentration ranges are 4-10 ng/microL for IGFBP-3 and 2-8 ng/microL for IGF-1. Preliminary data regarding repeatability show that relative standard deviations (RSDs) range between 13 and 32 percent for IGFBP-3 and between 7 and 29 percent for IGF-1 [07155].

In July 2012, the detection of growth hormone abuse by means of a biomarker-based test method was approved by WADA. This complementary assay employs the biomarkers IGF-1 and the amino-terminal pro-peptide of type-III collagen (P-III-NP) as GH-sensitive parameters increasing in response to exogenous growth hormone administration. By means of doping control serum samples collected from 404 male and 94 female elite athletes, gender-specific GH-2000 score decision limits were established using currently available commercial immunoassays. Since parameters such as serum IGF-1 and other bone remodeling markers might be influenced by circumstances other than doping, the effect of tibia fracture healing on IGF-1, C-terminal telopeptide of type-I collagen (CTX), osteocalcin, and bone-specific alkaline phosphatase was studied in a clinical setting with 406 adults. In a double-blind and placebo-controlled trial, participants received a daily dose of hGH between 0.015 mg and 0.060 mg/kg bodyweight or placebo for a period of 16 weeks and the bone turnover biomarkers were recorded. In all treatment groups, a statistically significant difference in IGF-1, CTX, and OST was observed, corroborating the utility of these markers for GH abuse detection. Besides its function as biomarker, IGF-1 itself and its synthetic derivatives are prohibited substances according to the regulations of WADA. Although IGF-1’s mechanism of action concerning improved athletic performance is yet not fully understood, epigenetic aspects have been discussed and reviewed along with serious side effects attributed to long-term abuse of hGH and IGF-1. In order to unambiguously detect at least synthetic analogs of IGF-1 in urine multiplexed with other drugs and metabolites relevant for doping controls, a multi-analyte peptide screening assay was developed, allowing for the determination of IGF-1 and long-R3-IGF-1 as well as six insulins (animal, human, and synthetic), LH releasing hormone (LH-RH), growth hormone releasing hormone (GH-RH) and its synthetic analog CJC-1295, and synacthen. From both matrices, plasma and urine, detection limits between 1 and 50 pg/mL were accomplished, enabling the unequivocal detection of these analytes in doping control samples [12017].

Human growth hormone (hGH) abuse in sport is a challenge at present. The current strategy used, known as direct method, is based on the quantification of hGH variants in serum. An alternative strategy, known as indirect method, focuses on serum markers such as insulin-like growth factor I (IGF-I) and procollagen type III N-terminal propeptide (P-III-NP). The indirect method allows a longer window of detection (WOO) of hGH abuse. To evaluate the performance of the indirect method, in parallel to the direct method, a clinical trial with recombinant hGH (rhGH) was conducted on healthy male subjects during 7 days (0.026 mg/kg/day). The data were fit to the discriminant formula proposed in the previously published GH-2000 project. The low sensitivity of the scores, judged from the high number of false negative outcomes, imposed a new discriminant analysis, standarised using local population subjects demographically similar to the ones of the study. The sensitivity of the method significantly increased, highlighting the importance of the standardisation. The indirect method allowed extended window of opportunity (WOO), although two false positive evaluations were observed derived from elevated basal IGF-I and P-III-NP concentrations stressing the need for an independent confirmation method. When direct and indirect methods were combined the best selectivity and sensitivity were achieved [12206].
GH2000

The GH-2000 project developed a method for detecting GH misuse based on the measurement of insulin-like growth factor-I (IGF-I) and the amino-terminal pro-peptide of type III collagen (P-III-NP). The objective of one study was to develop decision limits for the GH-2000 score to detect GH misuse in elite athletes using two currently available commercial assays for each analyte. There was 404 male (mean age 24 years, range 12-37 years) and 94 female elite athletes (mean age 25 years, range 18-34 years) participated. Blood samples were collected according to World Anti-Doping Agency (WADA) guidelines at various sporting events including 238 samples collected as part of the UK Anti-Doping Testing Programme. For males and females separately, the distributions of GH-2000 scores were consistent with normal distributions. Using a specificity of 99.99 percent new decision limits were determined which included an allowance for uncertainty associated with calculations based on a finite sample size. One outlier was identified with results incompatible with normal physiology and tested positive with the current isoform GH test. It was thus developed decision limits using currently available commercial assays to measure IGF-I and P-III-NP in elite athletes. This should allow the introduction of a test for GH misuse based on the measurement of these GH sensitive biomarkers [12214].

The purpose of this research is to validate the biomarker-based approach for the detection of doping with recombinant human growth hormone (rhGH) in sport. The GH-2000 project proposed an indirect method for the detection of exogenously administered growth hormone (GH) based on the measurement of the GH-dependent markers: insulin-like growth factor-I (IGF-I) and Type III pro-collagen (P-III-P). These markers rise in a dose-dependent manner after GH application. In this study, the concentrations of IGF-I, IGF-BP3, and P-III-P in serum were determined to provide further incentives for the implementation of this detection assay in modern anti-doping programmes. One paper reports on an administration study of rhGH involving 25 Chinese male volunteers at a dose of 0.1 IU/kg/day for a continuous 14-day period. We observed that the serum IGF-I concentration increased rapidly in the rhGH treatment group and showed significantly higher levels compared to baseline between days 4 and day 16 after administration. Although the response of P-III-P to rhGH administration was delayed compared to the IGF-I axis, the P-III-P concentration remained increased for a longer period (from day 4 to day 28). Statistical analysis was carried out to establish a discriminant formula with Statistical Product and Service Solutions (SPSS) concluding that the biomarker methodology is valid and universally applicable [12207].

GH-2000

The GH-2000 marker method measures two serum proteins, insulin-like growth factor-I (IGF-I) and N-terminal propeptide of type III procollagen (P-III-NP), both of which increase in a dose-dependent manner in response to GH administration and therefore act as “markers” of GH administration. This method was first conceived by Peter Sönksen who established the large multicenter GH-2000 project, with funding from the European Union under their BIOMED 2 initiative, the International Olympic Committee and GH manufacturers Novo Nordisk and Pharmacia. Initially, 25 potential markers of GH action were considered; but IGF-I and P-III-NP were chosen for the GH-2000 test because these provided the best discrimination between individuals receiving GH or placebo during a 28-day randomized controlled GH administration trial. Both IGF-I and P-III-NP have little diurnal or day-to-day variation, low intraindividual variation and only change minimally in response to exercise. The markers are used in conjunction with the use of gender specific equations, “discriminant functions”, to improve the sensitivity and specificity of the test compared with single-marker
The markers decline with age as endogenous GH secretion declines and a factor relating to the inverse of age is also included in the formulae [13007].

The GH isoform approach

Circulating GH consists of multiple isoforms all derived from one gene in pituitary somatotrophs. The main isoform is 22 kDa GH, but besides this there are others such as 20 kDa isoform and 17 kDa fragment. Some isoforms are not biologically inert. There are reports that acute exercise in trained adults changes the ratio of isoforms and that exogenous 22 kDa GH administration by athletes could alter the natural GH isoform ratio. The same authors in another study conclude that a supraphysiological dose of rhGH in trained adult males suppresses exercise-induced endogenous isoforms of GH. This occurs via the classical negative feedback by IGF-I, which suppresses endogenous GH secretion, thereby suppressing endogenous molecular isoforms. However, the suppressive effect on 20 kDa GH in males is difficult to assess because at baseline 20 kDa GH levels are already undetectable. Moreover, the high degree of identity in the amino acid sequence between recombinant and endogenous GH, the pulsatile nature of GH secretion combined with inter-individual variations, presents a challenge for determination of GH [12011].

The detection test currently in use (GH isoform test) exploits the difference between recombinant GH (pure 22K-GH) and the heterogeneous nature of endogenous GH (several isoforms). Its main limitation is the short window of opportunity for detection (about 12-24 h after the last GH dose). A second test to be implemented soon (the biomarker test) is based on stimulation of IGF-I and collagen III synthesis by GH. It has a longer window of opportunity (1-2 week) but is less specific and presents a variety of technical challenges. GH doping in a larger sense also includes doping with GH secretagogues and IGF-I and its analogs. The scientific evidence for the ergogenicity of GH is weak, a fact that is not widely appreciated in athletic circles or by the general public. Also insufficiently appreciated is the risk of serious health consequences associated with high-dose, prolonged GH use. One review discussed the GH biology relevant to GH doping; the virtues and limitations of detection tests in blood, urine, and saliva; secretagogue efficacy; IGF-I doping; and information about the effectiveness of GH as a performance-enhancing agent [12215].

Intra-individual variability

Growth Hormone is abused by athletes for its lipolytic and anabolic properties. Its use is prohibited by the World Anti-Doping Agency. The GH-2000 research group developed a methodology to detect its abuse using the concentrations of two GH-dependent biomarkers, IGF-I and type 3 procollagen (P-III-P). The sensitivity of this method may be improved by considering intra-individual variability. The aim of one study was to examine the intra-individual variability of IGF-I, P-III-P and the GH-2000 score. IGF-I, P-III-P and GH-2000 score were evaluated in four longitudinal studies involving 303 elite and 78 amateur athletes. Samples were collected over a period of up to 12 months from a total of 238 men and 143 women aged between 17 and 53 years. The four studies showed good agreement with no apparent difference in within-individual variation between amateur and elite athletes. The intra-individual variability for IGF-I ranged between 14 and 16 percent while the variability for P-III-P was 7-18 percent. No athlete tested positive for growth hormone during any of the studies. The overall mean intra-individual variability of the GH-2000 score was less than 0.6 units in all studies. The high stability of marker levels suggests that concentrations are largely genetically determined. Adopting a test based on the concept of an athlete's “passport” or “profiling” would take advantage of this and most likely increase the sensitivity of the test. These data also provide strong evidence that a positive test result for GH abuse would not occur as a result of chance variability [09198].
The GH-2000 discriminant functions, using insulin-like growth factor I (IGF-I) and the N-terminal propeptide of type III procollagen (PIIINP), enabled the detection of growth hormone (GH) doping despite the broad inter-individual normal range of both peptides. The sensitivity of the discriminant function-based methodology may perhaps be further increased in future by applying individual athlete profiles. The purpose of one study was to evaluate the intra-individual variability of IGF-I, PIIINP and the GH-2000 scores in athletes. For this purpose a total of eight blood samples were taken from each of fifty male and female elite athletes over a period of up to 18 months. The IGF-I and PIIINP levels, it was found, lay predominantly within the reference range for elite athletes. The intra-individual variability for IGF-I ranged between 6 and 26 percent, while that for PIIINP ranged between 6 and 33 percent. The intra-individual variations of both parameters were higher in female than in male subjects and were found to be mostly moderate. It was found that the intra-individual variations of the GH-2000 test scores, expressed as CV, ranged from 4 to 36 percent and were in most of the subjects markedly smaller than the inter-individual variation. Individual cut-offs for the GH-2000 scores would be lower than population based ones in most of the cases [13366].

Effect of training on the analyse results

The major objective of this study was to investigate the effects of several days of intense exercise on growth hormone (hGH) testing using the World Anti-Doping Agencies hGH isoform differential immunoassays. Additionally the effects of circadian variation and exercise type on the isoform ratios were also investigated. Fifteen male athletes performed a simulated nine day cycling stage race. Blood samples were collected twice daily over a period of 15 days (stage race + three days before and after). hGH isoforms were analysed by the official WADA immunoassays (CMZ Assay GmbH). All measured isoform ratios were far below the WADA decision limits for an adverse analytical finding. Changes in the isoform ratios could not be clearly connected to circadian variation, exercise duration or intensity. The study demonstrates that the hGH isoform ratios are not significantly affected by exercise or circadian variation. It was demonstrated that heavy, long term exercise does not interfere with the decision limits for an adverse analytical finding [13375].

Theories for detection of doping with growth hormones

Isoform approach to detection abuse
Athletes recognized the performance-enhancing potential of human growth hormone when it became available for treatment of short stature in growth-retarded children. Although no controlled clinical studies have demonstrated a significant benefit in highly trained adults with normal pituitary function, the practice of doping increased with the introduction of recombinant human growth hormone. Evidence of widespread abuse has been gathered by police and customs authorities or provided by former athletes. It has been difficult to develop a test to prove the administration of exogenous growth hormone in athletes because of its specific physiological and biochemical properties. Significant progress has only recently been made, particularly via two differing approaches. The “marker approach” utilizes characteristic changes in concentrations of pharmacodynamic end points of growth hormone action, for example serum concentrations of insulin-like growth factor I and factors related to bone and soft tissue turnover. The “isoform approach” detects changes in the molecular isoform composition of circulating growth hormone evoked by the administration of exogenous recombinant growth hormone. The isoform approach was applied at the Olympic Games in Athens in 2004 and in Turin in 2006. Used in a complementary way in an out-of-competition setting, these methods are a powerful tool with which to detect growth hormone abuse in sports [07153].

The detection of exogenously administered growth hormone (GH) poses a formidable challenge but a detection method based on the measurement of two GH-dependent markers, IGF-I and type 3 pro-collagen (P-III-P) has been proposed. The measurement of multiple markers in conjunction with discriminant functions can improve the sensitivity and specificity of detection compared with single marker analysis. GH-2000 proposed a discriminant function involving IGF-I and P-III- P while the Kreischa function involved IGF-I, P-III-P and IGFBP-3. After adjustment for assay differences the formulae were applied to the other dataset. The GH-2000 formula was able to detect 90 percent of those receiving GH in the Kreischa study at one or more time points during the study period. This sensitivity was similar to that obtained on the original GH-2000 dataset. The Kreischa formula correctly identified 41 percent of individuals receiving GH in the GH-2000 study. The study provides further validation that the test proposed by GH-2000 based on IGF-I and P-III-P concentrations can be used to detect subjects receiving exogenous GH [07154].

It is believed that athletes have been abusing growth hormone (GH) for its anabolic and lipolytic effects since the early 1980s, at least a decade before endocrinologists began to treat adults with GH deficiency. There is an on-going debate about whether GH is performance enhancing. Although many of the early studies were negative, more recent studies suggest that GH improves strength and sprint capacity, particularly when it is combined with anabolic steroids. Although use of GH is banned by the World Anti-Doping Agency (WADA), its detection remains challenging. Two approaches have been developed to detect GH abuse. The first is based on measurement of pituitary GH isoforms; after injection of recombinant human GH, which comprises solely the 22-kDa isoform, endogenous production is down-regulated leading to an increase in the 22-kDa isoform relative to other isoforms. The second is based on measurement of markers of GH action. Insulin-like growth factor-I (IGF-I) and N-terminal pro-peptide of type III collagen (P-III-NP) increase in response to GH administration in a dose-dependent manner. When combined with discriminant function analysis, use of these markers differentiates between individuals taking GH and placebo. Subsequent studies have shown that the test is applicable across different ethnicities and is unaffected by injury. WADA regulations state that when analytes are measured by immunoassay, two assays are needed. Final validation of the marker test is currently being undertaken with modern commercially available immunoassays to finalise the threshold values to be used to determine whether a doping offence has been committed [11166].
Doping with growth hormone (GH) is banned; however, there is anecdotal evidence that it is widely abused. GH is reportedly often used in combination with anabolic steroids at high doses for several months. Development of a robust test for detecting GH has been challenging since recombinant human 22-kDa GH used in doping is indistinguishable analytically from endogenous GH and there are wide physiological fluctuations in circulating GH concentrations. One approach to GH testing is based on measurement of different circulating GH isoforms using immunoassays that differentiate between 22-kDa and other GH isoforms. Administration of 22-kDa GH results in a change in its abundance relative to other endogenous pituitary GH isoforms. The differential isoform method is, however, limited by its short time window of detection. A second approach that extends the time window of detection is based on detection of increased levels of circulating GH-responsive proteins, such as the insulin-like growth factor (IGF) axis and collagen peptides. As age and gender are the major determinants of variability for IGF-I and the collagen markers, a test based on these markers must take these factors into account. Extensive data now validate the GH-responsive marker approach, and implementation is largely dependent on establishing an assured supply of standardized assays [11162].

Doping with growth hormone (GH) is banned; however, there is anecdotal evidence that it is widely abused. GH is reportedly often used in combination with anabolic steroids at high doses for several months. Development of a robust test for detecting GH has been challenging since recombinant human 22-kDa GH used in doping is indistinguishable analytically from endogenous GH and there are wide physiological fluctuations in circulating GH concentrations. One approach to GH testing is based on measurement of different circulating GH isoforms using immunoassays that differentiate between 22-kDa and other GH isoforms. Administration of 22-kDa GH results in a change in its abundance relative to other endogenous pituitary GH isoforms. The differential isoform method is, however, limited by its short time window of detection. A second approach that extends the time window of detection is based on detection of increased levels of circulating GH-responsive proteins, such as the insulin-like growth factor (IGF) axis and collagen peptides. As age and gender are the major determinants of variability for IGF-I and the collagen markers, a test based on these markers must take these factors into account. Extensive data now validate the GH-responsive marker approach, and implementation is largely dependent on establishing an assured supply of standardized assays. Thus, robust tests are available to detect GH and enforce the ban on its abuse in sports. Novel approaches that include gene expression and proteomic profiling must continue to be pursued to expand the repertoire of testing approaches available and to maintain deterrence of GH doping [11163].

Although doping with growth hormone (GH) is banned, there is anecdotal evidence that it is widely abused. GH is reportedly used often in combination with anabolic steroids at high doses for several months. Development of a robust test for GH has been challenging because recombinant human 22 kDa (22K) GH used in doping is indistinguishable analytically from endogenous GH and there are wide physiological fluctuations in circulating GH concentrations. One approach to GH testing is based on measurement of different circulating GH isoforms using immunoassays that differentiate between 22K and other GH isoforms. Administration of 22K GH results in a change in its abundance relative to other endogenous pituitary GH isoforms. The differential isoform method has been implemented; however, its utility is limited because of the short window of opportunity of detection. The second approach, which will extend the window of opportunity of detection, is based on the detection of increased levels of circulating GH-responsive proteins, such as insulin-like growth factor (IGF) axis and collagen peptides. Age and gender are the major determinants of variability for IGF-I and the collagen markers; therefore, a test based on these markers must take age into account for men and women. Extensive data is now available that validates the GH-responsive marker approach and implementation is now largely dependent
on establishing an assured supply of standardized assays [08242].

Possible ethnic differences

The GH-2000 team proposed a method based on IGF1 and type III pro-collagen (P-III-P) to detect exogenously administered GH. As previous studies involved predominantly white European athletes, it is important to assess whether the response of these markers to recombinant human GH (rhGH) differs with ethnicity. In a double-blind placebo-controlled rhGH administration study the study included 31 male and 14 female amateur athletes of different ethnicities. The subjects were assigned to treatment with placebo or 0.1 IU/kg per day (low dose) or 0.2 IU/kg per day (high dose) rhGH for 28 days. Blood was collected weekly during treatment and on days 35, 42 and 84 during the washout period. Serum IGF1 and P-III-P were measured, and GH-2000 score was calculated. IGF1, P-III-P and GH-2000 score rose in response to both low- and high-dose GH in both men and women. When compared with the Caucasian volunteers of the previous GH-2000 study, mean baseline and placebo-treated P-III-P and GH-2000 score were lower in GH-2004 men and women. Post-GH, however, peak IGF1 or P-III-P did not differ between studies but the peak GH-2000 score was lower in GH-2004 men. There was no difference between studies in the maximal change in IGF1, P-III-P and GH-2000 score in response to GH in either gender. These data do not support a significant ethnic effect on the peak or maximal response to rhGH [10362].

A method based on the two GH dependent markers, IGF-I and type 3 pro-collagen (P-III-P) has been proposed to detect exogenously administered GH. As previous studies involved predominantly white European elite athletes, it is necessary to validate the method in other ethnic groups. Serum IGF-I and P-III-P were measured and GH-2000 discriminant function score was calculated. Effect of ethnicity was assessed. In men, IGF-I was 21.7 ± 2.6 percent lower in Afro-Caribbeans than white Europeans but there were no differences between other ethnic groups. In women, IGF-I was 14.2 ± 5.1 percent lower in Afro-Caribbeans and 15.6 ± 7.0 percent higher in Orientals compared with white Europeans. P-III-P was 15.2 ± 3.5 percent, 26.6 ± 6.6 percent and 19.3 ± 5.8 percent lower in Afro-Caribbean, Indo-Asian and Oriental men respectively compared with white European men. In women, P-III-P was 15.7 ± 4.7 percent lower in Afro-Caribbeans compared to white Europeans but there were no differences between other ethnicities. Despite these differences, most observations were below the upper 99 percent prediction limits derived from white European athletes. All GH-2000 scores lay below the cut-off limit proposed for doping [08246].

Pharmacokinetics and pharmacodynamics of GH

In growth hormone (GH)-deficient adult patients, subcutaneous (s.c.) administration of recombinant human GH (rhGH) at a fixed dose results in less pronounced effects in females than in males. This is thought to be at least partly due to modulation of hepatic insulin-like growth factor-I (IGF-I) generation by endogenous and exogenous estrogens. In addition, male and female patterns of fat distribution differ substantially and could potentially be associated with differences in absorption from the injection depot of rhGH. The administration route in early studies of rhGH was by intramuscular (i.m.) injection; sex differences were not noted but these studies were in children who would not have developed adult differences between the sexes. Exogenously administered rhGH is structurally identical to endogenous 22 kDa GH, which is the isoform predominantly secreted in humans. The most commonly used GH immunoassays recognize equally the 22 kDa isoform and the 20 kDa GH, which results from alternative splicing. It was suggested that development of
immunoassays that could differentiate between the isoforms could be used to assess misuse of rhGH. Ten males and ten females were selected from a cohort of 50 healthy young adults based on the level of sport activities. Inclusion criteria were: aged 18-35 years, body mass index (BMI) 19–27 kg/m², regular physical exercise at least three times per week and, in females, continuous use of oral contraceptives. Subjects were excluded if they had any chronic illness, took any medications known to interfere with endocrine function or reported any previous use of rhGH. The study used a randomized crossover design. Subjects were admitted to our clinical research unit for the three study periods, each starting at 0600 h after an overnight fast. Intravenous catheters were inserted in an antecubital vein and blood samples were drawn at 60 and 0 min (baseline) before rhGH administration then at 2-h intervals for the following 36 h. At 0 h, rhGH (Humatrope, Eli Lilly) was administered as a bolus of either 0.033 mg/kg body weight s.c., 0.083 mg/kg s.c. or 0.033 mg/kg i.m., according to a previously defined randomization scheme. Over the three study periods, each patient received each of the three rhGH doses in randomized order; patients were blinded regarding the low and high s.c. doses. Study periods were separated by a washout of 4 weeks to synchronize with the menstrual cycle in females. Serum GH concentration was assayed by two sandwich immunoassays. Assay 1 (mAb 3B4/biotinylated mAb 10A7) utilized a capture antibody, which preferentially recognizes the monomeric 22 kDa isoform of GH, which is identical to rhGH and the lower detection limit was 0.1 microg/L. Both 22 and 20 kDa GH at baseline were significantly higher in females than in males. In contrast, baseline serum IGF-I levels were significantly lower in females than in males. Differences between females studied in the follicular phase and in the luteal phase were not significant. When the same rhGH dose (0.033 mg/kg) was administered, a significantly higher 22 kDa GH peak maximal concentration ($C_{\text{max}}$) and AUC were observed with the i.m. compared with s.c. route in males but not females. There was no difference between males and females for $C_{\text{max}}$ and AUC with s.c. rhGH, irrespective of the dose. In contrast, after i.m. administration mean $C_{\text{max}}$ and AUC were significantly higher in males than females, with a concomitantly lower CL/F in males. MRT was shorter in males than females in the low-dose group, irrespective of route of administration. Subjects with higher baseline IGF-I concentrations showed a greater response to rhGH than those with a lower baseline concentration; this association was observed at all three study periods. The increase from baseline integrated over time (delta AUC 0–36) was higher with the high dose for both IGF-I and IGFBP-3. There were no significant differences for IGF-I or IGFBP-3 parameters between s.c. and i.m. routes with the same rhGH dose. $T_{\text{max}}$ for serum IGF-I differed between males and females in the high-dose group. IGF-I delta AUC 0–36 showed a clear sex difference at the low dose, with higher values in males compared with females; this was independent of the route of administration. At the high dose, the difference between the sexes was not significant. IGFBP-3 delta AUC 0–36 was significantly higher in males than females at the low s.c. dose, while at the high s.c. dose similar values were observed. At baseline, 20 kDa GH was detectable in all women in all three study periods; rapid suppression occurred after injection of rhGH. In females, mean 20 kDa GH levels decreased from 0.4 at baseline to below 0.2 μ g/l within 2 h after injection of rhGH. Duration of 20 kDa GH suppression in females was dose dependent; reoccurrence of 20 kDa GH secretion was observed in the low-dose s.c. group after 26 h, in the low-dose i.m. group after 28 h, and in the high dose s.c. group after 34 h. In contrast, in males 20 kDa GH levels were close to or below the lower limit of quantification (0.05 microg/L) of the assay at baseline and throughout the observation period. The most frequent adverse event was diarrhea occurring within 24 h after rhGH in six subjects receiving high dose and two subjects receiving low-dose s.c. injections. In four of the six subjects from the high-dose group, diarrhea was accompanied by moderate dizziness. Symptoms spontaneously ceased by the end of the study period (36 h). These episodes of diarrhea were not related to any identifiable causes such as dietary issues or gastrointestinal infections. Three subjects experienced enhanced sweating without obvious relation to the dose. One subject presented with decreased blood pressure, dizziness and vomiting 24 h
after administration of the high dose; the symptoms resolved within 6 h. No edema was observed, and neither arthralgia nor headache was reported. It was concluded that after rhGH administration, pharmacokinetic parameters are mainly influenced by route of administration, whereas pharmacodynamic variables and 20 kDa GH concentrations are determined mainly by gender. The present data demonstrate that gender, dose and route of administration specifically alter bioavailability of and response to exogenous rhGH in healthy young adults. Pharmacokinetic variables were mainly influenced by the route of administration, whereas pharmacodynamic responses were primarily determined by sex. Furthermore, suppression of the 20 kDa GH isoform after injection of rhGH could be demonstrated only in women; 20 kDa GH levels in males were already low at baseline [07152].

With no exogenous rhGH, reduced serum IGF-I and IGFBP-3 concentrations have been reported during intense training. The increase in IGF-I, but not the increase in IGFBP-3, shows a marked sexual dimorphism. It has been proposed that use of oral estrogens interferes with hepatic IGF-I production, but women not using estrogen supplementation also exhibit a lower IGF-I response than males. Studies in animals indicate that complex mechanisms, including modification of hepatic GH receptor expression, lead to the sexual dimorphism in the somatotropic axis. In contrast to serum GH concentrations, IGF-I and IGFBP-3 concentrations did not return to pre-treatment levels within the observation period, supporting the idea of use of these markers to detect doping with rhGH. The existing studies on the relationship between 22 kDa and 20 kDa isoforms suggest that the secretion is a part of constant percentage of total GH. Therefore, the lower 20 kDa level and the long-term suppression in males seem to be a consequence of the lower total GH concentration. The 20 kDa GH isoform was also suppressed in females after administration of rhGH, consistent with a negative feedback of exogenous rhGH on pituitary GH secretion; the duration of suppression was dose dependent and re-occurrence of 20 kDa in the circulation was seen 26–28 h after low-dose rhGH and 34 h after high dose rhGH. The prolonged changes provide further evidence that the GH isoform pattern can be used to detect the administration of rhGH in females [07152].

**Metabolism of GH**

Growth hormone (GH) can generate insulin-like growth factor-I production, provided that the liver encounters portal insulin as a permissive factor that switches on the liver sensitivity for GH. This phenomenon is important for a proper insight into the pathophysiology of diseases as type 1 and 2 diabetes which differ in portal insulin levels. Also, acromegaly and obesity can be better understood when this effect of insulin on liver sensitivity for GH is taken into account. Moreover, as all of these factors seem to influence activity of the 11beta-hydroxysteroid dehydrogenase (11beta-HSD) type 1 (and 2), an extensive knowledge on the interplay between them is crucial as nowadays treatment options for obesity using the 11beta-HSD1 are emerging [11167].

**Effect on red blood cells**

It has been shown that growth hormone (GH) exerts regulatory effects on hemorheology and other metabolic functions. GH stimulates the production of insulin-like growth factor I (IGF-I) and GH-IGF-I system has profound effects on body fluid status. There are speculations that GH has become widely used as a performance enhancing drug among athletes of various sports. One study evaluated the possible hemorheological effects of short term
administration of human recombinant growth hormone (rhGH) in healthy young males. Thirty young healthy males (27 ± 9) participated in a 29 days study where it was administered either 0.9 percent sodium chloride or 1 mg of human rhGH from day 1 to day 7. The participants were randomly assigned into either placebo (n=15) or rhGH 1 mg/day (rhGH) group (n=15). This study evaluated plasma fibrinogen levels, red blood cell (RBC) aggregation, deformability and serum IGF-I levels between and within the groups along 29 days. There was a significant increase in erythrocytes aggregation index post injection (day 8), in accordance to an increase in serum IGF-I [11168].

**Positive association with estrogens in men**

Growth hormone (GH) and insulin-like growth factor I (IGF-I) receptors are present on pituitary gonadotrophs and on testicular Leydig and Sertoli cells. Thus, the GH/IGF-I system may modulate the pituitary-gonadal axis in males. It was now performed a randomized cross-over study. Eight healthy male volunteers (mean age 35, range 29-46 years) were treated with GH for 3 weeks (1st week 0.01, 2nd week 0.02, 3rd week 0.03 mg/day/kg) or a GH receptor antagonist (Pegvisomant) (1st week 10, last 2 weeks 15 mg/day), separated by 8 weeks of washout. Before and after the two treatment periods, concentrations of luteinizing hormone (LH), follicle-stimulating hormone, testosterone, oestradiol, sex hormone-binding globulin, inhibin B and Anti-Müllerian Hormone (AMH) were measured. During GH treatment, IGF-I increased together with oestradiol, and the oestradiol/testosterone ratio. By contrast, AMH, Inhibin B, and LH decreased. During pegvisomant treatment IGF-I and oestradiol (86 ± 28 v. 79 ± 25 pm) decreased. No significant changes or trends in the other reproductive hormones occurred during the two treatment regimens. GH/IGF-I activity was positively associated with serum oestradiol, suggesting that GH/IGF-I stimulates aromatase activity in vivo. As a novel observation, it was found that high GH activity was associated with reduced levels of the Sertoli cell marker AMH. Further studies are needed to evaluate possible effects of GH on Sertoli cell function and/or spermatogenesis [13358].

**Negative effects on collagen synthesis**

The use of recombinant human form GH (rhGH) as an anabolic aid for clinically deficient individuals is well described. It has been reported that GH administration has an important role in the regulation of body composition by decreasing fat mass, with no effect on the net gain in muscle protein, in GH deficient men. However, the evidence is lacking for rhGH administration alone or together with anabolic steroids or weightlifting programmes to enhance gains in muscle mass and strength in healthy adults. There appears to be rhGH-induced stimulation of collagen protein synthesis in tendon and skeletal muscle in healthy adults as well as increased body water retention. The anabolic effect on connective tissue may, at least partly, explain the use of GH by the athlete to accelerate recovery and/or injury prevention. Again, there is no firm evidence to support this claim. It is noteworthy that there are documented adverse consequences of GH therapy (e.g. carpal tunnel syndrome, fluid retention, diabetic-like symptoms). These harmful effects of GH administration are usually attributed to the high doses that are given to the patient. The high-dose GH regimen is undoubtedly often used by the athlete as well. Interestingly, it was demonstrated that a single dose of GH administered prior to a bout of endurance exercise resulted in considerably higher blood lactate concentrations during an exercise bout in young adults. This outcome would not favour acute performance enhancement for an athlete wishing to gain a competitive advantage [13357].
Idiopathic adult growth hormone deficiency

GH secretion is controlled by hypothalamic as well as intrapituitary and peripheral signals, all of which converge upon the somatotroph, resulting in integrated GH synthesis and secretion. Enabling an accurate diagnosis of idiopathic adult GH deficiency (IAGHD) is challenged by the pulsatility of GH secretion, provocative test result variability, and suboptimal GH assay standardization. The spectrum between attenuated GH secretion associated with the normal aging process and with obesity and truly well-defined IAGHD is not distinct and may mislead the diagnosis. Adult-onset GHD is mainly caused by an acquired pituitary deficiency, commonly including prior head/neck irradiation, or an expanding pituitary mass causing functional somatotroph compression. To what extent rare cryptic causes account for those patients seemingly classified as IAGHD is unclear. About 15 percent of patients with adult GHD and receiving GH replacement in open-label surveillance studies are reported as being due to an idiopathic cause. These patients may also reflect a pool of subjects with an as yet to be determined occult defect, or those with unclear or incomplete medical histories (including forgotten past sports head injury or motor vehicle accident). Therefore, submaximal diagnostic evaluation likely leads to an inadvertent diagnosis of IAGHD. In these latter cases, adherence to rigorous biochemical diagnostic criteria and etiology exclusion may result in reclassification of a subset of these patients to a distinct known acquired etiology, or as GH-replete. Accordingly, rigorously verified IAGHD likely comprises less than 10 percent of adult GHD patients, an already rare disorder. Regardless of etiology, patients with adult GHD, including those with IAGHD, exhibit a well-defined clinical phenotype including increased fat mass, loss of lean muscle mass, decreased bone mass, and enhanced cardiac morbidity. Definition of unique efficacy and dosing parameters for GH replacement and resultant therapeutic efficacy markers in true IAGHD requires prospective study [13359].

Effect on memory

GH has previously been shown to promote cognitive functions in GH-deficient rodents. In this study we report the effects of GH on learning and memory in intact rats pretreated with the anabolic androgenic steroid nandrolone. Male Wistar rats received nandrolone decanoate (15 mg/kg) or peanut oil every third day for 3 weeks and were subsequently treated with recombinant human GH (1.0 IU/kg) or saline for 10 consecutive days. During the GH/saline treatment spatial learning and memory were tested in the Morris water maze. Also, plasma levels of IGF1 were assessed and the gene expression of the GH receptors, IGF-1 and IGF-2, in hippocampus and frontal cortex was analyzed. The results demonstrated a significant positive effect of GH on memory functions and increased gene expression of Igf1 in the hippocampus was found in the animals treated with GH. In addition, GH was demonstrated to increase the body weight gain and was able to attenuate the reduced body weight seen in nandrolone-treated animals. In general, the rats treated with nandrolone alone did not exhibit any pronounced alteration in memory compared with controls in the Morris water maze, and in many cases GH did not induce any alteration. Regarding target zone crossings, considered to be associated with spatial memory, the difference between GH- and steroid-treated animals was significant and administration of GH improved this parameter in the latter group. In conclusion, GH improves spatial memory in intact rats and can reverse certain effects induced by anabolic androgenic steroid [13368].

Growth hormone (GH) replacement unequivocally benefits growth, body composition, cardiovascular risk factors and quality of life. Less is known about the effects of GH on
learning and memory. A recent paper on “early onset” – GH deficiency (GHD) results in spatial memory impairment in mid life – and is prevented by GH supplementation’ by Nieves-Martinez importantly adds to this literature. Other data suggest that GH beneficially affects cognitive function in rats. In man, treatment of GHD has been associated with improvements in measures of memory and attention. There are also differences in verbal memory of patients with childhood onset GHD. Further questions remain, and the beneficial effects or otherwise of treating GHD in different age groups remain to be better defined. Certainly for reasons of maturation of neural connections and their development to young adulthood contemporaneous with rises in GH and IGF1 make these important areas for further study in man. Lastly because of what is already known in terms of cognitive effects of GHD, it is important to replace GH when studying other potential causes of adverse effects on cognition, for example, with radiotherapy [10478].

GH levels increase to high concentrations immediately before puberty then progressively decline with age. GH deficiency (GHD) originating in childhood is treated with GH supplementation to foster somatic development during adolescence. It is not clear if or how early GH replacement affects memory in adulthood, or whether it can prevent the cognitive deficits commonly observed in adults with childhood-onset GHD. Rats homozygous for the Dw-4 mutation (dwarf) do not exhibit the normal increase in GH at 4 weeks of age when GH levels normally rise and are used to model childhood or early-onset GHD (EOGHD). One group of these rats was injected with GH from 4 to 14 weeks of age to model GH supplementation during adolescence with GHD beginning in adulthood (adult-onset GHD; AOGHD). Another group received GH from 4 weeks throughout the lifespan to model normal lifespan GH (GH-replete). Age-matched, Dw-4 heterozygous rats (HZ) do not express the dwarf phenotype and were used as controls. At 8 and 18 months of age, spatial learning in the water maze was assessed. At 8 months of age all experimental groups were equally proficient. However, at 18 months of age, the EOGHD group had poor spatial learning compared to the AOGHD, GH-replete, and HZ groups. The data indicate that GHD during adolescence has negative effects on learning and memory that emerge by middle-age unless prevented by GH supplementation [09202].

**Gene expression in peripheral blood**

The objective of one study was to evaluate gene expression profiling in peripheral blood leukocytes in-vivo as a test for GH doping in humans. Seven men and thirteen women were administered GH, 2 mg/d sc for 8 wk. Blood was collected at baseline and at 8 wk. RNA was extracted from the white cell fraction. Microarray analysis was undertaken using Agilent 44K G4112F arrays using a two-color design. Quantitative RT-PCR using TaqMan gene expression assays was performed for validation of selected differentially expressed genes. GH induced an approximately 2-fold increase in circulating IGF-I that was maintained throughout the 8 wk of the study. GH induced significant changes in gene expression with 353 in women and 41 in men detected with a false discovery rate of less than 5 percent. None of the differentially expressed genes were common between men and women. The maximal changes were a doubling for up-regulated or halving for down-regulated genes, similar in magnitude to the variation between individuals. Quantitative RT-PCR for seven target genes showed good concordance between microarray and quantitative PCR data in women but not in men. Gene expression analysis of peripheral blood leukocytes is unlikely to be a viable approach for the detection of GH doping [10153].

**GH-receptor antagonists**
To examine the effects of GH receptor (GHR) antagonist treatment on exercise performance, 20 healthy males were treated with the GHR antagonist pegvisomant or placebo for 16 days. After the treatment period, they exercised to determine exercise performance, hormonal and metabolic responses. Subjects were treated with the GHR antagonist (n=10, 10 mg/d) or placebo (n=10). After treatment period, they performed a maximal oxygen uptake (\(\text{VO}_{2\text{max}}\)) test, and prolonged exercise test, consisting of 60 min submaximal cycling followed by exercise to fatigue at 90 percent of \(\text{VO}_{2\text{max}}\). \(\text{VO}_{2\text{max}}\) was measured before and after the treatment period. Hormonal and metabolic responses, and time to exhaustion during prolonged exercise were determined. Resting serum IGF-I concentration decreased by 20 percent in the GHR antagonist treated group, which was a significant difference, whereas no change was observed in the placebo group. Conversely, resting serum GH concentration was significantly higher in the treatment group compared with the placebo group. \(\text{VO}_{2\text{max}}\) did not change significantly in either group after the treatment period. Time to exhaustion at 90 percent of \(\text{VO}_{2\text{max}}\) was significantly shorter in the treatment group. No significant differences were observed between the groups in terms of changes in serum free fatty acids, glycerol, \(\text{VO}_2\), or relative fat oxidation. It was concluded that GH might be an important determinant of exercise capacity during prolonged exercise, but GHR antagonist did not alter fat metabolism during exercise [09211].

The objective of one study was to evaluate gene expression profiling in peripheral blood leukocytes in-vivo as a test for GH doping in humans. Seven men and thirteen women were administered GH, 2 mg/d sc for 8 weeks. Blood was collected at baseline and at 8 weeks. RNA was extracted from the white cell fraction. Microarray analysis was undertaken using Agilent 44K G4112F arrays using a two-color design. Quantitative RT-PCR using TaqMan gene expression assays was performed for validation of selected differentially expressed genes. GH induced an approximately 2-fold increase in circulating IGF-I that was maintained throughout the 8 wk of the study. GH induced significant changes in gene expression with 353 in women and 41 in men detected with a false discovery rate of less than 5 percent. None of the differentially expressed genes were common between men and women. The maximal changes were a doubling for up-regulated or halving for down-regulated genes, similar in magnitude to the variation between individuals. Quantitative RT-PCR for seven target genes showed good concordance between microarray and quantitative PCR data in women but not in men. Gene expression analysis of peripheral blood leukocytes is unlikely to be a viable approach for the detection of GH doping [09212].

**Growth hormone releasing peptides**

New, potentially performance enhancing compounds have frequently been introduced to licit and illicit markets and rapidly distributed via worldwide operating Internet platforms. Developing fast analytical strategies to follow these new trends is one the most challenging issues for modern doping control analysis. Even if reference compounds for the active drugs are readily obtained, their unknown metabolism complicates effective testing strategies. Recently, a new class of small C-terminally amidated peptides comprising four to seven amino acid residues received considerable attention of sports drug testing authorities due to their ability to stimulate growth hormone release from the pituitary. The most promising candidates are the growth hormone releasing peptide (GHRP)-1, -2, -4, -5, -6, hexarelin, alexamorelin, and ipamorelin. With the exemption of GHRP-2, the entity of these peptides represents nonapproved pharmaceuticals; however, via Internet providers, all compounds are readily available. To date, only limited information on the metabolism of these substances is available and merely one metabolite for GHRP-2 is established. Therefore, a
A comprehensive in vivo (po and iv administration in rats) and in vitro (with human serum and recombinant amidase) study was performed in order to generate information on urinary metabolites potentially useful for routine doping controls. The urine samples from the in vivo experiments were purified by mixed-mode cation-exchange solid-phase extraction and analyzed by ultrahigh-performance liquid chromatography (UHPLC) separation followed by high-resolution/high-accuracy mass spectrometry. Combining the high resolution power of a benchtop Orbitrap mass analyzer for the first metabolite screening and the speed of a quadrupole/time-of-flight (Q-TOF) instrument for identification, urinary metabolites were screened by means of a sensitive full scan analysis and subsequently confirmed by high-accuracy product ion scan experiments. Two deuterium-labeled internal standards (triply deuterated GHRP-4 and GHRP-2 metabolite) were used to optimize the extraction and analysis procedure. Overall, 28 metabolites (at least three for each GHRP) were identified from the in vivo samples and main metabolites were confirmed by the human in vitro model. All identified metabolites were formed due to exopeptidase- (amino- or carboxy-), amidase-, or endopeptidase activity [12212].

Legal framework

The world of doping and anti-doping in sport is an ongoing race between those who want to gain a performance advantage by using prohibited substances or methods and those who want to keep the sport clean. Sophisticated doping often involves substances that are difficult to detect, which presents both scientific and legal challenges for implementing new detection methods. One article provides an overview of legal considerations in anti-doping procedures that may apply to the use of the marker method for the detection of Human Growth Hormone. In cases where the blood markers IGF-1 and P-III-P indicate use of exogenous growth hormone, reference to positivity criteria and laboratory uncertainty measurements would assist anti-doping adjudicative bodies in concluding, to their comfortable satisfaction, that a positive test has been established. Use of established positivity criteria and laboratory uncertainty measurements place the application of the marker method for growth hormone within the existing, accepted legal framework for evaluating an Adverse Analytical Finding [09199].

Effect of dietary supplements on GH levels

Intramuscular carnosine buffers protons (H⁺) in skeletal muscle. It was examined the effects of supplementation with chicken breast meat extract (CBEX) containing carnosine and anserine on hormonal responses to resistance exercise. Twenty-two men were assigned to a CBEX drink group (CBEX containing total 2 g of carnosine and anserine) (n=14) or a placebo drink group (n=8). The subjects ingested the prescribed drink (100 mL) twice daily for 30 days without physical training. Before and after the supplementation period, the subjects
completed 5 sets of bilateral knee extension exercises (with a 90-s rest between sets). The magnitude of the increase in exercise-induced free testosterone did not change significantly after supplementation in either group. The blood lactate response to exercise was significantly attenuated after supplementation in both groups. In the CBEX group, the plasma epinephrine and norepinephrine concentrations after exercise were significantly lower after supplementation. The serum growth hormone response to exercise was also reduced in the CBEX group after supplementation. No significant differences in exercise-induced strength reduction (fatigue index) were observed in the 2 groups after supplementation. These results suggest that short-term supplementation with CBEX attenuates the exercise-induced epinephrine, norepinephrine, and growth hormone responses [11169].

**Effects of hypertemia on GH levels**

The aim of one study was to differentiate the effects of hyperthermia and physical activity on circulating growth hormone (GH) secretion. Nine healthy volunteer adults performed two 40 min exercise trials and two 50 min passive standing trials. The exercise was performed in either thermo-neutral (N-Ex: air temperature 18 degrees C, air humidity 40 %, and wet bulb globe temperature (WBGT) 17.7 degrees C) or hot environmental conditions (H-Ex: air temperature 33 degrees C, air humidity 30 %, and WBGT 34.6 degrees C). The passive exposure trials were also performed in either a comfortable (N-P: air temperature 18 degrees C, air humidity 40 %, and WBGT 17.7 degrees C) or a hot climatic chamber (H-P: air temperature 40 degrees C, air humidity 100 %, and WBGT 97.1 degrees C). Plasma GH, plasma volume (PV), tympanic temperature (Tty), and body mass loss (BML) were measured before and after each trial. The decrease in PV was significantly higher during H-Ex and H-P sessions than during N-Ex and N-P sessions. Comparisons showed significantly lower BML in the thermo neutral session than in the hot climatic sessions. The rise in Tty was significantly higher during the hot climatic session when compared with the other sessions. Plasma GH concentration increased significantly during all the trials, particularly during the hot environmental session. Both exercise and heat exposure, separately, are sufficient to increase significantly the plasma GH concentration, and their combined effect induced a highly synergistic rise in growth hormone [08250].

**Effects of exercise on GH levels**

Physical activity plays an important role in tissue anabolism, growth and development, but the mechanisms that link patterns of exercise with tissue anabolism are not completely understood. The effectiveness of physical training depends on the training load and on the individual ability to tolerate it, and an imbalance between the two may lead to under or over-training. Therefore, many efforts have been made to find objective parameters to quantify the balance between training load and the athlete's tolerance. One of the unique features of exercise is that it leads to a simultaneous increase of antagonistic mediators. On the one hand, exercise stimulates anabolic components of the growth hormone (GH) → IGF-1 (insulin-like growth factor-1) axis. On the other hand, exercise elevates catabolic pro-inflammatory cytokines such as interleukin-6 (IL-6), IL-1 and tumor necrosis factor-α (TNF-α). This emphasizes probably the importance of optimal adaptation to exercise in particularly during adolescence. The very fine balance between the anabolic and inflammatory/catabolic response to exercise will determine the effectiveness of exercise training and the health consequences of exercise. If the anabolic response is stronger, exercise will probably lead ultimately to increased muscle mass and improved fitness. A greater catabolic response, in particularly if persists for long duration, may lead to overtraining. Therefore, changes in the
anabolic-catabolic hormonal balance and in circulating inflammatory cytokines can be used by adolescent athletes and/or their coaches to gauge the training intensity in individual and team sports [10476].

In-flight muscle mass and strength losses are likely exacerbated by low growth hormone (GH) concentrations. Factors associated with exercise may foretell resultant GH levels and thereby help blunt future mass and strength losses. To assess the ability of variables to predict GH variance from resistive exercise done on a flywheel ergometer designed for in-flight exercise, subjects (n=17) performed three types of workouts on the device. With a randomized design, subjects performed the workouts with the intent to determine if changes in post-exercise GH concentrations are impacted by contractile mode and workload. Body mass, blood lactate concentrations, and peak angular velocity (PAV), average power (AP), and total work (TW) from workouts attempted to predict GH variance. Pre-exercise blood draws, and at 1 and 30 min after workouts, were used to determine GH concentrations. BLac levels were measured before workouts and at 5 min post-exercise. Delta (8, post-pre) and 30-min post-workout GH levels served as criterion variables. Univariate correlations show body mass, delta-blood lactate, and total work were the best predictors of deltaGH variance [09197].

High intensity versus high volume endurance training

The purpose of one study was to examine the acute hormonal response of a short term high-intensity training (HIT) versus a high volume endurance training (HVT) and to determine the contribution of the metabolic acidosis as a stimulus for possibly different reactions of circulating hGH, IGF-1, IGFBP-3 and cortisol. Eleven subjects participated in three experimental trials separated by one week. Two times subjects performed four 30s maximal effort exercise bouts on a cycle ergometer separated by 5 min rest each. Before the exercise subjects either received (single-blinded) bicarbonate (HIT (B)) or a placebo (HIT (P)). The third exercise trail consisted of a constant load exercise for 1h at 50 percent VO₂max (HVT). Venous blood samples were taken under resting conditions, 10 min, 60 min and 240 min after each exercise condition to determine hGH, IGF-1, IGFBP-3 and cortisol concentrations. Capillary blood samples were taken to determine lactate concentrations and blood gas parameters. Power output, mean lactate concentrations and mean pH values were significantly higher during HIT (B) compared to HIT (P). Serum cortisol and hGH concentrations were significantly increased 10 min post exercise in both HIT interventions. IGFBP-3 was only significantly increased after HIT (P), whereas IGF-1 was not affected by any of the interventions. HVT showed no significant effects on cortisol, hGH, IGF-1 and IGFBP-3 levels. Additionally it was shown that the diminished acidosis during HIT (B) attenuates the cortisol and hGH response. It was concluded that the present study suggests that HIT/acidosis is a stimulus for exercise-induced cortisol/hGH secretion, but not for IGF-1 and IGFBP-3 under these experimental conditions. These findings might be relevant for arrangements of interval training, due to the fact that active or passive recovery during rest periods influence the acid base status and may therefore influence the hormonal response [10479].

Effects in immobilisation

It was examined the effect of growth hormone (GH) on connective tissue of tendon and skeletal muscle during immobilisation and re-training in humans. Young men (20-30 years; n=20) were randomly assigned to daily recombinant human GH (rhGH) (33-50 microg/kg/day) or placebo (Plc), and had one leg immobilised for 2 weeks, followed by 6 weeks of strength training. The cross-sectional area (CSA), maximal muscle strength
(maximal voluntary contraction, MVC) and biomechanical properties of the quadriceps muscle and patellar tendon were determined. Muscle and tendon biopsies were analysed for mRNA of collagen (COL1A1/3A1), insulin-like growth factors (IGF-1Ea/Ec), lysyl oxidase (LOX), matrix metalloproteases (MMP-2 and MMP-9), decorin and tenascin-C. Fibril morphology was analysed by transmission electron microscopy (TEM) to detect changes in the fibril diameter distribution. In muscle, CSA and MVC declined with immobilisation and recovered with rehabilitation similarly in both groups. Likewise, both groups showed increased IGF-1Ea/Ec and COL1A1/3A1 expression in muscle during re-training after immobilisation compared with baseline, and the increase was more pronounced when subjects received GH. The tendon CSA did not change during immobilisation, but increased in both groups during 6 weeks of rehabilitation (14%). A decline in tendon stiffness after immobilisation was observed only in the Plc group, and an increase during 6 weeks of rehabilitation was observed only in the GH group. IGF-1Ea and COL1A1/3A1 mRNA increased with immobilisation in the GH group only, and LOX mRNA was higher in the GH group than in the Plc group after immobilisation. Both groups showed an increase in MMP-2 with immobilisation, whereas no changes in MMP-9, decorin and tenascin-C were observed. The tendon fibril diameter distribution remained unchanged in both groups. In conclusion, GH stimulates collagen expression in both skeletal muscle and tendon, abolishes the normal inactivity-related decline in tendon stiffness and LOX, and results in increased tendon CSA and stiffness during rehabilitation. GH has a matrix-stabilising effect during periods of inactivity and rehabilitation in humans [13365].

Effects of GH on performance in sports

The major objective of one study was to investigate the effects of several days of intense exercise on growth hormone (hGH) testing using the World Anti-Doping Agencies hGH isoform differential immunoassays. Additionally the effects of circadian variation and exercise type on the isoform ratios were also investigated. Fifteen male athletes performed a simulated nine day cycling stage race. Blood samples were collected twice daily over a period of 15 days (stage race + three days before and after). hGH isoforms were analysed by the official WADA immunoassays (CMZ Assay GmbH). All measured isoform ratios were far below the WADA decision limits for an adverse analytical finding. Changes in the isoform ratios could not be clearly connected to circadian variation, exercise duration or intensity. The study demonstrates that the hGH isoform ratios are not significantly affected by exercise or circadian variation. It was demonstrated that heavy, long term exercise does not interfere with the decision limits for an adverse analytical finding [13360].

Endurance

Serum insulin-like growth factor-I (IGF-I) and procollagen type III peptide (P-III-P) have been proposed as indirect biomarkers of rhGH misuse in sports. The purpose of one study was to investigate concentrations of these biomarkers in athletes at different levels of physical fitness and endurance exercise. Serum total IGF-I and P-III-P were measured in 96 elite athletes of various sports along the training season; in 21 recreational athletes at baseline non-exercising conditions and in another 129 recreational athletes before and after long-distance races (10 and 21 km). No differences were evidenced for IGF-I concentrations, but statistically higher values of serum P-III-P were found in elite athletes compared to recreational ones. Among elite athletes, the specific sport did not affect serum IGF-I. However, P-III-P was statistically higher in the sport performed by the youngest athletes (rhythmic gymnastics), even after correction of the logarithm of the concentration by the reciprocal of age. Over the training season, the within-athlete variabilities of IGF-I and P-III-P
in elite athletes were low (23 % and 22 %, respectively). Recreational athletes taking part in a 21 km competition race showed a significant increase in serum values of IGF-I and P-III-P immediately after the event. Exercise workload and age had a significant effect on serum concentration of P-III-P, while age alone affected IGF-I serum concentrations. Therefore, athlete's reference concentration ranges for doping detection should include subjects from as many different ages and sports as possible [06139].

The growth hormone (GH)/ insulin-like growth factor-I (IGF-I) axis exerts short-and long-term metabolic effects that are potentially important during exercise. Exercise is a potent stimulus to GH release and there is some evidence that the acute increase in GH is important in regulating substrate metabolism post-exercise. Regular exercise also increases 24-hour GH secretion rates, which potentially contributes to the physiologic changes induced by training. The effects of GH replacement in GH-deficient adults provide a useful model with which to study the effects of the more long-term effects of the GH/IGF-I axis. There is convincing evidence that GH replacement increases exercise capacity. Measures of exercise performance including maximal oxygen uptake (VO$_{2\text{max}}$) and ventilatory threshold are impaired in GH deficiency and improved by GH replacement, probably through some combination of increased oxygen delivery to exercising muscle, increased fatty acid availability with glycogen sparing, increased muscle strength, improved body composition and improved thermoregulation. Administration of supraphysiologic doses of GH to athletes increases fatty acid availability and reduces oxidative protein loss particularly during exercise, and increases lean body mass. It is not known whether these effects translate to improved athletic performance, although recombinant human GH is known to be widely abused in sport. The model of acromegaly provides evidence that long-term GH excess does not result in improved performance but it is possible that a "window" exists in which the protein anabolic effects of supraphysiologic GH might be advantageous [09207].

**Resistance exercise**

Several recent studies have shown that resistance exercise combined with vascular occlusion effectively causes increases in muscular size and strength. Researchers speculated that the vascular occlusion-induced local hypoxia may contribute to the adaptations via promoting anabolic hormone secretions stimulated by local accumulation of metabolic subproducts. Now it was examined whether acute systemic hypoxia affects metabolic and hormonal responses to resistance exercise. Twelve male subjects participated in two experimental trials: 1) resistance exercise while breathing normoxic air (normoxic resistance exercise, NR), 2) resistance exercise while breathing 13 percent oxygen (hypoxic resistance exercise, HR). The resistance exercises (bench-press and leg-press) consisted of 10 repetitions for five sets at 70 % of maximum strength with 1-min rest between sets. Blood were measured before normoxia and hypoxia exposures, 15-min after the exposures, and at 0, 15, 30, 60 min after the exercises. Lactate significantly increased after exercises in both trials. In the HR trial, growth hormone and cortisol significantly increased after the exercise, but not in the NR trial. The epinephrine, nor-epinephrine, IGF-1, and testosterone significantly increased after the exercises in both trials. The mean values of lactate, GH, epinephrine, and norepinephrine after exercises were significantly higher in the HR trial than that in the NR trial. These findings suggest that resistance exercise in hypoxic condition caused greater accumulation of metabolites, and strong anabolic hormone response [09201].

The aim of one study was to compare the acute hormonal responses following two different eccentric exercise velocities. Seventeen healthy, untrained, young women were randomly placed into two groups to perform five sets of six maximal isokinetic eccentric actions at slow (30°/s ) and fast (210°/s ) velocities with 60-s rest between sets. Growth hormone, cortisol, free and total testosterone were assessed by blood samples collected at baseline,
immediately postexercise, 5, 15 and 30 min following eccentric exercise. Changes in hormonal responses over time were compared between groups, using a mixed model followed by a Tukey’s post hoc test. The main findings of the present study were that the slow group showed higher growth hormone values immediately and 15 min posteccentric exercise compared with the fast group and other hormonal responses were not different between groups. In conclusion, slow eccentric exercise velocity enhances more the growth hormone (GH) response than fast eccentric exercise velocity without cortisol and testosterone increases [13361].

Sprint

Growth hormone is widely abused by athletes, frequently with androgenic steroids. Its effects on performance are unclear. To determine the effect of growth hormone alone or with testosterone on body composition and measures of performance a randomized, placebo-controlled, blinded study of 8 weeks of treatment followed by a 6-week washout period. Randomization was computer-generated with concealed allocation. Ninety-six recreationally trained athletes (63 men and 33 women) with a mean age of 28 years. Men were randomly assigned to receive placebo, growth hormone (2 mg/d subcutaneously), testosterone (250 mg/wk intramuscularly), or combined treatments. Women were randomly assigned to receive either placebo or growth hormone (2 mg/d). Body composition variables (fat mass, lean body mass, extracellular water mass, and body cell mass) and physical performance variables (endurance: maximum oxygen consumption; strength: dead lift; power: jump height; and sprint capacity: Wingate value). Body cell mass was correlated with all measures of performance at baseline. Growth hormone significantly reduced fat mass, increased lean body mass through an increase in extracellular water, and increased body cell mass in men when coadministered with testosterone. Growth hormone significantly increased sprint capacity, by 0.71 kJ (95 % confidence interval 0.1 to 1.3 kJ; relative increase 3.9 %) in men and women combined and by 1.7 kJ (confidence interval 0.5 to 3.0 kJ; relative increase 8.3 %) when coadministered with testosterone to men; other performance measures did not significantly change. The increase in sprint capacity was not maintained 6 weeks after discontinuation of the drug. Growth hormone dosage may have been lower than that used covertly by competitive athletes. The athletic significance of the observed improvements in sprint capacity is unclear, and the study was too small to draw conclusions about safety. It was concluded that the growth hormone supplementation influenced body composition and increased sprint capacity when administered alone and in combination with testosterone [10142].

Exercise stimulates growth hormone (GH) release, but there are conflicting reports regarding the acute effects of exercise on circulating ghrelin and insulin-like growth factor (IGF) concentrations. This investigation examined the effect of a single sprint on circulating GH, ghrelin and IGF concentrations as well as a marker of IGF-I bioactivity, and whether the number of muscle actions performed during a sprint influences these responses. Seven healthy men completed 3 trials in a random order. In two exercise trials they performed a single 30-s sprint on a cycle ergometer against a resistance equivalent to either 7 percent (FAST) or 9 percent (SLOW) of their body mass. In the other they rested in the laboratory (CON). Blood samples were taken pre-, immediately post-, 10 and 30 min post-exercise, and at equivalent times in the CON trial. Total ghrelin concentrations declined after the sprint and were significantly lower after 30 min of recovery than they were pre-exercise (pre-exercise vs 30 min; FAST, 0.62 vs 0.49 mug/L; SLOW, 0.59 vs 0.47 mug/L). GH concentrations increased in both exercise trials and were greater in the FAST than the SLOW trial. Serum concentrations of total IGF-I, free IGF-I, total IGF-II, and IGF-I bioactivity did not change after sprinting. In conclusion, sprint exercise suppresses total ghrelin concentrations and stimulates GH release but does not alter IGF concentrations or bioactivity [10143].
**Muscle strength**

Olympic, professional and weekend athletes abuse hGH because of unsubstantiated reports that it is as effective as anabolic steroids with fewer side effects. They often abuse growth hormone as a steroid substitute to prevent loss of muscle after discontinuing the use of steroids. According to some controlled scientific studies, hGH does not increase muscle strength [08006].

Recombinant human growth hormone (rhGH) as opposed to cadaver pituitary GH is misused for physical improvement. Six days' rhGH administration, in abstinent anabolic-androgenic steroid dependents, was compared with controls. Male subjects (n=48) were randomly divided into two groups: control group, n=24; rhGH-using group (0.058 IU/kg/day GH; n=24). Strength, peak power output and IGF-I significantly increased and total protein, albumin and free tetra-iodothyronine significantly decreased compared to controls and within the GH group. Fat-free mass index and VO₂ peak significantly increased, while body fat and thyroid-stimulating hormone significantly decreased within the GH group. It was concluded that short-term rhGH increased strength and power [08251].

One article discussed the inevitable use of growth factors for enhancing muscle strength and athletic performance. Much effort has been expended on developing a treatment of muscle wasting associated with a range of diseases and aging. Frailty in the aging population is a major socioeconomic and medical problem. Emerging molecular techniques have made it possible to gain a better understanding of the growth factor genes and how they are activated by physical activity [10144].

**With and without carbohydrate + protein**

Endocrine responses to repeated exercise have barely been investigated, and no data are available regarding the mediating influence of nutrition. On 3 occasions, participants ran for 90 min at 70 percent VO₂max (R1) before a second exhaustive treadmill run at the same intensity (R2). During the intervening 4-hr recovery, participants ingested either 0.8 g sucrose/kg/h with 0.3 g/kg/h whey-protein isolate (CHO-PRO), 0.8 g sucrose/kg/h (CHO), or 1.1 g sucrose/kg/h (CHO-CHO). The latter 2 solutions therefore matched the former for carbohydrate or for available energy, respectively. Serum growth-hormone concentrations increased from 2 ± 1 microg/L to 17 ± 8 microg/L during R1 considered across all treatments (M ± SD; p ≤ .01). Concentrations were similar immediately after R2 irrespective of whether CHO or CHO-CHO was ingested (19 ± 4 microg/L and 19 ± 5 microg/L, respectively), whereas ingestion of CHO-PRO produced an augmented response (31 ± 4 microg/L). Growth-hormone-binding protein concentrations were unaffected by R1 but increased similarly across all treatments during R2 (from 414 ± 202 pmol/L to 577 ± 167 pmol/L), as was the case for plasma total testosterone (from 9.3 ± 3.3 nmol/L to 14.7 ± 4.6 nmol/L). There was an overall treatment effect for serum cortisol, with no specific differences at any given time point but lower concentrations immediately after R2 with CHO-PRO (608 ± 133 nmol/L) than with CHO (796 ± 278 nmol/L) or CHO-CHO (838 ± 134 nmol/L). Ingesting carbohydrate with added whey-protein isolate during short-term recovery from 90 min of treadmill running increases the growth-hormone response to a second exhaustive exercise bout of similar duration [13362].

**Slow eccentric exercise velocity**
The aim of one study was to compare the acute hormonal responses following two different eccentric exercise velocities. Seventeen healthy, untrained, young women were randomly placed into two groups to perform five sets of six maximal isokinetic eccentric actions at slow (30°/s) and fast (210°/s) velocities with 60-s rest between sets. Growth hormone, cortisol, free and total testosterone were assessed by blood samples collected at baseline, immediately postexercise, 5, 15 and 30 min following eccentric exercise. Changes in hormonal responses over time were compared between groups, using a mixed model followed by a Tukey's post hoc test. The main findings of the present study were that the slow group showed higher growth hormone values immediately (5.1 ± 2.9 ng/mL, 5 (5.5 ± 3.0 ng/mL) and 15 min (4.3 ± 2.9 ng/mL) posteccentric exercise compared with the fast group (1.4 ± 2.4 ng/mL, 1.3 ± 2.0 ng/mL and 1.2 ± 1.9 ng/mL, respectively), and other hormonal responses were not different between groups. In conclusion, slow eccentric exercise velocity enhances more the growth hormone (GH) response than fast eccentric exercise velocity without cortisol and testosterone increases [13363].

**Tendons**

In skeletal muscle and tendon the extracellular matrix confers important tensile properties and is crucially important for tissue regeneration after injury. Musculoskeletal tissue adaptation is influenced by mechanical loading, which modulates the availability of growth factors, including growth hormone (GH) and insulin-like growth factor-I (IGF-I), which may be of key importance. To test the hypothesis that GH promotes matrix collagen synthesis in musculotendinous tissue, it was investigated the effects of 14 day administration of 33-50 microg/kg per day recombinant human GH (rhGH) in healthy young individuals. rhGH administration caused an increase in serum GH, serum IGF-I, and IGF-I mRNA expression in tendon and muscle. Tendon collagen I mRNA expression and tendon collagen protein synthesis increased by 3.9-fold and 1.3-fold, respectively, and muscle collagen I mRNA expression and muscle collagen protein synthesis increased by 2.3-fold and 5.8-fold, respectively. Myofibrillar protein synthesis was unaffected by elevation of GH and IGF-I. Moderate exercise did not enhance the effects of GH manipulation. Thus, increased GH availability stimulates matrix collagen synthesis in skeletal muscle and tendon, but without any effect upon myofibrillar protein synthesis. The results suggest that GH is more important in strengthening the matrix tissue than for muscle cell hypertrophy in adult human musculotendinous tissue [10145].

**No effect on tendon healing**

There have been few scientific studies that have examined usage of human growth hormone to accelerate recovery from injury. The hypothesis of this study was that human growth hormone would accelerate tendon-to-bone healing compared with control animals treated with placebo in a rat model of acute rotator cuff injury repair. Seventy-two rats underwent repair of acute rotator cuff injuries and were randomized into the following postoperative dosing regimens: placebo, and human growth hormone at 0.1, 1, 2, 5, and 10 mg/kg/day, administered subcutaneously once per day for fourteen days (Protocol 1). An additional twenty-four rats were randomized to receive either (1) placebo or (2) human growth hormone at 5 mg/kg, administered subcutaneously twice per day for seven days preoperatively and twenty-eight days postoperatively (Protocol 2). All rats were killed twenty-eight days postoperatively. Mechanical testing was performed. Ultimate stress, ultimate force, stiffness, energy to failure, and ultimate distension were determined. For Protocol 1, analysis of variance testing showed no significant difference between the groups with regard to ultimate stress, ultimate force, stiffness, energy to failure, or ultimate distension. In Protocol 2, ultimate force to failure was significantly worse in the human growth hormone group compared with the placebo group. Failure was more likely to occur through the bone than the tendon-bone interface in the human growth hormone group compared with the placebo.
group. No significant difference was found for ultimate stress, ultimate force, stiffness, energy to failure, or ultimate distension between the groups in Protocol 2. In this rat model of acute tendon-bone injury repair, daily subcutaneous postoperative human growth hormone treatment for fourteen days failed to demonstrate a significant difference in any biomechanical parameter compared with placebo. Furthermore, subcutaneous administration of 5 mg/kg of human growth hormone twice daily from seven days preoperatively until twenty-eight days postoperatively demonstrated lower loads to ultimate failure and a higher risk of bone fracture failure compared with placebo [13367].

Meta-analysis

To evaluate evidence about the effects of growth hormone on athletic performance in physically fit, young individuals randomized, controlled trials that compared growth hormone treatment with no growth hormone treatment in community-dwelling healthy participants between 13 and 45 years of age were reviewed articles. There were 44 articles describing 27 study samples that met inclusion criteria; 303 participants received growth hormone, representing 13.3 person-years of treatment. Participants were young (mean age, 27 years), lean (mean body mass index, 24 kg/m²), and physically fit (mean maximum oxygen uptake, 51 mL/kg of body weight per minute). Growth hormone dosage (mean, 36 microg/kg per day) and treatment duration (mean, 20 days for studies giving growth hormone for >1 day) varied. Lean body mass increased in growth hormone recipients compared with participants who did not receive growth hormone (increase, 2.1 kg; 95 % confidence interval 1.3 to 2.9 kg]), but strength and exercise capacity did not seem to improve. Lactate levels during exercise were statistically significantly higher in 2 of 3 studies that evaluated this outcome. Growth hormone-treated participants more frequently experienced soft tissue edema and fatigue than did those not treated with growth hormone. However, few studies evaluated athletic performance. Growth hormone protocols in the studies may not reflect real-world doses and regimens. This means that claims that growth hormone enhances physical performance are not supported by the scientific literature. Although the limited available evidence suggests that growth hormone increases lean body mass, it may not improve strength; in addition, it may worsen exercise capacity and increase adverse events. More research is needed to conclusively determine the effects of growth hormone on athletic performance [08252].

In women

The purpose of one study was to examine the effects of combined exercise training on growth hormone (GH), insulin-like growth factor-1 (IGF-1), and metabolic-syndrome factors and determine whether the changes in GH and/or IGF-1 induced by exercise correlate to the metabolic-syndrome factors in healthy middle-aged women (50-65 years of age). The participants were randomly assigned into an aerobic-exercise training (walking + aerobics) group (AEG; n=7), a combined-exercise training (walking + resistance training) group (CEG; n=8), or a control group (CG; n=7). Exercise sessions were performed 3 times per wk for 12 wk. The aerobic-exercise training consisted of walking and aerobics at 60-80 percent of heart-rate reserve, and the combined-exercise training consisted of walking and resistance exercise at 50-70 percent of 1-repetition maximum. Growth hormone, percentage body fat, fasting glucose, systolic blood pressure, and waist circumference were significantly improved in CE. However, GH induced by exercise training showed no correlation with metabolic-syndrome factors. IGF-1 was not significantly increased in either AEG or CEG compared with CG. These results indicate that the combined-exercise training produced more enhancement of GH, body composition, and metabolic-syndrome factors than did aerobic-exercise training [10146].
Impact of injuries

Growth-promoting agents are purported to increase the size of existing and newly regenerating muscle fibres and, therefore, could be used to improve muscle function if administered at appropriate times during the repair process. One review provided an update on the efficacy of some growth-promoting agents, including anabolic steroids, insulin-like growth factor-I (IGF-I) and beta₂-adrenoceptor agonists, to improve muscle function after injury. Although these approaches have clinical merit, a better understanding of the androgenic, IGF-I and beta-adrenoceptor signalling pathways in skeletal muscle is important if it may be devised safe and effective therapies to enhance muscle regeneration and function after injury [08255].

The objective of the study was to assess the effect of musculoskeletal or soft tissue injury on IGF-I and P-III-P concentrations in amateur and elite athletes and assess the effect of injury on the proposed GH detection method. There was no change in IGF-I concentration after an injury. By contrast, P-III-P concentrations rose by 41 ± 17 percent, reaching a peak around 14 days after an injury. The rise in P-III-P varied according to injury type and severity. This rise had a trivial effect on the GH-2000 discriminant function score, and no subject reached the threshold needed for a doping offense. The authors concluded that although there was a rise in P-III-P after injury, this was insufficient to invalidate the GH-2000 detection method based on IGF-I and P-III-P concentrations [08256].

Boxers

To investigate the pituitary function in retired or active amateur boxers 61 actively competing (n=44) or retired (n=17) male boxers of the Turkish National Boxing Team were investigated. Nine of 61 boxers (15 %) had growth hormone (GH) deficiency and 5 of 61 boxers (8 %) had adrenocorticotropic hormone deficiency. All boxers with GH deficiency except 1 were retired from boxing. Of 17 retired boxers, 8 (47 %) had GH deficiency. Retired boxers with GH deficiency had significantly lower pituitary volume than retired boxers with normal GH. This study suggests that retired boxers have a high rate of pituitary dysfunction [08257].

It has been recently reported that boxing and kickboxing may cause pituitary dysfunction, GH deficiency in particular. The strong link between poor cognitive performance and GH deficiency due to causes other than head trauma and the improvement of cognitive function after GH replacement therapy have been previously shown. P300 auditory event-related potential (ERP) measure is widely used to evaluate cognitive performance. In one study, it was investigated the relation between the GH-IGF-I axis and cognitive performance in boxers and kickboxers. Forty-one actively competing or retired male boxers (n=27) and kickboxers (n014) with a mean age of 29 year and 14 age- and education-matched healthy male controls were included in the study. For neuropsychological tests, the mini-mental state examination (MMSE) and Quality of Life Assessment of GH Deficiency in Adults (QoL-AGHDA) questionnaires were administered. Moreover, cognitive performance was evaluated according to P300 ERPs. Nine of 41 (22 %) athletes had GH deficiency. P300 amplitudes were lower at all electrode sites in the GH-deficient group than in controls, and the differences were statistically significant at Fz and Oz electrode sites. When GH-deficient athletes were compared with GH-sufficient athletes, the P300 amplitudes were lower at all electrode sites in the GH-deficient group; these differences were statistically significant at Fz, Pz and Cz electrode sites. In all athletes, there were significant negative correlations between IGF-I levels vs P300 latencies, and there were significant positive correlations...
between IGF-I levels vs P300 amplitudes. The study provides the first electrophysiological evidence for the close relation between the P300 ERPs and the GH-IGF-I axis in boxers and kickboxers [13369].

**Horse growth hormones**

Since the Australian commercialisation of the recombinant equine growth hormone (reGH) in 1998 (EquiGen-5), this reGH, which differs only from eGH by an additional methionine at the N-terminal end (met-eGH), is worldwide suspected to be administered to racehorses as a doping agent. Indeed, the use of this biological drug is considered as a threat to horseracing since it acts both on growth, development or reproductive functions, and on the improvement of performances. It was now described two reliable techniques based on surface plasmon resonance biosensor immunoassay and solid-phase enzyme-linked immunosorbent assay (ELISA) as new, rapid and efficient long-term screening methods applicable to horseracing antidoping analysis. The first kinetic study of serum/plasma antibodies raised as a consequence of recombinant equine growth hormone administrations, which allows the detection from eight days up to 200 days after the beginning of the treatment, was performed. In order to trace the occurrence of anti-reGH antibodies in routine analysis and to monitor the animal level exposure to this forbidden molecule, a random population study was conducted on 233 post-race horses [08258].

Equine growth hormone (eGH) has been available since 1998 as an approved drug (EquiGen-5, Bresagen) containing recombinant eGH (reGH). It is suspected of being illegally administered to racehorses in order to improve physical performance and to speed-up wound healing. Thus it may be considered a doping agent which would require a sensitive and reliable method of identification and confirmation in order to regulate its use in racehorses. reGH differs from the native eGH by an additional methionine at the N-terminal (met-eGH) and has never been unambiguously detected in any type of biological matrix at trace concentrations (1-10 mug/L). A plasma sample (4 mL) was treated with ammonium sulfate at the reGH isoelectric point and the pellet was purified by solid-phase extraction. Specific peptides were generated by trypsin digestion and analyzed by LC-MS/MS. The detection limit was 1 mug/L. Furthermore, it was successfully applied to determining the plasma concentrations of reGH with time using linear ion trap mass analyzer. The presence of the prohibited hormone was also successfully detected by triple quadrupole mass spectrometry up to 48 h postadministration of reGH to a horse [08259].

**Detection of different brands**

The detection of recombinant human growth hormone (rhGH) doping using the World Anti-Doping Agency (WADA) approved kits is reported in this research. Twenty-five young male students were selected and divided randomly into two groups with six belonging to the placebo and nineteen to the administration group. Thirteen volunteers in one group were administered with a Chinese preparation of rhGH while six volunteers included in the other group were given rhGH made in Switzerland. Both preparations were administered at a dose of 0.1 IU/kg body weight, one injection per day for 14 consecutive days. Blood samples were collected using WADA guidelines and all blood samples were analyzed with WADA-approved Kits 1 and 2. The time window for detection of rhGH doping using WADA-approved kits and criteria are discussed. Based on the comparison of the data obtained from this excretion study and from our routine (Chinese population as reference), consideration of the recent WADA criteria for rhGH AAF (Analytical Adverse Findings) is reported statistically. A
comparison of data obtained from the two sample groups administered with pharmaceutical preparations, one Chinese rhGH obtained from prokaryotic cells and the other from eukaryotic cells is reported and did not show any significant difference for the detection of doping with rhGH [11472].

**Laboratory techniques**

Recombinant human growth hormone (rhGH) is used for the treatment of several disorders. Structural integrity of rhGH is of critical importance for its clinical use and modifications thereof may act as markers in situations such as rhGH doping, as illegal rhGH-abuse in sports is of increasing interest. In the current study we investigated homogeneity of Norditropin, a recombinant human growth hormone frequently used in medicine, expressed in E. coli, strain MC1061. The most recent proteomics technologies including 2-DE, MALDI-MS followed by MALDI-MS/MS and LC-MS followed by LC-MS/MS were used for the characterisation of rhGH. MALDI-TOF-TOF and electrospray LC-MS analysis revealed one major protein with an average molecular mass of 22 126.0 Da and some additional minor components. Electrospray LC-MS/MS of the enzymatically digested Norditropin sample showed deamidation of N(12)N(149) and N(159), oxidation of M(14), M(125) and M(170) and one amino acid exchange V(14) for M(14) present in <1% of Norditropin. While deamidation and oxidation may be due to technical reasons, the single amino acid exchange may reflect infidelity of translation rather than codon usage and copy editing by E. coli [06140].

Growth hormone is abused by athletes for its lipolytic and anabolic properties. Its use is prohibited by the World Anti-Doping Agency. The GH-2000 project developed a methodology to detect its abuse using the concentrations of two GH-dependent biomarkers, IGF-I and type 3 procollagen (P-III-P). The sensitivity of this method may be improved by considering intra-individual variability. The aim of one study was to examine the intra-individual variability of IGF-I, P-III-P and the GH-2000 score. IGF-I, P-III-P and GH-2000 score were evaluated in four longitudinal studies involving 303 elite and 78 amateur athletes. Samples were collected over a period of up to 12 months from a total of 238 men and 143 women aged between 17 and 53 years (mean 24). The four studies showed good agreement with no apparent difference in within-individual variation between amateur and elite athletes. The intra-individual variability for IGF-I ranged between 14-16 percent while the variability for P-III-P was 7-18 percent. No athlete tested positive for growth hormone during any of the studies. The overall mean intra-individual variability of the GH-2000 score was less than 0.6 units in all studies. The high stability of marker levels suggests that concentrations are largely genetically determined. Adopting a test based on the concept of an athlete's “passport” or “profiling” would take advantage of this and most likely increase the sensitivity of the test. These data also provide strong evidence that a positive test result for GH abuse would not occur as a result of chance variability [10147].

Detection of athletes who use synthetic human growth hormone (hGH; or somatotropin) to enhance physical strength and obtain an advantage in competitive sports is a formidable problem, as rhGH is virtually identical to the natural pituitary hormone. However, some post-translational and other modifications have been documented by chromatographic separation and mass spectrometry (MS) in a small percentage of rhGH. In the present work, development of DNA aptamers against research-grade rhGH and natural hGH with adsorption of the rhGH aptamers against natural hGH was shown to produce a small family of aptamer sequences that bound consistently with greater affinity to rhGH over a low nanogram-to-microgram range in ELISA-like microplate assays. This collection of rhGH discriminatory aptamer sequences shared some short sequence segments and secondary
Emerging molecular techniques have made it possible to gain a better understanding of the growth factor genes and how they are activated by physical activity [10149].

Detection of athletes who use synthetic human growth hormone (hGH; or somatotropin) to enhance physical strength and obtain an advantage in competitive sports is a formidable problem, as rhGH is virtually identical to the natural pituitary hormone. However, some post-translational and other modifications have been documented by chromatographic separation and mass spectrometry (MS) in a small percentage of rhGH. In the present work, development of DNA aptamers against research-grade rhGH and natural hGH with adsorption of the rhGH aptamers against natural hGH was shown to produce a small family of aptamer sequences that bound consistently with greater affinity over a low nanogram-to-microgram range in ELISA-like microplate assays. This collection of rhGH discriminatory aptamer sequences shared some short sequence segments and secondary structural features. The top rhGH discriminatory aptamers also appeared to cross-react with human myoglobin and BSA but not with bone collagen peptides and an unrelated viral envelope peptide. The cross-reactivity results suggested several strings of up to five consecutive amino acids that might serve as common epitopes for aptamer binding. SDS-PAGE revealed that the rhGH existed largely as a 45-kDa dimer, and the natural hGH was almost exclusively monomeric. The existence of the rhGH dimer suggests that a discontinuous "bridge" epitope may exist on the rhGH, which spans the subunits, thereby accounting somewhat for the difference in detection. Overall, these results suggest that aptamers might be useful for routine, presumptive laboratory screening to identify athletes who are potentially cheating by administration of rhGH [11170].

A method based on IGF1 and type III pro-collagen (P-III-P) to detect exogenously administered GH was proposed. As previous studies involved predominantly white European athletes, it is important to assess whether the response of these markers to recombinant human GH (rhGH) differs with ethnicity. The study included 31 male and 14 female amateur athletes of different ethnicities. The subjects were assigned to treatment with placebo or 0.1 IU/kg per day (low dose) or 0.2 IU/kg per day (high dose) rhGH for 28 days. Blood was collected weekly during treatment and on days 35, 42 and 84 during the washout period.
Serum IGF1 and P-III-P were measured, and GH-2000 score was calculated. IGF1, P-III-P and GH-2000 score rose in response to both low- and high-dose GH in both men and women. When compared with the Caucasian volunteers of the previous GH-2000 study, mean baseline and placebo-treated P-III-P and GH-2000 score were lower in GH-2004 men and women. Post-GH, however, peak IGF1 or P-III-P did not differ between studies but the peak GH-2000 score was lower in GH-2004 men. There was no difference between studies in the maximal change in IGF1, P-III-P and GH-2000 score in response to GH in either gender. These data do not support a significant ethnic effect on the peak or maximal response to rhGH [10150, 10151].

Mass spectrometric approaches have been used to determine various peptide hormones in sports drug testing. While insulin-like growth factor-1 (IGF-1) and its synthetic analogs are qualitatively and/or quantitatively measured by liquid chromatography-tandem mass spectrometry after immunoaffinity purification, methods of uncovering doping rule violations with illegal applications of human growth hormone (hGH) have not yet been established using mass spectrometry-based assays. However, substantial information on the heterogeneity of hGH, splice variants and post-translational modifications with respective locations as elucidated by mass spectrometry are of utmost importance for improving currently employed immunological procedures [10152].

Application of methods for detecting GH doping depend on being able to discriminate between abnormal levels due to doping and normal physiological levels of circulating proteins that change in response to exogenous administration. Constituents of the IGF and collagen systems have been shown to be promising markers of GH abuse. Their ultimate utility, however, depends on identification of the factors that regulate their concentrations in blood. Among these are demographic factors that are known to influence these markers in the general population. In a large cross-sectional study of the GH-responsive markers in over 1000 elite athletes from 12 countries representing 4 major ethnic groups and 10 sport types, it was shown that there is a significant negative correlation between age and all the IGF and collagen markers that was studied, with a rapid decrease in early adolescence. Age was the major contribution to the variability, equivalent to >80 percent of the attributable variation in IGF-I and the collagen markers. The IGF axis markers were all significantly higher in women, and the collagen markers significantly higher in men, however, the contribution of gender was smaller than that of age, except for IGFBP-3 and ALS. BMI had a minor contribution to variability of the GH-responsive markers. After adjustment for the confounding influences of age, gender and BMI, the effect of ethnicity in elite athletes was trivial except for IGFBP-3 and ALS, which were both lower in Africans and higher in Caucasians. Compared to age and gender, the contribution of sport type was also modest. The findings on the influence of age, gender, BMI and sport type have also been confirmed in a study of mostly Caucasian elite athletes in the post-competition setting. It was concluded that age and gender are the major determinants of variability for IGF-I and the collagen markers, whereas ethnicity and sport type have a minor influence. Therefore, a test based on IGF-I and the collagen markers must take age into account for men and women, and ethnicity and sport type are unlikely to be confounders for these markers [09208].

Following the successful production of recombinant 20K-GH, several studies investigating the physiology of this GH isoform have been undertaken. In one report, it was reviewed studies of its biological effect, measurement and secretion. To use serum 20K-GH level in detecting GH abuse, new method has been established and serum 22K-GH, 20K-GH were measured in normal subjects and athletes, and no abnormal results were found among athletes. Another study confirmed that serum 22K-GH increased remarkably and 20K-GH decreased following the exogenous administration of 22K-GH. The duration was relatively short, approximately 24-36h in several studies. The increase of the ratio, 22K-GH/20K-GH...
was the most suitable indicator of GH abuse. Studies supported by the WADA were undertaken in collaboration with an Australian Group. A new approach for the GH isoform assay by beads assay platform is being developed. It is concluded that the direct measurement of 20K-GH is a valid scientific approach, for detecting GH abuse, although the duration of the positive results is short. The method will be useful in combination with the marker method, an out-of-competition test or test for target cases [09209].

It was developed a semiquantitative method for the analysis of main growth hormone isoforms. The use of immunoaffinity sorbents, two-dimensional electrophoresis, and immunoblotting allows detection of more than 90 percent circulating growth hormone. It was demonstrated that the proportion of growth hormone isoforms in human serum before and after strenuous exercise remained unchanged [09210].

The utility of insulin-like growth factor (IGF) axis and collagen markers for a growth hormone (GH) doping test in sport depends on their stability and reproducibility. It was sought to determine short-term within-subject variability of these markers in a large cohort of healthy individuals by measuring IGF-I, IGF binding protein 3 (IGFBP-3), acid labile subunit (ALS), and the collagen markers N-terminal propeptide of type I procollagen (PINP), C-terminal telopeptide of type I collagen (ICTP), and N-terminal propeptide of type III procollagen (PIIINP) in serum samples obtained on multiple occasions (median 3 per participant) over a 2- to 3-week period from 1103 elite athletes (699 men, 404 women) aged (mean) 22 years. Within-subject variance accounted for 32-36 percent and 4-13 percent of the total variance in IGF markers and collagen markers, respectively. The within-subject CV ranged from 11 to 21 percent for the IGF axis markers and from 13 to 15 percent for the collagen markers. The index of individuality for the IGF axis markers was 0.66-0.76, and for the collagen markers, 0.26-0.45. For each marker, individuals with initial extreme measured values tended to regress toward the population mean in subsequent repeated measurements. These results indicate that in healthy individuals the within-subject variability was greater for IGF-I than for the collagen markers, and that where a single measurement is available, it is possible to estimate the long-term probable value of each of the markers by applying the Bayesian approach. Such an application can increase the reliability and decrease the cost of detecting GH doping [08253].

IGF axis proteins and collagen peptides are promising markers of GH abuse. The objective was to investigate whether responses of serum IGF axis and collagen markers to GH differ between men and women, and are influenced by testosterone in a randomized, double-blind, placebo-controlled study of 8-week treatment followed by 6-week washout. A total of 96 recreationally trained healthy athletes (63 men, 33 women), aged 18-40 year, were studied. All subjects received GH (2 mg/d sc) or placebo for 8 weeks; men also received testosterone (250 mg/week im) or placebo for 5 weeks. Serum IGF axis proteins (IGF-I, IGF binding protein-3, and acid labile subunit) and collagen peptides (N-terminal propeptide of type I procollagen, C-terminal telopeptide of type I collagen, and N-terminal propeptide of type III procollagen) were measured. GH induced significant increases in IGF axis and collagen markers that were greater in men than women. Of the IGF axis markers, IGF-I showed the greatest increase. The relative incremental responses of the collagen markers in general were greater than the IGF markers, especially for PIIINP. The collagen markers increased and decreased more slowly with most remaining elevated after 6 weeks, in comparison to IGF markers, which returned to baseline within 1 week. Addition of T to GH amplified the response of PIIINP by more than 1.5-fold but did not affect any other marker. Testosterone alone did not affect IGF axis markers but modestly increased collagen markers. These markers of GH abuse are less responsive in women. The increases in collagen markers have a different time course to the IGF markers and extend the window of detection in both sexes. The response of PIIINP is increased by coadministration of testosterone [08254].

1112
It has been argued that increased levels of bone remodelling markers are not suitable indicators of GH abuse, as bone injuries per se increase the expression levels of these markers. To investigate the impact of a recovering tibia fracture on circulating bone markers in subjects receiving placebo or GH treatment in a randomised, double-blind, placebo-controlled trial of up to 16 weeks GH treatment, followed by a 16-week washout was conducted. Subjects (406 adult males and females) with a tibia fracture were randomly allocated within three days after surgery, to either placebo or GH treatment (15, 30 or 60 microg/kg daily) until fracture healing or 16 weeks after treatment initiation. IGF-I, serum C-terminal telopeptide of type I collagen (CTX), osteocalcin (OST) and bone-specific alkaline phosphatase (BAP) were measured during and after treatment. Dose-dependent increases were observed in groups receiving GH, and mean levels in the highest GH dose group peaked at eight (IGF-I, CTX) or 12 weeks (OST) after treatment initiation. Statistically significant differences between GH treatment and placebo were seen for IGF-I, CTX and OST in all GH dose groups throughout the treatment period, and persisted until eight (CTX) or 12 (OST) weeks after cessation of treatment. It was concluded that IGF-I, CTX and OST are suitable candidate markers of prolonged, illicit administration of GH. Furthermore, CTX and OST have potentials to serve as markers also after cessation of GH administration [11473].

GH is believed to be widely employed in sports as a performance-enhancing substance. Its use in athletic competition is banned by the World Anti-Doping Agency, and athletes are required to submit to testing for GH exposure. Detection of GH doping is challenging for several reasons including identity/similarity of exogenous to endogenous GH, short half-life, complex and fluctuating secretory dynamics of GH, and a very low urinary excretion rate. hGH has been widely abused as a doping agent in sports for many years. There are some important approaches for the detection of hGH doping, and the ratio of 22:20 kDa GH was considered one of the most suitable detection indicators of GH abuse. Currently, effective anti-GH antibodies and related reagents are needed to develop a detection method, in particular, highly specific anti-20 kDa hGH monoclonal antibodies are a prerequisite. Herein we constructed the expression vector of 20 kDa hGH and prepared the corresponding antibodies by the immunization of the recombinant human 20 kDa into mice. Positive clones that can specifically recognize 20 kDa hGH were screened and characterized by enzyme immunoassay, Dot-ELISA and surface plasmon resonance. In total, 14 specific monoclonal cell lines were screened out. By a series of characterization, it was found that the 6C8, 44H3, 12G7 and 33Y19 clones were showing much higher specificity and affinity to 20 kDa hGH, and P3H9 could recognize both 20 and 22 kDa hGH isoforms. 6C8 and 44H3 matched well with P3H9 in the surface plasmon resonance testing. The 12G7 clone had the best surface properties with an association constant of $3.4 \times 10^9$ M$^{-1}$ and a dissociation constant of $2.95 \times 10^{10}$ M. Highly specific monoclonal antibodies against 20 kDa hGH were generated, and also two paired antibodies (P3H9 and 6C8 or P3H9 and 44H3) were characterized, which can serve as the potential components for 22:20 kDa detection kit [12213].

It was implemented a surface plasmon resonance (SPR) immunosensor based on a sandwich assay for the simultaneous detection of the two main hGH isoforms, of 22 kDa (22K) and 20 kDa (20K). An oriented-antibody sensor surface specific for both hormone isoforms was assembled by using the biotin-streptavidin system. The immunosensor functionality was checked for the direct detection of the 22K hGH isoform in buffer, which gave high specificity and reproducibility (intra and inter-assay mean coefficients of variation of 8 % and 9 % respectively). The selective determination of the 22K and 20K hGH isoforms in human serum samples in a single assay was possible by using two specific anti-hGH monoclonal antibodies. The detection limit for both hormone isoforms was 0.9 ng mL$^{-1}$ and the mean coefficient of variation was below 7.2 percent. The excellent reproducibility and
sensitivity obtained indicate the high performance of this immunosensor for implementing an anti-doping test [130370].

Growth hormone abuse in sports has been suspected and purported for decades and also occasionally been proven in the last years. As the major temptations the assumed ergogenic activity of hGH, accelerated recovery (e.g. after injury) and also its former ‘stealth’ and undetectable nature have been mentioned. In a comprehensive overview concerning health risks associated with hGH (and IGF-1) abuse, detection strategies (GH isoform and biomarker test) and their advantages as well as limitations is presented. Despite the substantial knowledge concerning adverse effects of GH abuse, incidences and case reports with bovine growth hormone self-administrations have been reported. Since 2004, the isoform test for hGH abuse has been in use in routine doping controls and has undergone fine-tuning and continuous finishing to increase its sensitivity and thus broaden the window of opportunity for detection. In 2011, a controlled administration study with two preparations of recombinant hGH (Chinese and Swiss products, 0.1 IU/kg bodyweight) was conducted and the traceability of the drug (i.e. its influence on the circulating GH isoforms) was determined using the WADA-approved analytical kits. Following a single injection, detection windows between 12 and 18 h were observed, while repeated hGH application (one injection/day over 14 days) allowed for hGH abuse detection up to 21 h after cessation. In a different study, the performance of two isoform-based growth hormone detection assays, namely the above mentioned WADA-approved test and a 22 kDa/20 kDa isoform immunoassay, was compared. Volunteers received recombinant hGH subcutaneously at 0.026 mg/kg bodyweight once daily for seven consecutive days, and collected serum samples were analyzed on both platforms. The assays demonstrated good correlation concerning the detection of abnormal isoform concentrations in serum and exhibited comparable detection windows of up to 24 h [13012].

In July 2012, the detection of growth hormone abuse by means of a biomarker-based test method was approved by WADA. This complementary assay employs the biomarkers IGF-1 and the amino-terminal pro-peptide of type-III collagen (P-III-NP) as GH-sensitive parameters increasing in response to exogenous growth hormone administration. By means of doping control serum samples collected from 404 male and 94 female elite athletes, gender-specific GH-2000 score decision limits were established using currently available commercial immunoassays. Since parameters such as serum IGF-1 and other bone remodeling markers might be influenced by circumstances other than doping, the effect of tibia fracture healing on IGF-1, C-terminal telopeptide of type-I collagen (CTX), osteocalcin, and bone-specific alkaline phosphatase was studied in a clinical setting with 406 adults. In a double-blind and placebo-controlled trial, patients received a daily dose of hGH between 0.015 mg and 0.060 mg/kg bodyweight or placebo for a period of 16 weeks and the bone turnover biomarkers were recorded. In all treatment groups, a statistically significant difference in IGF-1, CTX, and OST was observed, corroborating the utility of these markers for GH abuse detection [13012].

It was implemented a surface plasmon resonance (SPR) immunosensor based on a sandwich assay for the simultaneous detection of the two main hGH isoforms, of 22kDa (22K) and 20kDa (20K). An oriented-antibody sensor surface specific for both hormone isoforms was assembled by using the biotin-streptavidin system. The immunosensor functionality was checked for the direct detection of the 22K hGH isoform in buffer, which gave high specificity and reproducibility (intra and inter-assay mean coefficients of variation of 8 % and 9 %, respectively). The selective determination of the 22K and 20K hGH isoforms in human serum samples in a single assay was possible by using two specific anti-hGH monoclonal antibodies. The detection limit for both hormone isoforms was 0.9 ng/mL and the mean coefficient of variation was below 7.2 percent. The excellent reproducibility and
sensitivity obtained indicate the high performance of this immunosensor for implementing an anti-doping test [13371].

Successful application clinical-grade human growth hormone (hGH) immunoassays to the discovery of illegal doping cases has been rare. Indeed, the preferred biological matrix in doping control is urine, where the estimated baseline concentration of hGH falls well below the linear range and sensitivity threshold of all commercially available immunoassays, including hGH isoform differential immunoassays which can discriminate pituitary endogenous hGH from recombinant hGH. It was employed hydrogel nanoparticles as a pre-processing step that concentrates urinary hGH into the linear range of isoform differential immunoassays. It was explored the characteristics of immunoassays in urine spiked with both phGH or rhGH, after pre-treatment with the nanoparticles. Subsequently, pre-treatment was applied to urine obtained from 3 healthy volunteers administered during three days with daily subcutaneous injections of 0.026 mg/kg/day rhGH, Genotonorm®). Linearity between both rhGH and phGH concentrations in urine measured by a chemoluminescent assay (Immulfite) and in the particle eluate was evident for differential immunoassays (R square higher than 0.999). In case of treated individuals the recombinant/pituitary concentration ratios remained above the established World Anti-Doping Agency (WADA) criterion for hGH misuse up to 24h after the last administration dose, using both assays for volunteer 1 and 2 while in case of volunteer 3 results were inconclusive. The use of nanoparticles appears to open the possibility of assessing rhGH misuse in urine [13372].

The isoform methods

Endogenous pituitary GH occurs in multiple isoforms of which 70 percent is in the form of a 22 kDa polypeptide. By contrast, rhGH comprises solely the 22-kDa isoform. When rhGH is administered, endogenous pituitary secretion is downregulated through negative feedback and the concentration of non-22-kDa isoforms is suppressed. The isoform method relies on the measurement of the ratio of 22 kDa GH to total GH. The proportions of GH isoforms are unaffected by age, sex, sporting discipline, and pathological states, but exercise causes a transient relative increase in the 22-kDa isoform, thereby reducing the sensitivity of the test if samples are taken immediately after competition. This method was introduced prior to the 2004 Athens Olympic Games and subsequently improved when the assays used for the method were commercialized. The Achilles’ heel of the isoform method is its short window of detection. Recombinant GH, even when injected subcutaneously, is cleared rapidly and GH is frequently undetectable in a blood sample taken the morning after an injection, while spontaneous GH secretion returns to normal within 48 h of the last dose of rhGH. Consequently, any athlete who ceases GH several days prior to a competition will not be detected. A further disadvantage of this method is that it will not detect the use of cadaveric GH or GH secretagogues as these do not alter the isoform profile [13007].

With nano-technology

Successful application clinical-grade human growth hormone (hGH) immunoassays to the discovery of illegal doping cases has been rare. Indeed, the preferred biological matrix in doping control is urine, where the estimated baseline concentration of hGH falls well below the linear range and sensitivity threshold of all commercially available immunoassays, including hGH isoform differential immunoassays which can discriminate pituitary endogenous hGH from recombinant hGH. It was employed hydrogel nanoparticles as a pre-processing step that concentrate urinary hGH into the linear range of isoform differential immunoassays. It was explored the characteristics of immunoassays in urine spiked with both phGH or rhGH, after pre-treatment with the nanoparticles. Subsequently, pre-treatment...
Stability of GH during testing procedures

IGF-I and type III procollagen (P-III-P) have been proposed as markers to detect GH abuse. One study aimed to determine whether the pre-analytical storage temperature or delayed centrifugation affect the measured IGF-I and P-III-P concentrations. The storage temperature or timing of centrifugation did not appear to affect IGF-I concentration. In contrast, the measured P-III-P concentration rose by 6.5-7 percent per day in clotted and lithium heparin samples when stored as whole blood or serum (6.2-6.5 % per day) at room temperature. P-III-P did not change when the samples were stored at 4 degrees C. Although collection into EDTA inhibited the rise in P-III-P, the baseline measured values were significantly higher than in other media and spiking experiments demonstrated that EDTA exerted a significant matrix effect on the assay. While the optimum collection method is immediate centrifugation and storage at -80 degrees C, it would seem acceptable to store serum or clotted blood samples at 4 degrees C, but not ambient temperature, for up to five days [08247].

Monoclonal antibodies

Recombinant human growth hormone (rhGH) is abused in sports, but adequate routine doping tests are lacking. Analysis of serum hGH isoform composition has been shown to be effective in detecting rhGH doping. It was developed and validated selective immunoassays for isoform analysis with potential utility for screening and confirmation in doping tests. Monoclonal antibodies with preference for pituitary hGH (phGH) or rhGH were used to establish 2 pairs of sandwich-type chemiluminescence assays. It was analyzed specimens from volunteers before and after administration of rhGH. Functional sensitivities were <0.05 microg/L, with intra- and interassay imprecision ≤ 8.4 percent and ≤ 13.7 percent, respectively. In 20 recreational athletes, ratios (median) increased after a single injection of rhGH, reaching 350 percent and 400 percent of baseline ratios. At a moderate dose (0.033 mg/kg), mean ratios remained significantly increased for 18 h (men) and 26 h (women). After high-dose rhGH (0.083 mg/kg), mean ratios remained increased for 32-34 h in men and were still increased after 36 h in women. It was concluded that using sensitive chemiluminescence assays with preferential recognition of phGH or rhGH, detection of a single injection of rhGH was possible for up to 36 h [09195].

Electrophoresis and mass spectrometry

The heterogeneity of human endogenous growth hormone (GH) is used in doping control analysis to distinguish it from the homogeneous recombinant analogue in plasma samples. Pituitary GH variants were characterized by gel electrophoresis and mass spectrometry. Besides 22 and 20 kDa isoforms, fragments of 9 and 12 kDa were identified and a glycosylated 23 kDa GH variant was elucidated to bear a HexHexNac 2 NeuAc modification presumably located at Thr 60 [09196].
Immunoaffinity purification

Human growth hormone (GH) has several central metabolic functions including bone growth in childhood, and its anabolic and lipolytic effects in particular are assumed reasons for the abuse of GH by athletes. Human endogenous GH consists of a main 22 kDa variant and several isoforms. In contrast, recombinant GH consists of only one variant being identical to the main endogenous isoform. The method presented here separates different isoforms by 2-D PAGE after isolation of GH from plasma using an immunoaffinity purification system. While samples containing endogenous GH yield up to four isoforms, samples with recombinant GH contain the main 22 kDa spot only. Normalized spot volumes (NSV) are calculated after addition of an internal standard and a discrimination limit was determined at 0.52 for the NSV of the main 22 kDa spot. Above this value, samples containing endogenous GH show at least the main 22 kDa isoform and the 20 kDa splice variant. In contrast, samples with a NSV >0.52 and only one spot are suspicious to contain recombinant GH. This method detects discrete isoforms of GH from plasma and discriminates endogenous GH from its recombinant analog, which makes it useful for doping control purposes [08241].

Immunoassays

Detecting recombinant human growth hormone (rhGH) abuse in sport remains one of the major challenges in doping control. It was compared two different approaches to detect the hGH (human growth hormone) abuse. The first measures the concentrations of the 22 kDa hGH isoform (rec assay) and pituitary derived isoforms (pit assay) and a ratio rec/pit is obtained. The second measures the concentrations of 22 and 20 kDa hGH isoforms and also a ratio 22/20 kDa is derived. Using a single set (nine healthy male subjects, 7 days, 0.026 mg/kg/day of rhGH, 2 week wash out period) both approaches were compared. To quantify the agreement between the immunoassays, B.A. (Bland-Altman) analysis and P.r. (Pearson correlation) were used. To fully understand the assay readings, all relevant antibodies were characterised by surface plasmon resonance (SPR). In either approach the ratio numerator produces similar results and the denominator determines both signal-amplitude and time-frame of possible application. The rec vs pit approach displays a higher distinctive capacity to detect hGH abuse but the complex binding properties of the capture antibodies make it very difficult to evaluate the precise contributions of the individual hGH variants to the assay result. In the 22 vs 20 approach, the 20 kDa hGH concentration measures determine its applicability. Both approaches are based on a different principle, should be preferably applied within 24 h after rhGH administration, and are perfectly comparable given the results obtained. The reduced time frame of application indicates that their principle application should be preferably in an out-of-competition setting [12216].

Freeze-thaw cycling

A method based on two serum biomarkers – insulin-like growth factor-I (IGF-I) and pro-collagen type III N-terminal propeptide (P-III-NP) – has been devised to detect growth hormone (GH) misuse. The aims of this study were to determine the stability of IGF-I and P-III-NP concentrations in serum stored at -20°C and to establish the effects of one freeze-thaw cycle. Blood was collected from 20 healthy volunteers. Serum aliquots were analyzed after storage for one day at 4°C and one day, one week, five weeks, and three months at -20°C. IGF-I and P-III-NP results were combined to calculate a GH-2000 discriminant function score for each volunteer. Inter-assay precision was determined by analysing one quality control sample at each time-point. A single freeze-thaw cycle, storage of serum at 4°C for one day and at -20°C for up to three months had no significant effect on IGF-I or P-III-NP concentration. Intra-sample variability for IGF-I was 7 percent (Immunotech assay) and 13
percent (DSL assay). Intra-sample variability for P-III-NP was 11 percent (Cisbio assay) and 14 percent (Orion assay). When IGF-I and P-III-NP results were combined, intra-sample variability of the GH-2000 score expressed as a standard deviation varied between 0.31 and 0.50 depending on the assay combination used. Variability in IGF-I and P-III-NP results of stored samples is largely determined by the characteristics of the assays. A single freeze-thaw cycle, storage of serum at 4°C for one day or at -20°C for up to 3 months does not result in a significant change in GH-2000 score [12217].

Intra- and inter-laboratory validation

Insulin-like growth factor-II (IGF-II), insulin-like growth factor binding proteins (IGFBPs) -2 and -3 and C-terminal telopeptide of type I collagen (ICTP) have been proposed, among others, as indirect biomarkers of the recombinant human growth hormone misuse in sport. An extended intra- and inter-laboratory validation of commercially available immunoassays for biomarkers detection was performed. Although the majority of evaluated assays showed an overall reliability not always suitable for antidoping control analysis, relatively high concordances between laboratory results were obtained for all assays. Evaluated immunoassays were used to measure serum concentrations of IGF-II, IGFBP-2 and -3 and ICTP in elite athletes of various sport disciplines at different moments of the training season; in recreational athletes at baseline conditions and finally in sedentary individuals. Serum IGF-II was statistically higher both in recreational and elite athletes compared to sedentary individuals. Elite athletes showed lower IGFBP-2 and higher IGFBP-3 concentration with respect to recreational athletes and sedentary people. Among elite athletes, serum IGFBP-3 (synchronized swimming), and ICTP (rhythmic gymnastics) concentrations were sport-dependent. Over the training season, within athlete variability was observed for IGFBP-2 in case of taekwondo and IGFBP-2 and -3 in case of weightlifting. Variations due to those aspects should be taken in careful consideration in the hypothesis of setting reference concentration ranges for doping detection [08245].

Tests for GH deficiency

The diagnostic accuracy of tests used to diagnose GH deficiency (GHD) in adults is unclear. It was conducted a systematic review and meta-analysis of studies that provided data on the available diagnostic tests. It was searched electronic databases (MEDLINE, EMBASE, Cochrane CENTRAL, Web of Sciences, and Scopus) through April 2011. Review of reference lists and contact with experts identified additional candidate studies. Reviewers, working independently and in duplicate, determined study eligibility. Reviewers, working independently and in duplicate, determined the methodological quality of studies and collected descriptive, quality, and outcome data. Twenty-three studies provided diagnostic accuracy data; none provided patient outcome data. Studies had fair methodological quality, used several reference standards, and included over 1100 patients. Several tests based on direct or indirect stimulation of GH release were associated with good diagnostic accuracy, although most were assessed in one or two studies decreasing the strength of inference due to small sample size. Serum levels of GH or IGF1 had low diagnostic accuracy. Pooled sensitivity and specificity of the two most commonly used stimulation tests were found to be 95 and 89 percent for the insulin tolerance test and 73 and 81 percent for the GHRH plus arginine test respectively. Meta-analytic estimates for accuracy were associated with substantial heterogeneity. It was concluded that several tests with reasonable diagnostic accuracy are available for the diagnosis of GHD in adults. The supporting evidence, however, is at high risk of bias (due to heterogeneity, methodological limitations, and imprecision) [11474].
Ethics of use of growth hormone in sports

Athletes have enjoyed almost a thirty year amnesty of rhGH abuse, which they consider has contributed to the winning of medals and the breaking of world records. Such a reprieve is almost at an end, since WADA have identified a method to detect rhGH abuse. The anecdotal word "on the street" is that rhGH is still undetectable and athletes believe that the benefits, at the dosages they administer, far outweigh the risks! Scientists are aware that in a hormone deficiency condition, replacement can halt and in certain situations reverse some of the adverse effects. Growth hormone deficiency can lead to a loss of skeletal muscle mass and an increase in abdomino-visceral obesity, which is reversed on replacement with rhGH. Since the availability of GH, athletes have been trying to extrapolate these effects from the deficiency state to the healthy corpus and increase their sporting prowess. Past confessions from athletes, such as Ben Johnson, Kelly White, Tim Montgomery, Marion Jones and currently Dwain Chambers have demonstrated that they are prepared to tread the very fine lines that separate the "men from the boys". Rewards are so great, that anonymous surveys have identified that athletes will risk ill health, if they believe they can cheat, win and not get caught. The question that still needs to be answered is, "does growth hormone enhance performance"? Recent research suggests that it could. There is also a suspicion that in "cycled" low supraphysiological doses, it is no where near as harmful as WADA claim it to be [09203].

The hype about human growth hormone (hGH) goes far beyond the available data. The issue of administration of recombinant rhGH to adolescents, whether for athletic performance or for esthetic purposes adds another wrinkle because normal pubertal growth and the acquisition of adult body composition depends upon the GH/IGF-I and the hypothalamic-pituitary-gonadal axes. The range of normal is wide and it is more difficult to determine the natural evolution of pubertal development from that fueled by rhGH (or anabolic steroids). There are no compelling data based on clinical trials to indicate enhanced athletic performance (young adults); however, one cannot be sure how rhGH is used in combination with other agents, including anabolic steroids and anabolic "supplements". There are no studies in adolescent athletes. The detection of administration of rhGH to adolescents using the analytes of the GH/IGF-I and of collagen turnover (bone modeling and remodeling) is complicated by the physiologic increases in these parameters during normal puberty. It should be noted that many older adolescents are physiologically younger, especially in those aesthetic sports that demand the thin (linear) physique [09204].
The recent introduction of IGF-I to clinical practice is likely to increase its availability and abuse. Insulin and IGF-I work together with GH to control the supply of nutrients to tissues in the fasted and fed state. The actions of insulin and IGF-I that may enhance performance include increased protein anabolism and glucose uptake and storage. The detection of IGF-I and insulin abuse is challenging. There are established mass spectrometry methods for insulin analogs [10155].

There is significant evidence that athletes are using recombinant human growth hormone (rhGH) to enhance performance, and its use is banned by the World Anti-Doping Agency and professional sports leagues. Insulin-like growth factor-1 (IGF-1) is the primary mediator of growth hormone action and is used as a biomarker for the detection of rhGH abuse. The current biomarker-based method requires collection and expedited shipment of venous blood which is costly and may decrease the number of tests performed. Measurement of GH biomarkers in dried blood spots (DBS) would considerably simplify sample collection and shipping methods to allow testing of a greater number of samples regardless of location. A method was developed to quantify intact IGF-1 protein in DBS by liquid chromatography-tandem mass spectrometry. A step-wise acid-acetonitrile extraction was optimized to achieve a sensitive assay with a lower limit of quantification of 50 ng/mL. IGF-1 remained stable at room temperature for up to 8 days, which would allow shipment of DBS cards at ambient temperature. In a comparison between plasma concentrations of IGF-1 and concentrations measured from venous and finger prick DBS, there was good correlation and agreement, r (2) of 0.8551 and accuracy of 86-113 percent for venous DBS and r (2) of 0.9586 and accuracy of 89-122 percent for finger prick DBS. The method is intended for use as a rapid screening method for IGF-1 to be used in the biomarker method of rhGH abuse detection [12218].

It is believed that insulin and insulin-like growth factor I (IGF-I) are abused by professional athletes, either alone or in combination with growth hormone (GH) and anabolic steroids. The recent introduction of IGF-I to clinical practice is likely to increase its availability and abuse. Insulin and IGF-I work together with GH to control the supply of nutrients to tissues in the fasted and fed state. The actions of insulin and IGF-I that may enhance performance include increased protein anabolism and glucose uptake and storage. The detection of IGF-I and insulin abuse is challenging [10156].

The rationale for using rhIGF-I as an ergogenic aide differs little from that of rhGH. This compound has only recently become more available and its use in athletes will only increase. The potential benefits include increased muscle protein synthesis and the sparing of glycogenolysis with glycogen synthesis and increased fatty acid availability. IGF-I is the main effector for the action of hGH. Whereas hGH is insulin antagonistic several hours after ingesting a meal, the main effect of hIGF-I is to reduce glucose levels (insulin-like) and it is this effect that has been noted clinically. It is strongly anabolic in muscle, but has a very much diminished effect in comparison to hGH on lipids. In fact, children with virtually no IGF-I (growth hormone receptor deficiency, Laron-type) gain a disproportionate amount of fat when treated for many years with rhIGF-I [10001].

Performance-enhancing substances are illicitly used in elite or amateur sports and may be obtained from the black market due to a cheaper and easier availability. Although various studies have shown that black market products frequently do not contain the declared substances, enormous amounts of illegally produced and/or imported drugs are confiscated.
from athletes or at customs with alarming results concerning the outcome of the analyses of the ingredients. This case report describes the identification of His-tagged Long-R3-IGF-I, which is usually produced for biochemical studies, in an injection vial. The ingredients were isolated by immunoaffinity purification and identified by nano-UPLC, high-resolution/high accuracy mass spectrometry of the intact and trypsinated substance and by an enzyme-linked immunosorbent assay. (Tandem) mass spectra characterized the protein as Long-R3-IGF-I with a His(6)-tag attached to the C-terminus by the linker amino acids Leu-Glu was used. It was concluded that His-tags are commonly added to proteins during synthesis to allow a convenient and complete purification of the final product and His-tags are subsequently removed by specific enzymes when being attached to the N-terminus. The effects of His-tagged Long-R3-IGF-I in humans have not been elucidated or described and the product may rather be a by-product from biochemical studies than synthesized for injection purposes [10364].

Exercise stimulates growth hormone (GH) release, but there are conflicting reports regarding the acute effects of exercise on circulating ghrelin and insulin-like growth factor (IGF) concentrations. One investigation examined the effect of a single sprint on circulating GH, ghrelin and IGF concentrations as well as a marker of IGF-I bioactivity, and whether the number of muscle actions performed during a sprint influences these responses. Seven healthy men completed 3 trials in a random order. In two exercise trials they performed a single 30-s sprint on a cycle ergometer against a resistance equivalent to either 7 percent (FAST) or 9 percent (SLOW) of their body mass. In the other they rested in the laboratory (CON). Blood samples were taken pre-, immediately post-, 10 and 30 min post-exercise, and at equivalent times in the CON trial. Total ghrelin concentrations declined after the sprint and were significantly lower after 30 min of recovery than they were pre-exercise. GH concentrations increased in both exercise trials and were greater in the FAST than the SLOW trial. Serum concentrations of total IGF-I, free IGF-I, total IGF-II, and IGF-I bioactivity did not change after sprinting. In conclusion, sprint exercise suppresses total ghrelin concentrations and stimulates GH release but does not alter IGF concentrations or bioactivity [10365].

Possible performance enhancement is unknown at present as there just haven’t been studies in adults or children. rhIGF-I has been used as a growth promoting agent in children with both primary IGF-I deficiency and in a few genetic condition which are associated with short stature. It is quite early for the “efficacy” results, but growth rates have increased and it is the only presently available drug for those with complete growth hormone insensitivity. The major adverse event in children with growth hormone insensitivity has been hypoglycemia; however, most of the instances can be overcome with food ingestion around the time of the administration. Some unique side effects include jaw pain, headache, fluid retention and myalgia. As with rhGH there has been an incidence of idiopathic intracranial hypertension. Similar to the findings with rhGH stopping the drug for several days and perhaps restarting at one-half dose seems prudent in those who have experienced this adverse event. In the longer term there is the theoretical aspect of tumorigenesis, although no data exist, other than associative ones for patients with certain cancers (for example, breast, prostate, and colon) have had higher IGF-I levels in the years before their cancers became detected [10001].

Insulin like growth factor-I (IGF-I), the prime target of growth hormone action, is one candidate gene for improving performance. In recent years a number of transgenic and somatic gene transfer studies on animals have shown that upregulation of IGF-I stimulates muscle growth and improves function. This increase in muscle IGF-I is not reflected in measurable increases in circulating IGF-I. Whilst the responses obtained in the animal studies would appear to give clear benefits for performance, the transfer of such techniques
to humans still presents many technical challenges. Further challenges will also be faced by the anti doping authorities in detecting the endogenously produced products of enhanced gene expression [10157].

As the tests for detecting growth hormone (GH) abuse develop further, it is likely that athletes will turn to doping with insulin-like growth factor-I (IGF-I). IGF-I mediates many of the anabolic actions of growth hormone. It stimulates muscle protein synthesis, promotes glycogen storage and enhances lipolysis, all of which make IGF-I attractive as a potential performance-enhancing agent. Pharmaceutical companies have developed commercial preparations of recombinant human IGF-I (rhIGF-I) for use in disorders of growth. The increased availability of rhIGF-I increases the opportunity for athletes to acquire supplies of the drug on the black market. The long-term effects of IGF-I administration are currently unknown but it is likely that these will be similar to the adverse effects of chronic GH abuse. The detection of IGF-I abuse is a challenge for anti-doping organisations. Research has commenced into the development of a test for IGF-I abuse based on the measurement of markers of GH action. Simultaneously, the effects of rhIGF-I on physical fitness, body composition and substrate utilisation in healthy volunteers are being investigated [09213].

Human insulin-like growth factor-1 (IGF-1) is a peptide hormone that acts as a mediator of most of the somatotropic effects of growth hormone (GH). Therefore, it is supposed to be a biomarker indicating GH abuse in sports as well as diseases associated with a change in IGF-1 plasma concentration. It can be applied locally by injection to increase total protein and DNA content in tissues such as skeletal muscle – a highly desirable effect in various sports disciplines. In order to improve its growth-promoting properties, the primary structure of IGF-1 has been modified, yielding analogues such as des(1-3)IGF-1 and LONGR3IGF-1, which show a considerably reduced affinity to the respective binding proteins in plasma and, thus, an increased bioavailability at target tissues. Due to their capability to enhance performance, IGF-1 and its analogues belong to the prohibited list of the World Anti-Doping Agency. Hence, it was necessary to develop a reliable assay for the quantification of human IGF-1 as well as the detection of its derivatives. Immunoaffinity isolation and purification from 60 microL of plasma followed by liquid chromatography/electrospray ionisation tandem mass spectrometry enabled the unequivocal determination of all target analytes. Diagnostic product ions were characterised utilising an Orbitrap mass spectrometer with high resolution/high accuracy properties and employed for triple quadrupole MS/MS analysis. The described assay provided lower limits of detection (LLODs) between 20 and 50 ng/mL, recovery rates between 34-43 percent and a precision <15 percent at the lower limits of detection as well as higher concentration levels. In order to prove the applicability of the developed assay, human plasma samples were analysed and the results were compared with the values obtained from a commercially available immunoradiometric assay (IRMA). Four of six samples resulted in concentration ratios with good correlation between both assays, whereas the absolute concentrations were lower for the presented procedure [08260].

Skeletal muscle is highly adaptive to environmental stimuli and can alter its mass accordingly. This tissue is almost unique in that it can increase its size through two distinct mechanisms. It can grow through a cellular process mediated by cell fusion, or it can increase its size simply by increasing its protein content. Understanding how these processes are regulated is crucial for the development of potential therapies against debilitating skeletal muscle wasting diseases. Two key signalling molecules, Insulin like Growth Factor (IGF) and GDF-8/myostatin, have emerged in recent years to be potent regulators of skeletal muscle size. In this review we bring together recent data highlighting the important and novel aspects of both molecules and their signalling pathways, culminating in a discussion of the cellular and tissue phenotypic outcomes of their stimulation or
antagonism. It was emphasise the complex regulatory mechanisms and discuss the temporal and spatial differences that control their action, understanding of which is crucial to further their use as potential therapeutic targets [10480].

The effect of exercise training on anabolic hormones and inflammatory mediators is particularly important during childhood and puberty, since during this period there is a spontaneous increase in anabolic hormones that leads to the marked puberty-related growth spurt. Therefore, any training-associated hormonal and/or inflammatory effect during this critical period may have profound consequences on growth and development, especially if the effect is maintained for long periods. Several studies suggest the hypothesis that a sudden imposition of a training program which is associated with substantial increase in energy expenditure leads initially to an increase in pro-inflammatory cytokines, and as a consequence, to decreases in IGF-1 levels. Further, if the training adaptation is successful, the proinflammatory cytokines fall, and with that decrease, the suppression of IGF-1 diminishes, an anabolic ‘rebound’ in the GH-IGF-1 axis may ensue, and IGF-1 level exceed the pretraining level. Exactly how and when this switch takes place, and whether the initial catabolic-type stage is necessary for the ultimate anabolic adaptation remains unknown. Consistent with the two phases hypothesis, longer periods of training were indeed associated with stable or with increases in circulating GH and IGF-1 levels. Despite the early training-associated decrease in circulating IGF-1 levels, there is an increase in muscle mass and fitness may improve, suggesting that the local tissue effect of exercise on growth factors differ from systemic effects. Total caloric intake as well as macronutrient content, consumption and timing influence the anabolic and inflammatory response to training. Finally, changes in the balance of anabolic and catabolic hormones and inflammatory mediators during the training season may help elite athletes and their coaches in their training and preparation for competition [10481].

Growth hormone (GH) regulates important physiological processes, including somatic growth and development as well as muscle protein synthesis and carbohydrate and lipid metabolism, directly by binding to and activation of its receptors or indirectly by stimulation of IGF1. Several pathways contribute to initiate myogenesis in response to different extracellular signals. The PI3K/Akt pathway, activated by IGF-1, the stress activated MKK6/p38 MAPK pathway and the calcium/calmodulin-dependent kinase (CaMK) pathway promote muscle-specific gene expression. In myogenesis, IGF-1 and myostatin are key signalling molecules and control skeletal muscle mass. IGF-1 is a positive and myostatin is a negative regulator. IGF-1 induces satellite cell proliferation, myoblast differentiation and subsequent myoblast fusion into myotubes. Knock-out mice of IGF-1 or its GH receptor show increased growth retardation and reduced organ and skeletal muscle mass, while overexpression of IGF-1 within skeletal muscle causes significant myofibre hypertrophy and myoblast proliferation. Investigational studies have demonstrated that acute exercise increases circulating IGF-1 levels in blood. On the other hand, mice that lacked myostatin, a member of the transforming growth factor beta superfamily of secreted growth and differentiation factors, were found not only to be stronger and more muscular than their counterparts with normal myostatin levels, but also to have reduced fibrosis and fatty remodelling, suggesting improved regeneration of muscle. Abuse of GH is widespread; overdose of GH leads to increased muscle protein synthesis along with increased fatty acid availability and sparing of glycogen stores. Most of these anabolic effects of GH are mediated by IGF-1. Thus, based on their attributes which make GH and IGF-1 attractive as potential performance-enhancing agents, they are often used as doping substances by athletes. Approximately every fourth sportsman who uses anabolic androgenic steroids also takes these both drugs. As measured by maximal oxygen uptake, the combination of GH and testosterone improves the fitness, which is larger than with one compound alone. Anabolic androgenic steroids stimulate hypertrophy and mass of muscle fibres by regulation of
satellite cell proliferation, the number of myonuclei and the balance of muscle proteins. The exact biochemical mechanisms responsible for increased skeletal muscle mass and strength by anabolic androgenic steroids are partly unknown. In myoblast culture systems, testosterone has been shown to be able to stimulate the mitotic activity of satellite cells, and IGF-1 signalling pathway plays an important role in mediating these effects of testosterone on skeletal muscle cell growth and differentiation. Following anabolic steroid administration, increased expression of IGF-1 together with alterations in expression of several IGF-1 binding proteins has been observed in muscle. Hence, at least in part the muscle IGF-1 seems to mediate the growth-promoting influences of anabolic steroids. Up-regulation of GH in hepatic chromatin induced rapid and dramatic changes at the IGF-1 locus and activated IGF-1 gene transcription by distinct promoter-specific mechanisms. Alterations in the IGF-1 axis, which predispose individuals to diseases, have been reported to be due to an altered epigenetic regulation that can modify IGF-1 transcript levels. Systemic GH treatment caused an approximately robust increase in transcription from each IGF-1 promoter within an hour of hormone administration and led to a sustained accumulation of IGF-1 mRNA. The coordinated induction of both IGF-1 promoters by GH was accompanied by hyperacetylation of histones H3 and H4 in promoter-associated chromatin, a decline in monomethylated lysine 4 of histone H3 (H3K4), and recruitment of RNA polymerase II to IGF-1 promoter 2. These findings show that GH may regulate the transcript levels of IGF-1 by modifying the chromatin architecture. The molecular mechanism underlying the improved muscle performance by the action of IGF-1 is not well understood. It is speculated that IGF-1 may modulate genomic methylation to promote normal development of muscles. Investigations on cell cultures showed that after a 6-hour exposure of cells, IGF-1 increased the global DNA methylation. This change in the nuclear methylation pattern is based on the fact that IGF-1 is able to stimulate the activity of methionine synthase via a mechanism that requires the activity of both PI3 kinase and MAP kinase pathways. Moreover, during early embryonic development the occurrence of IGF-1 may affect the DNA methylation pattern allowing the activation of expression of particular genes important for embryonic survival. Consequently, the administration of IGF-1 as a doping agent might also affect DNA methylation in athletes. However, the long-term intakes of GH or IGF-1, along with their effects on DNA methylation signal transductions or modulations of gene expression, are currently unknown. Due to the consensus statement of the Growth Hormone Research Society there seems to be no increased risk of cancer when GH is given at physiological replacement doses, but there is mounting evidence that the intake of GH higher than physiological doses for many years may be associated with increased incidences of colorectal, thyroid, breast, and prostate cancers. In these cancer patients, high levels of circulating IGF-1 were detected in serum and have been associated with cancer risk and cancer prognosis. Drug candidates that target IGF1 signal transduction have revealed anti-neoplastic activity. Moreover, the signalling pathway of IGF-1 is involved in tumour development and progression. Experiments have shown that cancer cells have an increased expression of IGF-1 receptors. Activation of IGF-1 receptor, an inducer of Akt and MAPK signalling networks, by IGF-1 has mitogenic and anti-apoptotic effects in neoplastic tissue. Thus, IGF-1 may provide an anti-apoptotic environment that may favour survival of cancer cells. Regarding the global chromatin changes during the malignant transformation of cells and the involvement of IGF-1 in DNA methylation, it is equitable to speculate that the increased abuse of GH and IGF-1 may at least partly contribute to the tumour-associated epigenetic changes. However, too little data are available to sustain this theory. Future investigations are warranted to clarify the implication of DNA methylation in doping increasing cancer risk. Recent findings have indicated that IGF-1 may play a role in neoplasia. Although the extent of DNA methylation of IGF-1 gene was highly variable in most tumours as its mRNA expression levels, a relationship could be detected between IGF-1 overexpression and gene demethylation in hepatocarcinomas and tumours associated with hypoglycaemia. In multiple myeloma IGF-1 mediated down-regulation of the proapoptotic BH3-only protein Bim by the activation of Akt and MAPK pathway. It has been reported that
IGF-1 is involved in epigenetic regulation of the Bim promoter. Chromatin immunoprecipitation of IGF-1 showed both a reduced acetylation of lysine 9 of histone H3 (H3K9) and an increased H3K9 dimethylation, which contributed actively to the silencing of BIM. These data identified a new mechanism in the IGF-1 dependent survival of multiple myeloma cells. Using chromatin immunoprecipitation assays, histone methyltransferase RIZ1 was shown to bind to the IGF-1 promoter and to increase histone H3 lysine 9 methylation. In chronic myelogenous leukemia (CML), blastic transformation is associated with decreased expression and activity of RIZ1. Overexpression of RIZ1 in model CML blast crisis cell lines decreased proliferation, increased apoptosis and supported differentiation which was accompanied with a reduced IGF-1 receptor activation and activation of downstream signalling components ERK1/2 and AKT. These data highlight the therapeutic potential of inhibiting IGF-1 signalling pathway by modulating the histone pattern at IGF-1 promoters [11475].

There is significant evidence that athletes are using recombinant human growth hormone (rhGH) to enhance performance, and its use is banned by the World Anti-Doping Agency and professional sports leagues. Insulin-like growth factor-1 (IGF-1) is the primary mediator of growth hormone action and is used as a biomarker for the detection of rhGH abuse. The current biomarker-based method requires collection and expedited shipment of venous blood which is costly and may decrease the number of tests performed. Measurement of GH biomarkers in dried blood spots (DBS) would considerably simplify sample collection and shipping methods to allow testing of a greater number of samples regardless of location. A method was developed to quantify intact IGF-1 protein in DBS by liquid chromatography-tandem mass spectrometry. A step-wise acid-acetonitrile extraction was optimized to achieve a sensitive assay with a lower limit of quantification of 50 ng/mL. IGF-1 remained stable at room temperature for up to 8 days, which would allow shipment of DBS cards at ambient temperature. In a comparison between plasma concentrations of IGF-1 and concentrations measured from venous and finger prick DBS, there was good correlation and agreement. The method is intended for use as a rapid screening method for IGF-1 to be used in the biomarker method of rhGH abuse detection [13376].

To athletes, insulin-like growth factor-1 (IGF-I) is an attractive performance-enhancing drug, particularly as an alternative to growth hormone (GH) because IGF-I mediates many of the anabolic actions of GH. IGF-I has beneficial effects on muscle protein synthesis and glycogen storage that could enhance performance in several sporting disciplines. Recombinant human IGF-I (rhIGF-I) is used in clinical practice, but a variety of IGF-I compounds and IGF-I analogues are also advertised on the internet and many have been available on the black market for several years. Although methods for detecting GH misuse are now well established and there have been several cases in which athletes have tested positive for GH, no test is yet in place for detecting IGF-I misuse. The GH-2004 research group has been investigating methods for detection of IGF-I misuse and a test is being developed on the basis of the principles of the successful GH-2000 marker method, in which markers from the IGF axis and markers of collagen and bone turnover are used to detect GH misuse. Commercial immunoassays for these markers have been validated for anti-doping purposes but new methods, including IGF-I measurement by use of mass spectrometry, should improve the performance of the tests and help in the detection of athletes who are doping with these peptide hormones [13377].

Besides its function as biomarker, IGF-1 itself and its synthetic derivatives are prohibited substances according to the regulations of WADA. Although IGF-1's mechanism of action concerning improved athletic performance is yet not fully understood, epigenetic aspects
have been discussed and reviewed along with serious side effects attributed to long-term abuse of hGH and IGF-1. In order to unambiguously detect at least synthetic analogs of IGF-1 in urine multiplexed with other drugs and metabolites relevant for doping controls, a multi-analyte peptide screening assay was developed, allowing for the determination of IGF-1 and long-R3-IGF-1 as well as six insulins (animal, human, and synthetic), LH releasing hormone (LH-RH), growth hormone releasing hormone (GH-RH) and its synthetic analog CJC-1295, and synacthen. From both matrices, plasma and urine, detection limits between 1 and 50 pg/ml were accomplished, enabling the unequivocal detection of these analytes in doping control samples. A consideration that at least synacthen and long-R3-IGF-1 have demonstrated limited stability (approx. 24 h) in urine samples stored at +4°C; here, frozen conditions are highly recommended. The relevance of growth hormone releasing peptides (GHRPs) as well as new analytical techniques including ion mobility have further been reviewed in the context of sports drug test protocols; the use of ion mobility particularly can complement existing strategies in terms of substantiated analytical results (by adding another characterizing dimension, e.g. drift time of the compound of interest) as well as speed of analysis [13012].

To athletes, insulin-like growth factor-I (IGF-I) is an attractive performance-enhancing drug, particularly as an alternative to growth hormone (GH) because IGF-I mediates many of the anabolic actions of GH. IGF-I has beneficial effects on muscle protein synthesis and glycogen storage that could enhance performance in several sporting disciplines. Recombinant human IGF-I (rhIGF-I) is used in clinical practice, but a variety of IGF-I compounds and IGF-I analogues are also advertised on the internet and many have been available on the black market for several years. Although methods for detecting GH misuse are now well established and there have been several cases in which athletes have tested positive for GH, no test is yet in place for detecting IGF-I misuse. The GH-2004 research group has been investigating methods for detection of IGF-I misuse and a test is being developed on the basis of the principles of the successful GH-2000 marker method, in which markers from the IGF axis and markers of collagen and bone turnover are used to detect GH misuse. Commercial immunoassays for these markers have been validated for anti-doping purposes but new methods, including IGF-I measurement by use of mass spectrometry, should improve the performance of the tests and help in the detection of athletes who are doping with these peptide hormones [13378].

In the absence of analytical proof, speculations as to the prevalence of IGF-1 as doping agent have arisen, particularly with regard to elite sprinters, and also deer antler velvet-derived nutritional supplements enriched with IGF-1 were recently reported. In order to provide a platform for the generation of factual information on peptide hormone-based therapeutics and drug candidates, metabolism studies and method development/expansion for substances such as growth hormone releasing peptides (GHRPs, including GHRP-1, -2, -4, -5, and 6, as well as hexarelin, alexamorelin, and ipamorelin), luteinizing hormone releasing hormone (LHRH), and desmopressin were conducted. In a comprehensive rat in vivo study, the metabolic fate of eight GHRPs was investigated following oral as well as intravenous administration. Urinary metabolites were identified by UHPLC-high resolution/high accuracy (tandem) mass spectrometry, and three metabolites per GHRP were characterized being potential target compounds for routine doping controls. In subsequent human serum in vitro incubations, the production of the main metabolites was also observed, corroborating the utility of these analytes as viable target compounds in sports drug testing. With the increasing number of potential peptidic drugs, detection assays have to be extended and updated to cover these additional substances [13009].
Polymorphism

Insulin-like growth factor-I (IGF-I) plays a key role in exercise-associated muscle growth and development. The regulatory region of the promoter of the IGF-I gene is labile, but changes in this region were studied mostly in the elderly and in relation to pathological states. C-1245T (rs35767) is a genetic variation in the promoter region of the IGF-I gene. The minor allele T was found to be associated with higher circulating IGF-I levels, and possibly with increased muscle mass. The aim of one study was to analyze the frequency distribution of C-1245T SNP in athletic and nonathletic Israeli populations. One hundred and sixty-five athletes (78 endurance-type athletes, and 87 power-type athletes) and 159 nonathletic healthy individuals participated in the current study. Genomic DNA was extracted from peripheral EDTA treated anti-coagulated blood using a standard protocol. Genotyping of the IGF1 C-1245T polymorphism was performed using polymerase chain reaction (PCR). It was found that the endurance and power athletes’ allele and genotype frequencies were significantly different from those of the control group. Only 5 percent of the athletes were TT carriers, but none of the controls carried this genotype. The T allele was found to be more frequent in the top-level power athletes (international and Olympic level) compared to national level athletes, but such a difference was not found in endurance athletes. The findings suggest a possible contribution for the relatively rare IGF-I TT genotype to endurance performance, and in particular to power sport excellence in Israeli athletes [13379].

Effect of substitution with GH

Indirect biomarkers of recombinant human growth hormone (rhGH), insulin-like growth factor-I (IGF-I), insulin-like growth factor-II (IGF-II), insulin-like growth factor binding proteins (IGFBP-2 and IGFBP-3) and insulin (C-peptide) were measured together with urinary parameters of renal damage (beta2-microglobulin and proteinuria) by immunoassays, in house validated for the purpose, in 61 subjects (36 elite athletes, 18 recreational athletes and 7 sedentary individuals) with different levels of physical fitness and endurance exercise. Validation parameters were good for the evaluated assays, excluding a high inter-assay imprecision and inaccuracy of 24 and 26 percent obtained for GH assay. The range of
concentrations found in urine samples under investigation was generally covered by the calibration curves of the studied immunoassays. However, for the samples below or above the calibration curve, opportune dilution or concentration were performed. Particularly, C-peptide samples had to be diluted 1:5 and beta2-microglobulin ones assayed using a triple sample volume, to fall within the calibration range. Urinary C-peptide was the only biomarker statistically higher in samples of elite athletes when compared to recreational athletes and sedentary individuals. Among elite athletes, tae-kwon-do athletes showed the highest IGF-II basal values while weightlifting athletes showed the lower IGF-I and IGFBP-3 basal values. The trend observed in weightlifters' basal samples was confirmed in their training samples: IGF-I, IGF-II, IGFBP-3 and beta2-microglobulin were lower in with respect to those from synchronised swimming. Over the training season, within athlete variability was observed for IGFBP-3 for weightlifting athletes. In the studied subjects, no direct associations were found between biomarkers of GH or insulin misuse and urinary parameters of renal damage, eventually due to high-workload endurance training. The variations observed in different biomarkers should be taken in consideration in the hypothesis of setting reference concentration ranges for doping detection [10361].

**Physiology**

The offer of human saliva IGF-I (sIGF-I) measurement in athletes investigation is a new proposal. The aim was now to investigate the physical exercise effect on sIGF-I and explore plasma free IGF-I relation. Saliva and blood were collected from well-trained athletes, investigated immediately before and at the end of a physical exercise test. sIGF-I was significantly increased at the end of the physical exercise. The plasma free IGF-I concentrations did not demonstrate any difference. The saliva total protein level (sTP) was also significantly increased. A positive correlation between sTP and sIGF-I, was observed, both before and after physical exercise, and between salivary and plasma free IGF-I only after physical exercise. The salivary free IGF-I level significantly increased after physical exercise, moreover a correlation with the plasma levels exists in post-exercise condition. The physical exercise affects sIGF-I as well as the sTP. The correlation between plasma and salivary free IGF-I levels only in post-exercise condition suggests further studies to investigate the effects of different type and duration of physical exercise. The comparison with other salivary biochemical parameter investigation would also further increase comprehension on the role of salivary IGF-I [09214].

The aim of one study was to investigate possible relationships between different right-hand finger-length ratios and different fasting hormone concentrations in young swimmers. Fifty-five young swimmers participated in this study (26 boys and 29 girls, aged 10-17 years). All finger-length ratios were significantly higher in girls compared with boys. Ghrelin, leptin, testosterone in boys, estradiol in girls, insulin-like growth-factor I (IGF-I), IGFBP-3, and insulin were analyzed. Leptin and insulin concentrations were lower in boys compared with girls. In both groups, the relationships between finger-length ratios and basic anthropometric parameters were not significant. In conclusion, ghrelin appears to be a further biochemical parameter in addition to the sex steroids which correlated with different digit-length ratios at least in boys [08243].

**In peripubertal females**

Intense physical activity in peripubertal girls may delay menarche and cause menstrual disorders and estrogen deficiency, particularly in sport disciplines that require strict weight
control. It may also have a deleterious effect on bone mass acquisition. The aim of one study was to determine the time-course of bone mass accretion in peripubertal elite female rhythmic gymnasts over a 1-year period, as well as the anthropometric and hormone parameters that could be helpful for predicting bone mineral density (BMD) gain. It was conducted a 1-year follow-up study in 29 female rhythmic gymnasts (11-16 years old). Whole body composition and BMD of the whole body, proximal femur, lumbar spine, mid-radius, and skull were measured by dual energy X-ray absorptiometry (DXA). Moreover, baseline growth- and bone metabolism-related hormones such as IGF1, IGF-binding protein 3 (IGFBP3), leptin, and bone markers were measured. BMD increased significantly at all bone sites throughout puberty, particularly between Tanner stages II and IV-V. The IGF1 level, IGF1/IGFBP3 ratio, and leptin level were higher in late pubertal stages (i.e. IV-V) compared with early stage (i.e. I). In simple and multivariate analyses, only the IGF1/IGFBP3 ratio was strongly correlated with the BMD change at all bone sites. It was concluded that the plasma IGF1/IGFBP3 ratio was associated with bone mass acquisition in this period, and it may thus serve as a surrogate marker of bone mass gain in this population [10158].

**Effects of training**

Increased concentrations of circulating insulin-like growth factor-I (IGF-I) or IGF-I relative to IGF-binding proteins (IGFBPs) are associated with increased risk of developing several forms of cancer. Conversely, exercise is linked with reduced risk. This study aims to investigate the effect of a low-intensity exercise program on circulating levels of IGF-I, IGFBP-1, and IGFBP-3, in previously sedentary males. Fourteen healthy men participated in cycle ergometer training at lactate threshold intensity for 60 min/day, 5 days/week for 6 weeks. After aerobic training, insulin sensitivity improved by 20 percent, while fasting insulin levels decreased by 13 percent. Simultaneously, low-intensity aerobic training decreased the circulating levels of IGF-I by 9 percent, while IGFBP-1 levels increased by 16 percent. An interesting finding was that higher pretraining level of IGF-I was associated with greater decline in IGF-I with training. Insulin-sensitizing low-intensity aerobic exercise is thus considered to be an effective method for downregulating IGF-I and upregulating IGFBP-1 levels [10366].

One study examined the impact of 4 weeks of either complete cessation of training (DTR) or a tapering period (TAP; short-term reduction of the strength training volume, while the intensity is kept high), subsequent to 16 weeks of periodized heavy resistance training (PRT) on strength/power gains and the underlying physiologic changes in basal circulating anabolic/catabolic hormones in strength-trained athletes. Forty-six physically active men were matched and randomly assigned to a TAP (n=11), DTR (n=14), or control group (C; n=21), subsequent to a 16-week PRT program. Muscular and power testing and blood draws to determine basal hormonal concentrations were conducted before the initiation of training (T0), after 16 weeks of training (T1), and after 4 weeks of either DTR or TAP (T2). Short-term DTR (4 weeks) results in significant decreases in maximal strength (-6 to -9 %) and muscle power output (-17 and -14 %) of the arm and leg extensor muscles. However, DTR had a significant larger effect on muscle power output more than on strength measurements of both upper and lower extremity muscles. Short-term (4 weeks) TAP reached further increases for leg (2 %) and arm (2 %) maximal strength, whereas no further changes were observed in both upper and lower muscle power output. Short-term DTR resulted in a tendency for elevation resting serum insulin-like growth factor (IGF)-1 concentrations, whereas the corresponding TAP experienced elevation in resting serum insulin-like binding protein-3 (IGFBP-3). These data indicated that DTR may induce larger declines in muscle power output than in maximal strength, whereas TAP may result in further strength enhancement.
(but not muscle power), mediated, in part, by training-related differences in IGF-1 and IGFBP-3 concentrations [07156].

The purpose of the research was to compare changes in circulating levels of total IGF-I and IGFBP-3 during continuous, moderate-intensity exercise (CE) and high-intensity interval exercise (IE) of equal duration. Ten healthy males completed 2 exercise sessions and a resting control session (R) in random order. The CE was 20 minutes of cycling at 60-65 percent of VO$_{2\text{max}}$. During IE, subjects cycled at 80-85 percent of VO$_{2\text{max}}$ for 1 minute followed by 40 seconds of active recovery, with the cycle repeated for a total of 20 minutes. In each session blood samples were drawn at -10, 0, 5, 10, 20 and 30 minutes. Both IGF-I and IGFBP-3 increased significantly during exercise and repeated measures ANOVA revealed a significant effect for session. Area under the curve (AUC) analyses showed no difference in IGF-I between sessions, however, the IGFBP-3 AUC was significantly greater during IE than R. These results suggest interval and continuous exercise will result in similar changes in circulating IGF-I and IGFBP-3. This could be beneficial to individuals who can exercise longer and at a higher intensity in intervals than would be possible using a continuous protocol [07157].

**Resistance exercise**

Does resistance exercise order affect hormone availability? Participants performed arm exercise before and after leg exercise. Hormone delivery was estimated by multiplying brachial artery blood flow and hormone concentrations. Blood flow increased after arm (276 %) and leg (193 %) exercise. Testosterone, growth hormone, and insulin-like growth factor 1 showed with distinct delivery patterns between conditions; however net exposure was similar. The anabolic potential of postexercise hormones was not affected by exercise order [13381].

One study examined the effects of short-term physical training on the acute hormonal response (i.e. growth hormone, total and free insulin-like growth factor I [IGF-I], and IGF binding proteins [IGFBP]-1, IGFBP-2, and IGFBP-3) to resistance exercise (RE) in women. Forty-six women (20) were randomly assigned to an endurance training (E), resistance training (R), combined training (R + E), or control (C) group for 8 weeks. Subjects completed a standardized bout of RE (six sets of back squats at 10 repetition maximum) before and after training. Blood samples were obtained at rest (PRE), after the third set, immediately postexercise (POST), and at 15 min and 30 min after exercise. Acute RE significantly increased serum growth hormone, total IGF-I, IGFBP-1, IGFBP-2 and IGFBP-3 concentrations and decreased free IGF-I concentrations. After 8 weeks of training, total IGF-I concentrations were significantly increased, and IGFBP-1 concentrations were significantly decreased during exercise in groups that participated in resistance training (R and R + E); no significant changes were seen after E or C. In conclusion, participation in resistance training increased total IGF-I and reduced IGFBP-1 concentrations during acute RE, indicating exercise mode-specific adaptations in the circulating IGF-I system [13382].

One study was designed to determine endocrine responses during 2 days of strenuous resistance training. Ten healthy men performed resistance training twice a day for two successive days to induce acute fatigue (excessive physical stress). The resistance training consisted of four exercises for the lower body in the morning and seven exercises for the upper body in the afternoon. Maximal isometric and isokinetic strengths were measured from day 1 (before the training period) to day 3 (after the training period). Fasting blood samples were taken on days 1-3. Maximal isometric and isokinetic strengths significantly decreased with two successive days of training, with significant increases in serum creatine phosphokinase and myoglobin concentrations. Significant reductions in the fasting
concentrations of serum insulin-like growth factor-1, free testosterone, insulin and high-molecular-weight adiponectin were observed on day 3, whereas there were no changes in the serum cortisol concentration or the free testosterone/cortisol ratio. Plasma active ghrelin and serum leptin concentrations decreased by -20.7 ± 2.8 and -29.6 ± 4.1 percent, respectively. Two days strenuous resistance training significantly affects the profiles of anabolic hormone and endocrine regulators of appetite and energy balance, such as ghrelin and leptin. The present findings suggest that decreased ghrelin and leptin concentrations might reflect excessive physical stress and may be early signs of accumulated fatigue [13383].

Training with calorie restriction and sleep deprivation

The pulsatile release of growth hormone (GH) and luteinizing hormone (LH) from the anterior pituitary gland is integral for signaling secretion of insulin-like growth factor (IGF)-I and testosterone, respectively. One study examined the hypothesis that 84 h of sustained physical exertion with caloric and sleep restriction alters the secretion of GH and LH. Ten male soldiers (22 years 183 cm, 87 kg) had blood drawn overnight from 1800 to 0600 every 20 min for GH, LH, and leptin and every 2 h for IGF-I (total and free), IGF binding proteins-1 and -3, testosterone (total and free), glucose, and free fatty acids during a control week and after 84 h of military operational stress. Time-series cluster and deconvolution analyses assessed the secretion parameters of GH and LH. Significant results were as follows: body mass (-3 %), fat-free mass (-2 %), and fat mass (-7 %) declined after military operational stress. GH and LH secretion burst amplitude (approximately 50 %) and overnight pulsatile secretion (approximately 50 %), IGF binding protein-1 (+67 %), and free fatty acids (+33 %) increased, whereas leptin (-47 %), total (-27 %) and free IGF-I (-32 %), total (-24 %) and free testosterone (-30 %), and IGF binding protein-3 (-6 %) decreased. GH and LH pulse number were unaffected. Because GH and LH positively regulate IGF-I and testosterone, these data imply that the physiological strain induced a certain degree of peripheral resistance. During periods of energy deficiency, amplitude modulation of GH and LH pulses may precede alterations in pulse numbers [06141].

The endocrine response to sustained physical exertion superimposed on caloric and sleep restriction serves to provide adequate fuels to meet metabolic needs for such physiological processes as tissue repair, regeneration, and recovery. In particular, the somatotrophic (i.e. growth hormone and insulin-like growth factor) and pituitary-testicular (i.e. luteinizing hormone and testosterone) axes mediate many metabolic and anabolic processes during altered energy states. The pulsatile release of GH and LH from the anterior pituitary gland is integral for the trophic effects that these hormones exert on IGF-I and testosterone, respectively. The manner in which anterior pituitary hormones are released and delivered to target tissues is more biologically significant than the overall mean hormonal concentrations. It was demonstrated that GH administered in a pulsatile manner elicited greater increases in IGF-I than GH administered in a continuous manner. Because of the episodic release pattern of GH and LH, multiple time-point measures are necessary to fully characterize the trophic effects these hormones may have. Although alterations in IGF-I and testosterone are known to be mediated by fluctuations in GH and LH, few studies have concomitantly measured these hormones, especially in healthy subjects exposed to multiple physiological stressors. Additionally, recent work has suggested that leptin may also serve as an integrator of neuroendocrine secretion of GH and LH. Information concerning the pulse parameters (i.e. frequency, amplitude, etc) of GH and LH is important to understand when delineating central vs. peripheral mechanisms underlying alterations in circulating endogenous hormones. Although prior pulsatility programs were limited in that they provided only descriptive information about hormone concentration peaks, recent advances in time series software analysis now allow accurate determination of underlying glandular hormonal secretion rate
and halflife from measurements obtained from the systemic circulation [06141].

Of the IGF-I system components measured, IGFBP-1 demonstrated the largest magnitude change at training. It has been speculated that the IGFBP-1 increase may be viewed as a protective mechanism by neutralizing the insulin-like hypoglycemic activity of IGF-I and serving to mobilize energy from fats and protein. Furthermore, it has been suggested that low levels of liver glycogen are linked to an increased secretion of IGFBP-1. IGFBP-1 remains an important regulatory BP to study relative to physiological stress as increased levels may be one mechanism whereby IGF-I bioactivity is adjusted to meet metabolic needs [06141].

In Kenyans

Overnight fasting blood plasma insulin-like growth factor-I (IGF-I), insulin-like growth factor binding protein-1 (IGFBP-1), coenzyme Q10, (CoQ) vitamin E and plasma lipids were compared between a semi-nomadic Samburu population and relatively urbanized cohorts from Nairobi, Kenya. 143 middle aged subjects without known diabetes were included. IGF-I and IGFBP-1 were analyzed by RIA, and CoQ and vitamin E by HPLC. Plasma lipid levels were analyzed by standard laboratory methods routinely used in the clinics. The age adjusted IGF-I serum levels were low in the Samburu male and female populations, ranging from 0 to -4 IGFSD-score, and a minor part of the investigated population reaching as low as -5 and -7 SDS. The Nairobi cohorts showed significantly higher values reaching from -2.5 to +1 SDS. The nomadic Samburu population showed fasting IGFBP-1 values ranging from 30-100 microg/L, while that of the urbanized Nairobi cohorts was considerably lower (25-60 microg/L) (P<0.0001). CoQ concentrations of the Nairobi cohorts were 1.5-2.0 nmol/mL similar to the levels found in several European countries. The Samburu population on the other hand showed extremely high CoQ values ranging from 2 to 9 nmol/mL. Vitamin E levels of the Nairobi group were low (5-20 nmol/mL), but the Samburu population had even lower levels ranging from 3 to 15 nmol/mL. Plasma lipid levels such as cholesterol, triglycerides, LDL/HDL, ApoB/ApoA ratios as well as BMI and weight were significantly higher in the Nairobi population. It was concluded that low IGF-I and high IGFBP-1 levels of the Samburu cohorts indicate malnutrition. High lipid levels of the Nairobi cohorts indicate that these groups have several risk factors for cardiovascular diseases and diabetes type 2 [13384].

Local administration

Collagen is the predominant structural protein in tendons and ligaments, and can be controlled by hormonal changes. In animals, injections of insulin-like growth factor I (IGF-I) has been shown to increase collagen synthesis in tendons and ligaments and to improve structural tissue healing, but the effect of local IGF-I administration on tendon collagen synthesis in human has not been studied. The purpose of one study was to study whether local injections of IGF-I would have a stimulating effect on tendon collagen synthesis. Twelve healthy nonsmoking men (age 62 ± 1 years, BMI 27 ± 1) participated. Two injections of either human recombinant IGF-I (0.1 mL Increlex©) or saline (control) into each patellar tendon were performed 24-h apart, respectively. Tendon collagen fractional synthesis rate (FSR) was measured by stable isotope technique in the hours after the second injection. Simultaneously, interstitial peritendinous (IGF-I) and (procollagen type I N-terminal propeptide, PINP), as a marker for type I collagen synthesis, were determined by microdialysis technique. Tendon collagen FSR and PINP were significantly higher in the IGF-I leg compared with the control leg. In conclusion, local IGF-I administration can directly enhance tendon collagen synthesis both within and around the human tendon tissue [13385].
IGF-1 in deer antler

Reported incidents of the use of nutritional supplements containing deer antler velvet by athletes has increased significantly in recent years. The supplements have been reported to contain insulin-like growth factor-1 (IGF-1), which is a banned substance included on the World Anti-Doping Agency (WADA) prohibited list. The presence of deer and human IGF-1 was tested in six commercially available supplements. IGF-1 was extracted from the six deer antler velvet supplements using chloroform and acetonitrile precipitation methods. Ultra-performance liquid chromatography/tandem mass spectrometry (UPLC/MS/MS) methods were developed to measure intact IGF-1 protein and IGF-1 trypsin peptides using a triple quadrupole mass spectrometer. Five deer-specific and five human-specific multiple-reaction monitoring (MRM) transitions for intact IGF-1 were measured as well as six deer-specific and seven human-specific MRM transitions for an IGF-1 trypsin peptide. The peak area from each MRM transition was used to calculate the product ion ratios relative to the most abundant transition. Product ion ratios measured in the supplements were matched to ratios measured in purified protein standards. A match to human IGF-1 was identified for all the MRM transitions measured in four of the supplements tested. The presence of a pharmaceutical protein, human IGF-1, was confirmed in four commercially available products sold as all natural, nutritional supplements. These methods can be used to screen additional products to further prevent the illegal sale of adulterated supplements [13387].

Markers for IGF-1

Insulin-like growth factor-I (IGF-I) is reportedly misused by elite athletes, either alone or with growth hormone (GH). The GH-2000 and GH-2004 research groups previously developed a method for detecting GH misuse based on the GH-sensitive markers IGF-I and procollagen type III amino-terminal propeptide (P-III-NP). Both markers increase in response to rhIGF-I/rhIGFBP-3 administration in recreational athletes. The aim of one pilot study was to assess the effect of rhIGF-I/rhIGFBP-3 administration on other serum markers of the GH-IGF axis and on other bone and collagen markers. Twenty-six female and 30 male recreational athletes were randomized to 28 days' treatment with placebo or rhIGF-I/rhIGFBP-3 complex, followed by 56 days' washout. GH-IGF axis markers (IGFBP-2, IGFBP-3, acid-labile subunit (ALS) and IGF-II) and bone and collagen markers (procollagen type I carboxy-terminal propeptide (PICP), type I collagen cross-linked carboxy-terminal telopeptide (ICTP) and osteocalcin) were measured using commercial immunoassays. In women in the high dose treatment group, mean IGF-II decreased by 53 percent on day 21. Mean IGFBP-2 increased by 119 percent and mean ALS decreased by 40 percent on day 21. There were no significant changes in IGFBP-3, osteocalcin, ICTP or PICP. In men in the high dose group, mean IGF-II decreased by 51 percent on day 21. Mean IGFBP-2 increased by 125 percent on day 21. There were no significant changes in IGFBP-3, ALS, osteocalcin, ICTP or PICP. Serum IGFBP-2 and IGF-II may be useful markers of rhIGF-I/rhIGFBP-3 administration in both women and men while ALS may also be a useful marker in women; these markers are now undergoing further evaluation [13386].

Laboratory techniques

Performance-enhancing substances are illicitly used in elite or amateur sports and may be obtained from the black market due to a cheaper and easier availability. Although various
studies have shown that black market products frequently do not contain the declared substances, enormous amounts of illegally produced and/or imported drugs are confiscated from athletes or at customs with alarming results concerning the outcome of the analyses of the ingredients. One case report describes the identification of His-tagged Long-R³-IGF-I, which is usually produced for biochemical studies, in an injection vial. The ingredients were isolated by immunoaffinity purification and identified by nano-UPLC, high-resolution/high accuracy mass spectrometry of the intact and trypsinated substance and by an enzyme-linked immunosorbent assay. Tandem mass spectra characterized the protein as Long-R³-IGF-I with a His₆-tag attached to the C-terminus by the linker amino acids Leu-Glu [10482].

Peptide analysis in doping controls by means of nano-UPLC coupled high resolution/high mass accuracy mass spectrometry provides the state-of-the-art technique in modern sports drug testing. The present study describes a recent application of this technique for the qualitative determination of different urinary insulin-like growth factor (IGF) related peptides. After simultaneous isolation by solid phase extraction and magnetic particle-based immunoaffinity purification, target analytes (IGF-1, IGF-2, Des1-3-IGF-1, R³-IGF-1 and longR³-IGF-1) were separated by nano-liquid chromatography prior to mass spectrometric detection. Endogenously produced IGF-1 and IGF-2, as well as the degradation product Des1-3-IGF-1, were frequently detected in urine samples from healthy volunteers in a concentration range of 20-400 pg/mL. The impact of IGF binding proteins (IGFBPs), being also present in urine, was potentially estimated by an additional ultrafiltration step in the sample preparation procedure. The synthetic analogue longR³-IGF-1, which is assumed to be subject to misuse by cheating athletes, was also analysed and detected in fortified urine samples. Besides the intact molecule, an N-terminally truncated degradation product Des1-10-longR³-IGF-1 was identified as the more stable target for doping controls using urine samples. The method was validated for qualitative purposes considering the parameters specificity, limit of detection (20-50 pg/mL), recovery (10-35 %), precision (<20 %), linearity, robustness and stability [11171].

Detection

Indirect biomarkers of recombinant human growth hormone (rhGH), insulin-like growth factor-I (IGF-I), insulin-like growth factor-II (IGF-II), insulin-like growth factor binding proteins (IGFBP-2 and IGFBP-3) and insulin (C-peptide) were measured together with urinary parameters of renal damage (beta₂-microglobulin and proteinuria) by immunoassays, in house validated for the purpose, in 61 subjects (36 elite athletes, 18 recreational athletes and 7 sedentary individuals) with different levels of physical fitness and endurance exercise. Validation parameters were good for the evaluated assays, excluding a high inter-assay imprecision and inaccuracy of 24 and 26 percent obtained for GH assay. The range of concentrations found in urine samples under investigation was generally covered by the calibration curves of the studied immunoassays. However, for the samples below or above the calibration curve, opportune dilution or concentration were performed. Particularly, C-peptide samples had to be diluted 1:5 and beta₂-microglobulin ones assayed using a triple sample volume, to fall within the calibration range. Urinary C-peptide was the only biomarker statistically higher in samples of elite athletes when compared to recreational athletes and sedentary individuals. Among elite athletes, tae-kwon-do athletes showed the highest IGF-II basal values while weightlifting athletes showed the lower IGF-I and IGFBP-3 basal values. The trend observed in weightlifters' basal samples was confirmed in their training samples: IGF-I, IGF-II, IGFBP-3 and beta₂-microglobulin were lower in with respect to those from synchronised swimming. Over the training season, within athlete variability was observed for IGFBP-3 for weightlifting athletes. In the studied subjects, no direct associations were found
between biomarkers of GH or insulin misuse and urinary parameters of renal damage, eventually due to high-workload endurance training. The variations observed in different biomarkers should be taken in consideration in the hypothesis of setting reference concentration ranges for doping detection [10483].

**Variation in measurements**

Insulin-like growth factor 1 (IGF-1) is a key mediator of growth hormone (GH) action and a well-characterized biomarker of GH abuse. Current immunoassays for IGF-1 suffer from poor concordance between platforms, which makes comparison of results between laboratories difficult. Although previous work has demonstrated good interlaboratory imprecision of LC-MS/MS methods when plasma is supplemented with purified proteins, the interlaboratory imprecision of an endogenous protein in the nanogram-per-milliliter concentration range has not been reported. It was deployed an LC-MS/MS method to quantify serum IGF-1 in 5 laboratories using 5 different instruments and analyzed 130 healthy human samples and 22 samples from patients with acromegaly. It was determined measurement imprecision (CV) for differences due to instrumentation, calibration curve construction, method of calibration, and reference material. Instrument-dependent variation, exclusive of digestion, across 5 different instrument platforms was determined to be 5.6 percent. Interlaboratory variation was strongly dependent on calibration. Calibration materials from a single laboratory resulted in less variation than materials made in individual laboratories (CV 5.2 % vs 12.8 %, respectively). The mean imprecision for 152 samples between the 5 laboratories was 16.0% when a calibration curve was made in each laboratory and 11.1% when a single-point calibration approach was used. The interlaboratory imprecision of serum IGF-1 concentrations is acceptable for use of the assay in antidoping laboratories and in standardizing results across clinical laboratories. The primary source of variability is not derived from the sample preparation but from the method of calibration [13388].

**In saliva**

To examine an immunoassay for measuring free IGF-I in a saliva specimen (free sIGF-I) and to study the levels in relation to the training conditions comparing young athletes and sedentary females an analysis was carried out by modifying a commercial kit for plasma matrix to measure the free sIGF-I. The plasma free and total IGF-I fractions, hGH and salivary total proteins were also measured. Saliva and blood specimens were collected from 15 well-trained young female volleyball athletes and from a control group of 14 young sedentary females. The calibration curve to assay free sIGF-I covered the range 0.05-5.00 microg/L. The detection limit was 0.07 microg/L. The within-run and between-run imprecision CVs were 10 percent and 13 percent respectively. The average recovery was 88 percent. Free sIGF-I, measured in 15 athletes and in 14 young sedentary females, was 0.10 ± 0.03 and 0.20 ± 0.05 microg/L respectively. There were decreased levels of free sIGF-I in well-trained athletes, compared with sedentary females. This decrease could be related to a greater tissue requirement by the active muscle subjected to intense exercise for several days [07158].
INSULIN

Men and women differ substantially in regard to degrees of insulin resistance, body composition, and energy balance. Adipose tissue distribution, in particular the presence of elevated visceral and hepatic adiposity, plays a central role in the development of insulin resistance and obesity-related complications. One review summarized published data on gender differences in insulin resistance, body composition, and energy balance, to provide insight into novel gender-specific avenues of research as well as gender-tailored treatments of insulin resistance, visceral adiposity, and obesity. English-language articles were identified from searches of the PubMed database through November 2008, and by reviewing the references cited in these reports. Searches included combinations of the following terms: gender, sex, insulin resistance, body composition, energy balance, and hepatic adipose tissue. For a given body mass index, men were reported to have more lean mass, women to have higher adiposity. Men were also found to have more visceral and hepatic adipose tissue, whereas women had more peripheral or subcutaneous adipose tissue. These differences, as well as differences in sex hormones and adipokines, may contribute to a more insulin-sensitive environment in women than in men. When normalized to kilograms of lean body mass, men and women had similar resting energy expenditure, but physical energy expenditure was more closely related to percent body fat in men than in women. Greater amounts of visceral and hepatic adipose tissue, in conjunction with the lack of a possible protective effect of estrogen, may be related to higher insulin resistance in men compared with women [09187].

An acute bout of endurance exercise enhances insulin sensitivity, but the effects of sprint interval exercise have not yet been described. It was compared insulin sensitivity at baseline and after an acute bout of exercise in healthy men (n=8) and women (n=5) (age 21 years; peak oxygen consumption (VO_{2} peak), 42.6 ± 1.7 mL/kg/min; <1.5 days/Week structured exercise; body fat, 21.1 ± 1.9 % ). Subjects underwent 3 oral glucose tolerance tests (OGTT) the day after each of the following 3 conditions: no exercise, baseline, sprint interval exercise at approximately 125 percent VO_{2} peak, and endurance exercise at approximately 75 percent VO_{2} peak). There were no differences by sex for any condition (men vs women). The findings demonstrated that an acute bout of endurance exercise, but not sprint interval exercise, increases insulin sensitivity relative to a no-exercise control condition in healthy males and females. While these findings underscore the use of regular endurance exercise as an effective intervention strategy against insulin resistance [09188].

Although physical exercise is an important part of metabolic control, endurance sports are considered hazardous for patients with type 1 diabetes because of the extreme physiological stress they represent. To further elucidate the metabolic challenge this form of exercise presented we investigated the performance of triathlon competitors with type 1 diabetes. Ten patients (32-61 years) with type 1 diabetes (disease duration 2-35 years) were followed for three years, during which each year they participated in one triathlon long-distance competitions (2.4 miles swimming, 26.2 miles running and 112 miles cycling; Ironman Germany 2005-2007). Glucose, cortisol, aldosterone, renin, thyroid hormones, testosterone, growth hormone and catecholamines were measured in blood and saliva. Five non-diabetic competitors served as controls. The performance equalled those of age-matched healthy athletes. Several participants experienced hyperglycemia early in the bike leg, whereas all of them developed low blood glucose levels during the marathon leg. Basal insulin supply was reduced up to 50 percent on race day. Hormone levels in athletes with type 1 DM and healthy controls were similar [09189].
Insulin and C-peptide have been proposed as possible biomarkers of human insulin hormone misuse in sport. An extended intra- and inter-laboratory validation of commercially available immunoassays was performed. Enzyme Amplified Sensitivity Immunoassay (EASIA) assays (Human Insulin-EASIA and C-peptide EASIA kits from BioSource) were evaluated for insulin and C-peptide in serum. The intra- and inter-laboratory precision and accuracy values were good for the evaluated assays with maximum imprecision and inaccuracy of 16 and 23 percent, respectively, obtained just for one day C-peptide assay evaluation. The range of concentrations found in serum samples under investigation was always covered by the calibration curves of the studied immunoassays. However, a 20 percent of the samples felt below the estimated insulin limit of quantification. High concordance between laboratory results was obtained for insulin assay, whereas that for C-peptide was lower. Evaluated immunoassays were used to measure serum concentrations of insulin and C-peptide in elite athletes of various sport disciplines at different moment of training season, in recreational athletes at baseline conditions and finally in sedentary individuals. Serum insulin was statistically lower both in recreational and elite athletes when compared to sedentary individuals. Among elite athletes, the specific sport affected serum insulin (e.g. weightlifting) and C-peptide (e.g. triathlon) concentrations. Over the training season, a within athletes variability was observed for taekwondo, swimming and weightlifting athletes. Variations due to those aspects should be taken in careful consideration in the hypothesis of setting reference concentration ranges for doping detection [09190].

Weight status and abnormal liver function are the two factors that influence whole-body insulin sensitivity. The main goal of the study was to compare insulin sensitivity in athletes (n=757) and physically active controls (n=670) in relation to the two factors. Homeostatic metabolic assessment for insulin resistance (HOMA-IR), weight status, and abnormal liver function (alanine aminotransferase and aspartate aminotransferase) were determined from 33 sports disciplines under morning fasted condition. The study was initiated in autumn 2006 and repeated in autumn 2007 (n=1508) to ensure consistency of all observations. In general, HOMA-IR and blood pressure levels in athletes were significantly greater than those in physically active controls but varied widely with sport disciplines. Rowing and short-distance track athletes had significantly lower HOMA-IR values and archery and field-throwing athletes had significantly higher values than the control group. Intriguingly, athletes from 22 sports disciplines displayed significantly greater body mass index values above control values. Multiple regression analysis showed that, for non-athlete controls, body mass index was the only factor that contributed to the variations in HOMA-IR. For athletes, body mass index and alanine aminotransferase independently contributed to the variation of HOMA-IR. Weight status and abnormal liver function levels appear to be the major contributors predicting insulin sensitivity for the physically active population [09191].

Insulin’s anabolic actions are believed to improve performance, by increasing protein synthesis and inhibiting protein catabolism and enhancing transport of selected amino acids in human skeletal muscle. Physiological hyperinsulinemia stimulates the activity of amino acid transport in human skeletal muscle, thereby stimulating protein synthesis [08261]. Insulin-treated diabetics are known to have increased lean body mass versus control [08262]. In addition to its role in regulating glucose metabolism, insulin increases amino acid transport into cells. Its stimulation of lipogenesis, and diminished lipolysis, is one of the reasons why bodybuilders and athletes will take rhGH in conjunction, to counteract this adverse effect, whilst optimizing protein synthesis [08042]. It is the inhibition of proteolysis that the athlete is interested in and the physiology of the diabetic patient has been extrapolated by the athlete to the sporting arena. Insulin administration is protein anabolic in the insulin-resistant state of chronic renal failure. It inhibits proteolysis and when administered with amino-acids, it increases net protein synthesis [08263]. The administration of exogenous insulin, establishes an in-vivo hyperinsulinemic clamp, increasing muscle glycogen before and in the recovery
stages of strenuous exercise. This may increase power, strength, and stamina and assist in recovery from strenuous exercise. Secondly, by inhibiting muscle protein breakdown and in conjunction with a high protein and high carbohydrate diet, insulin will have the action of increasing muscle bulk, potentially improving performance [08133].

In Gruber and Pope’s study [08132], 14 percent of surveyed subjects abused both insulin and anabolic steroids. Unless caught by urinalysis in the act, convicting a competitive sporting individual who has taken insulin is not possible [08133]. The few cases that have been published are case histories of individuals who have been admitted to hospital following accidental insulin overdose [08264-08273]. Dawson [08274] identified that 10 percent of 450 patients attending a needle exchange programme self-prescribed insulin for nontherapeutic purposes.

Simultaneously with insulin’s excitatory action in stimulating lipogenesis, insulin also exhibits an inhibitory action in preventing glycerol release. It is this inhibitory action on lipolysis (and also glycolysis, gluconeogenesis, ketogenesis, and proteolysis) that accounts for most of insulin’s physiological actions in man. The inhibitory actions are also responsible for insulin’s net anabolic actions [08133].

There is a correlation between substance misuse and inappropriate compliance with treatment in chronic medical conditions, which can induce anxiety and depressive disorders [08275]. Insulin dependent diabetics (type 1) have higher co-morbid substance misuse compared with the general population [08276] and their compliance with their medical management is reduced [08277]. Insulin dependent diabetics have an increased incidence of a psychiatric disorder, predominantly in the early course of their condition. Treating the psychiatric disorder improves diabetic control [08278]. Hypoglycemia is a regular occurrence in insulin-dependent diabetics and may be associated with cognitive and affective outcomes [08279]. Mood changes induced by fluctuations in glycemic control are characteristically individual, with depressive and anxiety affective states being most prevalent, however euphoria can also occur [08280]. The literature is interspersed with cases of deliberate misuse of insulin, associated with either suicide, parasuicide or factitious illness [08281, 08282]. Even intelligent individuals have abused their therapeutically prescribed insulin to induce feelings of “happiness, disorientation, drunkenness, altered perception of helplessness, and euphoria”. However, there always appears to be an underlying mood or personality disorder [08283]. There appears to be a class of individuals who are not diabetic and inject insulin to induce euphoria, to alter perception and for the “exquisite pleasure” associated with the risk of death [08284].

Accumulating data suggest that exercise may affect breast cancer risk and outcomes. Studies have demonstrated that high levels of insulin, often seen in sedentary individuals, are associated with increased risk of breast cancer recurrence and death. Now 101 sedentary, overweight breast cancer survivors were randomly assigned either to a 16-week cardiovascular and strength training exercise intervention or to a usual care control group. Fasting insulin and glucose levels, weight, body composition, and circumference at the waist and hip were collected at baseline and 16 weeks. Baseline and 16-week measurements were available for 82 patients. Fasting insulin concentrations decreased, significantly, by an average of 2.86 microU/mL in the exercise group, with no significant change in the control group (decrease of 0.27 microU/mL). The change in insulin levels in the exercise group seemed greater than the change in controls, but the comparison did not reach statistical significance. There was a trend toward improvement in insulin resistance in the exercise group but no change in fasting glucose levels. The exercise group also experienced a significant decrease in hip measurements, with no change in weight or body composition. This means that the relationship between physical activity and breast cancer prognosis may
be mediated, in part, through changes in insulin levels and/or changes in body fat or fat deposition [08285].

Insulin is a peptide hormone consisting of two peptide chains (A- and B-chain) that are cross-linked by two disulfide bonds. To obtain improved pharmacokinetic onset of action profiles of insulin treatment in diabetic patients, recombinant long-, intermediate-, and rapid-acting insulin analogs are produced, in which the C-terminal end of the B-chain plays an especially important role. A review of the veterinary literature reveals the low prevalence of equine type I diabetes mellitus, which indicates that the therapeutic use of insulin in racing horses is unlikely. Although there is no unequivocal evidence of an overall performance-enhancing effect of insulin, in human sports the misuse of insulin preparations is reported among elite athletes. The desired effects of insulin include the increase of muscular glycogen prior to sports event or during the recovery phase, in addition to a chalonic action, which increases the muscle size by inhibiting protein breakdown. In one study urinary insulin was detected in equine samples and differences between equine insulin, human insulin, as well as rapidly acting recombinant insulin variants were examined. Product ion scan experiments of intact proteins and B-chains enabled the differentiation between endogenously produced equine insulin, its DesB30 metabolite, human insulin and recombinant insulin analogs, and the assay allowed the assignment of individual product ions, especially those originating from modified C-termini of B-chains [08286].

Due to its versatile nature and its corresponding anabolic and anticatabolic properties, insulin has been prohibited in sports since 1999. Numerous studies concerning its impact on glycogen formation, protein biosynthesis, and inhibition of protein breakdown have illustrated its importance for healthy humans and diabetics as well as elite athletes. Various reports described the misuse of insulin to improve performance and muscle strength, and synthetic analogs were the subject of several studies describing the beneficial effects of biotechnologically modified insulins. Rapid- or long-acting insulins were developed to enhance the injection-to-onset profile as well as the controllability of administered insulin, where the slightest alterations in primary amino acid sequences allowed the inhibition of noncovalent aggregation of insulin monomers (rapid-acting analogs) or promoted microprecipitation of insulin variants upon subcutaneous application (long-acting analogs). Information on the metabolic fate and renal elimination of insulins has been rather limited, and detection assays for doping control purposes were primarily established using the intact compounds as target analytes in plasma and urine specimens. However, recent studies revealed the presence of urinary metabolites that have been implemented in confirmation methods of sports drug testing procedures. So far, no screening tool is available providing fast and reliable information on possible insulin misuse; only sophisticated procedures including immunoaffinity purification followed by liquid chromatography and tandem mass spectrometry have enabled the unambiguous detection of synthetic insulins in doping control blood or urine samples [10159].

The primary source of carbohydrate during exercise derives from muscle glycogen stores. The greater the amount of glycogen stored, the longer one should be able to exercise. Since insulin is a potent agent for the uptake of glucose and the subsequent glycogen storage in muscle, then the use of insulin ought to permit longer exercise time. In addition, insulin leads to the accumulation of amino acids in muscle and theoretically additional substrate for protein synthesis. Insulin may very well add to the anabolic properties of anabolic steroids and/or rhGH or rhIGF-I. The most likely scenario for a strength athlete would be to ingest a high carbohydrate diet, especially around the time of injecting rapidly acting insulin or its analogues [10001].

Insulin stimulates the uptake of glucose into muscle and fat by making available an increased
number of glucose transporters (Glut-4) at the cell membrane thus increasing the flux of glucose to the interior of the cell. However, its main effect is inhibitory to lipolysis, glycolysis, gluconeogenesis, ketogenesis and proteolysis. The theoretical efficacy to improve performance-muscle glycogen storage and the inhibition of proteolysis have not been shown in experimental protocols. That does not deter athletes from injecting insulin and its analogues, likely because insulin is but one of a "cocktail" or drugs along with training to enhance anabolic activity. In addition one must consider more rapid recovery from training and competition, but again there are no data to show this effect [10001].

The main adverse event is the most obvious, that of hypoglycemia. Most athletes who abuse insulin are likely adept at balancing the ingestion of carbohydrate when injecting rapidly-acting insulin analogues. Much of the use of insulin, which is readily available, is likely covert, kept even from friends and family. It is unlikely that one would tumble to the diagnosis of hypoglycemia in young healthy, non-diabetic individuals when they present to medical evaluation with confusion or coma. That can be a fatal mistake. There are no foolproof mechanisms for detecting insulin, unless one uses an analogue and that or one of its metabolites can be detected. One would think that anti-insulin antibody detection techniques would be definitive, but there is a low frequency of circulating anti-insulin antibodies in some normal (non-diabetic) individuals [10001].

One study evaluated the effects of various resistance exercise protocols on 24-hour postexercise insulin sensitivity. Seventeen participants with impaired fasting glucose (100-125 mg/dL) completed 4 separate bouts of resistance exercise under moderate intensity (65 % 1 repetition maximum, 1RM) or high intensity (85 % 1RM) conditions within the confines of single set and multiple set protocols. Intravenous fasting blood was taken at baseline and 24 hours postexercise for each exercise condition to measure fasting plasma glucose (G0) and fasting serum insulin (I0) to calculate insulin sensitivity. A minimum of 3 days washout was given between each exercise protocol. A 4 x 2 factorial analysis of variance was performed to compare insulin sensitivity and fasting glucose within subjects and between treatments. All of the exercise protocols significantly improved subsequent insulin sensitivity and G0. In comparison with single set, there was a significantly greater decrease in G0 24 hours after multiple set bouts. High intensity showed significant decreases in insulin sensitivity as compared with moderate intensity protocols. Effect size data suggest a dose response relationship between program variables of volume and intensity and 24-hour postexercise insulin sensitivity. High-intensity protocols resulted in greater effect sizes for insulin sensitivity (0.83 multiple set; 0.53 single set) as compared with moderate-intensity protocols. The high-intensity, multiple set bout yielded the greatest treatment effect in both fasting glucose (0.61) and insulin sensitivity (0.83). Overall, single set protocols were less effective than multiple set protocols in lowering fasting blood glucose. Findings suggest a dose-response relationship between volume and intensity on insulin sensitivity and fasting blood glucose. Results indicate that resistance exercise is an effective treatment for acutely enhancing insulin sensitivity and regulating blood glucose in individuals with impaired fasting glucose [10160].

To compare serum glucose and insulin responses to 3 preexercise snacks before, during, and after exercise in individuals with impaired fasting glucose (IFG) and healthy (H) men in an IFG population, the authors sought to determine whether a natural fruit snack (i.e., raisins) yields more desirable glucose and insulin concentrations than an energy bar or a glucose solution. The IFG (n=11, age 55 ± 1 years, fasting blood glucose 6.3 ± 0.1 mmol/L) and H groups (n=9, age 48 ± 3 years, fasting blood glucose 4.9 ± 0.1 mmol/L) cycled at 50 percent of VO2peak for 45 min on 4 occasions after consuming water or 50 g of carbohydrate from raisins (R), an energy bar (EB), or a glucose beverage (GLU). Metabolic markers were measured before, during, and after exercise. In all nutritional conditions, glucose concentrations of the IFG group were consistently higher than in the H group. Differences
between IFG and H groups in insulin concentrations were sporadic and isolated. In the IFG group, preexercise glucose concentration was lower in the R condition than in GLU. Ten and 20 min into exercise, glucose concentrations in the R and EB conditions were lower than in GLU. Insulin concentrations were lower in the R condition than in EB and GLU immediately before exercise and at minute 10 but at 20 min R remained lower than only GLU. Glucose concentrations were higher in the IFG group regardless of preexercise snack. Compared with the glucose solution, raisins lowered both the postprandial glycemic and insulinemic responses, whereas the energy bar reduced glycemia but not insulinemia [11172].

The purpose of one study was to gain insight into the current diabetes management practices of endurance athletes with type 1 diabetes and to compare these practices with the guidelines for athletes established by the American Diabetes Association (ADA). Participants included in this descriptive study were endurance athletes aged 18 years and older with type 1 diabetes. The survey questions were based on the current clinical recommendations for endurance athletes with type 1 diabetes, as established by the ADA. A link to the questionnaire was posted on the Web site of the Diabetes Exercise and Sports Association (DESA). A total of 38 questions were included in the survey, and 91 usable surveys were received. Analysis of variance was used for several comparisons using SPSS version 17. Half of the clinical guidelines were followed by the participants. Among these, about 50 percent followed many of the guidelines "most of the time" or "almost always" and 40 percent followed the guidelines "sometimes" or "most of the time." Results of ANOVA showed several trends (nonsignificant) in the occurrence of low blood glucose when the guidelines were not followed. It was concluded that endurance athletes with type 1 diabetes do not consistently follow the clinical guidelines for blood glucose management as recommended by the ADA. The results of this study reflect a need among athletes for diabetes management education programs that promote a better understanding of the potential negative side effects of suboptimal blood glucose control [11173].

The search for target analytes to uncover the misuse of long acting insulin analogues (Lantus, Insulin Glargine; Levemir, Insulin Detemir) in doping control samples led to the identification of several degradation products of insulin or its synthetic analogues. Specimens obtained from healthy volunteers or patients and athletes suffering from diabetes mellitus contained DesB30, DesB24-30, and DesB25-30 human insulin or DesB30-32, DesB31-32, and DesB24-32 Lantus, respectively. Analytes were purified from urine by immunoaffinity chromatography (IAC) with subsequent liquid chromatography-tandem mass spectrometry analysis. The employed analytical procedure was validated for qualitative determination considering the main metabolic products DesB30 human insulin and DesB30-32 Lantus. The occurrence of the identified Lantus degradation products in urine provided the direct and unambiguous evidence for an administration of this insulin analogue. For the determination of surreptitious Levemir or recombinant human insulin applications, an unequivocal argument was not detected, but promising approaches based on a modified insulin degradation profile with altered relative intensities of metabolites are presented [07161].

Human insulin has been considered relevant for sports drug testing since 1999 due to its assumed positive effects on muscle glycogen formation, antitabloc (so-called chalonic) actions on muscle protein, and improvements in protein biosynthesis. Besides conventional formulations consisting of recombinantly produced human insulin, numerous synthetic analogs, termed rapid- and long-acting insulins, have been introduced that possess improved injection-to-onset and pharmacokinetic profiles. In particular, the rapid-acting insulins such as Humalog, Novolog and Apidra have been targeted by new analytical methods, and top-down sequencing-based approaches have enabled their determination in human plasma and urine using immunoaffinity chromatography (IAC), solidphase extraction (SPE) and microbore LC-MS/MS procedures. While Humalog differs from human insulin only by the switched positions
of proline B28 and lysine B29, Novolog and Apidra comprise substituted amino acid residues, resulting in them having different molecular weights compared to that of human insulin (5807 Da). Product ion scan experiments yielded diagnostic ions that unequivocally identify the synthetic nature of these insulin analogs, and detection limits of 0.5 and 0.05 ng/mL, respectively, were obtained, enabling the determination of normal insulin levels in both matrices. Several athletes selected for doping control sample collection suffer from diabetes mellitus, and numerous authentic specimens from these tested "positive," providing the proof-of-principle of these new procedures [07050].

Given the fact that raising the plasma insulin concentration is key to stimulating muscle protein synthesis and limiting protein catabolism after exercise, it is not surprising that some athletes abuse insulin to increase skeletal muscle hypertrophy. Insulin injections reportedly can produce "rapid and noticeable (muscle) growth... almost immediately after starting insulin therapy". Most athletes choose to administer insulin immediately after a workout; they apparently realise that it is the most anabolic time to use this hormone. However, insulin abuse is extremely risky – one mistake in dose or diet can be fatal. Fortunately, recent studies have focused on safe insulinotropic nutritional mixtures containing protein hydrolysates, certain added amino acids (especially leucine), and high-glycaemic CHO; for example, dextrose and maltodextrine [06143].

Diabetes mellitus is the most common group of metabolic diseases and is characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both. Most patients with diabetes are type 2 (90 %); the remaining patients have type I disease. Athletes with diabetes range from the athlete participating in various youth sports to the competitive Olympic athlete and present a significant challenge to themselves and the medical staff who care for them on a daily basis. Each sport and the type of exercise have their own effects on diabetes management with numerous factors that significantly affect glucose levels, including stress, level of hydration, the rate of glycogenolysis and gluconeogenesis, and the secretion of counter-regulatory hormones. One article provided a general overview of diabetes mellitus, the effects of exercise on glucose levels, and a detailed review of the potential complications encountered in the management of diabetes in the athlete [12219].

Besides its particular importance as a widely used therapeutic agent, insulin (and its synthetic derivatives) has been suspected, purported, and proven to be a lethal weapon in numerous cases of attempted or successful homicide and suicide. In addition to blood and urine as common matrices for clinical diagnosis and post-mortem analysis, vitreous humour has gained considerable attention in autopsy and follow-up investigations due to its ability to provide valuable information on cause and time of death. However, post-mortem insulin analyses using such specimens have been rare due to the limited penetration of peptide hormones into the vitreous body, and immunoassays were exclusively employed in those studies. In the present communication, the determination of insulin(s) from vitreous humour by means of immunopurification combined with ultrahigh performance liquid chromatography-high resolution/high accuracy (tandem) mass spectrometry is reported. Exploiting the constantly increasing sensitivity and robustness of modern mass-spectrometry-based instruments, the option to identify insulin in post-mortem vitreous samples is demonstrated with a specimen collected from a non-diabetic victim who died from an insulin overdose. This communication represents the first successful mass-spectrometry-based analysis of post-mortem material related to an insulin poisoning case [12220].

Insulin, a polypeptide hormone secreted by pancreatic cells, is a key regulator in glucose homeostasis. Its deficiency leads to insulin-dependent (type I) diabetes whereas resistance to insulin is common in type II diabetes, obesity and a range of endocrine disorders. Its
determination is of considerable value, particularly in the clinical diagnosis of diabetes mellitus and the doping control of athletes. It has, additionally, been noted as a potential breast cancer marker (serum insulin levels being found to be raised in comparison to control patients). Electrochemical assays are potentially very cheap, highly sensitive, and very readily transposed to a point of care. Though there exist numerous examples of label free impedimetric or capacitative assaying of biomolecules, these are rarely demonstrated to be effective in complex biological mixtures or to be applicable to low molecular weight targets (since they operate through the interfacial displacement of water/ions and/or the steric blocking of a redox probe). It was reported an ultrasensitive electrochemical and label-free biosensor for insulin in blood serum with a clinically relevant linear range and detection limit of 1.2 pM. The transducing surfaces, based on readily prepared, antibody modified, polyethylene glycol monolayer modified polycrystalline gold surfaces, respond in a highly specific and re-useable manner to the target in up to 50 percent blood serum [13389].

To evaluate the effects of an overtraining (OT) protocol based on eccentric exercise (EE) sessions on the insulin and inflammatory signalling pathways in skeletal muscles of Swiss mice the rodents were divided into control (C; sedentary mice), trained (TR; performed the aerobic training protocol) and overtrained (OTR; performed the OT protocol). The incremental load test (ILT) and exhaustive test (ET) were used to measure performances before and after exercise protocols. Twenty-four hours after the exhaustive test performed at the end of week 8, the extensor digitorum longus (EDL) and soleus muscles were removed for subsequent protein analysis by immunoblotting. The phosphorylation of insulin receptor beta (pIRbeta; Tyr1146) diminished for EDL and soleus in OTR compared to C. The phosphorylation of insulin receptor substrate 1 (pIRS-1; Ser307) increased for EDL and soleus in OTR compared to C and TR. The phosphorylation of protein kinase B (pAkt; Ser473) diminished for EDL and soleus in OTR compared to C and TR. The phosphorylation of protein kinase B (pAkt; Ser473) diminished for EDL and soleus in OTR compared to C and TR. The phosphorylation of IκB kinase alpha and beta (pIKKalpha/beta; Ser176/180), stress-activated protein kinases/Jun amino-terminal kinases (pSAPK/JNK; Thr183/Tyr185) and the protein levels of suppressor of cytokine signaling 3 (SOCS3) increased for EDL and soleus in OTR compared to C and TR. In summary, the current used OT protocol based on EE sessions impaired the insulin signalling pathway with concomitant increases of IκK, SAPK/JNK and SOCS 3 protein levels [13390].

Insulin analogues represent a major and growing class of biotherapeutics, and their quantitation is an important focus of commercial and public effort across a number of different fields. As LC-MS has developed, it has become an increasingly practicable and desirable alternative to ligand-binding-based approaches for quantitation of this class of compounds. The sensitivity challenge of measuring trace levels of this large peptide molecule in a protein-containing matrix is considerable; however, different approaches to detection, extraction and separation are described to overcome this challenge, including immunoaffinity capture, SPE and low-flow HPLC. Considerations such as bioanalytical assay acceptance criteria and antidrug antibody effects during drug development are included, alongside descriptions of recent sports doping and clinical applications. Factors affecting the correlation and agreement of MS with biological ligand-binding methods are discussed, with ways to anticipate and appreciate differences between the values derived from each technique. A high degree of scientific creativity, combined with science-defined regulatory approaches that define suitable validation criteria, will be needed to meet the demanding requirements for high-throughput analysis of insulin by LC-MS [13391].

In weightlifting
Use of performance-enhancing drugs (PEDs) is common among strength-trained individuals, and a growing concern is the misuse of insulin. A 99-item Internet-based survey was posted on discussion boards of various fitness, bodybuilding, weightlifting, and anabolic steroid Web sites between February and June 2009. A case series of 41 nondiabetic insulin users is described. The typical insulin user was 31 ± 9 years old, male (98 %), and Caucasian/white (87 %) who classified himself as a "recreational exerciser" (48 %). The average insulin user also used anabolic steroids (95 %) and practiced polypharmacy by incorporating 16 ± 6 PEDs in his or her yearly routine. Hypoglycemia was reported by most of the subjects (57 %), and one individual reported unconsciousness. Insulin was obtained most commonly from local sources (e.g. friends, training partners, gym member/dealer; 41 %) and community pharmacies (38 %), with most (81 %) finding it "easy" to acquire their insulin. Strategies aimed to prevent insulin misuse are needed [12221].

**Amino acid-stimulated insulin secretion**

The importance of amino acid availability for the stimulatory effects of insulin to be evident was reported. Insulin, given with sufficient amino acids, can stimulate leg and whole body protein balance by mechanisms including stimulation of protein synthesis and inhibition of protein breakdown. This is in line with the recent data showing that protein balance over the muscle remains negative after resistance exercise when only carbohydrate (CHO) is ingested. In sharp contrast, amino acid ingestion alone significantly increases muscle protein anabolism after resistance exercise. However, consumption of both amino acids and CHO results in much greater effects on muscle protein anabolism, suggesting an interactive effect between insulin, amino acid availability, and resistance exercise. Also, it is well established that the stimulatory effect of amino acids on muscle protein synthesis is greater after exercise than at rest. Thus, nutrient timing is also an important consideration. Appropriate resistance exercise leads to significant skeletal muscle hypertrophy, which can occur through an increase in protein synthesis, a decrease in protein degradation, or both. Although stimulation – that is, resistance exercise – is important for muscle hypertrophy, nutrient availability appears to be a critical factor regulating the degree of hypertrophy. Obviously, the hormonal milieu of the muscle also has a major impact on protein synthesis. It is now apparent that both increased insulin and increased availability of amino acids are important for maximizing muscle protein anabolism. If hyperinsulinaemia is not supported by an exogenous amino acid supply, plasma as well as muscle free amino acid concentrations fall because of reduced splanchnic release. On the other hand, if amino acid concentrations are maintained at normal or higher concentrations, net protein deposition in muscle will occur because of stimulation of synthesis and possibly because of a simultaneous decrease in breakdown. Dietary supplements and other ergogenic aids are popular among athletes. Recent studies have shown that nutritional mixtures containing protein hydrolysates, added leucine, and high-glycaemic carbohydrates greatly augment insulin secretion compared with high-glycaemic carbohydrates only. When post-exercise hyperinsulinaemia is supported by hyperaminoacidaemia induced by protein hydrolysate and leucine ingestion, net protein deposition in muscle should occur. Thus, consumption of post-exercise recovery drinks containing these nutrients in conjunction with appropriate resistance training may lead to increased skeletal muscle hypertrophy and strength. However, the long-term effects on body composition and exercise performance remain to be determined [06143].

Formerly, it was believed that insulin secretion was controlled almost entirely by blood glucose concentration. However, it later become apparent that amino acids also play a very important role in controlling insulin secretion. Certain amino acids cause insulin release in humans even under conditions where the blood sugar changes little from its basal level. However, changes in blood sugar concentrations markedly influence the responsiveness of
beta cells to individual amino acids. Studies on isolated perfused rat pancreas and islets have shown that physiological amino acid mixtures and even pharmacological concentrations of individual amino acids require the presence of permissive concentrations of glucose (2.5-5.0 mM) to be effective beta cell stimulants. However, leucine is an exception. Contrary to popular belief, oral arginine is not an effective insulin secretagogue [06143].

**Effects of leucine on post-exercise muscle protein synthesis**

The key branched-chain amino acid leucine acts as a nutrient signal to stimulate muscle protein anabolism. Leucine affects muscle protein metabolism by decreasing the rate of protein degradation, probably by increasing circulating insulin. In addition, leucine affects phosphorylation of key proteins involved in the regulation of protein synthesis, which has been shown to occur even in the absence of an increase in circulating insulin. After exercise, recovery of muscle protein synthesis requires dietary protein or branched-chain amino acids to increase tissue concentrations of leucine. The important bottom line is that insulin and leucine allow skeletal muscle to coordinate protein synthesis with physiological state and dietary intake [06143].

**Protein hydrolysates**

Protein hydrolysates are produced from purified protein sources by heating with acid or, preferably, addition of proteolytic enzymes, followed by purification procedures. Extreme bitterness is a negative attribute of most protein hydrolysates. Fortunately, specific “debittering” strategies have focused on the application of proline-specific exopeptidases and endopeptidases given the contribution of proline residues to hydrolysate bitterness. The hydrolytic process mimics our own digestive actions; thus some feel it is an ideal way to process dietary protein. Extensively hydrolysed proteins containing mostly dipeptides and tripeptides are absorbed more rapidly than free-form amino acids and much more rapidly than intact (non-hydrolysed) proteins. The considerably greater absorption rate of amino acids from dipeptides and tripeptides than from an amino acid mixture appears to be the result of uptake by a system that has a greater transport capacity than the amino acid carrier system, thus minimising competition between its substrates. Each protein hydrolysate is a complex mixture of peptides of different chain length together with free amino acids, which can be defined by a global value known as degree of hydrolysis, which is the fraction of peptide bonds that have been cleaved in the starter protein. However, two protein hydrolysates made by different methods – for example, oligopeptides/significant free amino acids versus mainly dipeptides and tripeptides – may have a similar degree of hydrolysis even though their absorption kinetics are probably quite different. Consequently, it has been suggested that it is better to use the term “peptide chain length profile”. It seems that only dipeptides and tripeptides, which remain after luminal and brush-border peptidase digestion, are absorbed intact. Tetrapeptides and higher peptides appear to require prior brush-border hydrolysis before their hydrolysis products can be absorbed. Although the starter protein and method of hydrolysis affect absorptive characteristics, the peptide chain length is the most important variable. Protein hydrolysates produced from various sources showed increased amino acid absorption in humans when the proportion of dipeptides and tripeptides was increased. Thus, to maximise absorption rate, the ideal protein hydrolysate should contain mainly dipeptides and tripeptides. Such a protein hydrolysate seems to produce the most immediate hyperaminoacidaemia. In general, it is the kinetics of the absorption (rather than the net absorption of amino acids) that determines the greater nutritional value of the protein hydrolysates. The use of a protein hydrolysate in post-exercise drinks is preferred because it results in a faster increase in plasma amino acid concentrations during a 2 h period than does intact protein, and in turn the concentrations of essential amino acids in the blood.
regulate muscle protein synthesis. A practical advantage is that one can ingest a protein hydrolysate-containing supplement immediately after exercise without becoming bloated and not excessively suppressing appetite, so one can eat another meal sooner, possibly optimising the post-exercise “anabolic window”. In addition, protein hydrolysate ingestion has a strong insulinotropic effect [06143].

Whey

Clearly, hydrolysed whey protein is the most popular protein hydrolysate among athletes. Whey protein has been singled out as the ultimate source of protein on the basis of an excellent amino acid profile. Whey may offer other benefits too. Casein hydrolysate is also used in some commercial protein mixtures. It should be realised that the biological value of hydrolysed collagen (also known as gelatin) is zero; thus, collagen supplementation as a protein source is not recommended. However, it has been suggested that hydrolysed collagen may be useful in counteracting degenerative joint diseases. Finally, some commercial products are enriched with wheat gluten hydrolysate; that is, “glutamine peptides”. Wheat gluten has a unique amino acid profile: glutamine residues account for about 40 protein of the amino acids. Glutamine is an important fuel for some cells of the immune system and may have specific immunostimulatory effects. It is worth noting that the “classical” model of protein metabolism, which views nitrogen intake in terms of the flux of free amino acids from dietary protein and their exchange between plasma and intracellular compartments and between free and protein-bound amino acids, is misleading because it ignores the flux of amino acids through intermediate pools of small peptides [06143].

It has been shown that consumption of whey protein induced a rapid aminoacidemia with a greater amplitude than did casein protein. Whey protein consumption resulted in a rapid stimulation of whole-body protein synthesis and also oxidation, whereas casein resulted in a suppression of whole-body proteolysis. The result was that casein ingestion induced a more positive whole-body leucine balance than did whey. Recent findings showed that milk proteins appear superior to, or at least equivalent to, either isolated whey or casein alone in terms of supporting postprandial dietary nitrogen utilization [07309].

Timing of nutrient ingestion has been demonstrated to influence the anabolic response of muscle following exercise. Previously, it was demonstrated that net amino acid uptake was greater when free essential amino acids plus carbohydrates were ingested before resistance exercise rather than following exercise. However, it is unclear if ingestion of whole proteins before exercise would stimulate a superior response compared with following exercise. One study was designed to examine the response of muscle protein balance to ingestion of whey proteins both before and following resistance exercise. Healthy volunteers were randomly assigned to one of two groups. A solution of whey proteins was consumed either immediately before exercise (PRE; n=8) or immediately following exercise (POST; n=9). Each subject performed 10 sets of 8 repetitions of leg extension exercise. Phenylalanine concentrations were measured in femoral arteriovenous samples to determine balance across the leg. Arterial amino acid concentrations were elevated by approximately 50 percent, and net amino acid balance switched from negative to positive following ingestion of proteins at either time. Amino acid uptake was not significantly different between PRE and POST when calculated from the beginning of exercise or from the ingestion of each drink. Thus the response of net muscle protein balance to timing of intact protein ingestion does not respond as does that of the combination of free amino acids and carbohydrate [07359].

Myostatin decreases muscle mass and this is accomplished, in part, by inhibiting muscle satellite cell proliferation and differentiation by regulating the expression of cell cycle-related proteins (e.g. p21 and cdk2) and myogenic regulatory factors (e.g. myogenin and MyoD).
The purpose of one investigation was to determine whether protein ingestion before and after a resistance exercise (RE) bout affects myostatin and cell cycle-related gene expression. Strength-trained middle-aged to older men were divided into a protein group (61 years, n=9) or a placebo group (62 years, n=9). Muscle biopsies from the vastus lateralis muscle were taken at rest and 1 and 48 h after a 5 x 10 repetition leg press RE bout. Protein (15 g whey) or non-caloric placebo was taken immediately before and after the RE bout. mRNA expression levels of myostatin and related genes (AcvrIIb, FLRG, p21, p27, cdk2, myogenin and MyoD) were determined by Taqman probe-based real-time RT-PCR and normalized to GAPDH mRNA. Myostatin mRNA decreased after a RE bout, but only in the placebo group. Conversely, myostatin binding protein FLRG and cell cycle kinase cdk2 mRNA increased only in the protein group. p21 mRNA was increased at 1 h post-RE in placebo and tended to be increased in the protein group. Myostatin, its binding protein and cell cycle-related gene expressions are affected by single RE bout and these responses are further modified by whey protein intake. Therefore, controlling nutrition intake is important when studying gene expression responses to exercise.

Whey protein is a supplemental protein source often used by athletes, particularly those aiming to gain muscle mass; however, direct evidence for its efficacy in stimulating muscle protein synthesis (MPS) is lacking. We aimed to determine the impact of consuming whey protein on skeletal muscle protein turnover in the post-exercise period. Eight healthy resistance-trained young men (age 21) participated in a double-blind randomized crossover trial in which they performed a unilateral leg resistance exercise workout (EX: 4 sets of knee extensions and 4 sets of leg press; 8-10 repetitions/set; 80 % of maximal), such that one leg was not exercised and acted as a rested (RE) comparator. After exercise, subjects consumed either an isocaloric whey protein plus carbohydrate beverage (WHEY: 10 g protein and 21 g fructose) or a carbohydrate-only beverage (CHO: 21 g fructose and 10 g maltodextran). Subjects received pulse-tracer injections of L-[ring-2H5]phenylalanine and L-[15N]phenylalanine to measure MPS. Exercise stimulated a rise in MPS in the WHEY-EX and CHO-EX legs, which were greater than MPS in the WHEY-RE leg and the CHO-RE leg, respectively. The rate of MPS in the WHEY-EX leg was greater than in the CHO-EX leg. It was concluded that a small dose (10 g) of whey protein with carbohydrate (21 g) can stimulate a rise in MPS after resistance exercise in trained young men that would be supportive of a positive net protein balance, which, over time, would lead to hypertrophy.

Ingestion of whey or casein yields divergent patterns of aminoacidemia that influence whole-body and skeletal muscle myofibrillar protein synthesis (MPS) after exercise. Direct comparisons of the effects of contrasting absorption rates exhibited by these proteins are confounded by their differing amino acid contents. The objective was to determine the effect of divergent aminoacidemia by manipulating ingestion patterns of whey protein alone on MPS and anabolic signaling after resistance exercise. In separate trials, 8 healthy men consumed whey protein either as a single bolus (BOLUS; 25-g dose) or as repeated, small, "pulsed" drinks (PULSE; ten 2.5-g drinks every 20 min) to mimic a more slowly digested protein. MPS and phosphorylation of signaling proteins involved in protein synthesis were measured at rest and after resistance exercise. BOLUS increased blood essential amino acid (EAA) concentrations above those of PULSE (162 % compared with 53 %, 60 min after exercise, whereas PULSE resulted in a smaller but sustained increase in aminoacidemia that remained elevated above BOLUS amounts later (180-220 min after exercise). Despite an identical net area under the EAA curve, MPS was elevated to a greater extent after BOLUS than after PULSE early (1-3 h: 95 % compared with 42 %) and later (3-5 h: 193 % compared with 121 %). There were greater changes in the phosphorylation of the Akt-mammalian target of rapamycin pathway after BOLUS than after PULSE. Thus, rapid aminoacidemia in the postexercise period enhances MPS and anabolic signaling to a greater extent than an
identical amount of protein fed in small pulses that mimic a more slowly digested protein. A pronounced peak aminoacidemia after exercise enhances protein synthesis [11394].

It was recently shown that a week-long, high-fat diet reduced whole body exercise efficiency in sedentary men by >10 percent. To test if a similar dietary regime would blunt whole body efficiency in endurance-trained men and, as a consequence, hinder aerobic exercise performance, 16 endurance-trained men were given a short-term, high-fat (70 % kcal from fat) and a moderate carbohydrate (50 % kcal from carbohydrate) diet, in random order. Efficiency was assessed during a standardized exercise task on a cycle ergometer, with aerobic performance assessed during a 1-h time trial and mitochondrial function later measured using $^{31}$P-magnetic resonance spectroscopy. The subjects then underwent a 2-wk wash-out period, before the study was repeated with the diets crossed over. Muscle biopsies, for mitochondrial protein analysis, were taken at the start of the study and on the 5th day of each diet. Plasma fatty acids were 60 percent higher on the high-fat diet compared with moderate carbohydrate diet. However, there was no change in whole body efficiency and no change in mitochondrial function. Endurance exercise performance was significantly reduced, most probably due to glycogen depletion. Neither diet led to changes in citrate synthase, ATP synthase, or mitochondrial uncoupling protein 3. It was concluded that prior exercise training blunts the deleterious effect of short-term, high-fat feeding on whole body efficiency [11397].

With a growing number of dietary interventions that claim to improve lipid profile, it is important to ensure that these claims are evidence based. The objective of one study was to make recommendations for dietary regimens by analyzing their effectiveness and the level of evidence. It was searched MEDLINE as well as the Cochrane Database of Systematic Reviews for nutritional studies. Meta-analyses and randomized controlled trials published in English and including data on the effect on blood lipid levels were used. Randomized controlled trials were included if they were at least 4 weeks in duration and had a minimum of 50 participants. It was identified 22 different dietary interventions and reviewed 136 studies published between January 1990 and December 2009 that met our inclusion criteria. The literature review showed that to improve lipid profile, the following regimens can be recommended fully: Mediterranean and Portfolio diets; low-fat diet; diet high in soy protein, fibre, or phytosterols; whole grain foods, and omega-3 fatty acid supplementation. The consumption of nuts, a diet high in carbohydrates and protein, green tea, and red wine, as well as the supplementation with policosanol and red yeast rice extract, can be considered for improvement of the lipid profile, while the supplements of guggulipid, garlic, chromium, vitamin C, magnesium-pyridoxal-phosphate-glutamate, tocotrienols, and absorbitol cannot be recommended [11398].

**Effects of insulinotropic nutritional mixtures on insulin secretion**

A study was implemented to determine the effects of different protein-containing solutions on insulin response and amino acid availability in healthy humans. Four different 600 mL solutions were used. The glucose solution (control) contained only glucose (25 g/L), and the three additional solutions contained the same quantity of glucose plus protein (0.25 g/kg body mass) but proteins were derived from different sources: whey hydrolysate, pea hydrolysate, and a complete cow's milk solution. This study indicated that:

- Ingestion of glucose and protein hydrolysate results in a synergistic and fast increase in plasma insulin. In fact, protein hydrolysates stimulated an increase in plasma insulin that was two and four times greater than that produced by the intact milk protein solution and glucose solution, respectively
Protein hydrolysates are absorbed at a faster rate from the small intestine than are intact milk proteins, as reflected by the rapid increase in the plasma concentration of branched-chain amino acids in peripheral blood. Whey protein hydrolysate elicited the greatest availability of amino acids during the 3 h postprandial period. The authors attributed this difference to the rapid increase in plasma amino acids evoked during the first 40 min of the digestive period, during which the increase was about 37 percent greater after the ingestion of whey protein hydrolysate solution than that after ingestion of the intact milk protein solution.

It is likely that the high concentrations of plasma amino acids and increased insulin explains the superiority of protein hydrolysates over intact proteins in promoting nitrogen utilisation. The co-ingestion of carbohydrate appears to affect the absorption kinetics, as one study showed that whey and casein proteins and their respective hydrolysates administered alone produce similar rates of intestinal absorption of amino acids. Alternatively, it is possible that this study used protein hydrolysates containing mainly oligopeptides [06143].

It was also determined the extent to which the combined ingestion of high-glycaemic CHO and a casein protein hydrolysate with or without additional free leucine can increase insulin concentrations during post-exercise recovery. Fourteen male athletes were participated in three randomised crossover trials in which they performed 2 h of exercise. Thereafter, the subjects were studied for 3.5 h during which they ingested CHO only (0.8 g/kg/h), CHO + protein hydrolysate (0.8 and 0.4 g/kg/h, respectively), or CHO + protein hydrolysate + free leucine (0.8, 0.4, and 0.1 g/kg/h, respectively) in a double-blind fashion. The results revealed that plasma insulin responses were 108 percent and 190 percent greater in the CHO + protein hydrolysate and CHO + protein hydrolysate + leucine trial, respectively, compared with the CHO only trial. The study also indicated that addition of free phenylalanine, as applied in earlier studies, is not necessary to obtain such high post-exercise insulin responses. Similarly, it was examined plasma insulin responses after co-ingestion of casein protein hydrolysate with and without additional free leucine with a single bolus of high-glycaemic CHO. Again, the subjects participated in three trials in which blood insulin responses were determined after the ingestion of beverages of different composition: CHO only (0.7 g/kg), CHO + protein hydrolysate (0.7 and 0.3 g/kg, respectively) or CHO + protein hydrolysate + free leucine (0.7, 0.3 and 0.1 g/kg, respectively). The result indicated that plasma insulin responses were 66 and 221 percent greater in the healthy subjects in the CHO + protein hydrolysate and CHO + protein hydrolysate + free leucine trials, respectively, compared with those in the CHO only trial. In other words, this study also showed that co-ingestion of a protein hydrolysate with additional leucine strongly augments insulin secretion after the consumption of a single bolus of CHO [06143].

The notion that the protein hydrolysates have strong insulinotropic properties is also supported by the studies examining the effects of intact protein-containing post-exercise drinks. Ivy et al[46] compared the effects of CHO + intact protein (80 g CHO, 28 g protein, 6 g fat), low-CHO (80 g CHO, 6 g fat), or high-CHO (108 g CHO, 6 g fat) and reported that plasma insulin concentrations did not differ at any time among treatments. However, it has also been observed that plasma insulin concentrations for the CHO + intact protein treatment (112 and 40.7 g, respectively) were somewhat higher than those for the CHO treatment (112 g CHO). A post-exercise drink containing a mixture of free amino acids also has a potent effect on insulin secretion. However, a large dose of amino acids can cause gastrointestinal discomfort. This may have something to do with the drink's osmolarity. A protein hydrolysate containing dipeptides and tripeptides reduces osmolarity because equal solution weights of dipeptides and tripeptides have the same and one-third the osmolarity of free amino acids, respectively [06143].
A sophisticated study investigated post-exercise muscle protein synthesis and whole body protein balance after the combined ingestion of high-glycaemic CHO with or without whey protein hydrolysate and/or leucine. Their nutritional protocol was rather rigorous; the subjects received a beverage volume of 3 ml/kg every 30 min to ensure a given dose of 0.3 g high-glycaemic CHO/kg and 0.2 g of a protein hydrolysate/kg every hour, with or without the addition of 0.1 g/kg/h free leucine. Repeated boluses were taken every 30 min until 330 min after exercise. The results revealed that the rates of whole body protein synthesis were highest in the CHO + protein hydrolysate + leucine trial. Similarly, the fractional synthetic rate in the vastus lateralis muscle was significantly higher in the CHO + protein hydrolysate + leucine trial than the CHO trial, with intermediate values observed in the CHO + protein hydrolysate trial. Furthermore, the investigators found plasma insulin responses to correlate negatively with whole body protein degradation, whereas whole body protein synthesis correlated positively with plasma insulin response. However, the fractional synthetic rate did not correlate with the plasma insulin response, whereas the mixed muscle protein fractional synthetic rate did correlate with the amount of leucine that was ingested. It is difficult to interpret these results given the massive supplementation. Nevertheless, the authors concluded that, “the additional ingestion of free leucine in combination with protein and carbohydrate likely represents an effective strategy to increase muscle anabolism following resistance exercise.” Other recent studies have shown that relatively small doses of leucine can improve exercise performance and enhance the acquisition of strength [06143].

**Protein shake**

Contrary to popular belief, higher protein intake has no adverse effects on healthy kidneys, fluid status, or bone. In fact, proteins appear to have positive effects on bone health, as they increase circulating insulin-like growth factor I (IGF-I), which plays an important role in bone formation. It was reported that a protein supplement during a strength and conditioning programme led to an increase in plasma concentrations of IGF-I in those subjects compared with the concentrations in a group who also trained but consumed an isocaloric CHO supplement. Also, serum bone alkaline phosphatase concentrations increased over time and tended to be higher in the protein group than in the CHO group, indicating increased bone formation. In addition, IGF-I plays a critical role in development, growth, repair, and maintenance of skeletal muscle. Thus, it may partially explain why many strength/power athletes (especially bodybuilders) feel that a very high protein intake is beneficial for skeletal muscle hypertrophy. Indeed, studies indicate increased positive nitrogen balance when protein intake is increased. Traditionally, the term “protein requirement” has meant the amount of dietary protein that must be consumed to provide the amino acids needed for the synthesis of those proteins irreversibly catabolised in the course of the body's metabolism. It should be noted, however, that strength/power athletes are not concerned with the minimum amount of protein necessary to sustain normal body functions, but, rather, their absolute gains in muscle mass and strength. Other potential benefits of higher protein intake should be considered too. Interestingly, a placebo-controlled study reported that post-exercise protein/CHO supplementation [06143]:

- reduces bacterial/viral infections
- decreases the number of medical visits for muscle or joint problems
- diminishes episodes of heat exhaustion
- reduces muscle soreness
- improves rifle scores in US marine recruits during basic training.
Effects of post-exercise hyperinsulinaemia on fat oxidation and de novo lipogenesis

The chief lipid-related functions of insulin are inhibition of lipolysis and lipid oxidation (at 13 and 44 microU/ml, respectively). When insulin concentration falls below 13 microU/ml, lipolysis is powerfully and exponentially stimulated. It was reported that a very-low-CHO diet significantly decreased serum insulin (~34 %) and that about 70 percent of the variability in fat loss was accounted for by the decrease in serum insulin concentrations. Further, exogenous insulin promotes body fat accumulation, so one could speculate that insulinotropic supplements have similar effects. However, I feel this is hardly a concern for healthy athletes when these supplements are ingested immediately after rigorous exercise when the muscle cells are highly receptive to insulin and “screaming” for new fuel. The physiological state of a sedentary person and that of a well-trained athlete after exercise are poles apart. AMP-activated protein kinase acts as a “metabolic switch” in multiple tissues after exercise; the net effect of its activation is to increase fatty acid oxidation and diminish glycerolipid synthesis [06143].

To investigate the hormonal and metabolic adaptations occurring when high-glycaemic CHOs are ingested after exercise, it was compared the fate of a 100 g oral glucose load in healthy volunteers after an overnight fast at rest either without previous exercise or after 3 h of exercise performed on a treadmill at about 50 percent of the individual VO2max. Indirect calorimetry indicated that glucose ingestion in post-exercise recovery was associated with decreased CHO oxidation and increased lipid oxidation when compared with control conditions. It has also been reported that de novo lipogenesis was totally suppressed after exercise, even when a very large CHO load was ingested, and that fat oxidation remained high in subjects who had exercised after both the small and large CHO meal. Certainly, this does not mean that insulinotropic supplements should be used while watching TV. It is possible that the hyperinsulinaemic condition prevalent in obese, insulin-resistant individuals is responsible for the repartitioning of fatty acids away from oxidation and toward storage [06143].

Anti-inflammatory effects of insulin

It has been proposed that insulin is the ideal anti-inflammatory agent for critically ill patients, because it normalises plasma glucose concentrations (glucose is proinflammatory) while exerting its anti-inflammatory effect. In addition, insulin suppresses generation of reactive oxygen species and the expression of p47phox, a key component of NADPH oxidase, the enzyme that generates the superoxide radical. Thus, insulin has antioxidant effects too. As strenuous exercise produces muscle inflammation as well as increases generation of reactive oxygen species, it is possible that post-exercise hyperinsulinaemia offers additional benefits beyond muscle protein synthesis [06143].

Laboratory techniques

Insulin, a polypeptide hormone secreted by pancreatic cells, is a key regulator in glucose homeostasis. Its deficiency leads to insulin-dependent (type I) diabetes whereas resistance to insulin is common in type II diabetes, obesity and a range of endocrine disorders. Its determination is of considerable value, particularly in the clinical diagnosis of diabetes mellitus and the doping control of athletes. It has, additionally, been noted as a potential breast cancer marker (serum insulin levels being found to be raised in comparison to control patients). Electrochemical assays are potentially very cheap, highly sensitive, and very
readily transposed to a point of care. Though there exist numerous examples of label free impedimetric or capacitative assaying of biomolecules, these are rarely demonstrated to be effective in complex biological mixtures or to be applicable to low molecular weight targets (since they operate through the interfacial displacement of water/ions and/or the steric blocking of a redox probe). It was reported an ultrasensitive electrochemical and label-free biosensor for insulin in blood serum with a clinically relevant linear range and detection limit of 1.2 pM. The transducing surfaces, based on readily prepared, antibody modified, polyethylene glycol monolayer modified polycrystalline gold surfaces, respond in a highly specific and re-useable manner to the target in up to 50 percent blood serum [12222].

Insulin and related synthetic therapeutics have been prohibited by the World Anti-Doping Agency for athletes demonstrably not suffering from diabetes mellitus. The primary specimen for doping controls has been urine, but the renal excretion of intact human insulin as well as synthetic analogues such as the rapid-acting products Humalog LisPro, Novolog Aspart, and Apidra Glulisine has been reported negligible owing to metabolic degradation. Nevertheless, employing solid-phase extraction in combination with immunoaffinity purification followed by a top-down sequencing-based mass spectrometric approach, an assay was established allowing the identification of three intact rapid-acting synthetic insulins in doping control urine samples. A volume of 25 mL of urine was concentrated, insulin analogues were isolated from the concentrate by immunoaffinity chromatography, and the eluate was analyzed using microbore liquid chromatography/tandem mass spectrometry. Characteristic product ion spectra obtained from 5-fold protonated intact analytes as well as isolated insulin B-chains allowed the unambiguous identification of target analytes with detection limits of 0.05 ng/mL (9 fmol/mL). Moreover, assay validation demonstrated recoveries between 72 and 80 percent for Humalog LisPro, Novolog Aspart, and Apidra Glulisine, and assay precisions ranged from 9 to 16 percent. A reliable tool is provided that allows the qualitative determination of rapid-acting insulins in urine specimens collected for sports drug testing [06144].
OTHER DEFINED PEPTIDE HORMONES

Gonadotropins

The administration of gonadotropins is prohibited in sport but the effect in men of recently available recombinant hCG and LH on serum and urine concentrations of gonadotropins and androgens has not been systematically evaluated in the anti-doping context. To determine the time-course of recombinant LH (LHrh) and hCG (rhCG) on blood and urine hormone profiles in men to develop effective tests to detect rhLH and rhCG doping. Two randomized controlled studies with a 2 x 2 factorial design used healthy male volunteers aged 18-45 years. In the rhLH study, men were randomized into (a) either of two single doses of rhLH (75 IU or 225 IU) and (b) suppression of endogenous LH and testosterone by nandrolone or no suppression. In the rhCG study men were randomized into (a) either of two single doses of rhCG (250 mug or 750 mug) and (b) suppression of endogenous LH and testosterone by nandrolone decanoate or no suppression. Nandrolone suppression comprised a single dose of 200 mg nandrolone decanoate 3 days prior to, and in the rhCG study an additional dose 1 day after, gonadotropin injection. Neither rhLH dose produced a significant increase in serum or urine LH or testosterone or in the T/E or T/LH ratios regardless of nandrolone-induced suppression of endogenous LH and testosterone. Nor did an even higher dose (750 IU) in 3 healthy men with unsuppressed gonadal axis. These findings were confirmed with two different commercial LH immunoassays together with adjustment for any influence of urine sediment and dilution. Both rhCG doses produced a steep, dose-proportional increase in serum and urine hCG with increases in serum and urine testosterone and suppression of serum and urine LH, regardless of hCG dose. Serum but not urine testosterone was lowered by nadrolone suppression. The testosterone/LH ratio showed a progressive increase unrelated to rhCG dose or nandrolone suppression whereas both rhCG and nandrolone suppression minimally increased T/E ratio. This means that both rhCG doses produce a striking increase in serum hCG and testosterone with suppression of serum LH but, at single doses up to 750 IU, rhLH has no influence on serum or urine LH or testosterone. Effective rhLH doping, which relies on a sustained increases in endogenous testosterone, would require much higher and more frequent daily rhLH doses. Use of LH immunoassays optimised for serum to detect rhLH doping by urine LH measurement requires more standardisation and validation and, at present, is unreliable. The testosterone/LH ratio is, however, a useful screening test for hCG doping although its utility requires further evaluation [09186].

Parenteral administration of human chorionic gonadotropin (hCG) or luteinizing hormone (LH) stimulates the production of testosterone in males and these gonadotropins can therefore be used by athletes to enhance muscle strength. However, they are more expensive and less efficient than testosterone and anabolic steroids. Therefore their main use is probably to stimulate gonadal testosterone production during and after self-administration of testosterone or anabolic steroids. A positive effect of hCG on muscle strength has not been demonstrated in women and elevated concentrations of hCG in females are often caused by pregnancy. The use of gonadotropins is therefore prohibited only in males but not in females. HCG occurs at low but measurable concentrations in plasma and urine of healthy males and can be measured by sensitive methods. However, the characteristics of the method to be used for doping control have not been defined. Virtually all commercially available hCG assays have been designed for determination of hCG in serum rather than urine, which is used for doping control. Methods based on mass spectrometric detection of fragments derived from hCG extracted from urine by immunoadsorption have been developed but their suitability for doping control remains to be
determined. The concentrations of LH in serum and urine are variable and more then 10-fold higher than those hCG. It is therefore difficult to detect illicit use of LH. The characteristics and reference values for hCG and LH assays used in doping control and the cutoff values need to be defined [08287].

Doping with (glyco)protein hormones represent an extremely challenging, analytical problem as nearly all are constitutively present at low concentrations that fluctuate according to circadian or alternative periodical, or external stimuli. Thus the mere concentration in a biological sample is only resolutive when this surpasses extreme values. As the vast majority of these molecules are produced by recombinant DNA technology it is believed that the exogenous molecules could bear the signature of the host cell. In particular, these could comprise structural differences originated from co or post-translational differences. In one study it was employed both proteomics and glycomics strategies to compare recombinant and urinary human chorionic gonadotrophin in order to evaluate this hypothesis. As anticipated the recombinant hormone could be shown to contain N-glycolyl neuraminic acid, a sialic acid that cannot be produced by humans. Furthermore, differences were observed in the overall glycosylation, in particular the presence of abundant hybrid-type glycans that were much less pronounced in the recombinant species. These differences were determined to occur predominantly in the alpha-subunit for which antidoping strategies focussed on these elements could be used for both chorionic gonadotrophin and lutrophin as they share the same alpha-subunit [08288].

Concentrations of intratesticular (IT) testosterone (T) are known to be 100-200 times those of serum T; however, the IT concentrations of T’s precursors, their testicular to serum gradients, gonadotropin dependence, and response to stimulation with human chorionic gonadotropin (hCG) have not been studied in detail. It was hypothesized that serum and IT androstenedione (ADD) and IT dehydroepiandrosterone (DHEA) would be significantly suppressed by the administration of a GnRH antagonist and increased when stimulated by hCG, without a similar suppression of serum DHEA. It was suppressed gonadotropins in 23 normal men with the GnRH antagonist acyline and randomly assigned them to one of four doses of hCG, 0, 15, 60, or 125 IU sc every other day for 10 d. Blood and IT fluid for the measurement of serum and IT hormones were obtained at baseline and after 10 d of treatment. Baseline IT ADD was 629 nmol/liter, and IT DHEA was 564 nmol/liter, which were 175 and 27 times higher than their respective serum concentrations. IT ADD and IT DHEA were suppressed by 98 and 82 percent, respectively, by acyline and significantly increased with hCG administration. Likewise, serum ADD was suppressed by 50 percent, but serum DHEA was unchanged. It was thus found that ADD and DHEA are highly concentrated within the human testes compared with serum. Serum and IT ADD and IT DHEA are markedly suppressed with GnRH administration and stimulated by hCG, but serum DHEA is not, suggesting that most circulating DHEA is not of testicular origin [11174].

The synthesis and secretion of the gonadotropic hormones involves coordination of signal transduction, gene expression, protein translation, post-translational folding and modification and finally secretion. The production of biologically active gonadotropin thus requires appropriately folded and glycosylated subunits that assemble to form the heterodimeric hormone. It was overviewed recent literature on regulation of gonadotropin subunit gene expression and current understanding of the assembly and secretion of biologically active gonadotropic hormones. Finally, it was discussed the therapeutic potential of understanding glycosylation function towards designing new forms of gonadotropins based on observations of physiologically relevant parameters such as age related glycosylation changes. The glycoprotein hormone family includes lutinizing hormone (LH), follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH) and chorionic gonadotropin (CG). Production of these hormones occurs in either the pituitary (LH, FSH, TSH) or by the chorion of a
developing fetus (CG). These hormones are heterodimeric, consisting of a common alpha subunit and a unique beta subunit, and they are also glycosylated. Therefore, their production requires coordination of transcriptional regulation of the subunit genes [11476].

**Human chorionic gonadotropin**

Human chorionic gonadotrophin (hCG) is routinely analyzed in doping control samples of males athletes due to its ability to stimulate the testicular production of testosterone. Today, two immunoassays are recommended by WADA to be used as initial testing and confirmation tools. The implementation of such immunoassays into sports drug testing routine protocols demonstrated the fitness-for-purpose of both the screening (Immulite 2000 XPi) and the confirmatory (Delfia Xpress) test for human urine. While the initial testing assay recognizes several different hCG variants including the intact heterodimeric hCG and the beta-core fragment of hCG, the Delfia Xpress confirmation test detects intact hCG and nicked hCG only. Eventually, only urinary concentrations of intact hCG exceeding 5 IU/L should be considered as indication for an anti-doping rule violation [13009].

Determination of human chorionic gonadotropin (hCG) is used for diagnosis and monitoring of pregnancy, pregnancy related disorders, for trophoblastic and some nontrophoblastic tumors. In addition, hCG is determined for doping control in males. Assay of hCG is complicated by the occurrence of different molecular forms, which are detected to various degrees by different assays. The main form of hCG in circulation and in patients with trophoblastic tumors is intact heterodimeric hCG. The free beta subunit (hCG-beta) is a minor form in plasma in both conditions, but it may be the major form in aggressive trophoblastic cancer. Therefore, assays measuring hCG and hCGβ together are mainly used for diagnosis of pregnancy and trophoblastic diseases. When excreted into urine, most of hCG (and hCG-beta) is broken down to the core fragment of hCGβ (hCG-beta-cf), which is the main immunoreactive form of hCG in urine during pregnancy. Specific determination of hCG-beta is of value in screening for Down's syndrome and diagnosis of nontrophoblastic cancer. hCG-beta-cf is of limited utility but it is important because it may disturb assay of hCG in pregnancy [13392].

Human chorionic gonadotrophin (hCG) as well as LH are prohibited in sports (for males only) due to their ability to stimulate testosterone production and release. Both substances are commonly analyzed by ELISA, which was recently shown to be critical particularly concerning hCG if urine samples collected for doping controls are stored at -20°C. In a study a significant loss (up to 100 %) of immunoreactive hCG was observed in urine specimens stored at -20°C, attributed to a negative impact of urea. Noteworthy, at +4°C and -80°C the same samples (with identical urea concentrations) did not decrease in hCG immunoreactivity, which might be relevant to consider in case of doping control sample transportation and storage. In a complementary and indirect manner, the option to determine hCG abuse in sport by steroid profiling as well as LH measurements in blood and urine was evaluated. While commonly used urinary steroid profiles as such did not exhibit the required sensitivity to detect hCG abuse, accurate quantification of the testosterone concentration, T/LH ratio as well as the direct analysis of hCG were found to reliably contribute to an efficient detection of hCG abuse [13012].

Human chorionic gonadotrophin (hCG) is dimeric glycoprotein produced by placenta in pregnancy and also in low levels by pituitary gland. The main clinical use for exogenous hCG-administration is typically linked to infertility. The desired effect of hCG misuse in sport is due to the enhancement of testicular production of testosterone. Therefore, hCG is listed by the World Anti-Doping Agency (WADA) as a prohibited substance in male athletes and
according to the recently published WADA guideline urinary concentrations of hCG > 5 IU/L may be an indicator of doping. In this study two independent immunoassays were used to implement the new WADA guideline. The assay for initial testing (Siemens Immulite 2000 XPi hCG assay) recognizes various hCG variants (e.g. hCG and β-core fragment of hCG) whereas the confirmatory assay (PerkinElmer DELFIA Xpress hCG) is sensitive to intact and nicked hCG only. Both assays showed adequate sensitivity and were proven fit-for-purpose in routine doping control. Population-based distribution of the assays was in good agreement with results of earlier studies and supported well the current threshold of 5 IU/L [13393].

The performance of a method for MS determination of human chorionic gonadotropin (hCG) was compared with a reference method currently used in World Anti-Doping Agency accredited doping laboratories - the DELFIA® immunoassay. A strong correlation was demonstrated for the serum samples. However, for the urine samples, DELFIA reported significantly lower quantitative hCG measurements than the MS method. This was explained by the relatively unstable content of intact hCG-heterodimer in urine during storage compared with in serum. Discrepancies observed for the urine analyses might be related to the molecular dissociation of intact hCG-heterodimer into free subunits during storage, and the direct effect this has on the intact hCG measurements provided by DELFIA. The MS method quantified both intact hCG and free hCG β-subunit simultaneously, and was thus less susceptible to this problem. However, both methods detected illicit levels of serum hCG an equally long time after administration. The presented work advocated the implementation of this MS method as a confirmatory method for hCG determination in doping laboratories [13394].

Human chorionic gonadotropin (hCG) is dimeric glycoprotein produced by placenta in pregnancy and also in low levels by pituitary gland. The main clinical use for exogenous hCG-administration is typically linked to infertility. The desired effect of hCG misuse in sport is due to the enhancement of testicular production of testosterone. Therefore, hCG is listed by the World Anti-Doping Agency (WADA) as a prohibited substance in male athletes and according to the recently published WADA guideline urinary concentrations of hCG > 5 IU/L may be an indicator of doping. In this study two independent immunoassays were used to implement the new WADA guideline. The assay for initial testing (Siemens Immulite 2000 XPi hCG assay) recognizes various hCG variants (e.g. hCG and beta-core fragment of hCG) whereas the confirmatory assay (PerkinElmer DELFIA Xpress hCG) is sensitive to intact and nicked hCG only. Both assays showed adequate sensitivity and were proven fit-for-purpose in routine doping control. Population-based distribution of the assays was in good agreement with results of earlier studies and supported well the current threshold of 5 IU/L [13395].

Regulation of chorionic gonadotropin expression is less well understood in part because no obvious placental signal has been identified. Chorionic gonadotropins have been found in only two groups of mammals, primates and equids. When only human and horse chorionic gonadotropins were well characterized, chorionic gonadotropin expression was apparently exclusively placental in humans, as a separate pituitary LH existed, whereas in the horse, pituitary LH and placental CG were found to be comprised of identical polypeptides. In the human, the CGβ gene appeared to be derived from an ancestral LHβ gene, which was located on the same chromosome and in the same gene cluster. In the horse it was not known if a similar gene duplication was followed by loss of one gene, as donkeys and zebras also appear to possess only a LH/CGβ-like gene. Recent studies of new world monkey CG may provide an example of a path from separate LH and CG β-subunit genes to a single LH/CGβ gene. The common marmoset (Callithrix jacchus) was found to possess both LH and CGβ-subunit genes, however, only the CGβ gene was expressed in the pituitary. As the structural gene appeared normal, the absence of expression probably reflects changes in regulatory elements. Two other new world monkeys, the squirrel monkey (Saimiri
Sciureus) and the owl monkey (Aotus trivirgatus) were also reported to express only the CGbeta gene in the pituitary. The potential for pituitary expression of CGbeta exists even in humans, as the presence of pituitary-derived hCG was confirmed by its possession of pituitary-specific sulfated glycans [11476].

The objective of the study was to review the rationale underlying the banning of human chorionic gonadotropin (hCG) and estrogen blockers (antiestrogens, specific estrogen receptor modulators, aromatase inhibitors) in sports for male and female athletes in the light of gender differences in regulation of reproductive physiology. It was reviewed well-controlled clinical studies of exogenous testosterone effects on human muscle size and strength in men and all available evidence relevant to the effects of hCG and estrogen blockers on blood testosterone in men and women. Well-designed placebo-controlled clinical studies in men with suppressed pituitary-testicular axis establish a strong case that, across a wide range from sub- to supraphysiological doses, muscle growth and strength is proportional to exogenous testosterone dose and resulting blood testosterone concentrations. In men, there is unequivocal evidence that hCG and estrogen blockers cause consistent and sustained rise in blood testosterone concentrations. In women, although there has been no direct testing of ergogenic or myotrophic properties of exogenous testosterone in healthy women, either hCG or estrogen blockers do not produce any consistent or biologically significant increase blood testosterone concentrations. It was concluded that in men undergoing potential stimulation of endogenous blood testosterone concentrations, blood testosterone concentration is a reasonable surrogate measure for muscle growth and increased strength in men. Because hCG and estrogen blockers produce marked increase in blood testosterone concentration in men, this provides strong evidence to support the banning of hCG and estrogen blockers in men. In women, however, the negligible effect on blood testosterone suggests that drug-induced performance enhancement by hCG or estrogen blockers is highly unlikely. Furthermore, routine urinary hCG testing in young women risks invasion of privacy by detecting unrecognized pregnancy. These considerations suggest that prohibition of hCG and estrogen blockers should be restricted to men in which they are well justified [06127].

Although there is increasing concern about the possible abuse of erythropoietin, GH, and glucocorticoids, the major form of sports doping remains androgen abuse. Although androgen physiology differs fundamentally in men and women, at suitable doses exogenous androgens enhance muscle mass and strength in all athletes. As a result, since the early 1970s exogenous androgens have been banned for men and women in sports. This ban has been enforced by urine testing using mass spectrometry-based methods to detect illicit administration of natural and synthetic androgens. The notorious toleration of androgen abuse in U.S. baseball and football, undermining both the integrity of sport and its respectability as the pinnacle of healthfulness, exemplifies the likely fate of other sports if they failed to go beyond outmoded and laissez faire self-regulatory policing of drug cheating. In recent years, human chorionic gonadotropin (hCG) and estrogen blockers were added to the WADA Prohibited List for women as well as men. Whereas banning these agents appears well justified for men, there are doubts about the validity as well as adverse privacy implications for hCG testing when applied to female athletes. Similarly, the justification for prohibiting estrogen blockers in women is also dubious based on the absence of any plausible mechanism for potential estrogen-mediated ergogenic effects. One review focused on the reproductive endocrinology of these agents in men and women and the validity of their prohibition [06127].

The presence of proteolytic enzymes in urine samples, coming from exogenous or endogenous sources, enhances the cleavage of human chorionic gonadotropin (hCG). Moreover, elevated temperatures occurring occasionally during the delayed transportation of sport urine samples, favor the nicking of the hCG molecule. The aim of one study, funded by
the World Anti-Doping Agency (WADA), was the application of a stabilization mixture in athletes' urine samples to chemically inactivate proteolytic enzymes coming from exogenous or endogenous sources so as to prevent the degradation of hCG. The stabilization mixture applied, already tested for the stabilization of endogenous steroids and recombinant erythropoietin (rEPO), was a combination of antibiotics, antimycotic substances, and protease inhibitors. Incubation experiments were conducted in the presence or absence of the stabilization mixture in urine aliquots spiked with six proteases (first series of experiments) and one microorganism associated with urinary tract infections (UTI) (second series of experiments). Intact hCG levels were evaluated by using the EIAgene Total hCG kit. In the first series of experiments, hCG levels were reduced in the untreated aliquots following incubation at 37 degrees C. The addition of the chemical stabilization mixture prevented degradation of hCG induced by four of the proteases applied. In the second series of experiments, no significant difference was found in urine inoculated with E. coli, between aliquots treated with chemical mixture and the untreated aliquots. The addition of the proposed chemical stabilization mixture improves the quality of athletes' urine samples against possible deterioration due to high temperatures or attempts of proteolytic manipulation [10367].

The presence of proteolytic enzymes in urine samples, coming from exogenous or endogenous sources, enhances the cleavage of human chorionic gonadotropin (hCG). Moreover, elevated temperatures occurring occasionally during the delayed transportation of sport urine samples, favor the nicking of the hCG molecule. The aim of one study, funded by the World Anti-Doping Agency (WADA), was the application of a stabilization mixture in athletes' urine samples to chemically inactivate proteolytic enzymes coming from exogenous or endogenous sources so as to prevent the degradation of hCG. The addition of the proposed chemical stabilization mixture improves the quality of athletes' urine samples against possible deterioration due to high temperatures or attempts of proteolytic manipulation [10367].

Human chorionic gonadotropin (hCG) is a 37-kDa glycoprotein predominantly produced by the placenta during pregnancy, and its use has been prohibited for male athletes since 1987. Its ability to induce the secretion of endogenously produced testosterone from testes has necessitated its detection in doping controls, which have primarily been accomplished using immunological methods. A new approach was presented, based on immunoaffinity purification followed by trypsin digestion and subsequent LC-MS/MS analysis of marker peptide beta-T5. Thus, qualitative and quantitative evidence for hCG was obtained, allowing detection limits of 5 mIU/mL of urine to be obtained. This approach provided the discriminative power required, which common immunological test methods lack due to possible cross-reactivity [07050].

The principal objective of one study was to compare the analytical performance of the Elecsys2010 (Roche Diagnostics) system with the IMx (Abbott laboratories) system for beta-
hCG assay in order to assess its possible utility as a confirmation test for the quantitative measurement of beta-hCG in urine for doping control purposes. Urine samples with spiked standard known concentrations of beta-hCG and different urine samples from athletes were used in order to determine the calibration curve stability and linearity, detection limit, total, within-run and between-run precision, and method comparison for the IMx and Elecsys2010 systems for beta-hCG assay, along with the stability of samples, at room temperature and at 4 degrees C. The IMx assay was linear up to 500 IU/L, whereas the Elecsys2010 assay was linear up to 1000 IU/L. The detection limit for the IMx and Elecsys2010 systems were 0.75 IU/L and 0.25 IU/L, respectively. The total precision of the IMx and Elecsys2010 systems were \( \leq 5 \) percent for beta-hCG concentrations ranging from 20 to 900 IU/L and from 7 to 55 IU/L, respectively. The within-run precision tests for the IMx and Elecsys2010 systems yielded CV results of 2-3 percent and 3-4 percent respectively, while the between-run precision for the Elecsys2010 was less than 4 percent, whereas that of IMx was 9-16 percent. Sample stability studies evidenced a nonsignificant effect at 4 degrees C and room temperature (25 degrees C) for up to 1 month. It was concluded that for doping control, the IMx and Elecsys2010 may be used to screen and confirm the presence of beta-hCG in urine of athletes, respectively. Additional studies are needed to verify this finding. This study also underscores the need for beta-hCG assays standardization for doping control [07159].

Several factors influencing the carbon isotope ratios (CIR) of endogenous urinary steroids have been identified in recent years. One of these should be the metabolism of steroids inside the body involving numerous different enzymes. A detailed look at this metabolism taking into account differences found between steroids excreted as glucuronides or as sulphates and hydrogen isotope ratios of different steroids pointed out possibility of unequal CIR at the main production sites inside the male body – the testes and the adrenal glands. By administration of beta-HCG it is possible to strongly stimulate the steroid production within the testes without influencing the production at the adrenal glands. Therefore, this treatment should result in changed CIR of urinary androgens in contrast to the undisturbed pre-treatment values. Four male volunteers received three injections of beta-HCG over a time course of 5 days and collected their urine samples at defined intervals after the last administration. Those samples showing the largest response in contrast to the pre-administration urines were identified by steroid profile measurements and subsequent analysed by GC/C/IRMS. CIR of androsterone, etiocholanolone, testosterone, 5alpha- and 5beta-androstanediol and pregnanediol were compared. While pregnanediol was not influenced, most of the investigated androgens showed depleted values after treatment. The majority of differences were found to be statistically significant and nearly all showed the expected trend towards more depleted delta\(^{13}\)C-values. These results support the hypothesis of different CIR at different production sites inside the human body. The impact of these findings on doping control analysis will be discussed [12202].

Human chorionic gonadotrophin (hCG) is measured on a routine basis in all doping control urine samples collected from male athletes, most commonly by means of immunological methods. Stability issues have been observed particularly with hCG in the past. In the course of establishing a generic urine sample preservation protocol, the impact of chemical protease inhibitors on the stability of hCG in doping control urine samples at different storage temperatures was tested. Degradation of hCG was reduced by four of the tested proteases and temperature rather than bacterial contamination was found to be a relevant aspect in degradation tests [12016].

The applicability of a mass spectrometry (MS)-based method for determination of various forms of human chorionic gonadotropin (hCG) in doping analysis was demonstrated. A clinical study involving the hCG-containing pharmaceuticals Pregnyl and Ovitrelle was carried out, comprising a single injection of one pharmaceutical per participant to a total of 24
healthy male voluntaries. Hereafter, serum and urine samples were collected over a period of 14 days. The analysis of the samples using immuno-MS demonstrated elimination profiles of intact hCG for both pharmaceuticals, with last day of detection following administration at day 7 in serum, and at day 10 in urine, at limit of detections as defined by the World Anti-Doping Agency. Furthermore, the method allowed detection and differentiation of the various forms of hCG known to be present in serum and urine as a function of metabolism. For both pharmaceuticals, only the intact hCG was detected in serum, whereas in urine the injection of Pregnyl as hCG source (containing urinary hCG, i.e., most hCG variants) was shown to generate a more complex hCG variant pattern compared to Ovitrerelle (contains only intact hCG). By detecting hCG using this MS-based approach in doping analysis, strong analytical evidence is provided minimizing the risk of false-positive and false-negative results [12203].

Physiology
hCG is a dimeric glycoprotein consisting of an alpha- and beta-subunit normally produced by the human placenta. The alpha-subunit is the product of a single copy gene identical with the alpha-subunit of the other three pituitary glycoprotein hormones LH, FSH, and TSH. The β-beta-subunit of hCG is derived from a multicopy gene arising by duplication of the homologous single copy LH beta-subunit gene. Crucially, hCG beta-subunit includes a read-through C-terminal extension of 29 amino acids, containing four O-linked sialic acid capped glycosylation sites that markedly prolong the circulating half-life and biopotency of hCG, making it a naturally occurring long-acting analog of LH. Endogenous hCG is produced by the normal placenta in pregnancy or placental trophoblastic (hydatidiform mole, choriocarcinoma), gonadal (ovarian, testicular or extragonadal teratoma), or ectopic and nontrophoblastic tumors. In clinical practice, the identification of hCG immunoreactivity in blood or urine is used for early pregnancy diagnosis as well as a tumor marker. Biologically active heterodimeric hCG is manufactured pharmaceutically as a biological product either purified from human pregnancy urine or as a recombinant glycoprotein purified from genetically engineered mammalian cells [06127].

Effects in men
For men, the prohibition on hCG and estrogen blockers is unequivocally justified. Both produce sustained and significant increases in endogenous testosterone production and blood testosterone concentrations. Whereas there are no direct studies of the ergogenic effects of hCG or of estrogen blockers, the case for prohibition is well established using blood testosterone concentrations as a reliable surrogate variable for increases in muscle mass and strength. One study of 40 healthy older men (>60 yr of age) showed increased lean (muscle) mass but no increase in shoulder or knee strength measured by dynamometry during 3 months treatment with recombinant hCG, compared with placebo. It is likely, however, that the modest, replacement dosage and older age of the participants may underestimate the ergogenic potential of hCG for elite male athlete who would seek to abuse this drug [06127].

Clinically, hCG is used as a naturally occurring long-acting and potent LH analog. The only legitimate clinical indication for hCG is to restore endogenous testosterone production and normalize blood testosterone concentrations in gonadotrophin-deficient men including delayed male puberty. There are virtually no proven off-label uses for hCG in routine clinical endocrinology practice. Among androgen abusers, however, hCG is apparently misused by male athletes in two settings according to the underground androgen abuse folklore. In one scenario men who have developed sustained inhibition of their hypothalamo-pituitary testicular axis from prolonged high-dose androgen abuse seek to rectify this by increasing testicular testosterone production using hCG. In reality, this continues hypothalamic-pituitary suppression, which causes the reduced testis size and testosterone production and defers the problem of hypothalamo-pituitary recovery, which is usually slow but complete, so that
hCG treatment, although feasible is rarely justified clinically. The other setting is that of androgen abusers seeking to avoid detection of synthetic androgens or exogenous testosterone by stimulating endogenous testosterone production. Preliminary information suggests that the testosterone-to-epitestosterone (T/E) ratio is unaffected by hCG treatment consistent with its stimulation of endogenous testosterone production by Leydig cells, producing a characteristic testosterone to estrogen ratio for that individual, which is no different from natural endogenous testosterone production [06127].

In normal men, hCG produces a sustained and dose-dependent increase in blood testosterone concentrations through stimulation of Leydig cell testosterone secretion. This is well established for purified urinary and recombinant hCG. Typically, the basal blood testosterone concentrations (about 20 nmol/liter) are increased to concentrations of 30-40 nmol/L, peaking between 2 and 4 d after a single injection at typical clinical doses. Both the peak blood testosterone responses and the time of peak are log-dose dependent for purified urinary and recombinant hCG. These markedly increased blood testosterone concentrations, with increments of 10-30 nmol/L, are within the range defined experimentally as having a log-linear relationship with increased muscle mass and strength in men. They are therefore highly likely to increase muscle mass and strength. Hence, prohibition of hCG for men is well justified. An unintended consequence of testing for male athletes urine for hCG is the incidental diagnosis of hCG-secreting germ cell tumors. Whereas minute amounts of hCG are detectable in highly concentrated urine from healthy young men, readily detectable quantities usually signify the diagnosis of a germ cell tumor of testicular or, rarely, of extratesticular origin or an ectopic hCG-secreting tumor. Such incidental diagnoses are made through sports doping tests [06127].

Effects in women
The prohibition of hCG in women is not clearly justified in terms of performance enhancement or athlete safety. In addition, routine urine hCG measurement results in significant invasion of female athlete privacy as a result of the unintended screening for pregnancy. The available evidence suggests that hCG has negligible, if any, stimulation of blood testosterone concentrations in healthy young women. Together with the prevailing low blood testosterone levels in women, this makes it highly unlikely that any myotrophic or ergogenic effects are produced by administration of hCG to women [06127].

A major consideration setting the framework for considering the effects of hCG in women is the relatively high population prevalence of women with PCOS and its variants. These conditions span a wide spectrum of ovarian disorders all featuring mild increased blood testosterone concentrations in the female range, although still an order of magnitude lower than in men. Key features of PCOS are multiple ovarian cysts associated with ovulatory and menstrual dysfunction, hyperandrogenism (acne, hirsutism), and insulin resistance (obesity, metabolic syndrome). Definitions of the disorder vary from higher prevalence rates using a European definition with a focus on ultrasound criteria, compared with the American definition, which focus on clinical criteria requiring ovarian dysfunction and hyperandrogenism. Because asymptomatic polycystic ovaries are a relatively common finding among unselected women with pooled prevalence estimates approximately 20 percent, population estimates depend heavily on the criteria used. Using the narrower American definition for PCOS, the population prevalence has been estimated at 4 percent, whereas the broader European definition identifies 8-10 percent of unselected women as having PCOS. An even larger proportion of women have isolated features such as acne, hirsutism, and obesity insufficient to make the formal diagnosis of PCOS. Mild increase in blood testosterone concentration is a very common, near universal feature of women with PCOS and, to a lesser extent, women with incomplete forms of PCOS. Hence, blood testosterone concentrations of up to 3-4 nmol/L in untreated women with severe PCOS are
typical, compared with women with normal ovarian function (upper limit is 2–2.5 nmol/L). It is tacitly accepted that women with even severe PCOS are not barred from sports. Indeed, it is common experience that they appear to be overrepresented in power sports. This indicates that mild hyperandrogenism is already an accepted feature in female sports and thereby sets an existing upper limit for what is considered acceptable. This yardstick has relevance to considering the acceptability of the minimal, if any, increases in blood testosterone produced by hCG in women [06127].

The best available evidence indicates that administration of 250 microg recombinant hCG to healthy young women produces a rise of approximately 0.25 nmol/liter in blood testosterone concentrations. This increase is less than (about half) the diurnal rhythm in blood testosterone concentrations in women. Based on the findings increases of such small magnitude are highly unlikely to have any measurable effect on muscle mass or strength. Corroborative findings are available showing minimal or no increase in blood testosterone concentrations in women treated with urinary-purified hCG at chronic low dose or conventional high dose. Administration of urinary hCG (5,000 to 10,000 IU, about 330-660 microg) to young women with normal ovarian function produced either no or minimal (about 1 nmol/L) increase in blood testosterone concentrations. The minority of women with PCOS with higher baseline blood testosterone concentrations have slightly higher increases (2-3 nmol/L), but these remain of small magnitude in quantitative terms for myotrophic effects. An important caveat on blood testosterone measurements in some of these studies is the unreliability of conventional commercial immunoassays for blood testosterone, compared with well validated in-house immunoassays. In the low range of blood testosterone concentrations, such as in samples from women, children, or castrate men, the validity of commercial testosterone immunoassays has been described as comparable with random number generation. Because most studies of hCG effects in women have used unreliable testosterone assays, their findings remain questionable and will require further critical evaluation using mass spectrometry based methods. Beyond evaluating blood testosterone concentrations, measurements of muscle mass in women with PCOS suggest blood testosterone concentrations may be significantly correlated with their muscle mass; however, the significance of these correlations at such low blood testosterone concentrations remains speculative as far as performance capabilities go. As usual, the directionality of such correlations cannot be reliably determined from observational data [06127].

Effects of trauma to the brain
Traumatic brain injury (TBI) is a common cause of death and disability in young adults with consequences ranging from physical disabilities to long-term cognitive, behavioral, psychological and social defects. Recent data suggest that pituitary hormone deficiency is not infrequent among TBI survivors; the prevalence of reported hypopituitarism following TBI varies widely among published studies. The most common cause of TBI is motor vehicle accidents, including pedestrian-car and bicycle car encounters, falls, child abuse, violence and sports injuries. Prevalence of hypopituitarism, from total to isolated pituitary deficiency, ranges from 5 to 90 %. The time interval between TBI and pituitary function evaluation is one of the major factors responsible for variations in the prevalence of hypopituitarism reported. Endocrine dysfunction after TBI in children and adolescents is common. Adolescence is a time of growth, freedom and adjustment, consequently TBI is also common in this group. Sports-related TBI is an important public health concern, but many cases are unrecognized and unreported. Sports that are associated with an increased risk of TBI include those involving contact and/or collisions such as boxing, football, soccer, ice hockey, rugby, and the martial arts, as well as high velocity sports such as cycling, motor racing, equestrian sports, skiing and roller skating. The aim of this paper is to summarize the best evidence of TBI as a cause of pituitary deficiency in children and adults [13397].
Laboratory techniques

The applicability of a mass spectrometry (MS)-based method for determination of various forms of human chorionic gonadotropin (hCG) in doping analysis was demonstrated. A clinical study involving the hCG-containing pharmaceuticals Pregnyl and Ovitrelle was carried out, comprising a single injection of one pharmaceutical per participant to a total of 24 healthy male voluntaries. Hereafter, serum and urine samples were collected over a period of 14 days. The analysis of the samples using immuno-MS demonstrated elimination profiles of intact hCG for both pharmaceuticals, with last day of detection following administration at day 7 in serum, and at day 10 in urine, at limit of detections as defined by the World Anti-Doping Agency. Furthermore, the method allowed detection and differentiation of the various forms of hCG known to be present in serum and urine as a function of metabolism. For both pharmaceuticals, only the intact hCG was detected in serum, whereas in urine the injection of Pregnyl as hCG source (containing urinary hCG, i.e. most hCG variants) was shown to generate a more complex hCG variant pattern compared to Ovitrelle (contains only intact hCG). By detecting hCG using this MS-based approach in doping analysis, strong analytical evidence is provided minimizing the risk of false-positive and false-negative results [12204].

Immuno-massspectrometry. The applicability of a mass spectrometry (MS)-based method for determination of various forms of human chorionic gonadotropin (hCG) in doping analysis was demonstrated. A clinical study involving the hCG-containing pharmaceuticals Pregnyl and Ovitrelle was carried out, comprising a single injection of one pharmaceutical per participant to a total of 24 healthy male voluntaries. Hereafter, serum and urine samples were collected over a period of 14 days. The analysis of the samples using immuno-MS demonstrated elimination profiles of intact hCG for both pharmaceuticals, with last day of detection following administration at day 7 in serum, and at day 10 in urine, at limit of detections as defined by the World Anti-Doping Agency. Furthermore, the method allowed detection and differentiation of the various forms of hCG known to be present in serum and urine as a function of metabolism. For both pharmaceuticals, only the intact hCG was detected in serum, whereas in urine the injection of Pregnyl as hCG source (containing urinary hCG, i.e., most hCG variants) was shown to generate a more complex hCG variant pattern compared to Ovitrelle (contains only intact hCG). By detecting hCG using this MS-based approach in doping analysis, strong analytical evidence is provided minimizing the risk of false-positive and false-negative results [13396].

Chorionic gonadotrophin (CG) and luteinizing hormone (LH)

Human chorionic gonadotrophin (hCG) as well as LH are prohibited in sports (for males only) due to their ability to stimulate testosterone production and release. Both substances are commonly analyzed by ELISA, which was recently shown to be critical particularly concerning hCG if urine samples collected for doping controls are stored at -20 °C. In a complementary and indirect manner, the option to determine hCG abuse in sport by steroid profiling as well as LH measurements in blood and urine was evaluated. While commonly used urinary steroid profiles as such did not exhibit the required sensitivity to detect hCG abuse, accurate quantification of the testosterone concentration, T/LH ratio as well as the direct analysis of hCG were found to reliably contribute to an efficient detection of hCG abuse [12017].

Clomiphene

Many AAS users take additional drugs or supplements to counteract the adverse effects of AASs. Among 500 users of AASs, more than 50 percent reported taking clomiphene, antiaromatases (e.g. anastrozole), or the antiestrogen tamoxifen; 40 percent admitted to
using human chorionic gonadotropin. Human chorionic gonadotropin and clomiphene are taken at the end of or after an AAS cycle to reduce hypogonadotropic hypogonadism and reverse testicular atrophy and infertility. Some studies have shown maintenance of spermatogenesis with the concurrent use of human chorionic gonadotropin, but there are still significantly more abnormal and hypokinetic spermatozoa. The maintenance of spermatogenesis by human chorionic gonadotropin occurs without an increase in FSH. The low FSH concentration explains why sperm quality remains abnormal. The effect on offspring is unknown. The side effects of human chorionic gonadotropin include hyperglycemia, insulin resistance, decreased thyroid function, adrenal insufficiency, carpal tunnel syndrome, arthralgia, myopathy, pancreatitis, hepatotoxicity, and an increased risk for certain malignancies. Clomiphene stimulates the release of gonadotropins and is used in women with infertility; however, clomiphene may not increase serum gonadotropins when taken by power athletes during an AAS cycle. Antiaromatase or antiestrogen drugs, such as anastrozole and tamoxifen, are taken to counteract the effects of aromatization of the AAS to estrogens (e.g. gynecomastia). There is no data to support their effectiveness, and they also have side effects.

Clomiphene is a selective estrogen receptor modulator (SERM) that increases production of gonadotropins by inhibiting negative feedback on the hypothalamus. Clomifene inhibits estrogen receptors in hypothalamus, inhibiting negative feedback of estrogen on gonadotropin release, leading to up-regulation of the hypothalamic–pituitary–adrenal axis. Clomiphene is prohibited by World Anti Doping Agency (WADA) out-of-competition and in-competition. As it is extensively metabolized, further investigation of clomiphene metabolic profile will be essential to routine anti-doping analysis. The metabolic pathway and the different metabolites of clomiphene in human urine collected from three healthy volunteers during 1 week were studied by liquid chromatography-quadrupole time-of-flight mass spectrometry (LC-QTOFMS) based on accurate mass measurement. Seven unreported metabolites were identified and characterized, and all of the newly found urinary metabolites belonged to a new metabolic pathway (hydrogenation). An approach for the metabolism study of clomiphene and its analogs by LC-QTOFMS was presented. Two metabolites, 3,4-dihydroxy-dihydro-clomiphene (m/z 440.1991) and 3,4-dihydroxy-dihydro-deethyl-clomiphene (m/z 412.1674), are the potential biomarkers for monitoring oral administration of clomiphene in doping control.

Clomiphene, a representative of “other anti-estrogenic substances” (S4.3), was also studied concerning its metabolism in humans. As a major difference to earlier studies, the renal elimination of dihydrogenated and subsequently hydroxylated and/or methoxylated compounds was suggested, based on LC-MS/MS data with high resolution/high accuracy mass spectrometry. Since also here the evidence by derivatization, H/D-exchange, or chemical synthesis is missing, the postulated structures can only be considered as tentative and serve for screening rather than confirmatory purposes.

**Release of GnRH**

The canonical regulator of gonadotropin secretion is the hypothalamic decapeptide, GnRH, which can induce stimulus-secretion coupling as well as gene expression. However, it is clear now that many paths coalesce to achieve the complexity and disparate regulation of LH and FSH expression, a necessary first step to production and secretion. GnRH mediated gonadotropin secretion can be enhanced by the transcription factor Isl-1, which is elevated in response to GnRH as well as by activin and leptin stimulation, although the responses to activin and leptin were higher and more prolonged than that induced by GnRH. However, subsequent experiments indicated Isl-1 mainly is responsible for leptin-mediated FSHbeta.
and LHβ production, not GnRH- or activin-mediated secretion, as knocking down Isl-1 expression had no significant effect on gonadotropin regulation by either GnRH or activin. The secretion of LH appears to be induced, whereas the secretion of FSH is constitutive, as will be discussed below. The release of GnRH from hypothalamic neurons is pulsatile. Given the effect of GnRH as a releasing hormone, one might expect that all secretagogues including GnRH would engender gene expression that would co-vary with pulse. Although a mechanism for differential gonadotropin gene expression, which can posit transcriptional factor dampening of transcription is compelling, it also suggests that adenylate cyclase is not the only downstream effector of GnRH. In this regard, it has been shown quite elegantly that the prostaglandin biosynthetic pathway, and in particular PGF2α and PGI, can regulate not only LHβ and FSHβ gene transcription, but also the levels of GnRH receptor. Since 1976 evidence has been provided, which showed the presence of the α subunit protein in non-pituitary and non-placental tissues. It is reasonable to suggest that the expression of the α subunit is not cell type dependent and the promoter likely embodies cyclic AMP response element (CRE) binding sites for CRE binding protein transcription factors. In addition, the control of this promoter can also be anticipated to respond to transcription factors that are regulated by intracellular levels of calcium. Of course, every reproductive physiologist knows that castration gives rise to elevated gonadotropins in blood. Indeed, as ovarian function wanes in mid-life, and gonadal steroid production is decreased, FSH rises. Therefore, the long loop feedback of gonadal steroids on gonadotropin production was a harbinger of the potential for regulation of gonadotropin gene expression by gonadal steroids. It is also important to mention the hypothalamic factor, Gonadotropin Inhibitory Hormone (GnIH or RFRP-1,-2,-3 peptides), which inhibits release of gonadotropins mediated by GnRH. During the 1970s a search for non-steroidal factors that regulate gonadotropin release led to the identification of inhibin, which suppresses FSH secretion, and then serendipitously activin, which increases FSH secretion. Both inhibin and activin are members of the TGFβ superfamily which appear to preferentially control the secretion of FSH. Activin acts as an autocrine/paracrine factor in the anterior pituitary, and stimulates FSHβ gene transcription, whereas inhibin, acting as an ovarian hormone, is inhibitory [11476].

**Luteinizing hormone**

Urine luteinizing hormone (LH) concentration is routinely measured in all anti-doping laboratories to exclude recombinant LH abuse and to test any potential alteration of the hypophyseal-gonadal axis. Before establishing proper reference values among professional top level athletes, an extended validation of two commercial immunoassays for LH measurements was performed. Elecsys 1010 and Access are two automated immunoanalyzers for central laboratories. The limits of detection, the limits of quantification, intra-laboratory, inter-technique correlation, precision, accuracy were determined. Furthermore, reference urinary LH distribution values for male and female top level athletes were determined. Stability studies of LH in urine following freezing and thawing cycles (n=3) as well as storage conditions at room temperature, 4 degrees C and -20 degrees C were performed. Male and female subjects showed important urinary corrected (specific gravity correction) LH distribution differences. Intra-assay precision for the Access analyzer was less than 8.0 percent whereas inter-assay was close to 11 percent. Intra and inter-assay precision for the Elecsys 1010 analyzer was slightly better. No urinary LH loss was observed after two freezing and thawing cycles. On the other hand, time and bad storage conditions such as elevated temperature can deteriorate rapidly urinary LH. In conclusion, both analyzers showed acceptable performances and are suitable for screening anti-doping analyses. Each anti-doping laboratory has to settle its own reference distribution values and then determine when to launch a confirmation procedure. This takes place then depending on the positivity criteria the anti-doping laboratory has established and validated. This study also clearly showed that the time delay between the urine collection and the analysis should be reduced.
as much as possible and urine samples should be transported in optimal conditions (low
temperature and quickly) to decrease urinary LH deterioration [07160].

Urine provides a convenient non-invasive alternative to blood sampling for measurement of
certain hormones. Urinary luteinizing hormone (LH) measurements have been used for
endocrinology research and anti-doping testing. However, the commercially available LH
immunoassays are developed and validated for human blood samples but not urine so that
LH assays intended for use with urine samples need thorough validation. Therefore, the
present study evaluated the measurement of urinary LH immunoreactivity using previously
validated immunofluorometric (IF) and immunochemiluminometric (ICL) LH assays after
prolonged frozen storage. LH was measured in serial urine samples following administration
of a single injection of one of two doses of recombinant human chorionic hormone (rhCG)
with assays run at the end of study (2008) and again after four years of frozen (-20 °C)
storage where samples were stored without adding preservatives. The ICL assay showed
quantitatively reproducible LH measurements after prolonged -20 °C storage. However, the
IF immunoassay gave consistently lower LH levels relative to ICL (2008) with a further
proportionate reduction after four years of sample storage (2012). Yet, both the assays
displayed similar patterns of the time-course of urine LH measurement both before and after
four years of frozen storage. In conclusion, we found that both immunoassays are suitable
for urinary LH measurements with ICL assay being more robust for quantitative urinary LH
measurement such as for anti-doping purposes, whereas the IF could be applicable for
research studies where urine LH levels are compared within-study but not in absolute terms
[13398].

In boxing
Luteinizing hormone (LH) is physiologically produced by the anterior pituitary gland. Male
athletes may use pharmaceutical LH for doping since it increases the production of
testosterone by testes. The World Anti-Doping Agency (WADA) has put luteinizing hormone
(LH) on its list of prohibited substances for male athletes. Indeed, this gonadotropin, which is
one of the numerous hormones produced by the anterior pituitary gland, stimulates the
conversion of cholesterol to testosterone in the Leydig cells of testes. Pharmaceutical LH is
obtained either by extraction from the urine of postmenopausal women or by genetic
engineering to produce recombinant LH. No method is currently able to differentiate between
endogenous and pharmaceutical LH. Anti-doping control is based on the assay of this
gonadotropin in urine in order to detect abnormally elevated levels. This approach requires a
reliable threshold value for the limit of physiological levels. Since there is no consensus
value, each anti-doping laboratory has to estimate a reference interval (normal range) that
depends on the assay method. In the course of conducting this analysis, one laboratory
observed disturbing results related to boxing. It was observed a highly significant prevalence
of abnormal results in samples taken after a boxing match. Comparison of the descriptive
statistics for 426 LH values observed in boxing and other sports showed significant
differences. An experimental study comparing urinary LH levels in 17 boxers before and after
a match demonstrated a clear increase after the match. The same observation was made for
urinary follicle stimulating hormone (FSH) in all of the eight boxers tested for this other
pituitary gonadotropin. These observations have consequences for anti-doping controls, as
the reference range for urinary LH levels must take into account the specificities of boxers.
They also suggest consequences for the health of boxers. Although to our knowledge such
observations have never been described, other pituitary disorders have been reported. Our
results deserve further investigation from a medical point of view [13399].

Laboratory techniques
Urine luteinizing hormone (LH) concentration is routinely measured in all anti-doping
laboratories to exclude recombinant LH abuse and to test any potential alteration of the
hypophyseal-gonadal axis. Before establishing proper reference values among professional top level athletes, an extended validation of two commercial immunoassays for LH measurements was performed. Elecsys 1010 and Access are two automated immunoanalyzers for central laboratories. The limit of detection, the limit of quantification, intra-laboratory, inter-technique correlation, precision, accuracy were determined. Furthermore, reference urinary LH distribution values for male and female top level athletes were determined. Intra-assay precision for the Access analyzer was less than 8.0% whereas inter-assay was close to 11%. Intra and inter-assay precision for the Elecsys 1010 analyzer was slightly better. A good inter-technique correlation was obtained. No urinary LH loss was observed after two freezing and thawing cycles. On the other hand, time and bad storage conditions such as elevated temperature can deteriorate rapidly urinary LH. In conclusion, both analyzers showed acceptable performances and are suitable for screening anti-doping analyses. Each anti-doping laboratory has to settle its own reference distribution values and then determine when to launch a confirmation procedure. This takes place then depending on the positivity criteria the anti-doping laboratory has established and validated. The study also clearly showed that the time delay between the urine collection and the analysis should be reduced as much as possible and urine samples should be transported in optimal conditions (low temperature and quickly) to decrease urinary LH deterioration [06142].

Conceptually, a mechanism to maintain normal testosterone concentrations could be an enhanced pulsatile release of LH. Decreased testosterone concentrations relieve the inhibition of the negative feedback loop at the hypothalamus/pituitary gland, resulting in an enhanced release of gonadotropin-releasing hormone and subsequently enhancing LH secretory dynamics. For example, compared with younger men, older men tend to possess greater LH secretion, which is hypothesized to represent a biological attempt to maintain normal testosterone concentrations. Endurance-trained athletes have also shown decreased testosterone and increased LH concentrations. The literature with regard to acute exercise stress has been equivocal. It has also been reported decreased concentrations of testosterone and increased LH concentrations for up to 2 days after a marathon and suggested that elevated catecholamines may be partially responsible for the decreased testicular sensitivity. LH pulsatility within hours in a number of different species. Thus, although LH pulsatility is slowly restored in women, there is evidence to suggest that gonadotropin-releasing hormone neurons may rapidly respond to caloric intake [06141].

Natural agonists

The gonadotropins, luteinizing hormone, human chorionic gonadotropin and follicle-stimulating hormone, are key regulators of reproduction. As a result of this function, they have been the focus of research for many years. Isolated or recombinant proteins have been successfully used therapeutically for the treatment of infertility; and, in the case of compounds that block gonadotropin activity, for their potential utility in contraception. Until recently, selective small molecules modulating gonadotropin receptor activity have proven difficult to identify. The gonadotropins are glycoproteins that are released into the plasma as differently glycosylated isoforms and bind to specific G protein-coupled receptors. The degree of glycosylation on the gonadotropins has been shown to be important for the biological activities of these hormones and is differentially regulated depending on the steroidal status. Recent data from the study of glycosylated variants of LH, hCG and FSH have revealed that these isoforms have distinct signaling properties that allow for gonadotropin pleiotropic signals to be transduced effectively at the level of the receptor.
Thus, glycosylated variants of the gonadotropins behave as biased agonists. Recently, newly developed, small molecule, synthetic allosteric compounds have been identified that are capable of mimicking this biased signaling. This opens the door to development of orally available, drug-like therapies for reproductive disorders that offer similar pleiotropic richness as that offered by the complex, endogenous hormones [11477].

**Secretagogues: gonadotrophin-releasing hormone**

GHRP-2 (pralmorelin, D-Ala-D-(beta-naphthyl)-Ala-Ala-Trp-D-Phe-Lys-NH(2)), which belongs to a class of growth hormone secretagogue (GHS), is intravenously used to diagnose growth hormone (GH) deficiency. Because it may be misused in expectation of a growth-promoting effect by athletes, the illicit use of GHS by athletes has been prohibited by the World Anti-Doping Agency (WADA). Therefore, the mass spectrometric identification of urinary GHRP-2 and its metabolite D-Ala-D-(beta-naphthyl)-Ala-Ala-OH (AA-3) was studied using liquid chromatography/electrospray ionization tandem mass spectrometry for doping control purposes. The method consists of solid-phase extraction using stable-isotope-labeled GHRP-2 as an internal standard and subsequent ultra-performance liquid chromatography/tandem mass spectrometry, and the two target peptides were determined at urinary concentrations of 0.5-10 ng/mL. The recoveries ranged from 84 to 101%, and the assay precisions were calculated as 1.6-3.8 percent (intra-day) and 1.9-4.3 percent (inter-day). Intravenous administration of GHRP-2 in ten male volunteers was studied to demonstrate the applicability of the method. In all ten cases, unchanged GHRP-2 and its specific metabolite AA-3 were detected in urine [10363].

The decapeptide gonadotrophin-releasing hormone (GnRH) is endogenously produced in the hypothalamus and secreted into the microcirculation between hypothalamus and pituitary gland. Here, the bioactive hormone is responsible for the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) into the systemic circulation. Because an intermittent application of exogenous GnRH in young males increases the testosterone plasma level by stimulation of the Leydig cells, the potential misuse of the administered substance offers a reasonable relevancy for doping controls and is prohibited in accordance to the list of banned substances of the World Anti-Doping Agency. One presented method provides a mass spectrometric approach to determine the nondegraded hormone in regular doping control samples by utilizing a sample preparation procedure with solid phase extraction, immunoaffinity purification and a subsequent separation by liquid chromatography with ESI-MS/MS detection. For liquid chromatography/mass spectrometry two alternative instrumental equipments were tested. In urine specimens provided from healthy volunteers GnRH was not detected in accordance to the recent literature, but in postadministration samples urinary concentrations between 20 to 100 pg/ml of the intact peptide were determined. The method offered good validation results considering the parameter specificity, linearity (5-300 pg/ml), limit of detection (LOD, approx. 5 pg/ml), precision (inter/intraday, < 20 %) and accuracy (105 %) using Des-pGlu(1)-GnRH as internal standard to control each sample preparation step [08248].

**Myostatin**

A decade has passed since myostatin was first identified as a negative regulator of muscle growth. Since then, studies in both humans and animals have demonstrated that decreasing the levels of this growth factor or inhibiting its function can dramatically increase muscle size, and a number of therapeutic applications of myostatin inhibition to the treatment of
myopathies and muscle atrophy have been proposed. As such treatments would be likely to also stimulate muscle growth in healthy individuals, there is a growing concern among anti-doping authorities that myostatin inhibitors may be among the next generation of ergogenic pharmaceuticals or even in the vanguard of “gene doping” technology. While the ability to stimulate muscle growth through myostatin inhibition is well documented, a growing body of evidence suggests such increases may not translate into an improvement in athletic performance [08289].

Myostatin is a member of the transforming growth factor-beta/bone morphogenetic protein (TGF-beta/BMP) superfamily of secreted factors that functions as a potent inhibitor of skeletal muscle growth. Moreover, considerable evidence has accumulated that myostatin also regulates metabolism and that its inhibition can significantly attenuate the progression of obesity and diabetes. Although at least part of these effects on metabolism can be attributable to myostatin’s influence over skeletal muscle growth and therefore on the total volume of metabolically active lean body mass, there is mounting evidence that myostatin affects the growth and metabolic state of other tissues, including the adipose and the liver. In addition, recent work has explored the role of myostatin in substrate mobilization, uptake, and/or utilization of muscle independent of its effects on body composition. Finally, the effects of both endurance and resistance exercise on myostatin expression, as well as the potential role of myostatin in the beneficial metabolic adaptations occurring in response to exercise, have also begun to be delineated in greater detail. The purpose of this review was to summarize the work to date on the expression and function of myostatin in obesity, diabetes, and exercise adaptation [11478].

Myostatin is a potent negative regulator of skeletal muscle mass, but its role in human skeletal muscle hypertrophy and atrophy is sparsely described. Muscle biopsies were obtained from young male subjects before and after 30 and 90 days of resistance training as well as after 3, 10, 30, 60 and 90 days of subsequent detraining. Myostatin mRNA increased significantly with detraining. It was observed a 28 kDa myostatin immunoreactive protein, which, however, was also present in myostatin knock out mice skeletal muscle. As a novel finding it was consistently detected a 10 kDa band, which may represent a mature myostatin monomer under reducing conditions or a novel, unknown myostatin form. Further, it was observed a significant increase in this 10 kDa band after 3 days of detraining preceding the rapid type II fiber atrophy, in which almost half of the acquired fiber area was lost after only 10 days of detraining. Accordingly, an increase in the level of the 10 kDa protein is associated with rapid type II fiber atrophy, suggesting myostatin-mediated specific type II fiber atrophy, which in combination with the mRNA data support a role for myostatin in the negative regulation of adult human skeletal muscle mass [09216].

Inhibition of myostatin signalling or its biological activity has recently emerged as a potential remedial approach against muscle wasting and degenerative diseases such as muscular dystrophies. In one study it was systemically administered a recombinant AAV8 vector expressing a mutated myostatin propeptide (AAV8ProMyo) to healthy mice in order to assess its impact on the histological, cellular and physiological properties of the skeletal muscle, exploiting the fact that myostatin is naturally inhibited by its own propeptide. It was reported that a single intravenous administration of AAV8ProMyo leads to increases in muscle mass of tibialis anterior, extensor digitorum longus and gastrocnemius muscles 8 weeks post-injection and tibialis anterior, gastrocnemius and rectus femoris muscles 17 weeks post-injection. Moreover, treatment resulted in muscle fibre hypertrophy but not hyperplasia, with IIB myofibres responding to the greatest extent following propeptide-induced myostatin inhibition. Additionally, myofibre nuclear:cytoplasmic ratio was decreased in the AAV8ProMyo treated animals. Importantly, the hypertrophic EDL muscle 8 weeks after AAV8ProMyo treatment did not show the dramatic decrease in specific force displayed by
The objective of one study was to examine the effects of short-term exercise training, myostatin inhibition (PF-354), and exercise + PF-354, all relative to a vehicle control, on performance and metabolic measures in 24-month-old mice. At study termination, PF-354-treated mice exhibited significantly greater muscle weights. Performance measures revealed that exercise + PF-354 increased treadmill running time and distance to exhaustion (more than twofold) and increased habitual activity. Measures of strength were not different; however, all treatment groups demonstrated more than 30 percent reductions in muscle fatigue. Metabolic measures showed that basal metabolic rates were higher in PF-354- and exercise + PF-354-treated mice, and exercise and exercise + PF-354 groups exhibited significantly greater insulin sensitivity. PF-354 was associated with decreased Smad3 phosphorylation and increased peroxisome proliferator-activated receptor gamma coactivator-1alpha expression and, similar to exercise, decreased MuRF-1. The data suggest that the combination of exercise training and myostatin blockade may significantly improve physical function and whole-body metabolism in older individuals.

Methodological problems, including binding of myostatin to plasma proteins and cross-reactivity of assay reagents with other proteins, have confounded myostatin measurements. Here it was described development of an accurate assay for measuring myostatin concentrations in humans. Monoclonal antibodies that bind to distinct regions of myostatin served as capture and detector antibodies in a sandwich ELISA that used acid treatment to dissociate myostatin from binding proteins. Serum from myostatin-deficient Belgian Blue cattle was used as matrix and recombinant human myostatin as standard. The quantitative range was 0.15-37.50 ng/mL. Myostatin protein was undetectable in sera of Belgian Blue cattle and myostatin knockout mice. Recovery in spiked sera approximated 100 percent. ActRIIB-Fc or anti-myostatin antibody MYO-029 had no effect on myostatin measurements when assayed at pH 2.5. Myostatin levels were significantly higher in young than older men 8.0 ± 0.3 ng/mL versus 7.0 ± 0.4 ng/mL. In men treated with graded doses of testosterone, myostatin levels were significantly higher on day 56 than baseline in both young and older men; changes in myostatin levels were significantly correlated with changes in total and free testosterone in young men. Myostatin levels were not significantly associated with lean body mass in either young or older men.

It was examined associations among myostatin 2379 A > G and 163 G > A and follistatin (FST) -5003 A > T and -833 G > T single nucleotide polymorphisms (SNP) on the muscle size and the strength response to resistance training (RT). There were 645 subjects (age = 24 ± 0.2 yr, body mass index = 24.2 ± 0.2 kg) who self-disclosed themselves as Caucasian (79 %), African American (4 %), Asian (8 %), Hispanic (5 %), or other (4 %). They were genotyped for myostatin 2379 A > G (n = 645), myostatin 163 G > A (n = 639), FST -5003 A > T (n = 580), and FST -833 G > T (n = 603). It was assessed dynamic (one repetition maximum [1RM]) and isometric (maximum voluntary contraction [MVC]) muscle strength and size (cross-sectional area [CSA]) of the elbow flexors before and after 12 weeks of unilateral upper-arm RT. Baseline MVC was greater among African Americans who were carriers of the myostatin G(2379) allele (AG/GG, n=15) than the A2379A homozygotes. African Americans who were carriers of the FST T(-5003) allele (n=12) had greater baseline 1RM and CSA than African Americans with the A-5003A genotype (n = 14; P < 0.05). No myostatin or FST genotype and muscle phenotype associations were found among the other ethnic groups.

Dexamethasone, alone or in association with estrogens, is often illegally administered per os at very low dosage as a growth promoter in beef cattle, with effects that are opposite to the muscle wasting and atrophy induced by repeated administration at therapeutic dosages. In
vitro and in vivo studies have investigated the catabolic effects of dexamethasone at therapeutic doses on skeletal muscle, demonstrating an increase in the expression of GDF8 (myostatin) gene, a well-known negative regulator of skeletal muscle mass, in a dose-dependent way. This suggested a direct role of myostatin in dexamethasone-induced muscle wasting. In one study, an oligonucleotide microarray platform was used to compare expression profiles of beef cattle muscle in animals treated with either dexamethasone or dexamethasone plus 17-beta estradiol administered at subtherapeutic dosage, against untreated controls. Data analysis demonstrates that the expression profiles were strongly affected by dexamethasone treatment with hundreds of genes upregulated with relevant fold-change, whereas seven genes were downregulated including the myostatin gene. On the contrary, the number of differentially regulated genes was lower in response to the addition of estradiol to the dexamethasone treatment. Differentially regulated genes were analyzed to describe the effects of these treatments on muscle physiology, highlighting the importance of specific pathways (e.g. Wnt or cytokine signaling) and cellular processes (e.g. cell shape and motility). Finally, the observed differences in the expression profile will allow the development of indirect bio-markers to detect illegal dexamethasone treatments in beef cattle using quantitative RT-PCR [09221].

Myostatin is a dominant inhibitor of skeletal muscle development and growth. As transgenic over-expression of myostatin propeptide dramatically enhanced muscle mass, we hypothesized that administration of myostatin propeptide will increase muscle growth. In this study, the wild-type form of porcine myostatin propeptide and its mutated form at the cleavage site of metalloproteinases of BMP-1/TLD family were produced from insect cells. In vitro A204 cells reporter assays showed that both wild-type and the mutated propeptides depressed myostatin activity. The recombinant propeptides at four-fold myostatin concentration can effectively block myostatin function during co-incubation with A204 cells. In particular, the mutated propeptide appeared much more effective than wild-type propeptide over a long period during the in vitro co-incubation. Administration of the mutated propeptide to neonatal mice at the age of 11 and 18 days was tested and showed significant increase in growth performance by 11-15 percent from the age of 25 to 57 days. The major skeletal muscles of mice that were injected with mutated propeptide were 14-25 percent heavier than the control group – a significant difference – as a result of muscle fiber hypertrophy. In conclusion, administration of the mutated myostatin propeptide during the neonatal period is an effective way for promoting muscle growth [09222].

Myostatin, a negative regulator of muscle growth, has recently been found to be expressed in tendons. Myostatin-deficient mice have weak and brittle tendons, which suggest that myostatin could be important for tendon maintenance. Follistatin expression in the callus tissue after tendon transection is influenced by loading. It was found that follistatin antagonises myostatin, but not GDF-5 or OP-1 in vitro. To study if myostatin might play a physiological role in soft tissue, it was transected 64 rat Achilles tendons and studied the gene expression for myostatin and its receptors at four different time-points during healing. Intact tendons were also studied. All samples were studied with or without mechanical loading. Unloading was achieved with botulinum toxin injections in the calf muscles. The expression of the myostatin gene was more than 40 times higher in intact tendons than in the callus tissue during tendon healing. The expression of myostatin was also influenced by loading status in both intact and healing tendons. Thereafter, it was measured the mechanical properties of healing tendons after local myostatin administration. This treatment increased the volume and the contraction of the callus after 8 days, but did not improve its strength. The results indicate that myostatin plays a positive role in tendon maintenance and that exogenous protein administration stimulates proliferation and growth of early repair tissue. However, no effect on further development towards connective tissue formation was found [09223].
The objective of one study was to examine the effects of short-term exercise training, myostatin inhibition (PF-354), and exercise + PF-354, all relative to a vehicle control, on performance and metabolic measures in 24-month-old mice. At study termination, PF-354-treated mice exhibited significantly greater muscle weights. Performance measures revealed that exercise + PF-354 increased treadmill running time and distance to exhaustion (more than twofold) and increased habitual activity. Measures of strength were not different; however, all treatment groups demonstrated more than 30 percent reductions in muscle fatigue. Metabolic measures showed that basal metabolic rates were higher in PF-354- and exercise + PF-354-treated mice, and exercise and exercise + PF-354 groups exhibited significantly greater insulin sensitivity. PF-354 was associated with decreased Smad3 phosphorylation and increased peroxisome proliferator-activated receptor gamma coactivator-1alpha expression and, similar to exercise, decreased MuRF-1. The data suggest that the combination of exercise training and myostatin blockade may significantly improve physical function and whole-body metabolism in older individuals [09224].

Methodological problems, including binding of myostatin to plasma proteins and cross-reactivity of assay reagents with other proteins, have confounded myostatin measurements. Here it was described development of an accurate assay for measuring myostatin concentrations in humans. Monoclonal antibodies that bind to distinct regions of myostatin served as capture and detector antibodies in a sandwich ELISA that used acid treatment to dissociate myostatin from binding proteins. Serum from myostatin-deficient Belgian Blue cattle was used as matrix and recombinant human myostatin as standard. The quantitative range was 0.15-37.50 ng/mL. Myostatin protein was undetectable in sera of Belgian Blue and myostatin knockout mice. Recovery in spiked sera approximated 100 percent. ActRIIB-Fc or anti-myostatin antibody MYO-029 had no effect on myostatin measurements when assayed at pH 2.5. Myostatin levels were significantly higher in young than older men 8.0 ± 0.3 ng/mL versus 7.0 ± 0.4 ng/mL. In men treated with graded doses of testosterone, myostatin levels were significantly higher on day 56 than baseline in both young and older men; changes in myostatin levels were significantly correlated with changes in total and free testosterone in young men. Myostatin levels were not significantly associated with lean body mass in either young or older men [09225].

It was examined associations among myostatin 2379 A > G and 163 G > A and follistatin (FST) -5003 A > T and -833 G > T single nucleotide polymorphisms (SNP) on the muscle size and the strength response to resistance training (RT). There were 645 subjects (age = 24 ± 0.2 yr, body mass index = 24.2 ± 0.2 kg) who self-disclosed themselves as Caucasian (79 %), African American (4 %), Asian (8 %), Hispanic (5 %), or other (4 %). They were genotyped for myostatin 2379 A > G (n = 645), myostatin 163 G > A (n = 639), FST -5003 A > T (n = 580), and FST -833 G > T (n = 603). It was assessed dynamic (one repetition maximum [1RM]) and isometric (maximum voluntary contraction [MVC]) muscle strength and size (cross-sectional area [CSA]) of the elbow flexors before and after 12 weeks of unilateral upper-arm RT. Baseline MVC was greater among African Americans who were carriers of the myostatin G(2379) allele (AG/GG, n=15) than the A2379A homozygotes. African Americans who were carriers of the FST T(-5003) allele (n=12) had greater baseline 1RM and CSA than African Americans with the A-5003A genotype (n = 14; P < 0.05). No myostatin or FST genotype and muscle phenotype associations were found among the other ethnic groups [09226].

Dexamethasone, alone or in association with estrogens, is often illegally administered per os at very low dosage as a growth promoter in beef cattle, with effects that are opposite to the muscle wasting and atrophy induced by repeated administration at therapeutic dosages. In vitro and in vivo studies have investigated the catabolic effects of dexamethasone at
therapeutic doses on skeletal muscle, demonstrating an increase in the expression of GDF8 (myostatin) gene, a well-known negative regulator of skeletal muscle mass, in a dose-dependent way. This suggested a direct role of myostatin in dexamethasone-induced muscle wasting. In one study, an oligonucleotide microarray platform was used to compare expression profiles of beef cattle muscle in animals treated with either dexamethasone or dexamethasone plus 17-beta estradiol administered at subtherapeutic dosage, against untreated controls. Data analysis demonstrates that the expression profiles were strongly affected by dexamethasone treatment with hundreds of genes upregulated with relevant fold-change, whereas seven genes were downregulated including the myostatin gene. On the contrary, the number of differentially regulated genes was lower in response to the addition of estradiol to the dexamethasone treatment. Differentially regulated genes were analyzed to describe the effects of these treatments on muscle physiology, highlighting the importance of specific pathways (e.g. Wnt or cytokine signaling) and cellular processes (e.g. cell shape and motility). Finally, the observed differences in the expression profile will allow the development of indirect bio-markers to detect illegal dexamethasone treatments in beef cattle using quantitative RT-PCR [09227].

Myostatin propeptide (MYOPRO) and follistatin (FOLLI) are potent myostatin inhibitors. In one study it was analysed effects of training and androgens on MYOPRO and FOLLI concentrations in blood and skeletal muscle using Immuno PCR. Young healthy males performed either a 3-month endurance training or a strength training. Blood and biopsy samples were analysed. Training did not significantly affect MYOPRO and FOLLI concentrations in serum and muscle. To investigate whether total skeletal muscle mass may affect circulating MYOPRO and FOLLI levels, blood samples of tetraplegic patients, untrained volunteers and bodybuilders were analysed. MYOPRO was significantly increased exclusively in the bodybuilder group. In orchiectomised rats MYOPRO increased in blood and muscle after treatment with testosterone. In summary the data demonstrate that moderate training does not affect the concentrations of MYOPRO to FOLLI. In contrast androgen treatment results in a significant increase of MYOPRO in skeletal muscle and serum [10368].

There is mounting evidence that skeletal muscle produces and secretes biologically active proteins or "myokines" that facilitate metabolic cross talk between organ systems. The increased expression of myostatin, a secreted anabolic inhibitor of muscle growth and development, has been associated with obesity and insulin resistance. Despite these intriguing findings, there have been few studies linking myostatin and insulin resistance. To explore this relationship in more detail, we quantified myostatin protein in muscle and plasma from 10 insulin-resistant, middle-aged (53 ± 6 year) men before and after 6 months of moderate aerobic exercise training . To establish a cause-effect relationship, we also injected C57/Bl6 male mice with high physiological levels of recombinant myostatin protein. Myostatin protein levels were shown to decrease in muscle and matching plasma samples with aerobic exercise. Furthermore, the strong correlation between plasma myostatin levels and insulin sensitivity suggested a cause-effect relationship that was subsequently confirmed by inducing insulin resistance in myostatin-injected mice. A modest increase (44 %) in plasma myostatin levels was also associated with significant reductions in the insulin-stimulated phosphorylation of Akt (Thr308) in both muscle and liver of myostatin-treated animals. These findings indicate that both muscle and plasma myostatin protein levels are regulated by aerobic exercise and, furthermore, that myostatin is in the causal pathway of acquired insulin resistance with physical inactivity [10485].

Both 19-norandrostenedione (estr-4-ene-3,17-dione, NOR) and desoxymethyltestosterone (17alpha-methyl-5alpha-androst-2-en-17beta-ol, DMT or "madol") are “designer steroids” misused for doping purposes in the bodybuilding scene. It has previously been characterized
the pharmacological profile of madol and identified potential adverse side effects. The aim of one study was to investigate the anabolic potency of NOR, madol and the reference substance testosterone propionate (TP). Besides wet weight of the M. levator ani (LA), it was examined the effects on muscle fiber type composition and myosin heavy chain (MHC) expression in the M gastrocnemius (Gas) muscle as additional markers for anabolic potency. A Hershberger assay was performed, where orchiectomized (orchi) male Wistar rats were treated subcutaneously with NOR, madol, TP or vehicle control (all 1 mg/kg BW/day) for 12 days. Wet weights of the Gas, LA, prostate and seminal vesicle were examined to determine anabolic and androgenic effects. Fiber type composition of the Gas muscle was analyzed using ATPase staining, and MHC protein profiles were determined by silver stain and Western blot analysis. NOR and madol exhibited strong anabolic and weak androgenic potency by stimulating growth of the LA but not the prostate and seminal vesicle. Skeletal muscle fiber type composition characterized by ATPase staining was not significantly altered between the treatment groups, although there was a tendency toward lower levels of type IIB and increased type IIA fibers in all treatment groups relative to orchi. MHC protein expression determined by Western blot and silver stain analysis revealed that MHC IId/x was significantly up-regulated, while MHC IIb was significantly down-regulated in NOR, madol and TP groups relative to orchi. There were no significant differences for MHC Ila and MHC I expression between groups. Results suggest that the observed MHC expression shift could serve as a molecular marker to determine anabolic activity of anabolic steroids at least in skeletal muscle of orchi rats. The molecular mechanisms as well as the androgen-dependent regulation of MHC expression in intact skeletal muscle remain to be further investigated [11180].

It was hypothesized that suppression of endogenous testosterone blunts mRNA expression post strength training (ST). Twenty-two young men were randomized for treatment with the GnRH analogue goserelin (3.6 mg every 4 weeks) or placebo for a period of 12 weeks. The ST period of 8 weeks started at week 4. Strength test, blood sampling, muscle biopsies, and whole-body dual-energy X-ray absorptiometry (DXA) scan were performed at weeks 4 and 12. Muscle biopsies were taken during the final ST session (pre, post 4 h, and post 24 h). Resting serum testosterone decreased significantly in the goserelin group, whereas it remained unchanged in the placebo group. An acute increase of serum testosterone was observed during the final ST session in the placebo group, whereas a decreased response was observed in the goserelin group. mRNA expression of IGF-IE(bc) and myogenin increased, while expression of myostatin decreased; however, no differences were observed between the groups. Muscle strength and muscle mass showed a tendency to increase more in the placebo group than in the goserelin group. In conclusion, despite blocked acute responses of testosterone and 10- to 20-fold lower resting levels in the goserelin group, ST resulted in a similar mRNA expression of myoD, myogenin, IGF-IE(abc), myostatin and androgen receptor as observed in the placebo group. Therefore, in the present study, the molecular events were the same, despite divergent muscle hypertrophy and strength gains [07162].

Myostatin, a member of the transforming growth factor-beta (TGF-beta) superfamily, is a critical autocrine/paracrine inhibitor of skeletal muscle growth. Since the first observed double-muscling phenotype was reported in myostatin-null animals, a functional role of myostatin has been demonstrated in the control of skeletal muscle development. The deletion of myostatin in mice induces a dramatic and widespread increase in skeletal muscle mass due to both muscle hypertrophy and hyperplasia. The double-muscling phenotype of some cattle and sheep breeds is caused by mutations in their myostatin genes. Myostatin appears to trigger signaling by directly binding to its serine/threonine kinase receptor. Downstream of the receptors, Smads are first demonstrated to be mediators of signals for myostatin. Beyond the canonical Smad-mediated signal pathway, Non-Smad signal
pathways have recently been reported to participate in myostatin signaling. Myostatin expression is increased in glucocorticoid-induced muscle atrophy as well as skeletal muscle degeneration-related diseases, such as HIV infection and chronic illnesses. The increased myostatin expression is also associated with metabolic disorders, such as obesity and diabetes. Therefore, the most important myostatin function is the regulation of skeletal muscle growth. However, the biological function of myostatin is not only restricted to muscle growth inhibition but also might have other redundant functions. However, beyond the confines of its traditional role in muscle growth inhibition, myostatin has recently been shown to play an important role in metabolism. During the past several years, it has been well established that Smads are canonical mediators of signals for myostatin from the receptors to the nucleus. However, growing evidence supports the notion that Non-Smad signal pathways also participate in myostatin signaling. Myostatin expression is increased in muscle atrophy and metabolic disorders, suggesting that changes in endogenous expression of myostatin may provide therapeutic benefit for these diseases. MicroRNAs (miRNAs) are a class of non-coding RNAs that negatively regulate gene expression and recent evidence has accumulated supporting a role for miRNAs in the regulation of myostatin expression. The functional role of myostatin in the control of skeletal muscle development is well established. However, the biological function of myostatin is not only restricted to suppressing skeletal muscle growth. Muscle mass is tightly regulated by the balance between muscle cell replication and protein synthesis and muscle proteolysis and cell death. There is evidence that myostatin may reduce muscle mass by decreasing protein synthesis. Studies in vitro reported that myostatin inhibit protein synthesis in both myoblasts and particularly in myotubes. In vivo studies examined the rates of myofibrillar protein synthesis in normal mice and in mice with constitutive myostatin deficiency. They found that mice with constitutive myostatin deficiency have increased the rate of myofibrillar protein synthesis. Similar results were observed in mice with anti-myostatin antibody. In addition, it was reported that follistatin, an inhibitor of myostatin, stimulates protein synthesis in skeletal muscle of neonatal rats. In these in vivo studies, myostatin does not influence muscle proteolysis, which suggests that increased protein synthesis is probably the major mechanism for the muscle fiber hypertrophy arising from absence or blockade of myostatin. Recently, numerous studies have provided evidence that myostatin acts as a negative regulator of the Akt/mTOR signaling pathway, consistent with its inhibitory effect on protein synthesis. Taken together, these findings uncover a novel role for myostatin in protein metabolism and, more specifically, in the regulation of protein synthesis. Myostatin thus negatively regulates skeletal muscle growth, an effect attributed to inhibition of both myoblast proliferation and differentiation. Myostatin appears to inhibit myoblast proliferation by arresting cell cycle at the G1-phase. A number of studies have provided evidence that myostatin-induced myoblast inhibition is associated with the up-regulation of the cyclin-dependent kinase (Cdk) inhibitor p21, the down-regulation of Cdk2, the decrease in Cdk2 activity, and the decrease phosphorylation of retinoblastoma (Rb). In addition, myostatin was reported to augment cyclin D1 protein degradation to cause G1 cell cycle arrest through PI3K/Akt/GSK-3β signaling pathway. Myostatin appears to inhibit myoblast differentiation by downregulating expression of differentiation related genes, such as MyoD, myogenin, and Myf5, as well as the activity of their downstream target creatine kinase. Satellite cells are quiescent muscle stem cells that promote postnatal muscle growth and repair. Myostatin has also been shown to maintain the satellite cells in a quiescent state. Cell cycle analysis confirms that myostatin up-regulates the levels of p21 protein and decreases the levels and activity of Cdk2 protein, suggesting that myostatin inhibits the G1 to S phase transition and thus maintains the quiescent status of satellite cells. The approaches to blocking myostatin activity show promise for clinical application. Several strategies to depress myostatin activity have been developed over the years since it was cloned and identified as a novel TGF-beta superfamily member in 1997. Myostatin propeptide, an endogenous myostatin specific inhibitor, has been developed to suppress myostatin activity. Myostatin propeptide is capable of inhibiting
myostatin activity by binding to it directly and maintaining it in a latent state. In addition, a single intravenous administration of a recombinant AAV8 vector expressing a mutated myostatin propeptide leads to increases in mice muscle mass of tibialis anterior, extensor digitorum longus and gastrocnemius muscles 8 weeks post-injection and tibialis anterior, gastrocnemius and rectus femoris muscles 17 weeks post-injection. In addition to myostatin inhibitors, neutralizing antibody has been developed to inhibit myostatin activity. Blockade of endogenous myostatin by using intraperitoneal injections of anti-myostatin monoclonal antibody increased skeletal muscle mass in mice. More recently, it was reported that antibody-directed myostatin blockade enhances the mass and function of skeletal muscles of 21-mo-old aging mice. There are evidence that a neutralizing antibody to myostatin not only promotes gains in muscle mass, but improves glucose tolerance and lipid profiles in obese insulin resistant mice. These findings highlight the therapeutic potential of antibody-directed myostatin inhibition not only for muscular dystrophy but also for metabolic diseases, such as obesity and type II diabetes. In addition to myostatin inhibitors, neutralizing antibody has been developed to inhibit myostatin activity. Blockade of endogenous myostatin by using intraperitoneal injections of anti-myostatin monoclonal antibody increased skeletal muscle mass in mice. Inhibition of myostatin activity has also potential benefits for livestock producers, as it can increase growth performance of livestock and lean meat percentage of carcass. At present, only a few reports are available about suppression of myostatin activity in livestock species [13341]

The purpose of one pilot study was to investigate the impact of training, anabolic steroids and endogenous hormones on myostatin-interacting proteins in order to identify manipulations of myostatin signalling. To identify whether analysis of the myostatin interacting proteins follistatin and myostatin propeptide is suitable to detect the abuse of anabolic steroids, their serum concentrations were monitored in untrained males, bodybuilders using anabolic steroids and natural bodybuilders. In addition, it was analysed follistatin and myostatin propeptide serum proteins in females during menstrual cycle. The results showed increased follistatin concentrations in response to anabolic steroids. Furthermore, variations of sex steroid levels during the menstrual cycle had no impact on the expression of follistatin and myostatin propeptide. In addition, we identified gender differences in the basal expression of the investigated proteins. In general, follistatin and myostatin propeptide concentrations were relatively stable within the same individual both in males and females. In conclusion, the current findings provide an insight into gender differences in myostatin-interacting proteins and their regulation in response to anabolic steroids and endogenous hormones. Therefore the data provide new aspects for the development of doping prevention strategies [13400].

**Effect of psychological stress**

Psychological stress is known to attenuate body size and lean body mass. We tested the effects of 1, 3, or 7 days of two different models of psychological stress, 1 h of daily restraint stress (RS) or daily cage-switching stress (CS), on skeletal muscle size and atrophy-associated gene expression in mice. Thymus weights decreased in both RS and CS mice compared with unstressed controls, suggesting that both models activated the hypothalamic-pituitary-adrenal axis. Body mass was significantly decreased at all time points for both models of stress but was greater for RS than CS. Mass of the tibialis anterior (TA) and soleus (SOL) muscles was significantly decreased after 3 and 7 days of RS, but CS only significantly decreased SOL mass after 7 days. TA mRNA levels of the atrophy-associated genes myostatin (MSTN), atrogin-1, and the phosphatidylinositol 3-kinase inhibitory subunit p85alpha were all significantly increased relative to unstressed mice after 1 and 3 days of RS, and expression of MSTN and p85alpha mRNA remained elevated after 7 days of RS.
Expression of muscle ring finger 1 was increased after 1 day of RS but returned to baseline at 3 and 7 days of RS. MSTN, atrogin-1, and p85alpha mRNA levels also significantly increased after 1 and 3 days of CS but atrogin-1 mRNA levels had resolved back to normal levels by 3 days and p85alpha with 7 days of CS. p21CIP mRNA levels were significantly decreased by 3 days of CS or RS. Finally, body mass was minimally affected, and muscle mass was completely unaffected by 3 days of RS in mice null for the MSTN gene, and MSTN inactivation attenuated the increase in atrogin-1 mRNA levels with 4 days of RS compared with wild-type mice. Together these data suggest that acute daily psychological stress induces atrophic gene expression and loss of muscle mass that appears to be MSTN dependent [10369].

**Experimental**

The growth factor myostatin (Mstn) is a negative regulator of skeletal muscle mass. Mstn(-/-) muscles are hypertrophied, stronger, and more glycolytic than Mstn(+/+) muscles, suggesting that they might not perform endurance exercise as well as Mstn(+/+) mice. Indeed, it has previously been shown that treadmill exercise training reduces triceps weight in Mstn(-/-) mice. To analyze the response of Mstn(-/-) muscle to endurance exercise in detail, it was carried out endurance training over 4 weeks to examine muscle mass, histology, and oxidative enzyme activity. We found that muscle mass was reduced with training in several muscles from both genotypes, with no evidence of muscle damage. Citrate synthase activity was increased with training in control and mutant mice. Non-trained Mstn(-/-) mice did, however, have lower maximal exercise capacity compared with Mstn(+/+) mice. These results show that Mstn(-/-) muscle retains the metabolic plasticity necessary to adapt normally to endurance training [10370].

Myostatin is a TGF-β family member that normally acts to limit skeletal muscle mass. Follistatin is a myostatin-binding protein that can inhibit myostatin activity in vitro and promote muscle growth in vivo. Mice homozygous for a mutation in the Fst gene have been shown to die immediately after birth but have a reduced amount of muscle tissue, consistent with a role for follistatin in regulating myogenesis. Here, it was shown that Fst mutant mice exhibit haploinsufficiency, with muscles of Fst heterozygotes having significantly reduced size, a shift toward more oxidative fiber types, an impairment of muscle remodeling in response to cardiotoxin-induced injury, and a reduction in tetanic force production yet a maintenance of specific force. It was shown that the effect of haploinsufficient loss of Fst is at least partially retained in a Mstn-null background, implying that follistatin normally acts to inhibit other TGF-β family members in addition to myostatin to regulate muscle size. Finally, it was presented genetic evidence suggesting that activin A may be one of the ligands that is regulated by follistatin and that functions with myostatin to limit muscle mass. These findings potentially have important implications with respect to the development of therapeutics targeting this signaling pathway to preserve muscle mass and prevent muscle atrophy in a variety of inherited and acquired forms of muscle degeneration [10371].

**Mechanical growth factors**

Recently much interest has been shown in developing a treatment of muscle wasting associated with a range of diseases as well as in ageing, which are major medical and socioeconomic problems. Emerging molecular techniques have made it possible to gain a better understanding of the growth factor genes involved and how they are activated by physical activity including the IGF-1 gene that can be spliced to give rise to different isoforms, one of which is called Mechanical Growth Factor, MGF, that activates muscle progenitor cells
that provide the extra nuclei required for muscle hypertrophy, repair and maintenance. This fact that MGF 'kick starts' the hypertrophy process clearly has potential for abuse and has already attracted the attention of body builders [08290].

Growth factors (GFs) act as signalling agents for cells and become a more and more popular mean to influence the human body and its tissues. This review gives an overview of the current possibilities to use such agents in the field of sports related injuries and thus providing the athlete with a whole new potential to minimize recovery time. GFs and its application have been studied intensively for a long time starting with animal studies. For some of these GFs this research has been brought onto the next level to clinical phase trials. Agents such as insulin like growth factor 1 (IGF-1), mechano growth factor (MGF), basic fibroblast growth factor (B-FGF), platelet derived growth factor (PDGF), vascular endothelial growth factor (VEGF), transforming growth factor beta (TGF-beta), bone morphogenetic protein (BMP) and leukemia inhibitory factor (LIF) are being discussed in this review. These GFs not only have the potential to be used to cure injuries but also are being in the centre of interest for doping abusers and are a powerful yet not fully understood technique to gain performance [09215].

Although not approved for clinical use, illicitly distributed peptidic drug candidates such as the fibroblast growth factor (FGF) and mechano growth factor (MGF) were obtained from custom seizures and analyzed/characterized. FGF was obtained in an unlabelled vial and identified by means of 1D- and 2D-PAGE followed by bottom-up LC-MS/MS analysis, providing evidence for the presence of approximately 2 µg of FGF bearing a modified (or truncated) N-terminus. The presence of C-terminally amidated MGF (primary structure: YQPSTNKTSSQRRGSTFEERK) in injection vials was demonstrated by LC-HRMS and −MS/MS, further supporting the growing evidence that peptidic drugs are readily available via internet-based suppliers [13012].

Stretching

Stretching of skeletal muscle induces expression of the genes which encode myogenic transcription factors or muscle contractile proteins and results in muscle growth. Anabolic steroids are reported to strengthen muscles. It was previously studied the effects of muscle stretching on gene expression. The mechanism of mechanotransduction has been elucidated. Skeletal muscle stretch/overload increases the mRNA expression of IGF-I, particularly the specific autocrine IGF-I splicing variant mechano-growth factor (MGF). Mechanical environment and changes in muscle structure and physiology suggest that there may be pathways within muscle cells through which mechanical signals can be converted into chemical signals that in turn generate numerous, specific downstream events that determine the muscle's form and function. Several studies have reported that muscle stretching induces muscle growth and hypertrophy. Such mechanical stimulation is thought to be helpful for patients with muscle weakness and also applicable to clinically unconscious patients and those with paralysis. Administration of anabolic steroids also produces muscle hypertrophy. However, the effects of anabolic steroids on the results of mechanical stimulation to promote muscle strengthening are not well known. Here, it was studied the effect of a combination of passive stretching and the administration of an anabolic steroid on mRNA expression of a muscle growth factor, insulin-like growth factor-I autocrine variant, or mechano-growth factor (MGF). Twelve 8-week-old male Wistar rats were used. Metenolone was administered and passive repetitive dorsiflexion and plantar flexion of the ankle joint performed under deep anesthesia. After 24 h, the gastrocnemius muscles were removed and the mRNA expression of insulin-like growth factor-I autocrine variant was measured using quantitative real-time polymerase chain reaction. Repetitive stretching in combination with metenolone, but not stretching alone, significantly increased MGF mRNA expression. It was
concluded that anabolic steroids enhance the effect of passive stretching on MGF expression in skeletal muscle [13401].

Antibodies against human MGF E-peptide

Since 2005, as one of prohibited substances on the Prohibited List of the World Anti-Doping Agency (WADA), the occurrence of mechano growth factor (MGF) abuse in sport has likely increased. However, there is still no WADA-validated and -approved method for its detection. Four polyclonal antibodies (Ab-K01, Ab-B01, Ab-B02 and Ab-K02) against MGF C-terminal peptides were generated, purified and evaluated by western blot, ELISA and reverse-phase protein microarray, respectively. It was found that all the antibodies could identify their corresponding antigen in mouse serum by reverse-phase protein microarray, in particular, Ab-K01 showed the highest affinity among them and might be a potential tool for the detection of antibody affinity. Furthermore, Ab-B01 and Ab-K01 were successfully used for the determination of MGF-40 by reverse competitive ELISA. The quantitative measurement of MGF-40 has laid the foundation for doping detection of MGF and further biological research on MGF [13402].

Fibroblast growth factor (FGF) and mechano growth factor (MGF)

Although not approved for clinical use, illicitly distributed peptidic drug candidates such as the fibroblast growth factor (FGF) and mechano growth factor (MGF) were obtained from custom seizures and analyzed/characterized. FGF was obtained in an unlabelled vial and identified by means of 1D- and 2D-PAGE followed by bottom-up LC-MS/MS analysis, providing evidence for the presence of approximately 2 mg of FGF bearing a modified (or truncated) N-terminus [12017].

AGRP

The ability of acute exercise to stimulate appetite and food intake depends on intensity, duration, and agouti-related protein (AGRP) levels. Fasting, as well as any negative energy balance, has been reported to increase AGRP expression in the arcuate nucleus (ARC) of the hypothalamus and other extra-hypothalamic tissues in human and rats. The purpose of the present study was to investigate the response of plasma AGRP, GH and insulin to a single circuit-resistance exercise. Twenty volunteer male college students completed a single bout of circuit-resistance training (10 exercises at 35 % of 1RM). Blood samples were collected before, immediately and 30 min following the exercise protocol. Plasma AGRP and GH levels showed a significant increase immediately after exercise and returned to pre exercise values during the recovery period. The data indicate that exercise protocol was able to increase plasma AGRP and GH levels. A higher plasma AGRP level might result in an acute exercise-induced hyperphagia and help to fuel post-exercise restoration processes [07163].
CAFFEINE

Overviews

Caffeine, nicotine, ethanol and tetrahydrocannabinol (THC) are among the most prevalent and culturally accepted drugs in western society. For example, in Europe and North America up to 90 percent of the adult population drinks coffee daily and, although less prevalent, the other drugs are also used extensively by the population. Smoked tobacco, excessive alcohol consumption and marijuana (cannabis) smoking are addictive and exhibit adverse health effects. These drugs are not only common in the general population, but have also made their way into elite sports because of their purported performance-altering potential. Only one of the drugs (i.e. caffeine) has enough scientific evidence indicating an ergogenic effect.

Apart from water, tea and coffee are among the most popular beverages worldwide. The main pharmacologically active substance in both is the purine alkaloid of the xanthines class, 1,3,7-,trimethylxanthine or caffeine. According to European and North American statistics, about 90 percent of the adult population consider themselves as daily coffee users with an average daily caffeine consumption of about 200 mg or 2.4 mg/kg/day (about 2 cups of coffee). It is therefore considered the world’s most widely consumed pharmacologically active substance. Caffeine is both water and fat soluble and is quickly distributed in the body after absorption mainly by the small intestine and the stomach with peaking plasma levels after 15-120 min and a half-life of about 5-6 hours with individual variation. Due to its lipophilic nature, caffeine also crosses the blood-brain barrier, and is metabolized by the liver into paraxanthine, theophylline, and theobromine [130008].

The effect of caffeine to promote improvements in mood, cognition, and exercise performance has been well established in young and athletic adults. However, little is known about whether such nutritional ergogenic aids are effective in enhancing psychological well-being, physiological or cognitive performance in older adults. One study assessed the ergogenic effect of caffeine on mood, perceptual-motor coupling, and muscular strength in an older human population. Following a familiarization session, 12 apparently healthy volunteers (nine females and three males; 69 ± 6 years) completed two laboratory visits. "Pre ingestion" trials of mood state Brunel Mood State Inventory (BRUMS) and coincidence anticipation performance (Bassin anticipation timer) at slow (3 mph) and fast (8 mph) stimulus speeds were completed on both visits. Using a randomized, double-blind, cross-over design, participants consumed either caffeine (3 mg/kg body mass) or a placebo. Sixty minutes post-ingestion participants repeated the trials before completing a set of 10 consecutive repetitions of maximal knee extension using isokinetic dynamometry. Rating of perceived exertion (RPE) was assessed following the fifth and final repetition. Caffeine ingestion significantly improved mood state scores for vigor by 17 percent and reduced absolute error by 35 percent during coincidence anticipation assessment at 8 mph compared to placebo. There were no other significant effects. Caffeine ingestion failed to augment maximal voluntary contraction of the knee extensors and RPE did not prove to be significantly different to from placebo. Acute caffeine ingestion may not be an effective ergogenic aid for improving muscular strength in older adults but could possibly be used as a nutrition supplement for enhancing mood and improving cognitive performance in daily living tasks where interceptive timing skills are required [13435].

Numerous studies to date have shown that caffeine ingested prior to and during prolonged sub-maximal and high intensity exercise can improve performance. It is often cited that caffeine induces its ergogenic effects by an increase in fat oxidation through the sympathetic nervous system, and a sequential sparing of muscle glycogen. However, there is very little
support for an increase in fat oxidation or an enhancement to the sympathetic nervous system being the principal mechanism of caffeine's ergogenic effect. Since, recent investigations have elucidated that the principal mechanism of caffeine's ergogenic effects is through its ability to act as an adenosine receptor antagonist to induce effects on both central and peripheral nervous system to reduce pain and exertion perception, improve motor recruitment and excitation-contraction coupling. In the literature to date, the ergogenic effects are well documented with the time to exhaustion test at a fixed power output being the predominant performance measure used. It was questioned whether assessing endurance capacity in this way would have sufficient ecological validity to translate results to real life events. However since then, a number of studies have confirmed the ergogenic effects of caffeine using time trial protocols, which involves completing an energy based target or set distance in as fast as time possible, thus simulating variable intensities that are likely to occur during competitive events. In most of these studies pure (anhydrous) caffeine was ingested through capsules or dissolved in water. Based on this research it is often assumed that ingesting caffeine in a variety of dietary sources, such as coffee, will result in the same ergogenic effect. Very few studies, however, have shown a positive effect of coffee on exercise performance. Coffee improved performance in some, but not all studies. This may seem surprising as reports have shown that coffee is the most concentrated dietary source of caffeine as well as being one of the largest sources of caffeine used by athletes prior to competition. Amongst the current studies, only two investigations have actually used coffee rather than decaffeinated coffee plus anhydrous caffeine, with only one of these studies showing an ergogenic effect of the coffee. This further identifies the equivocal evidence surrounding the performance effects of coffee. It has been suggested that other components in coffee known as chlorogenic acids, may have antagonised the physiological responses of caffeine. However, in this study chlorogenic acids in the coffee or in the plasma were not measured. Chlorogenic acids are a group of phenolic compounds that possess a quinic acid ester of hydroxycinnamic acid. The consumption of chlorogenic acids varies significantly in coffee ranging from 20-675 mg per serving. It has previously been shown in vitro that chlorogenic acids antagonize adenosine receptor binding of caffeine and cause blunting to heart rate, blood pressure and cause a dose-dependent relaxation of smooth muscle. For this reason, it is unclear what role chlorogenic acids, found in coffee, will have on the physiological and metabolic effects of coffee and caffeine during exercise in humans. Therefore, due to the large variation of chlorogenic acids between coffee beverages and the unclear performance effects of coffee to date, it is yet to be determined if coffee causes differences in the performance and metabolic effects during exercise when compared to caffeine alone. Therefore the primary aim of the present study was to investigate whether acute intake of coffee (5 mg CAF/kg BW) and anhydrous caffeine (5 mg CAF/kg BW) are ergogenic to cycling performance compared to decaffeinated coffee or placebo beverages when using a validated 45-minute time trial performance test. In addition, completing a steady state exercise bout prior to the time trial performance test is a routine protocol used in one laboratory.. For this reason it provided any opportunity to also investigate the effect of acute anhydrous caffeine or coffee intake on substrate oxidation and plasma metabolite responses during 30-min steady state exercise (55 % VO2max). However, whether caffeine ingested through coffee has the same effects is still subject to debate. The primary aim of the study was to investigate the performance enhancing effects of caffeine and coffee using a time trial performance test, while also investigating the metabolic effects of caffeine and coffee. In a single-blind, crossover, randomised counter-balanced study design, eight trained male cyclists/triathletes (age 41 ± 7 years) 30 min of steady-state (SS) cycling at approximately 55 percent VO2max followed by a 45 min energy based target time trial (TT). One hour prior to exercise each athlete consumed drinks consisting of caffeine (5 mg CAF/kg BW), instant coffee (5 mg CAF/kg BW), instant decaffeinated coffee or placebo. The set workloads produced similar relative exercise intensities during the SS for all drinks, with no observed difference in carbohydrate or fat oxidation. Performance times during the TT were
significantly faster (5%) for both caffeine and coffee when compared to placebo and decaf. The significantly faster performance times were similar for both caffeine and coffee. Average power for caffeine and coffee during the TT was significantly greater when compared to placebo and decaf. No significant differences were observed between placebo and decaf during the TT. The present study illustrates that both caffeine (5 mg/kg/BW) and coffee (5 mg/kg/BW) consumed 1 h prior to exercise can improve endurance exercise performance [13436].

One study thus examined the effects of acute intake of coffee (5 mg CAF/kg BW) and caffeine (5 mg CAF/kg BW) on time trial cycling performance, as well as substrate utilisation during SS exercise. Numerous studies to date have shown the efficacy of acute caffeine ingestion for improving prolonged endurance exercise performance. The effects of caffeine on time trial endurance performance (>5 min) have recently been reviewed in a well conducted meta-analysis. The authors concluded that of the 12 studies that investigated caffeine intake (1-6 mg CAF/kg BW), performance was improved by about 3 percent. Fewer studies have investigated the ergogenic effects of coffee, with results being mixed thus far. In agreement with the literature, the current study found an improvement in performance following caffeine intake of 4.9 and 4.5 percent when compared to decaf coffee and placebo, respectively. Interestingly, the current study also showed that coffee improved performance to the same extent as caffeine when compared to decaf coffee and placebo, 4.7 and 4.3 percent respectively. Thus, this is a study that demonstrate that coffee consumed 1 h prior to exercise, at a high caffeine dose (5 mg CAF/kg BW), is equally as effective as caffeine at improving endurance exercise performance. The findings are in line with a number of studies that have shown improvements to performance following coffee intake. For example, decaf coffee plus caffeine (330 mg), improved exercise time to exhaustion (80 % VO_{2max}) compared with decaffeinated coffee (about 18%). More recently, it was shown that coffee was able to improve 1500 m treadmill running performance when compared to decaffeinated coffee (about 3%). Despite conflicting evidence from other studies, the current study clearly demonstrates that coffee is as effective as caffeine at improving endurance exercise performance. The composition and preparation of coffee in each of the studies may also explain the discrepancies in the ergogenic effects of coffee. Coffee is about 2 percent caffeine, with the remainder composed of chlorogenic acids, ferulic acid, caffeic acid, nicotinic acid as well as other unidentifiable compounds. It is evident that the source of coffee beans, roasting, storage and preparation (brewing and filtering) dramatically alters the caffeine and chlorogenic acid content of the coffee. In accordance, recent evidence has shown that the chlorogenic acid content of commercially available espresso coffees range from 24-422 mg/serving. Further, in vitro studies suggest that chlorogenic acids antagonize adenosine receptor binding of caffeine and cause blunting to heart rate and blood pressure in rats. Yet, in vivo there is no evidence to suggest that chlorogenic acids, especially at the low nanomolar concentration typically observed, impact on the mechanisms of action of caffeine that lead to the ergogenic effects. In support of this notion, regular coffee (1.1 mg/kg/BW) consumed prior to the ingestion of different doses of caffeine (3-7 mg/kg/BW) has been shown not to affect the ergogenic effects of caffeine. Interestingly, despite coffee producing similar ergogenic effects as caffeine, the metabolite responses were not identical. It was observed that the significant increase in plasma glucose, FA and glycerol with caffeine was paralleled with an attenuated response for coffee, and a significantly blunted response with decaf coffee when compared to placebo. This is likely due to the compounds in coffee inducing subtle effects on antagonism of adenosine receptors in a variety of exercising and non exercising tissues. It was previously shown that coffee resulted in a blunted adrenaline response when compared to caffeine at rest in humans, which was attributed to chlorogenic acids antagonizing adenosine receptor binding of caffeine. In addition nicotinic acid, a fatty acid ester found in coffee known to inhibit lipolysis, has been shown to lower FA concentrations in patients suffering from hyperlipidemia. Chlorogenic acids are also believed
to improve glucose uptake at the skeletal muscle when compared to caffeine, also by altering the antagonism of adenosine receptors. More recently, caffeic acid has been found to stimulate skeletal muscle glucose transport, independent of insulin, when accompanied with an elevation in AMPK in vitro. Despite the aforementioned evidence, it remains unclear why compounds in coffee appear to modulate the metabolite response but not the ergogenic effects of coffee [13436].

To determine the oral dose of caffeine needed to increase muscle force and power output during all-out single multi-joint movements 13 resistance-trained men, underwent a battery of muscle strength and power tests in a randomized, double-blind, cross over design, under four different conditions: a) placebo ingestion (PLAC) or with caffeine ingestion at doses of; b) 3 mg/kg body weight (CAFF3mg); c) 6 mg/kg (CAFF6mg) and; d) 9 mg/kg (CAFF9mg). The muscle strength and power tests consisted in the measurement of bar displacement velocity and muscle power output during free-weight full-squat (SQ) and bench press (BP) exercises against 4 incremental loads (25 %, 50 %, 75 % and 90 % 1RM). Cycling peak power output (PPO) was measured using a 4s inertial load test. Caffeine side-effects were evaluated at the end of each trial and 24 h later. Mean propulsive velocity at light loads (25 %-50 % 1RM) increased significantly above PLAC for all caffeine doses (5.4-8.5 %). At the medium load (75 % 1RM), CAFF3mg did not improve SQ or BP muscle power or BP velocity. CAFF9mg was needed to enhance BP velocity and SQ power at the heaviest load (9 0% 1RM) and cycling PPO (6.8-11.7 %). The CAFF9mg trial drastically increased the frequency of the adverse side-effects (15-62 %). It was concluded that the ergogenic dose of caffeine required to enhance neuromuscular performance during a single all-out contraction depends on the magnitude of load used. A dose of 3 mg/kg is enough to improve high velocity muscle actions against low loads, whereas a higher caffeine dose (9 mg/kg) is necessary against high loads, despite the appearance of adverse side-effects [13436].

Coffee is the leading worldwide beverage after water and its trade exceeds USD10 billion worldwide. Controversies regarding its benefits and risks still exist as reliable evidence is becoming available supporting its health promoting potential; however, some researchers have argued about the association of coffee consumption with cardiovascular complications and cancer insurgence. The health-promoting properties of coffee are often attributed to its rich phytochemistry, including caffeine, chlorogenic acid, caffeic acid, hydroxyhydroquinone (HHQ), etc. Many research investigations, epidemiological studies, and meta-analyses regarding coffee consumption revealed its inverse correlation with that of diabetes mellitus, various cancer lines, Parkinsonism, and Alzheimer's disease. Moreover, it ameliorates oxidative stress because of its ability to induce mRNA and protein expression, and mediates Nrf2-ARE pathway stimulation. Furthermore, caffeine and its metabolites help in proper cognitive functionality. Coffee lipid fraction containing cafestol and kahweol act as a safeguard against some malignant cells by modulating the detoxifying enzymes. On the other hand, their higher levels raise serum cholesterol, posing a possible threat to coronary health, for example, myocardial and cerebral infarction, insomnia, and cardiovascular complications. Caffeine also affects adenosine receptors and its withdrawal is accompanied with muscle fatigue and allied problems in those addicted to coffee. An array of evidence showed that pregnant women or those with postmenopausal problems should avoid excessive consumption of coffee because of its interference with oral contraceptives or postmenopausal hormones. One review article was an attempt to disseminate general information, health claims, and obviously the risk factors associated with coffee consumption to scientists, allied stakeholders, and certainly readers [11198].

A large body of scientific evidence describes the beneficial effects of human caffeine consumption on a number of physiologic systems. The consumption of moderate amounts of caffeine [10498]:

1183
- increases energy availability
- increases daily energy expenditure
- decreases fatigue
- decreases the sense of effort associated with physical activity
- enhances physical performance
- enhances motor performance
- enhances cognitive performance
- increases alertness, wakefulness, and feelings of "energy"
- decreases mental fatigue
- quickens reactions
- increases the accuracy of reactions
- increases the ability to concentrate and focus attention
- enhances short-term memory
- increases the ability to solve problems requiring reasoning
- increases the ability to make correct decisions
- enhances cognitive functioning capabilities and neuromuscular coordination

Caffeine is a unique compound. It is a drug with no nutritive value so entrenched in our food supply that it enjoys social acceptance and widespread use by the majority of adults around the world. Its well-known effects of reducing fatigue and increasing alertness are prized by populations who need to prolong their capacity for occupational activities, for example, students studying for exams, shiftworkers, long-haul truck drivers, members of the military forces and athletes. In fact, new products such as non-prescription medications, “energy drinks”, confectionery and sports supplements containing caffeine or guarana are now being specifically manufactured to allow caffeine to be consumed as an ergogenic (work-enhancing) aid. Caffeine (C₈H₁₀N₄O₂) has been used as an aid to sports performance for more than a century and has been widely studied by exercise scientists for the past 40 years. From 1980 to 2003, it was included on the list of substances banned by the International Olympic Committee, with limits on urinary caffeine levels above which caffeine use would be deemed to be a doping offence. These levels were intended to discriminate the intake of large amounts of caffeine – typically, above 6–9 mg/kg of an athlete’s body mass (kg BM). In 2004, however, caffeine was removed from the list of prohibited substances and methods of the World Anti-Doping Agency, meaning that athletes who compete under this code can consume caffeine either in their background diets or for the specific purposes of performance enhancement without fear of sanctions. Several aspects of the relationship between caffeine and exercise are intriguing, and differ from the situation with other ergogenic aids. First, caffeine appears to exert positive effects on exercise capacity (prolonging the duration for which exercise of a given intensity can be maintained) over a diverse range of protocols including prolonged submaximal exercise (>90 min), sustained high-intensity work (20-60 min) and short duration supra-maximal exercise (1–5 min). Of course, athletes are more interested in the effects of caffeine in trained individuals on measurements of sports performance. A much smaller number of studies in laboratory and field conditions show that caffeine supplementation is likely to be beneficial across a range of sports including endurance events, “stop and go” events (e.g. team and racquet sports) and sports involving sustained high-intensity activity lasting from 1-60 min (e.g. swimming, rowing, middle and distance running races). The direct effects on single events involving strength and power such as lifts, throws and sprints are unclear. The benefits of caffeine appear to be achieved by a number of different protocols of use, with variables including the timing and amount of the caffeine dose. Although the traditional supplementation regimen involves a single intake of about 6 mg/kg BM, 1 h pre-exercise, one studies show that ergogenic effects from caffeine intake may occur at very modest levels of intake (1-3 mg/kg BM or 70–200 mg caffeine). In fact, several studies suggest there is no dose-response relationship between caffeine intake
and benefits to endurance exercise or, if it exists, there is a plateau at about 3 mg/kg or about 200 mg. The intake of caffeine from the traditionally available sources (coffee, tea and cola drinks) is typically around 50–150 mg of caffeine per serving. However, it is possible to find products that provide 300–500 mg of caffeine per serving. In terms of variations to the timing of intake of caffeine doses, it appears, at least in endurance sports, that caffeine can be consumed pre-event or as single or multiple doses spread throughout an exercise bout or just prior to the onset of fatigue. The effects of caffeine can be long lasting, with one study showing that people who ingest caffeine to enhance a morning exercise task may still receive benefits during a session undertaken later in the day [10174].

The effect caffeine elicits on endurance performance is well founded. However, comparatively less research has been conducted on the ergogenic potential of anaerobic performance. Some studies showing no effect of caffeine on performance used untrained subjects and designs often not conducive to observing an ergogenic effect. Recent studies incorporating trained subjects and paradigms specific to intermittent sports activity support the notion that caffeine is ergogenic to an extent with anaerobic exercise. Caffeine seems highly ergogenic for speed endurance exercise ranging in duration from 60 to 180 seconds. However, other traditional models examining power output (i.e. 30-second Wingate test) have shown minimal effect of caffeine on performance. Conversely, studies employing sport-specific methodologies (i.e. hockey, rugby, soccer) with shorter duration (i.e. 4-6 seconds) show caffeine to be ergogenic during high-intensity intermittent exercise. Recent studies show caffeine affects isometric maximal force and offers introductory evidence for enhanced muscle endurance for lower body musculature. However, isokinetic peak torque, one-repetition maximum and muscular endurance for upper body musculature are less clear. Since relatively few studies exist with resistance training, a definite conclusion cannot be reached on the extent caffeine affects performance. It was previously thought that caffeine mechanisms were associated with adrenaline (epinephrine)-induced enhanced free-fatty acid oxidation and consequent glycogen sparing, which is the leading hypothesis for the ergogenic effect. It would seem unlikely that the proposed theory would result in improved anaerobic performance, since exercise is dominated by oxygen-independent metabolic pathways. Other mechanisms for caffeine have been suggested, such as enhanced calcium mobilization and phosphodiesterase inhibition. However, a normal physiological dose of caffeine in vivo does not indicate this mechanism plays a large role. Additionally, enhanced Na+/K+ pump activity has been proposed to potentially enhance excitation contraction coupling with caffeine. A more favourable hypothesis seems to be that caffeine stimulates the CNS. Caffeine acts antagonistically on adenosine receptors, thereby inhibiting the negative effects adenosine induces on neurotransmission, arousal and pain perception. The hypoalgesic effects of caffeine have resulted in dampened pain perception and blunted perceived exertion during exercise. This could potentially have favourable effects on negating decreased firing rates of motor units and possibly produce a more sustainable and forceful muscle contraction. The exact mechanisms behind caffeine's action remain to be elucidated [09251].

Caffeine is the pharmacologically active substance found in tea, coffee, and cola. The amount of caffeine present varies according to the type of drink and the way it has been prepared. Caffeine may also be a constituent of some common medicines such as cold preparations and pain relief treatments, usually in quantities of less than 100 mg per dose. Caffeine produces mild CNS stimulation, similar to that of amphetamines, reducing fatigue and increasing concentration and alertness. Physiological effects include increased heart rate and output, metabolic rate, and urine production. High doses can cause anxiety, insomnia, and nervousness. In 2004 caffeine was removed from the list of prohibited substances and is now part of the monitoring programme [06171].
Caffeine is a naturally occurring plant alkaloid. It is classified as a methylxanthine. Other examples of methylxanthines include theophylline and theobromine. It is found in over 60 different plant species including Caffea arabica (coffee), Thea sinenis (tea), and Cola acuminata (cola). Caffeine is consumed in a variety of forms, including coffee, soft drinks, and chocolate. It is also found in a variety of over the counter stimulants, appetite suppressants, analgesics, and cold and sinus preparations. In fact, caffeine is the world’s most commonly used and widely consumed pharmacologic substance. Approximately 75 percent of caffeine is consumed in the form of coffee. In terms of international commerce, coffee is second only to oil in dollar amount traded. The US imports approximately 30% of the world’s coffee and Americans consume about 45 million pounds of coffee annually. Consumption of caffeine is actually higher in the United Kingdom and Scandinavian countries (400 mg/person/d compared with 238 mg/person/d in the United States) [06183].

History of coffee drinking

Caffeine has been consumed in the form of coffee since around 850 AD when its use was popularized in Egypt. Caffeine has long held interest as a potential ergogenic aid. In fact, the fatigue-masking effects of caffeine have been known since the early 1900s. Research in the late 1970s indicating improved exercise performance with caffeine popularized its use as a potential ergogenic aid [06183].

Presence of caffeine in society

Caffeine (1,3,7-trimethylxanthine) is one of the most consumed drugs in sports. A recent study has shown that 3 out of 4 elite athletes consume caffeine prior to competing, based on the post-exercise urinary caffeine concentrations of 20,686 urine samples obtained for doping analysis. However, the manner in which athletes consume caffeine is diverse. Caffeine is present in coffee and chocolate beans, tea leaves and cola nuts and so can be consumed from natural sources (coffee, tea, chocolate, etc). In addition, caffeine can be artificially synthesized and included in food and drinks, like the recently created energy drinks. These beverages contain moderate amounts of caffeine (32 mg/100 mL) in addition to carbohydrates, taurine, glucoronolactone and B- group vitamins. Due to their low cost, accessibility, and the relatively low frequency of deleterious side-effects derived from their consumption, caffeine-containing energy drinks have become the most popular supplement in the sports population, with a prevalence of 73 percent in American college athletes, 75 percent in Canadian Varsity athletes and 42 percent in British elite athletes [12274].

Caffeine is the most commonly consumed psychoactive drug in the world, and some of its behavioral effects (such as arousal) may resemble those produced by cocaine, amphetamines, and other stimulants. Coffee consumption accounts for about 75 percent of the adult intake of caffeine in the United States, although that might be changing among younger adults with the growing popularity of energy drinks. The caffeine content of coffee varies greatly, depending on the beans, how they're roasted, and other factors, but the average for an 8-ounce cup is about 100 milligrams (mg). Tea has about half as much caffeine as coffee. Decaffeinated coffee has some caffeine, but the 2 to 4 mg in an 8-ounce cup is a smidgen compared with the caffeinated version. The lethal dose of caffeine is about 10 grams, which is equivalent to the amount of caffeine in 100 cups of coffee. Caffeine gets absorbed in the stomach and small intestine and then distributed throughout the body, including the brain. The amount circulating in the blood peaks 30 to 45 minutes after it’s
ingested and only small amounts are around eight to 10 hours later. In between, the amount circulating declines as caffeine gets metabolized in the liver [12275].

**Epidemiology of use**

Caffeine is a proven ergogenic aid, increasing athletic performance, endurance, and mental chronometry at doses as low as 1-3 mg/kg. As coffee is a readily available and commonly ingested form of caffeine, the two are often equated. However, coffee also contains hundreds of other biologically active compounds, many of which are metabolically distinct from caffeine. The purpose of one review was to examine the prevalence of coffee and (or) caffeine consumption among elite Canadian athletes, and to delineate the effects of coffee and caffeine on physical activity, weight maintenance, performance, and metabolism. A total of 270 self-reported 3-day food records were examined for caffeine intake from athletes registered with Canadian Sport Centres in 2005 and 2006. Athletes ranged in age from 16-45 years, and competed in 38 different sports. Results showed that 30 percent of athletes ingested >1 mg/kg per day from a variety of sources. Average daily intake was 0.85 ± 13 mg/kg. Caffeine intake was not correlated with any one sport; the 10 highest caffeine users were athletes from 9 different sports, including skill, endurance, and power sports. No differences were noted for average caffeine ingestion between summer and winter sports. High caffeine intakes corresponded to coffee ingestion, with the 25 highest individual intakes (193-895 mg/day) from coffee drinkers. In summary, it could be concluded that the majority of high-level Canadian athletes consume dietary caffeine primarily in the form of coffee. However, levels consumed are insufficient to elicit performance enhancement. Potential detrimental effects of caffeine consumption on exercise performance include gastric upset, withdrawal, sleep disturbance, and interactions with other dietary supplements [08305].

**Self-reported consumption**

One study was undertaken to examine self-reported caffeine consumption and reasons for its use, amongst UK athletes, following its removal from the 2004 World Anti-Doping Agency (WADA) Prohibited List. A convenience sample of track and field athletes (n=193) and cyclists (n=287) completed a postal or Web-based questionnaire. Messages were posted on athletics and cycling club Web sites and mailing lists to direct athletes to the Web-based questionnaire. Postal questionnaires were distributed at domestic sporting events. A higher proportion of cyclists (60 %) compared with track and field athletes (33 %) consumed caffeine to enhance performance. A higher proportion of elite as opposed to sub-elite athletes representing cycling and athletics used caffeine to enhance performance. Of all caffeine containing products used, coffee, energy drinks, pharmaceutical preparations and caffeinated sports supplements were most prevalent. Results revealed that amongst UK athletes, the intention to use caffeine as an ergogenic aid was high, and that use was more widespread and accepted in competitive sport, especially at elite level, when compared to recreational sport [07164].

**Emergency medicine residents’ use of psychostimulants**

It was evaluated the frequency that emergency medicine house staff report use of stimulants and sedatives to aid in shift work and circadian transitions. It was surveyed residents from 12 regional emergency medicine programs inviting them to complete a voluntary, anonymous electronic questionnaire regarding their use of stimulants and sedatives. Out of 485 eligible residents invited to participate in the survey, 226 responded (47 % response frequency). The reported use of prescription stimulants for shift work is uncommon (3 % of respondents.) In
contrast, 201 residents (89%) report use of caffeine during night shifts, including 118 residents (52%) who use this substance every night shift. Eighty-six residents (38%) reported using sedative agents to sleep following shift work with the most common agents being anti-histamines (31%), nonbenzodiazepine hypnotics such as zolpidem (14%), melatonin (10%), and benzodiazepines (9%). It was concluded that emergency medicine residents report substantial use of several classes of hypnotics to aid in shift work. Despite anecdotal reports, use of prescription stimulants appears rare, and is notably less common than use of sedatives and non-prescription stimulants [11495].

Athletes’ knowledge of effects of caffeine

One descriptive cross-sectional study assessed the perceptions, knowledge, and experiences of caffeine use by athletes competing at the 2005 Ironman Triathlon World Championships. Questionnaires were distributed to 140 athletes (105 men and 35 women, 40 ± 11 years old) representing 16 countries during prerace registration. A large proportion (73%) of these endurance athletes believe that caffeine is ergogenic to their endurance performance, and 84 percent believe it improves their concentration. The most commonly reported positive caffeine experiences related to in-competition use of cola drinks (65%) and caffeineated gels (24%). The athletes’ ability to accurately quantify the caffeine content of common food items was limited. The most popular sources of caffeine information were self-experimentation (16%), fellow athletes (15%), magazines (13%), and journal articles (12%). Over half the athletes (53%) could not identify an amount of caffeine required to improve their triathlon performance. Mean (+/- standard deviation) suggested doses were 3.8 ± 3.0 mg/kg body weight. Few side effects associated with taking caffeine during exercise were reported [07165].

Factors influencing serum caffeine concentrations

To determine whether differences in training status, body composition and/or habitual caffeine intake influenced serum caffeine concentrations following caffeine ingestion trained cyclists/triathletes (n=14) and active (n=14) males consumed 6 mg/kg anhydrous caffeine were studied. Peak, total and time to peak serum caffeine concentrations were determined from venous blood samples at baseline and 6 time-points over 4 h following intake. Body composition was assessed by dual energy X-ray absorptiometry and habitual caffeine intake by a questionnaire. Trained cyclists/triathletes had 16 percent lower peak caffeine concentrations following caffeine ingestion compared to active individuals, although this was not statistically significant. There was no significant difference between trained cyclists/triathletes and active males in total or time to peak serum caffeine concentrations. Fat mass was significantly associated with total but not peak or time to peak serum caffeine concentration. There were no associations between habitual caffeine intake and peak, total or time to peak serum caffeine concentrations. It was concluded that following caffeine ingestion three findings from the study it was evident that endurance-trained athletes trended towards lower peak caffeine concentrations compared to active males; that higher fat mass was associated with higher concentrations of caffeine in the blood over 4h, and that habitual caffeine intake does not appear to influence serum caffeine concentrations. Identification of the optimal conditions to ensure peak availability of caffeine within the blood and/or overcoming some of the variation in how individuals respond to caffeine requires consideration of the training status and body composition of the athlete [0458].
Bioavailability of coffee

Coffee and green tea are two of the most widely consumed hot beverages in the world. Their respective bioavailability has been studied separately, but absorption of their respective bioactive phenolics has not been compared. In a randomised cross-over design, nine healthy subjects drank instant coffee and green tea. Blood samples were collected over 12 h and at 24 h to assess return to baseline. After green tea consumption, (-)-epigallocatechin (EGC) was the major catechin, appearing rapidly in the plasma; (-)-EGC gallate (EGCg) and (-)-epicatechin (EC) were also present, but (-)-EC gallate and C were not detected. Dihydroferulic acid and dihydrocaffeic acid were the major metabolites that appeared after coffee consumption with a long time needed to reach maximum plasma concentration, suggesting metabolism and absorption in the colon. Other phenolic acid equivalents (caffeic acid (CA), ferulic acid (FA) and isoferulic acid (iFA)) were detected earlier, and they peaked at lower concentrations. Summations of the plasma area under the curves (AUC) for the measured metabolites showed 1.7-fold more coffee-derived phenolic acids than green tea-derived catechins. Furthermore, it was found a significant correlation between coffee metabolites based on AUC. Inter-individual differences were observed, but individuals with a high level of CA also showed a correspondingly high level of FA. However, no such correlation was observed between the tea catechins and coffee phenolic acids. Correlation between AUC and maximum plasma concentration was also significant for CA, FA and iFA and for EGCg. This implies that the mechanisms of absorption for these two classes of compounds are different, and that a high absorber of phenolic acids is not necessarily a high absorber of catechins [10501].

Caffeine dosages versus effects

Athletes are among the groups of people who are interested in the effects of caffeine on endurance and exercise capacity. Although many studies have investigated the effect of caffeine ingestion on exercise, not all are suited to draw conclusions regarding caffeine and sports performance. Characteristics of studies that can better explore the issues of athletes include the use of well-trained subjects, conditions that reflect actual practices in sport, and exercise protocols that simulate real-life events. There is a scarcity of field-based studies and investigations involving elite performers. Researchers are encouraged to use statistical analyses that consider the magnitude of changes, and to establish whether these are meaningful to the outcome of sport. The available literature that follows such guidelines suggests that performance benefits can be seen with moderate amounts (~3 mg/kg body mass) of caffeine. Furthermore, these benefits are likely to occur across a range of sports, including endurance events, stop-and-go events (e.g. team and racquet sports), and sports involving sustained high-intensity activity lasting from 1-60 min (e.g. swimming, rowing, and middle and distance running races). The direct effects on single events involving strength and power, such as lifts, throws, and sprints, are unclear. Further studies are needed to better elucidate the range of protocols (timing and amount of doses) that produce benefits and the range of sports to which these may apply. Individual responses, the politics of sport, and the effects of caffeine on other goals, such as sleep, hydration, and refuelling, also need to be considered [08304].

The most common form of caffeine consumption is coffee. One cup of coffee contains approximately 100 mg of caffeine. This is the same dosage of caffeine that is contained in most over the counter preparations that are used for promoting wakefulness. Soft drinks are another common form of caffeine consumption. Levels vary depending on the type of soft drink. A 12-oz Coca-Cola can contains approximately 45.6 mg of caffeine, a 12-oz glass of
iced tea contains approximately 70 mg of caffeine. The average American consumes about 200 mg of caffeine daily; adults average about 2.4 mg/kg/d whereas children average about 1.1 mg/kg/d. Interestingly, studies have shown that caffeine can produce its ergogenic potential at doses much less than 800 mg, probably as low as 250 mg. Most studies that show ergogenic potential of caffeine have used dosages of around 400 to 600 mg of caffeine which is equivalent to the amount of caffeine in four to six cups of coffee. A dose of 100 mg of caffeine (equivalent to one cup of coffee) will produce a urine concentration of approximately 1.5 mg/mL. Caffeine content (mg) of common substances in 2005 [06183]:

**Duration of effect**

It appears that the ergogenic effect of caffeine occurs regardless of the timing of intake (either before or during the event). The effect of caffeine intake appears to be prolonged to as much as 6 hours following ingestion. This ergogenic effect is seen at a similar magnitude with both a one-time ingestion prior to exercise as well as with multiple smaller, but equal dosages given throughout a period of prolonged exercise. An interesting finding is that the ergogenic effect of caffeine is more pronounced in nonusers (< 50 mg daily) compared with regular users (> 300 mg daily) of caffeine. This is most likely explained by the upregulation of adenosine receptors with the regular consumption of caffeine [06183].

**Administration mode**

In the majority of studies that look at caffeine as an ergogenic aid, the caffeine is consumed in capsule form. It was looked at the ergogenic potential of caffeine ingested in the form of coffee. The plasma concentrations of caffeine were similar whether ingested in the form of coffee or capsule. However, enhancement of endurance was seen only when caffeine was consumed independent of coffee. Likely, there are substances in coffee that antagonize the ergogenic potential of caffeine. Another source of caffeine that has been studied in terms of its ergogenic potential is caffeinated soft drinks. There is a practice among some endurance athletes to use a “defizzed” soft drink as a replacement for sports drinks during the latter stages of such events, believing that the caffeine intake produces an ergogenic effect. A study out of Australia suggests that the use of Coca-Cola produces an ergogenic effect similar to that of more conventional forms of caffeine intake. These findings are of undetermined significance, however, as the dose of caffeine consumed through Coca-Cola in this study are less than dosages of caffeine previously proven to be ergogenic [06183].

**Dosage versus endurance cycle time**
One study investigated the effects of two different doses of caffeine on endurance cycle time trial performance in male athletes. Using a randomised, placebo-controlled, double-blind crossover study design, sixteen well-trained and familiarised male cyclists (age 32 years) completed three experimental trials, following training and dietary standardisation. Participants ingested either a placebo, or 3 or 6 mg/kg body mass of caffeine 90 min prior to completing a set amount of work equivalent to 75 percent of peak sustainable power output for 60 min. Exercise performance was significantly improved with both caffeine treatments as compared to placebo (4.2 % with 3 mg/kg body mass and 2.9 % with 6 mg/kg body mass). The difference between the two caffeine doses was not statistically significant. Caffeine ingestion at either dose resulted in significantly higher heart rate values than the placebo conditions, but no statistically significant treatment effects in ratings of perceived exertion (RPE) were observed. A caffeine dose of 3 mg/kg body mass appears to improve cycling performance in well-trained and familiarised athletes. Doubling the dose to 6 mg/kg body mass does not confer any additional improvements in performance [12291].

Use as a flavor

Over 60 percent of soft-drinks sold in the United States contain caffeine, a mildly addictive psycho-active chemical, as a flavor additive. Using sweeteners as controls, we assessed whether caffeine has flavor activity in a cola soft-drink. A forced-choice triangle discrimination methodology was used to determine detection thresholds of caffeine in sweeteners and a cola beverage. The subjects (n=30, 28 female, 23 years old) were trained tasters and completed over 1600 discrimination tests during the study. The mean detection thresholds for caffeine in the sweet solutions were: 0.333 ± 0.1mM sucrose; 0.467 ± 0.29 mM aspartame; 0.462+/−0.3mM sucralose, well below the concentration in common cola beverages (0.55-0.67 mM). A fixed concentration of caffeine, corresponding to the concentration of caffeine in a common cola beverage (0.67 mM) was added to the sweeteners and a non-caffeinated cola beverage. Subjects could distinguish between caffeinated and non-caffeinated sweeteners, but all subjects failed to distinguish between caffeinated and non-caffeinated cola beverage. Caffeine has no flavor activity in soft-drinks yet will induce a physiologic and psychologic desire to consume the drink [06184].

Potential adverse effects

Caffeine can potentially cause some adverse effects. Reported effects at moderate doses include locomotor agitation, tachycardia, diuresis, insomnia, irritability, and increased anxiety. Severe caffeine toxicity has been linked to seizures and arrhythmias. In addition, it has been well documented that caffeine produces a withdrawal syndrome with cessation of repeated use. This can occur even with repeated usage at low dosages. Studies have demonstrated that withdrawal symptoms can occur with cessation of caffeine use for a short time period as soon as 3 days after administration in novel users and as soon as 12 hours in habitual users. Common symptoms of caffeine withdrawal include headache, irritability, increased fatigue, drowsiness, decreased alertness, difficulty concentrating, and decreased energy and activity levels. Symptoms can be mild to moderate in severity. Fortunately, withdrawal symptoms are generally short-lived. Several studies have shown that caffeine can increase core body temperature. Increased diuresis with a concomitant decrease in body weight has also been demonstrated after administration of caffeine [06183].

Addiction

The common-sense use of the term addiction is that regular consumption is irresistible and that it creates problems. Caffeine use does not fit this profile. Its intake does no harm to the
individual or to society and its users are not compelled to consume it. Though cessation of regular use may result in symptoms such as headache and lethargy, these are easily and reliably reversed by ingestion of caffeine. Some have argued that continued caffeine use is an attempt to suppress low grade withdrawal symptoms such as sleepiness and lethargy. In some moderate users, this is possible; however, in experimental contexts, the phenomenon is too inconsistent to constitute a reliably valid syndrome [06185].

Caffeine and ephedra
Unfortunately, there have been multiple deaths linked to the use of caffeine in combination with ephedra. It is felt that, when used in combination, the potential deadly effects are secondary to ephedra, rather than caffeine. However, the cardiovascular effects of ephedra are likely increased with concomitant stimulant use (e.g. caffeine). In fact, based on this evidence, ephedra was banned by the US Food and Drug Administration in 2004. None of the reported deaths were linked to the use of caffeine alone [06183].

Acceleration of caffeine metabolism of tobacco and cannabis
Tobacco and marijuana accelerate caffeine metabolism, which reduces the time caffeine circulates in the body. Oral contraceptives slow it down, so they have the opposite effect. Researchers have identified genes that influence a person’s natural risk of caffeine metabolism, which might explain why some people are exquisitely sensitive to caffeine while others are not [12275].

Overview of physiological effects of caffeine in health and disease
Caffeine probably has multiple targets in the brain, but the main one seems to be adenosine receptors. Adenosine is a brain chemical that dampens brain activity. By hogging adenosine’s receptors, caffeine sets off a chain of events that affects the activity of dopamine, another important brain chemical, and the areas of the brain involved in arousal, pleasure, and thinking. A part of the brain affected by Parkinson’s disease, called the striatum, has many adenosine receptors; by docking on them, caffeine seems to have some protective effects. Outside the brain, caffeine can be a performance enhancer, boosting the strength of muscle contraction and offsetting some of the physiological and psychological effects of physical exertion. But, especially in the short term, it also has negative effects, which include raising blood pressure, making arteries stiffer, and increasing levels of homocysteine, insulin, and possibly cholesterol. Habitual use may cause some of these effects to wear off. For some conditions, though, coffee may have some benefit despite, rather than because of, caffeine [12275].

Caffeine has been studied more than any other ingredient in coffee, and it tends to get credit if the body part benefited is the brain. But coffee contains literally a thousand different substances, and some of the lesser lights are thought to be responsible for healthful effects in other parts of the body. Some studies show caffeinated and decaffeinated coffee as having the same effect, which suggests that something else in coffee is involved. It gets complicated, though. Caffeine and some of these other substances in coffee seem to have their good and bad sides, and coffee’s overall effect may depend on how much they cancel each other out [12275]:

</tbody>
</table>
and anti-inflammatory substances could be responsible for possible anticancer activity.

**Diabetes**

Effects on insulin and blood sugar levels that would promote diabetes seem to be temporary. Regular use is associated with lower risk, and high intake (3-6 cups a day) seems to have a greater effect. Protection may come from increases in the hormone adiponectin and other factors that affect insulin and blood sugar levels.

Coffee drinking increases some factors (homocysteine) associated with higher risk. But moderate consumption (1-3 cups a day) has been linked to a small decrease in risk. The evidence for a possible protective effect is stronger for women.

Coffee drinking is associated with lower levels of enzymes that indicate liver damage and inflammation. Coffee may improve response to some treatments for hepatitis C. Findings suggest some protection against liver cancer. Cafestol and kahweol, substances found in unfiltered coffee, may be responsible for liver benefits.

**Heart attack**

Coffee drinking increases some factors (homocysteine) associated with higher risk. But moderate consumption (1-3 cups a day) has been linked to a small decrease in risk. The evidence for a possible protective effect is stronger for women.

Coffee drinking is associated with lower levels of enzymes that indicate liver damage and inflammation. Coffee may improve response to some treatments for hepatitis C. Findings suggest some protection against liver cancer. Cafestol and kahweol, substances found in unfiltered coffee, may be responsible for liver benefits.

**Liver disease**

Coffee drinking is associated with lower levels of enzymes that indicate liver damage and inflammation. Coffee may improve response to some treatments for hepatitis C. Findings suggest some protection against liver cancer. Cafestol and kahweol, substances found in unfiltered coffee, may be responsible for liver benefits.

**Parkinson's disease**

Studies show a moderate (25%) decrease in risk for coffee drinkers. The effect is less in women. Research has found evidence of activity in the part of the brain affected by Parkinson's.

Moderate consumption (3-4 cups a day) is associated with lower risk. But chance of a stroke may increase immediately after intake, particularly among infrequent consumers.

---

**Physiological effects of caffeine**

Caffeine's physiologic effects on the body have been well studied. Caffeine is metabolized through the liver via the cytochrome P450 enzyme system. It is rapidly absorbed through the gastrointestinal tract, with approximately 90 percent cleared from the stomach within 20 minutes. Peak plasma concentrations of caffeine are achieved in 40 to 60 minutes. Its half-life is approximately 3 to 5 hours. Caffeine is lipophilic and readily crosses most bodily membranes. It crosses to blood-brain barrier (BBB) and also crosses the placenta. Caffeine has been theorized to exert its effects through fat oxidation, central nervous system (CNS) stimulation, and direct action at skeletal muscle. There are several purported mechanisms for these effects including antagonism of adenosine receptors, inhibition of cyclic AMP, phosphodiesterase activity, increased calcium mobilization, and antagonism of benzodiazepine receptors. Caffeine has been reported to increase lipolysis throughout the body with a resultant increase in plasma free fatty acid levels. It is thought that by having increased levels of fatty acids available for use by the body, muscle glycogen can be spared. Current research suggests that the main mechanism responsible for the physiologic effects of caffeine is blockade of CNS adenosine receptors. Because it easily crosses the BBB, caffeine can readily have an effect on the CNS. The dosage of caffeine required to block adenosine receptors is much less than that required for caffeine to perform most of the other theorized physiologic mechanisms. A study using laboratory animals compared the results of centrally administered caffeine (adenosine antagonist) with 5'-N-ethylcarboxamidoadenosine (NECA), an adenosine agonist. Caffeine improved run time to fatigue whereas NECA reduced it. Administration of caffeine peripherally failed to produce the same effect. Adenosine is a modulator of CNS neurotransmission. It is a potent vasodilator. It also decreases catecholamine release and inhibits lipolysis. Caffeine nonselectively blocks adenosine receptors, thus competitively inhibiting the action of adenosine. Upregulation of these receptors occurs with regular consumption of caffeine [06183].
Caffeine produces its effect on various systems throughout the body. In the cardiovascular system, caffeine acts to increase heart rate and blood pressure. There is a positive relationship with caffeine consumption (in the form of coffee intake) and elevated systolic blood pressure. The extent of blood pressure elevation appears to depend on the individual's baseline blood pressure. Studies have shown that individuals with diagnosed hypertension have a greater increase in blood pressure in response to caffeine than do normotensive individuals. These effects are additive to that of other pressor agents, including cigarette smoking and psychologic stress. Caffeine may also increase the incidence of premature ventricular contractions (PVCs). Although these hemodynamic effects are similar despite gender, the underlying mechanism appears to differ slightly when comparing men and women. Men given caffeine show an increase in vascular resistance with no effect on cardiac output. However, women given similar amounts of caffeine show no difference in vascular resistance. There is an increase in stroke volume, which results in an increased cardiac output, which accounts for the hemodynamic changes that are seen. There is speculation that this effect may be due to estrogen effects, but has not been proven. In the respiratory system, caffeine produces bronchial dilation and relaxation of pulmonary smooth muscle. It also increases respiratory rate. In neonates, caffeine is used as a respiratory stimulant to prevent apneic episodes. Interestingly, caffeine ingestion potentiates the slowed reaction time that is induced by alcohol consumption. Therefore, the popularly held belief that coffee is an "antidote" for alcohol intoxication is false [06183].

**Effect on EMG frequency variables**

The ergogenic effect of caffeine and its mechanism of action on short-term, high-intensity exercise are controversial. One proposed mechanism is caffeine's stimulatory effect on the central nervous system and thus, motor-unit excitation. The latter is non-invasively determined from surface electromyographic signal (EMG) frequency measures. The purpose of this study was to determine if power output and surface EMG frequency variables during high-intensity cycling were altered following caffeine ingestion. Eighteen recreationally active college males (mean age, 22) performed the Wingate test (WG) after ingestion of gelatin capsules containing either placebo (PL; dextrose) or caffeine (CAFF; 5 mg/kg body mass). The trials were separated by 1 week and subjects were asked to withdraw from all caffeine-containing products for 48 h before each trial. From the resulting power-time records, peak power (PP; highest power output in 5 s), minimum power (MP; lowest power output in 5 s), and the percent decline in power (Pd) were calculated. Surface EMG records of the right vastus lateralis (VL) and the gastrocnemius (GA) muscles corresponding to the PP and MP periods were collected and used to determine the integrated electromyogram (IEMG), the mean (MNPF), and the median (MDPF) of the signal's power spectrum. A 2-way repeated measures analysis of variance (ANOVA) (treatment x time) was conducted to determine the effect of caffeine on these variables across levels of time. Caffeine ingestion had no effect on PP, MP, or the Pd compared with the placebo. For both muscles, MNPF and MDPF diminished significantly across time and to a similar degree in both the CAFF and PL trials. Regardless of muscle, CAFF had no effect on the percent change in IEMG from the first 5 s to the last 5 s. For both treatments, the GA displayed a significantly greater pre versus post percent decline in the EMG signal amplitude compared with the VL. These results indicate that caffeine does not impact power output during a 30 s high-intensity cycling bout. Furthermore, these data suggest that caffeine does not impact the neuromuscular drive as indicated by the similar IEMG scores between treatments. Similarly, caffeine does not seem to impact the frequency content of the surface EMG signal and thus the nature of recruited motor units before and after the expression of fatigue. The lack of decline in the IEMG in the VL despite the decline in power output over the course of the WG suggests a peripheral as
opposed to a neural mechanism of fatigue in this muscle. The significant difference in the pre vs. post percent decline in the GA IEMG score further supports this notion. The pre versus post decline in the IEMG noted in the GA may suggest a fatigue-triggered change in pedaling mechanics that may promote dominance of knee extensors with less reliance on plantar flexors [06186].

Effect on energy expenditure

PA energy expenditure (PAEE) is the most variable component of Total Energy Expenditure (TEE) and largely due to the balance of sedentary time (SedT) and low intensity physical activity (LIPA). There has been an emergence for seeking an understanding of factors which determine variations in SedT, LIPA, and PAEE. Sedentary behavior and physical activity are relatively resistant to change by experimental dietary treatments and significant body weight changes. Although caffeine (Caf) is by far the most heavily used nutritional agent ingested to promote a sense of vigor/alertness, it is still unknown if Caf is effective in increasing PAEE and physical activity. The aim of the study was to test the hypothesis that 2 daily doses of Caf (as a capsule to blind the treatment and divided equally during breakfast and lunch) increase PAEE and TEE, and it would do so through increasing the frequent and brief bouts of physical activity (1-5 min long) through the day as measured by accelerometry. In 21 low Caf users (<100 mg/day), it was used a double-blind crossover trial with two conditions (4-day each with a 3-day washout period) randomly ordered as 5 mg/kg/day of Caf and maltodextrin as placebo (Plc). Resting energy expenditure (REE) by indirect calorimetry, total energy expenditure (TEE) from doubly labeled water, PAEE calculated as TEE-(REE+0.1TEE), and accelerometry measurements of both LIPA and MVPA were not different between conditions. However, regardless of caffeine or placebo, there were several significant relationships between brief bouts of LIPA and MVPA with PAEE. In conclusion, this double-blind study found that low and moderate-vigorous activity as well as the total volume of PAEE in free-living conditions is resistant to dietary caffeine intake that was equivalent to 5 cups of espresso or 7 cups of tea [13449].

Effect on glucose homeostasis

Caffeine is a substance that has been used in our society for generations, primarily for its effects on the central nervous system that causes wakefulness. Caffeine supplementation has become increasingly more popular as an ergogenic aid for athletes and considerable scientific evidence supports its effectiveness. Because of their potential to alter energy metabolism, the effects of coffee and caffeine on glucose metabolism in diabetes have also been studied both epidemiologically and experimentally. Predominantly targeting the adenosine receptors, caffeine causes alterations in glucose homeostasis by decreasing glucose uptake into skeletal muscle, thereby causing elevations in blood glucose concentration. Caffeine intake has also been proposed to increase symptomatic warning signs of hypoglycemia in patients with type 1 diabetes and elevate blood glucose levels in patients with type 2 diabetes. Other effects include potential increases in glucose counterregulatory hormones such as epinephrine, which can also decrease peripheral glucose disposal. Despite these established physiological effects, increased coffee intake has been associated with reduced risk of developing type 2 diabetes in large-scale epidemiological studies. One review highlighted the known effects of caffeine on glucose homeostasis and diabetes metabolism during rest and exercise [13450].

Molecular effects
Caffeine activates 5’AMP-activated protein kinase (AMPK), a signalling intermediary implicated in the regulation of glucose, lipid, and energy metabolism in skeletal muscle. Skeletal muscle expresses two catalytic alpha subunits of AMPK, alpha1 and alpha2, but the isoform specificity of caffeine-induced AMPK activation is unclear. The aim of one study was to determine which alpha isoform is preferentially activated by caffeine in vitro and in vivo using rat skeletal muscle. Rat epitrochlearis muscle was isolated and incubated in vitro in the absence or presence of caffeine. In another experiment, the muscle was dissected after intravenous injection of caffeine. Isoform-specific AMPK activity, the phosphorylation status of AMPKalpha Thr(172) and acetyl-CoA carboxylase (ACC) Ser(79), the concentrations of ATP, phosphocreatine (PCr), and glycogen, and 3-O-methyl-d-glucose (3MG) transport activity were estimated. Incubation of isolated epitrochlearis muscle with 1 mM of caffeine for 15 min increased AMPKalpha1 activity, but not AMPKalpha2 activity; concentrations of ATP, PCr and glycogen were not affected. Incubation with 3 mM of caffeine activated AMPKalpha2 and reduced PCr and glycogen concentrations. Incubation with 1 mM of caffeine increased the phosphorylation of AMPK and ACC and enhanced 3MG transport. Intravenous injection of caffeine (5 mg/kg) predominantly activated AMPKalpha1 and increased 3MG transport without affecting energy status. The results suggest that of the two alpha isoforms of AMPK, AMPKalpha1 is predominantly activated by caffeine via an energy-independent mechanism and that activation of AMPKalpha1 increases glucose transport and ACC phosphorylation in skeletal muscle [10388].

Studies have proposed that caffeine-induced activation of glucose transport in skeletal muscle is independent of AMP-activated protein kinase (AMPK) because alpha-AMPK Thr172 phosphorylation was not increased by caffeine. However, previous studies, as well as the present, show that AMPK phosphorylation measured in whole muscle lysate is not a good indicator of AMPK activation in rodent skeletal muscle. In lysates from incubated rat soleus muscle, a predominant model in previous caffeine studies, both acetyl-CoA carboxylase-beta (ACCbeta) Ser221 and immunoprecipitated alpha1-AMPK activity increased with caffeine incubation, without changes in AMPK phosphorylation or immunoprecipitated alpha2-AMPK activity. This pattern was also observed in mouse soleus muscle, where only ACCbeta and alpha1-AMPK phosphorylation were increased following caffeine treatment. Preincubation with the selective CaMKK inhibitor STO-609 (5 microM), the CaM-competitive inhibitor KN-93 (10 microM), or the SR Ca\(^{2+}\) release blocking agent dantrolene (10 microM) all inhibited ACCbeta phosphorylation and alpha1-AMPK phosphorylation, suggesting that SR Ca\(^{2+}\) release may work through a CaMKK-AMPK pathway. Caffeine-stimulated 2-deoxyglucose (2DG) uptake reflected the AMPK activation pattern, being increased with caffeine and inhibited by STO-609, KN-93, or dantrolene. The inhibition of 2DG uptake is likely causally linked to AMPK activation, since muscle-specific expression of a kinase-dead AMPK construct greatly reduced caffeine-stimulated 2DG uptake in mouse soleus. It was concluded that a SR Ca\(^{2+}\)-activated CaMKK may control alpha1-AMPK activation and be necessary for caffeine-stimulated glucose uptake in mouse soleus muscle [07166].

Caffeine most likely exerts its performance enhancing effect on the human body mainly by five mechanisms:

- Antagonism of adenosine. Due to its close chemical resemblance of adenosine, caffeine blocks adenosine receptors (mainly A\(_1\) and A\(_2A\) receptor subtypes), thereby competitively inhibiting its action. Caffeine can decrease cerebral blood flow as well as antagonize A\(_1\), A\(_2A\) and A\(_2B\) adenosine receptors in blood vessels, thereby reducing adenosine-mediated vasodilation and consequently decrease myocardial blood flow.
- Increased fatty acid oxidation: increased lipolysis leads to decreased reliance on glycogen use. Caffeine switches the substrate preference from glycogen to fat by...
increasing hormone sensitive lipase (HSL) activity and inhibition of glycogen phosphorylase activity.

- Caffeine acts as a nonselective competitive inhibitor of the phosphodiesterase enzymes. Phosphodiesterases hydrolyze the phosphodiesterase bond in molecules such as cyclic adenosine monophosphate (cAMP), inhibiting the breakdown of cAMP. cAMP activates lipolysis by activating HSL and is an important molecule in the epinephrine cascade. It further activates protein kinase A, which in turn can phosphorylate a number of enzymes involved in glucose and lipid metabolism.

- Increased post-exercise muscle glycogen accumulation: enhanced recovery by increased rate of glycogen resynthesis following exercise. It has been reported that caffeine ingestion has no effect on glycogen accumulation during recovery in recreationally active individuals, but it has also been reported that caffeine (8 mg/kg body weight) co-ingested with carbohydrates (CHO) increases rates of postexercise muscle glycogen accumulation compared with consumption of CHO alone in well-trained athletes after exercise-induced glycogen depletion. Although this issue needs further study in different populations (untrained, trained) and at different time points (during exercise or recovery), caffeine added to postexercise CHO feeding seems to have the potential to improve glycogen resynthesis.

- Mobilization of intracellular calcium: It has been shown that caffeine can enhance calcium release from the sarcoplasmic reticulum and can also inhibit its reuptake. Via this mechanism, caffeine can enhance contractile force during submaximal contractions in habitual and nonhabitual caffeine consumers. Intracellular calcium favors the activation of endothelial nitric oxide synthase, which increases nitric oxide. Some of the ergogenic effects of caffeine might therefore as well be mediated partly by effecting the neuromuscular system and increasing contractile force. There is, however, still controversy about the translation of results from in vitro studies on muscle preparations to caffeine dose and calcium release in vivo.

As for many pharmacological substances, there is generally more than one potential mechanism explaining the ergogenic effects. This is also true for caffeine which might affect both the central nervous system (CNS) and skeletal muscle. Although questionable, a potential downside is that caffeine also has diuretic properties which can exert ergolytic effects during prolonged endurance events. Caffeine intake at very high doses (>500-600 mg or four to seven cups per day) can cause restlessness, tremor and tachycardia [13008].

**Blocking of adenosine receptors**

Caffeine, the most widely used psychoactive compound, is an adenosine receptor antagonist. It promotes wakefulness by blocking adenosine A(2A) receptors (A(2A)Rs) in the brain, but the specific neurons on which caffeine acts to produce arousal have not been identified. Using selective gene deletion strategies based on the Cre/loxP technology in mice and focal RNA interference to silence the expression of A(2A)Rs in rats by local infection with adeno-associated virus carrying short-hairpin RNA, it was reported that the A(2A)Rs in the shell region of the nucleus accumbens (NAc) are responsible for the effect of caffeine on wakefulness. Caffeine-induced arousal was not affected in rats when A(2A)Rs were focally removed from the NAc core or other A(2A)R-positive areas of the basal ganglia. The observations suggest that caffeine promotes arousal by activating pathways that traditionally have been associated with motivational and motor responses in the brain [13343].

**Coffee polyphenol caffeic acid**
Chlorogenic acid is an ester of caffeic and quinic acids, and is one of the most widely consumed polyphenols because it is abundant in foods, especially coffee. We explored whether chlorogenic acid and its metabolite, caffeic acid, act directly on skeletal muscle to stimulate 5’-adenosine monophosphate-activated protein kinase (AMPK). Incubation of rat epitrochlearis muscles with Krebs buffer containing caffeic acid (≥0.1 mM, ≥30 min) but not chlorogenic acid increased the phosphorylation of AMPKαThr(172), an essential step for kinase activation, and acetyl CoA carboxylase Ser(79), a downstream target of AMPK, in a dose- and time-dependent manner. Analysis of isoform-specific AMPK activity revealed that AMPKα2 activity increased significantly, whereas AMPKα1 activity did not change. This enzyme activation was associated with a reduction in phosphocreatine content and an increased rate of 3-O-methyl-d-glucose transport activity in the absence of insulin. These results suggest that caffeic acid but not chlorogenic acid acutely stimulates skeletal muscle AMPK activity and insulin-independent glucose transport with a reduction of the intracellular energy status [12287].

**Analgesic effect**

Another reason for the widespread use of caffeine within the exercise community might be its small but significant analgesic effect, possibly mediated by augmenting plasma endorphin concentrations. It is also established that caffeine reduces the rate of perceived exertion during exercise, suggesting that athletes are able to sustain higher intensities but do not perceive this effort to be different from placebo conditions [13008].

**Users versus non-users**

Some studies used caffeine-naïve whereas others used caffeine-habituated subjects. There seems to be a higher increase in plasma adrenalin in caffeine-naïves compared to caffeine habituated subjects after caffeine ingestion. However, no differences between habitual caffeine intake and 1500 m running performance or force of contraction could be observed. For both caffeine-naïve as well as caffeine-habituated subjects, moderate to high doses of caffeine are ergogenic during prolonged moderate intensity exercise. Although there is clearly the need to study caffeine habituation further, the differences between users and non-users do not seem to be major [13008].

**Metabolism**

Caffeine, theophylline, theobromine, and paraxanthine administered to animals and humans distribute in all body fluids and cross all biological membranes. They do not accumulate in organs or tissues and are extensively metabolized by the liver, with less than 2 percent of caffeine administered excreted unchanged in human urine. Dose-independent and dose-dependent pharmacokinetics of caffeine and other dimethylxanthines may be observed and explained by saturation of metabolic pathways and impaired elimination due to the immaturity of hepatic enzyme and liver diseases. While gender and menstrual cycle have little effect on their elimination, decreased clearance is seen in women using oral contraceptives and during pregnancy. Obesity, physical exercise, diseases, and particularly smoking and the interactions of drugs affect their elimination owing to either stimulation or inhibition of CYP1A2. Their metabolic pathways exhibit important quantitative and qualitative differences in animal species and man. Chronic ingestion or restriction of caffeine intake in man has a small effect on their disposition, but dietary constituents, including broccoli and herbal tea, as
well as alcohol were shown to modify their plasma pharmacokinetics. Using molar ratios of metabolites in plasma and/or urine, phenotyping of various enzyme activities, such as cytochrome monooxygenases, N-acetylation, 8-hydroxylation, and xanthine oxidase, has become a valuable tool to identify polymorphisms and to understand individual variations and potential associations with health risks in epidemiological surveys [11200].

**M mobilization of fat**

Part of caffeine's intrigue is that we still do not know the exact mechanism by which it enhances performance, with a number of effects on different body tissues being possible. Furthermore, individuals respond differently to caffeine (as with many drugs), across a range from positive to negative outcomes, and some tissues become tolerant to repeated caffeine use, while others do not. The potentially beneficial effects of caffeine include the mobilisation of fat from adipose tissue and the muscle cell, stimulation of the release and activity of adrenaline, effects on cardiac muscle, direct changes to muscle contractility and alterations to the central nervous system to change perceptions of effort or fatigue. Most scientists believe that the last factor is the most important and consistent factor in explaining performance enhancement. Recent evidence has changed our perspective on two of the widely promoted effects of caffeine. Whereas caffeine was believed to enhance endurance performance via increased utilisation of fat as an exercise fuel and reduced use of the limited muscle stores of glycogen, studies now show that the effect of caffeine on "glycogen sparing" during submaximal exercise is short-lived and inconsistent. It is often warned that caffeine-containing drinks have a diuretic effect and will cause an athlete to become dehydrated. In fact, small to moderate doses of caffeine have minor effects on urine losses or the overall hydration in people who are habitual caffeine users. In addition, caffeine-containing drinks such as tea, coffee and cola drinks provide a significant source of fluid in the everyday diets of many people [10174].

**Effects on performance after a fat meal**

One study examined the effects of caffeine, co-ingested with a high fat meal, on perceptual and metabolic responses during incremental (experiment 1) and endurance (experiment 2) exercise performance. Trained participants performed three constant-load cycling tests at approximately 73 percent of maximal oxygen uptake (VO$_{2\text{max}}$) for 30 min at 20 degrees C (experiment 1, n=8) and to the limit of tolerance at 10 degrees C (experiment 2, n=10). The 30 min constant-load exercise in experiment 1 was followed by incremental exercise (15 W/min) to fatigue. Four hours before the first test, the participants consumed a 90 percent carbohydrate meal (control trial); in the remaining two tests, the participants consumed a 90% fat meal with (fat + caffeine trial) and without (fat-only trial) caffeine. Caffeine and placebo were randomly assigned and ingested 1 h before exercise. In both experiments, ratings of perceived leg exertion were significantly lower during the fat + caffeine than fat-only trial. Ratings of perceived breathlessness were significantly lower in experiment 1 and heart rate higher in experiment 1 on the fat + caffeine than fat-only trial. In the two experiments, oxygen uptake, ventilation, concentration on blood glucose, lactate and plasma glycerol were significantly higher on the fat + caffeine than fat-only trial. In experiment 2, concentration of plasma free fatty acids, blood pyruvate and the lactate to pyruvate ratio were significantly higher on the fat + caffeine than fat-only trial. Time to exhaustion during incremental exercise and constant-load exercise was not different between the fat-only and fat + caffeine trials. In conclusion, while a number of metabolic responses were increased during exercise after caffeine ingestion, perception of effort was reduced and this may be attributed to the direct stimulatory effect of caffeine on the central nervous system. However,
this caffeine-induced reduction in effort perception did not improve exercise performance [06199].

Effects on blood pressure

The effect of coffee and caffeine on blood pressure (BP) and cardiovascular disease (CVD) in hypertensive persons is uncertain. The objective of one study was to summarize the evidence on the acute and longer-term effects of caffeine and coffee intake on BP and on the association between habitual coffee consumption and risk of CVD in hypertensive individuals. A systematic review and meta-analysis of publications identified in a PubMed and EMBASE search up to 30 April 2011 was undertaken. Data were extracted from controlled trials on the effect of caffeine or coffee intake on BP change and from cohort studies on the association between habitual coffee consumption and CVD. In 5 trials, the administration of 200–300 mg caffeine produced a mean increase of 8.1 mm Hg (95 % confidence interval 5.7 to 10.6 mm Hg) in systolic BP and of 5.7 mm Hg (95 % confidence interval: 4.1 to 7.4 mm Hg) in diastolic BP. The increase in BP was observed in the first hour after caffeine intake and lasted ≥3 h. In 3 studies of the longer-term effect (2 weeks) of coffee, no increase in BP was observed after coffee was compared with a caffeine-free diet or was compared with decaffeinated coffee. Last, 7 cohort studies found no evidence of an association between habitual coffee consumption and a higher risk of CVD. It was concluded that in hypertensive individuals, caffeine intake produces an acute increase in BP for ≥3 h. However, current evidence does not support an association between longer-term coffee consumption and increased BP or between habitual coffee consumption and an increased risk of CVD in hypertensive subjects [11491].

Effect on cardiac blood flow

Caffeine consumption has been receiving increased interest from both the medical and lay press, especially given the increased amounts now available in energy products. Acute ingestion of caffeine usually increases cardiac work; however, caffeine impairs the expected proportional increase in myocardial blood flow to match this increased work of the heart, most notably during exercise. This appears to be mainly due to caffeine’s effect on blocking adenosine-induced vasodilatation in the coronary arteries in normal healthy subjects. This review summarizes the available medical literature specifically relating to pure caffeine tablet ingestion and reduced exercise coronary blood flow, and suggests possible mechanisms. Further studies are needed to evaluate this effect for other common caffeine-delivery systems, including coffee, energy beverages, and energy gels, which are often used for exercise performance enhancement, especially in teenagers and young athletes [13444].

Caffeine-reduced myocardial blood flow during exercise

Caffeine consumption has been receiving increased interest from both the medical and lay press, especially given the increased amounts now available in energy products. Acute ingestion of caffeine usually increases cardiac work; however, caffeine impairs the expected proportional increase in myocardial blood flow to match this increased work of the heart, most notably during exercise. This appears to be mainly due to caffeine’s effect on blocking adenosine-induced vasodilatation in the coronary arteries in normal healthy subjects. This review summarizes the available medical literature specifically relating to pure caffeine tablet ingestion and reduced exercise coronary blood flow, and suggests possible mechanisms. systems, including coffee, energy beverages, and energy gels, which are often used for exercise performance enhancement, especially in teenagers and young athletes [13445].

**Dose-dependent neuromuscular effects**

The purpose of one study was to determine the oral dose of caffeine needed to increase muscle force and power output during all-out single multijoint movements. Thirteen resistance-trained men underwent a battery of muscle strength and power tests in a randomized, double-blind, crossover design, under four different conditions: (a) placebo ingestion (PLAC) or with caffeine ingestion at doses of (b) 3 mg/kg body weight (CAFF 3 mg), (c) 6 mg/kg (CAFF 6 mg), and (d) 9 mg/kg (CAFF 9 mg). The muscle strength and power tests consisted in the measurement of bar displacement velocity and muscle power output during free-weight full-squat (SQ) and bench press (BP) exercises against four incremental loads (25 %, 50 %, 75 %, and 90 % one-repetition maximum, 1RM). Cycling peak power output was measured using a 4-s inertial load test. Caffeine side effects were evaluated at the end of each trial and 24 h later. Mean propulsive velocity at light loads (25-50 % 1RM) increased significantly above PLAC for all caffeine doses (5.4-8.5 %). At the medium load (75 % 1RM), CAFF 3 mg did not improve SQ or BP muscle power or BP velocity. CAFF 9mg was needed to enhance BP velocity and SQ power at the heaviest load (90 % 1RM) and cycling peak power output (6.8-11.7 %). The CAFF 9 mg trial drastically increased the frequency of the adverse side effects (15-62 %). The ergogenic dose of caffeine required to enhance neuromuscular performance during a single all-out contraction depends on the magnitude of load used. A dose of 3 mg/kg is enough to improve high-velocity muscle actions against low loads, whereas a higher caffeine dose (9 mg/kg) is necessary against high loads, despite the appearance of adverse side effects [13467].

**Effect of caffeine on delayed onset muscle soreness**

The beneficial effects of caffeine on aerobic activity and resistance training performance are well documented. However, less is known concerning caffeine's potential role in reducing perception of pain and soreness during exercise. In addition, there is no information regarding the effects of caffeine on delayed onset muscle soreness (DOMS). The primary purpose of this study was to examine the effect of caffeine ingestion on muscle soreness, blood enzyme activity, and performance after a bout of elbow flexion/extension exercise. Nine low-coffeine-consuming males were randomly assigned to ingest either caffeine or placebo 1 hour before completing 4 sets of 10 bicep curls on a preacher bench, followed by a fifth set in which subjects completed as many repetitions as possible. Soreness and soreness on palpation intensity were measured using three 0-10 visual analog scales before exercise, and 24, 48, 72, 96, and 120 hours after exercise. After a washout period, subjects crossed over to the other treatment group. Caffeine ingestion resulted in significantly lower levels of soreness on day 2 and day 3 compared with placebo. Total repetitions in the final set of exercise increased with caffeine ingestion compared with placebo. The study demonstrates that caffeine ingestion immediately before an upper-body resistance training out enhances performance. A further beneficial effect of sustained caffeine ingestion in the days after the exercise bout is an attenuation of DOMS. This decreased perception of soreness in the days after a strenuous resistance training workout may allow individuals to increase the number of training sessions in a given time period [13469].

**Effects on performance**
In summary, caffeine, even at physiological doses (3-6 mg/kg), as well as coffee are proven ergogenic aids and as such – in most exercise situations, especially in endurance-type events – clearly work-enhancing. It most likely has a peripheral effect targeting skeletal muscle metabolism as well as a central effect targeting the brain to enhance performance, especially during endurance events. Also for anaerobic tasks, the effect of caffeine on the CNS might be most relevant. Further, post-exercise caffeine intake seems to benefit recovery by increasing rates of glycogen resynthesis [13008].

Most of the beneficial effects of caffeine have been shown in relation to alertness and neurocognitive performance, particularly in periods of sleep deprivation. Caffeine has also been implicated with having an analgesic as well as antinociceptive effect. Several studies have been conducted looking at caffeine as an ergogenic aid. Those looking at caffeine use during periods of sleep deprivation have shown a benefit to caffeine administration in terms of alertness and neurocognitive performance. Time to fall asleep on the multiple sleep latency test (MSLT) following periods of sleep deprivation was increased with administration of caffeine. Similarly, performance on a driving simulator following a period of sleep deprivation was found to be improved with caffeine administration [06183].

*Effect versus measurable levels*
Because some were afraid that the misuse of caffeine might increase after its removal from the doping list, the urinary concentrations have been monitored since. Data presented show that the misuse did not increase, although in some sport disciplines such as cycling some misuse of caffeine was still found. Some advocated that if unfair play should be prevented it might be reconsidered to add caffeine to the list again with a urinary threshold level of 12 microg/mL. However, it should be emphasized that research has shown that caffeine has performance enhancing properties up to approximately 5 mg/kg, above which no additional effect on performance was found. However, when dosages up to 5 mg/kg are taken the urine levels generally stay below 12 microg/mL. So, there is no scientific basis to support the statement that re-establishing a threshold of 12 micro/mL would avoid unfair competition. The misuse found in some sports may be attributed to lack of knowledge and education which appears to be supported by the facts in several doping cases. An important, but too often underscored aspect of the fight against doping is education of athletes and people around the athlete. The recommendation to add caffeine to the doping list again ignores the reasons why it was removed some years ago. Proper education in those sports where caffeine is still abused may be a more effective approach [07167].

**Effects on the brain**

Caffeine can improve exercise performance when it is ingested at moderate doses (3-6 mg/kg body mass). Caffeine also has an effect on the central nervous system (CNS), and it is now recognized that most of the performance-enhancing effect of caffeine is accomplished through the antagonism of the adenosine receptors, influencing the dopaminergic and other neurotransmitter systems. Adenosine and dopamine interact in the brain, and this might be one mechanism to explain how the important components of motivation (i.e. vigor, persistence and work output) and higher-order brain processes are involved in motor control. Caffeine maintains a higher dopamine concentration especially in those brain areas linked with “attention”. Through this neurochemical interaction, caffeine improves sustained attention, vigilance, and reduces symptoms of fatigue. Other aspects that are localized in the CNS are a reduction in skeletal muscle pain and force sensation, leading to a reduction in perception of effort during exercise and therefore influencing the motivational factors to sustain effort during exercise. Because not all CNS aspects have been examined in detail, one should consider that a placebo effect may also be present. Overall, it appears that the performance-enhancing effects of caffeine reside in the brain, although more research is necessary to reveal the exact mechanisms through which the CNS effect is established [13456].

**Caffeine, exercise and the brain**

Caffeine can improve exercise performance when it is ingested at moderate doses (3-6 mg/kg body mass). Caffeine also has an effect on the central nervous system (CNS), and it is now recognized that most of the performance-enhancing effect of caffeine is accomplished through the antagonism of the adenosine receptors, influencing the dopaminergic and other neurotransmitter systems. Adenosine and dopamine interact in the brain, and this might be one mechanism to explain how the important components of motivation (i.e. vigor, persistence and work output) and higher-order brain processes are involved in motor control. Caffeine maintains a higher dopamine concentration especially in those brain areas linked with “attention”. Through this neurochemical interaction, caffeine improves sustained attention, vigilance, and reduces symptoms of fatigue. Other aspects that are localized in the CNS are a reduction in skeletal muscle pain and force sensation, leading to a reduction in perception of effort during exercise and therefore influencing the motivational factors to sustain effort during exercise. Because not all CNS aspects have been examined in detail, one should consider that a placebo effect may also be present. Overall, it appears that the
performance-enhancing effects of caffeine reside in the brain, although more research is necessary to reveal the exact mechanisms through which the CNS effect is established [13457].

**Effects on mood and vigilance performance**

One study investigated the impact of pre-existent expectancy regarding the effects of the caffeine load of a drink and the perception of the caffeine content on subjective mood and vigilance performance. Caffeine deprived participants (n=25) were tested in four conditions (within subjects design), using a 2×2 design, with caffeine load and information regarding the caffeine content of the drink. In two sessions, they were given caffeinated coffee and in two were given decaffeinated coffee. Within these two conditions, on one occasion they were given accurate information about the drink and on the other they were given inaccurate information about the drink. Mood and vigilance performance were assessed post ingestion. Caffeine was found to enhance performance, but only when participants were accurately told they were receiving it. When decaffeinated coffee was given, performance was poorer, irrespective of expectancy. However, when caffeine was given, but participants were told it was decaffeinated coffee, performance was as poor as when no caffeine had been administered. There were no easily interpretable effects on mood. The pharmacological effects of caffeine appear to act synergistically with expectancy [10500].

**Effects on endurance**

Although there are a vast number of studies quantifying caffeine's effects, many research studies measure endurance performance using a time-to-exhaustion test (subjects exercise at a fixed intensity to volitional exhaustion). Time-to-exhaustion as a performance measure is not ideal because of the high degree of measurement variability between and within subjects. Also, one must stat that in modern endurance sports there is none in which individuals win by going a longer distance or for a longer amount of time than their competitors. Measuring performance with a time-trial test (set distance or time with best effort) has high reproducibility and is more applicable to sport. Therefore, the purpose of one review was to critically and objectively evaluate studies that have examined the effect of caffeine on time-trial endurance (>5 minutes) performance. A literature search revealed 21 studies with a total of 33 identifiable caffeine treatments that measured endurance performance with a time-trial component. The mean improvement in performance with caffeine ingestion was 3.2 ± 4.3 percent; however, this improvement was highly variable between studies. The high degree of variability may be dependent on a number of factors including ingestion timing, ingestion mode/vehicle, and subject habituation. Further research should seek to identify individual factors that mediate the large range of improvements observed with caffeine ingestion. The authors concluded that caffeine ingestion can be an effective ergogenic aid for endurance athletes when taken before and/or during exercise in moderate quantities (3-6 mg/kg body mass). Abstaining from caffeine at least 7 days before use will give the greatest chance of optimizing the ergogenic effect [08310].

Athletes in Malaysia need to perform in a hot and humid climate. Chronic supplementation of caffeine on endurance performance have been studied extensively in different populations. However, concurrent research on the effects of acute supplementation of caffeine on cardiorespiratory responses during endurance. Nine heat adapted recreational Malaysian male runners who were nonusers of caffeine (24 ± 13 mg per day) were recruited in a placebo-controlled double-blind randomized study. Caffeine (5 mg per kg of body weight) or placebo was ingested in the form of a capsule one hour prior to the running exercise trial at 70 per cent of VO\textsubscript{2}max on a motorised treadmill in a heat-controlled laboratory (31 degrees C, 70% relative humidity). Subjects drank 3 ml of cool water per kg of body weight every 20 min.
during the running trials to avoid the adverse effects of dehydration. Heart rate, core body temperature and rate of perceived exertion (RPE) were recorded at intervals of 10 min, while oxygen consumption was measured at intervals of 20 min. Running time to exhaustion was significantly higher in the caffeine trial compared to the placebo trial. Heart rate, core body temperature, oxygen uptake and RPE did not show any significant variation between the trials but it increased significantly during exercise from their respective resting values in both trials. The study showed that ingestion of 5 mg of caffeine per kg of body weight improved the endurance running performance but did not impose any significant effect on other individual cardiorespiratory parameters of heat-acclimated recreational runners in hot and humid conditions [10390].

The purpose of this work was to determine the effects of caffeine ingestion on cycling time trial performance in well trained male subjects. Eight males undertook three 1 h trial performances on a cycle ergometer, in a double blind, random fashion. The trials were Control, placebo and caffeine. The caffeine was given 60 min prior to exercise in a dose of 6 mg/kg body mass. Prior to ingestion, 60 min post ingestion, and at the end of the trial, subjects gave 10 mL of venous blood which was analysed for lactate, glucose, and free fatty acids. Expired air was collected throughout each test by indirect calorimetry. The cyclists rode significantly further in caffeine trial Control and placebo trials. No significant differences were seen between control and placebo trials. The free fatty acid (FFA) concentrations were significantly higher in the caffeine trials both post ingestion and post exercise than either other trials. It was concluded that performance was improved possibly based upon a greater reliance on fat metabolism, as indicated by increased FFA and a lower respiratory exchange ratio [08309].

It has been demonstrated that caffeine supplementation improved exercise endurance by about 20 percent and significantly reduced the perception of exertion whilst cycling at 18 and 35°C, compared to a placebo. Since no effects were observed on indicators of peripheral metabolic stress, it was concluded that the action was central and, furthermore, since there was no effect on the release of prolactin, it was concluded that caffeine may be acting on central pathways other than those in the hypothalamus which are sensitive to temperature. There is a wealth of literature describing the effects of caffeine on exercise performance [06192].

Most of the studies looking at caffeine in improving exercise or athletic performance of focused on endurance, submaximal exercise activities such as running and cycling. In these situations, caffeine has generally been shown to improve or sustain exercise performance, typically through an increase in the duration of the exercise or a decreased perception of exertion. In cycling, caffeine has been shown to increase time to exhaustion at 85 percent \( V_{O2\max} \) and decrease times to finish a fixed period of activity. Increased times to exhaustion have been seen in running as well as decreased times to run set distances. Other benefits on exercise that have been discovered are improved tennis performance and decreased 1500-meter swim times [06183].

There is little published data in relation to the effects of caffeine upon cycling performance, speed and power in trained cyclists, especially during cycling of approximately 60 s duration. To address this, eight trained cyclists performed a 1 km time-trial on an electronically braked cycle ergometer under three conditions: after ingestion of 5 mg caffeine per kg bodyweight, after ingestion of a placebo, or a control condition. The three time-trials were performed in a randomized order and performance time, mean speed, mean power and peak power were determined. Caffeine ingestion resulted in improved performance time. This change represented a 3.1 percent improvement compared with the placebo condition. Mean speed was also significantly higher in the caffeine than placebo and control conditions. Mean power
increased after caffeine ingestion. Peak power also increased from $864 \pm 107$ W (placebo) and $830 \pm 87$ W (control) to $940 \pm 83$ W after caffeine ingestion. These results provide support for previous research that found improved performance after caffeine ingestion during short-duration high-intensity exercise. The magnitude of the improvements observed in our study could be due to our use of sport-specific ergometry, a tablet form and trained participants [06193].

The aim of one study was to assess the effect of caffeine ingestion on 8 km run performance using an ecologically valid test protocol. A randomized double-blind crossover study was conducted involving eight male distance runners. The participants ran an 8 km race 1 h after ingesting a placebo capsule, a caffeine capsule (3 mg/kg body mass) or no supplement. Heart rate was recorded at 5 s intervals throughout the race. Blood lactate concentration and ratings of perceived exertion were recorded after exercise. A repeated-measures analysis of variance (ANOVA) identified a significant treatment effect for 8 km performance time; caffeine resulted in a mean improvement of 23.8 s in 8 km performance time (1.2 % improvement). In addition, a two-way (time x condition) repeated-measures ANOVA identified a significantly higher blood lactate concentration 3 min after exercise during the caffeine trial. It was concluded that ingestion of 3 mg/kg body mass of caffeine can improve absolute 8 km run performance in an ecologically valid race setting [06194].

The purpose of one study was to investigate if caffeine ingestion improves 5-km time-trial performance in well-trained and recreational runners. Using a double-blind placebo-controlled design, 15 well-trained and 15 recreational runners completed two randomized 5-km time-trials, after ingestion of either 5 mg/kg of caffeine or a placebo. Caffeine ingestion significantly improved 5-km running performance in both the well-trained and recreational runners. In comparison to the placebo trial, the caffeine trial resulted in 1.1 percent (90 % confidence interval 0.4 to 1.6) and 1.0 percent (90 % confidence interval 0.2 to 2.0 %) faster times for the well-trained and recreational runners. Reliability testing of the recreational runners indicated a test-retest error of measurement of 1.4 percent. It was concluded that caffeine ingestion is likely to produce small but significant gains in 5-km running performance for both well-trained and recreational runners [07171].

One double-blind experiment examined the effects of a caffeinated sports drink during prolonged cycling in a warm environment. Sixteen highly trained cyclists completed 3 trials: placebo, carbohydrate-electrolyte sports drink (CES), and caffeinated sports drink (CES+CAF). Subjects cycled for 135 min, alternating between 60 percent and 75 percent $\text{VO}_{2\text{max}}$ every 15 min for the first 120 min, followed by a 15-min performance ride. Maximal voluntary (MVC) and electrically evoked contractile properties of the knee extensors were measured before and after cycling. Work completed during the performance ride was 15-23 percent greater for CES+CAF than for the other beverages. Ratings of perceived exertion were lower with CES+CAF than with placebo and CES. After cycling, the MVC strength loss was two-thirds less for CES+CAF than for the other beverages (5 % vs 15 %). Data from the interpolated-twitch technique indicated that attenuated strength loss with CES+CAF was explained by reduced intrinsic muscle fatigue [07172].

Caffeine reduces fatigue and increases concentration and alertness, and athletes regularly use it as an ergogenic aid. Caffeine-induced increases in performance have been observed in aerobic as well as anaerobic sports. Trained athletes seem to benefit from a moderate dose of 5 mg/kg, however, even lower doses of caffeine (1.0-2.0 mg/kg) may improve performance. Some groups found significantly improved time trial performance or maximal cycling power, most likely related to a greater reliance on fat metabolism and decreased neuromuscular fatigue, respectively. Theophylline, a metabolite of caffeine, seems to be even more effective in doing so. The effect of caffeine on fat oxidation, however, may only be
significant during lower exercise intensities and may be blocked at higher intensities. It was found that ingestion of a high dose of caffeine before exercise reduced muscle glycogenolysis in the initial 15 min of exercise by increasing free fatty acid (FFA) levels which inhibits glycolysis and spares glycogen for later use. Caffeine’s effect of inhibition of glycogen phosphorylase has also been shown in vitro as well as its effect on increasing HSL activity. The effect of caffeine on adipose triglyceride lipase has not been studied and warrants investigation. Following caffeine administration prior to and after the onset of cycling, it was found that plasma free fatty acid levels were increased 30 percent compared to placebo. This action might be mediated by inhibition of the enzyme phosphodiesterase, thereby yielding higher levels of cAMP, which has been identified as an important molecule for glycogen metabolism and lipolysis. Phosphodiesterase inhibition has been observed only at high concentrations. When direct Fick measurements were applied, it was not found altered CHO or fat metabolism, at least in the monitored leg. Further research is needed to evaluate the effect of caffeine on lipolysis, especially during higher exercise intensities [13008].

Augmented post-exercise recovery by increased rates of muscle glycogen resynthesis has been observed. It was found higher rates of muscle glycogen accumulation after the co-ingestion of caffeine with CHO during recovery in highly trained subjects. This might, at least in part, be mediated by the activation of AMP-activated protein kinase (AMPK) as it is involved in the translocation of glucose transporter 4 (GLUT4) to the plasma membrane. This mechanism enables the cell to take up glucose from the plasma and store it as glycogen. Not only does caffeine impact endurance, it has also been reported to benefit cognitive function and fine motor skills. While the performance enhancing effects of caffeine in moderate-to-highly trained endurance athletes are quite clear and well documented, its effects on anaerobic, high-intensity tasks are less well investigated. Whereas caffeine supplementation did not yield significant performance increases in a Wingate test in untrained subjects, it was reported that caffeine ingestion of 3 mg/kg could counter reductions in maximum dynamic strength and muscle power output on the morning (2.5-7.0 %) thereby increasing muscle performance to the levels found in the afternoon. Especially with regard to anaerobic performance caffeine’s adenosine receptor blocking effect in the CNS may be important. A possible explanation for the diverging effect of caffeine on anaerobic performance is that caffeine seems to benefit trained athletes who show specific physiological adaptations whereas performance gains in untrained subjects might be lost or masked by a high variability in performance [13008].

It has been shown that coffee, by containing phenolic compounds such as chlorogenic acids, elicits metabolic effects independent of caffeine. These compounds may have the potential to antagonize the physiological responses of caffeine. The question therefore remains whether ingesting the same amount of caffeine via a food source (e.g. energy bar or coffee) is as effective as ingesting isolated caffeine in the form of a tablet. As mentioned above, the performance enhancing effect of caffeine is very clear. Only a few studies, however, have shown a positive effect of coffee on performance. Whereas some studies found enhanced performance after coffee consumption, others did not. One earlier works reported increases in time trial performance of competitive cyclists only in the coffee trial group (containing 330 mg caffeine 1 h prior to exercise) but not in the decaffeinated coffee trial. It was also studied exercise endurance in runners after ingestions of a caffeine (4.45 mg/kg BW) or placebo capsule with water or either decaffeinated coffee, decaffeinated coffee with added caffeine or regular coffee. The authors found that only caffeine significantly improved running time to exhaustion at 75 percent VO\textsubscript{2}\text{max} but neither did regular coffee or decaffeinated coffee plus caffeine. Based on these results, the authors speculated that some component(s) in coffee possibly interfere with the ergogenic response of caffeine alone [13008].
The use of caffeine as an ergogenic aid to promote endurance has been widely studied, with human literature showing the greatest benefit during submaximal muscle activities. Recent evidence suggests that the acute treatment of skeletal muscle with physiological concentrations of caffeine (70 microM maximum) will directly potentiate force production. The aims of the present study are: firstly, to assess the effects of a physiological concentration (70 microM) of caffeine on endurance in maximally activated mouse soleus (relatively slow) muscle; and secondly, to examine whether endurance changes when muscle is activated submaximally during caffeine treatment. Maximally stimulated soleus muscle treated with 70 microM caffeine resulted in a significant (18 %) decrease in endurance. In contrast, at a submaximal stimulation frequency, caffeine treatment significantly prolonged endurance (by 19 %). Findings are activation-dependent such that, during high frequency stimulation, caffeine accelerates fatigue, whereas, during low frequency stimulation, caffeine delays fatigue [0462].

**Effects on biking**

The purpose of one work was to determine the effects of caffeine on high intensity time trial cycling performance in well-trained subjects. Six male cyclists undertook three 1-h performances, control, placebo and caffeine, on a Velotron cycle ergometer conducted in a double-blind, random fashion. Subjects rested for 60 min and were then given caffeine or placebo in a dose of 6 mg/kg body mass and then commenced exercise after another 60 min of rest. Before ingestion, 60 min postingestion, and at the end of the test, finger-prick blood samples were analyzed for lactate. The cyclists rode significantly further in the caffeine trial (28.0 ± 1.3 km) than they did in the control performance (26.3 ± 1.5 km) or placebo (26.4 ± 1.5 km trials). No differences were seen in heart rate data throughout the tests. Blood lactate levels were significantly higher at the end of the trials than either at rest or postingestion, but there were no differences between the three trial groups. The authors concluded that on the basis of the data, it was concluded that performance was improved with the use of a caffeine supplement [09255].

The purpose of one experiment was to learn whether low doses of caffeine have ergogenic, perceptual, and metabolic effects during cycling. To determine the effects of 1, 2, and 3 mg/kg caffeine on cycling performance, differentiated ratings of perceived exertion (D-RPE), quadriceps pain intensity, and metabolic responses to cycling exercise, 13 cyclists exercised on a stationary ergometer for 15 min at 80 percent VO2, then, after 4 min of active recovery, completed a 15-min VO2peak performance ride 60 min after ingesting caffeine or placebo. Work done (kJ/kg) during the performance ride was used as a measure of performance. D-RPE, pain ratings, and expired-gas data were obtained every 3 min, and blood lactate concentrations were obtained at 15 and 30 min. Compared with placebo, caffeine doses of 2 and 3 mg/kg increased performance by 4 percent (95% confidence interval 1.0-6.8%) and 3 percent (95% confidence interval -0.4 % to 6.8 %), respectively. These effects were ergogenic, on average, but varied considerably in magnitude among individual cyclists. There were no effects of caffeine on D-RPE or pain throughout the cycling task. Selected metabolic variables were affected by caffeine, consistent with its known actions. The authors conclude that caffeine preparations of 2 and 3 mg/kg enhanced performance, but future work should aim to explain the considerable interindividual variability of the drug's ergogenic properties [08307].

The purpose of one study was to determine if improved supramaximal exercise performance in trained cyclists following caffeine ingestion was associated with enhanced O2 uptake (VO2 kinetics), increased anaerobic energy provision (accumulated O2-AO2-deficit), or a reduction in the accumulation of metabolites (for example, K+) associated with muscular fatigue. Six highly trained male cyclists (VO2peak 68 ± 8 mL/kg/min) performed supramaximal (120% VO2peak) exercise bouts to exhaustion on an electronically braked cycle ergometer, following
double-blind and randomized ingestion of caffeine/placebo (5 mg/kg). Time to exhaustion (TE), VO\(_2\) kinetics, AO\(_2\) deficit, blood lactate, plasma potassium, caffeine and paraxanthine concentrations were measured. Caffeine ingestion elicited significant increases in TE and AO\(_2\) deficit (7%). In contrast, no changes were observed in AO\(_2\) deficit at isotime, VO\(_2\) kinetics, blood lactate at exhaustion or peak potassium following caffeine ingestion. However, potassium was significantly reduced (13%) during warm-up cycling immediately prior to the onset of the supramaximal bout for the caffeine trials, compared with placebo. It appears that caffeine ingestion is beneficial to supramaximal cycling performance in highly trained men. The reduced plasma potassium during submaximal warm-up cycling may prolong the time taken to reach critical potassium at exhaustion, thus delaying fatigue. Considering caffeine ingestion did not change VO\(_2\) kinetics or isotime AO\(_2\) deficit, increases in absolute AO\(_2\) deficit may be a consequence of prolonged TE, rather than causal [10179].

Caffeine is thought to act as a central stimulant and to have effects on physical, cognitive, and psychomotor functioning. Twenty-four well-trained cyclists consumed the products (a performance bar containing 45 g of carbohydrate and 100 mg of caffeine, an isocaloric noncaffeine performance bar, or 300 mL of placebo beverage) immediately before performing a 2.5-h exercise at 60 percent VO\(_{2\text{max}}\) followed by a time to exhaustion trial at 75 percent VO\(_{2\text{max}}\). Additional products were taken after 55 and 115 min of exercise. Cognitive function measures were performed before exercise and while cycling after 70 and 140 min of exercise and again 5 min after completing the time to exhaustion ride. Participants were significantly faster after caffeine when compared with carbohydrate on both the computerized complex information processing tests, particularly after 140 min and after the time to exhaustion ride. On the beverage trial, performance was significantly slower than after both other treatments. There were no speed-accuracy tradeoffs. Time to exhaustion was significantly longer after caffeine consumption compared with both carbohydrates and beverage trials, and time to exhaustion was longer after carbohydrates than after beverages. No differences were found in the ratings of perceived exertion, mean heart rate, and relative exercise intensity (% VO\(_{2\text{max}}\)). The authors concluded that caffeine in a performance bar can significantly improve endurance performance and complex cognitive ability during and after exercise. These effects may be salient for sports performance in which concentration plays a major role [08311].

The purpose of one study was to investigate the effects of caffeine ingestion on the performance of an intermittent sprint cycling test (ISCT) with different rest intervals. Fourteen males with team sport experience consumed 6 mg/kg of caffeine or a placebo 60 min prior to completing two sets of an ISCT with 4-min rest intervals. Each set consisted of 12 × 4-s sprints with 20- or 90-s active recovery intervals at 60-70 rpm. Blood lactate was collected at baseline and immediately following the completion of six sprints in each set. At 20-s recovery intervals, peak power and total work were not significantly different between conditions during the ISCT; but caffeine reduced 6 percent effort for mean power in Sprint 10 of the later stage, as well as an increased fatigue index and elevated blood lactate levels during the ISCT. At 90-s recovery intervals, peak power, mean power, and total work under caffeine conditions were significantly higher than under placebo conditions during the ISCT, but no differences were apparent in fatigue index and blood lactate levels. In conclusion, caffeine ingestion may be ergolytic, affecting performance and fatigue development in the later stage during a prolonged and intermittent sprint test with a short recovery interval. However, caffeine produces an ergogenic effect in the initial stage of an intermittent sprint performance with a longer recovery interval [12280].

Caffeine has been reported to alter perceptions of exertion, muscle pain, and mood, yet the majority of existing data were obtained in resting volunteers or during steady-state exercise. The primary aim of one study was to examine the effects of caffeine on rating of perceived
exertion (RPE) and perceptions of leg pain, arousal, and pleasure/displeasure during a simulated cycling time trial. Endurance-trained (n=8, VO$_{2_{\text{max}}}$ 58 ± 4 mL/kg/min) and active (n=8) men initially completed two familiarization trials separated by at least 48 h. Over the next three trials, they completed a 10 km time trial preceded by ingestion of drinks containing caffeine (5 mg/kg ingested on 2 separate days) or placebo. Treatments were ingested using a single-blind, crossover design, and participants were deceived as to the content of all drinks. During exercise, RPE (6-20 scale), leg pain (0-10 scale), arousal (Felt Arousal Scale), and pleasure/displeasure (Feeling Scale) were recorded using various categorical scales. Repeated measures analysis of variance was used to assess differences in all variables across time and treatments, with fitness level used as a between-subjects variable. Pleasure/displeasure was altered with caffeine compared to placebo, although leg pain, RPE, and arousal were similar across treatments. Caffeine increased cycling performance by 0.3-2.0 percent versus placebo, with no effect of fitness level. Only in trained men; however, was there a significant caffeine-mediated improvement in cycling performance, which was consequent with diminished mood in trained and improved mood in active individuals [12281].

Both caffeine (CAF) and pseudoephedrine (PSE) are proposed to be central nervous system stimulants. However, during competition, CAF is a permitted substance, whereas PSE is a banned substance at urinary levels >150 microg/L. As a result, this study aimed to compare the effect of CAF versus PSE use on cycling time trial (TT) performance to explore whether the legal stimulant was any less ergogenic that the banned substance. Here, 10 well-trained male cyclists and/or triathletes were recruited for participation. All athletes were required to attend the laboratory on four separate occasions, inclusive of a familiarisation trial and three experimental trials which required participants to complete a simulated 40 km (1200 kJ) cycling TT, after the ingestion of either 200 mg CAF, 180 mg PSE or a non-nutritive placebo (PLA). The results showed that the total time taken and the mean power produced during each TT was not significantly different between trials, despite a 1.3 percent faster overall time (about 57 sec) after CAF consumption. Interestingly, the time taken to complete the second 50 percent of the TT was significantly faster in CAF as compared to PSE (by 99 sec), with magnitude based inferences suggesting a 91% beneficial effect of CAF during the second half of the TT. This investigation further confirms the ergogenic benefits of CAF use during TT performances, and further suggests this legal CNS stimulant has a better influence than a supra-therapeutic dose of PSE [13443].

**Cross-country skiing**

Caffeine (CAF) improves performance of both short and long duration in running and cycling where performance relies on power output, and endurance capacity of leg muscles. No studies have so far tested effects of CAF while using the double poling (DP) technique in cross-country skiing (XCS). When DP arm muscles provide the speed generating force, and therefore play an important role to performance outcome. The metabolism of arm muscles differs from that of leg muscles. Thus, results from studies on leg muscles and CAF may not be directly applicable to exercises while DP in XCS. The purpose of our study was therefore to investigate effects of CAF on exercise performance in DP. Ten highly trained male cross-country skiers performed a placebo (PLA) and CAF trial using a randomized, double-blinded, cross-over design. Performance was assessed by time to complete an 8 km cross country DP performance test (C-PT). CAF (6 mg/kg) or PLA was ingested 75 min before the C-PT. Results: CAF ingestion significantly reduced times to complete the 8 km C-PT. The subjects maintained higher speed and heart rate throughout the C-PT, and lactate was higher immediately after the C-PT with CAF exposure compared to PLA. Subjects reported lower rating of perceived exertion at submaximal intensities during CAF compared to PLA, although heart rate was similar. Conclusion: CAF intake enhances endurance performance in an 8 km C-PT where arm muscles limit performance. CAF ingestion allowed the participants
to exercise with a higher heart rate, and work intensity, possibly by reducing perception of effort or facilitating motor unit recruitment [13440].

**Effects on short term performance**

The efficacy of caffeine ingestion in enhancing aerobic performance is well established. However, despite suggestions that caffeine may enhance resistance exercise performance, research is equivocal on the effect of acute caffeine ingestion on resistance exercise performance. It has also been suggested that dampened perception of perceived exertion and pain perception might be an explanation for any possible enhancement of resistance exercise performance due to caffeine ingestion. Therefore, the aim of one study was to examine the acute effect of caffeine ingestion on repetitions to failure, rating of perceived exertion (RPE) and muscle pain perception during resistance exercise to failure. Eleven resistance trained individuals (9 males, 2 females, mean age 26 years), took part in this double-blind, randomised cross-over experimental study whereby they ingested a caffeinated (5 mg/kg) or placebo solution 60 minutes before completing a bout of resistance exercise. Experimental conditions were separated by at least 48 hours. Resistance exercise sessions consisted of bench press, deadlift, prone row and back squat exercise to failure at an intensity of 60 percent 1 repetition maximum. Results indicated that participants completed significantly greater repetitions to failure, irrespective of exercise, in the presence of caffeine. Mean of repetitions to failure was 20 and 19 in caffeine and placebo conditions, respectively. There were no differences in peak heart rate or peak blood lactate values across conditions. RPE was significantly lower in the caffeine compared to the placebo condition and was significantly higher during lower body exercises compared to upper body exercises irrespective of substance ingested. For muscle pain perception, a significant condition by exercise interaction revealed that muscle pain perception was lower in the caffeine condition, irrespective of exercise. With caffeine, pain perception was significantly higher in the deadlift and back squat compared to the bench press. However, with placebo, pain perception was significantly higher for the deadlift and back squat compared to the prone row only. Therefore, acute caffeine ingestion not only enhances resistance exercise performance to failure but also reduces perception of exertion and muscle pain [13463].

The efficacy of caffeine ingestion in enhancing aerobic performance is well established. The evidence for caffeine's effects on resistance exercise is mixed and has not fully examined the associated psychological and psychophysiological changes. One study examined acute effects of ingesting a caffeine-containing energy drink on repetitions to failure, the rating of perceived exertion (RPE), and the readiness to invest physical effort (RTIPE) and mental effort during resistance exercise to failure. Thirteen resistance-trained men took part in this double-blind, randomized cross-over experimental study whereby they ingested a caffeinated (179 mg) energy drink or placebo solution 60 minutes before completing a bout of resistance exercise comprising bench press, deadlift, prone row, and back squat exercise to failure at an intensity of 60 percent 1-repetition maximum. Experimental conditions were separated by at least 48 hours. Participants completed significantly greater repetitions to failure, irrespective of exercise, in the energy drink condition. Rating of perceived exertion was significantly higher in the placebo condition and was significantly higher during lower-body exercises compared with upper-body exercises irrespective of the substance ingested. Readiness to invest mental effort was greater with the energy drink condition, irrespective of time. A significant time × substance interaction for RTIPE indicated that RTIPE increased for both placebo and energy drink conditions preingestion to pre-exercise, but the magnitude of increase was greater with the energy drink condition compared with placebo. This resulted in higher RTIPE postexercise for the energy drink condition. These results suggest that acute ingestion of a caffeine-containing energy drink can enhance resistance exercise performance
to failure and positively enhance psychophysiological factors related to exertion in trained men [12276].

Whereas the outcomes of caffeine ingestion (from natural sources and pills) are well known, the effects of caffeine-containing energy drinks on sports performance have been the object of fewer studies. The first report concerning the effects of energy drinks on physical performance was carried out by Alford and co-workers in 2001. These authors found that about 1 mg of caffeine per kg of body weight (one 250-mL serving of an energy drink) improved reaction time, alertness and aerobic and anaerobic performance. In contrast, subsequent investigations using energy drinks have shown that about 1 mg/kg of caffeine is not enough to enhance maximal oxygen uptake, peak power during three repetitions of the Wingate test, or running velocity during 24 “all-out” sprints. In addition, the ingestion of about 2 mg/kg of caffeine in the form of an energy drink was ergogenic during a cycling time trial but did not prolong time-to-exhaustion during a running test at 80 percent VO2max. The ergogenic effect of caffeine on endurance activities has been typically demonstrated with doses from 3 to 9 mg/kg, while the ingestion of 1 mg/kg of caffeine did not improve performance. Similar results have been found in team-sports specific activities: the ingestion of 6 mg/kg of caffeine increased repeated sprint ability, while the ingestion of 1 mg/kg of caffeine did not alter repeated sprint performance. Since the ingestion of one serving of an energy drink (typically 250-mL that contains 80 mg of caffeine) provides a dose of about 1 mg/kg of caffeine in a man of average weight, previous results about the inefficacy of energy drinks to improve performance may be explained by the low dose of caffeine provided for the subjects. During a soccer match, players combine periods of high-intensity exercise interspersed with periods of lower-intensity exercise or recovery. Thus, the ability to perform repeated sprints with minimal recovery between sprint bouts is one of the most crucial capacities for team sport athletes. In addition, an enhanced ability to repeat sprints is related with playing at a higher competitive level, especially in soccer [12274].

The aims of one study were to evaluate the effects of caffeine supplementation on sprint cycling performance and to determine if there was a dose-response effect. Using a randomized, double-blind, placebo-controlled design, 17 well-trained men (age: 24) completed 7 maximal 10-second sprint trials on an electromagnetically braked cycle ergometer. Apart from trial 1 (familiarization), all the trials involved subjects ingesting a gelatine capsule containing either caffeine or placebo (maltodextrin) 1 hour before each sprint. To examine dose-response effects, caffeine doses of 2, 4, 6, 8, and 10 mg/kg bm were used. There were no significant differences in baseline measures of plasma caffeine concentration before each trial. There was, however, a significant supplement × time interaction, with larger caffeine doses producing higher postsupplementation plasma caffeine levels. In comparison with placebo, caffeine had no significant effect on peak power, mean power, or time to peak power. There was also no significant effect of supplementation on pretrial blood lactate, but there was a significant time effect, with blood lactate reducing over the 50 minute postsupplementation rest period from 1.29 ± 0.36 to 1.06 ± 0.33 mmol/L. The results of this study show that caffeine supplementation has no effect on short-duration sprint cycling performance, irrespective of the dosage used [12277].

One study aimed to determine whether caffeine ingestion would increase the workload voluntarily chosen by athletes in a limited-sleep state. In a double-blind, crossover study, 16 professional rugby players ingested either a placebo or 4 mg/kg caffeine 1 hr before exercise. Athletes classified themselves into nondeprived (8 hr+) or sleep-deprived states (6 hr or less). Exercise comprised 4 sets of bench press, squats, and bent rows at 85 percent 1-repetition maximum. Athletes were asked to perform as many repetitions on each set as possible without failure. Saliva was collected before administration of placebo or caffeine and again before and immediately after exercise and assayed for testosterone and cortisol. Sleep
deprivation produced a very large decrease in total load. Caffeine ingestion in the nondeprived state resulted in a moderate increase in total load, with a larger effect in the sleep-deprived state, resulting in total load similar to those observed in the nondeprived placebo condition. Eight of the 16 athletes were identified as caffeine responders. Baseline testosterone was higher and cortisol trended lower in non-sleep-deprived athletes. Changes in hormones from predose to preexercise correlated to individual workload responses to caffeine. Testosterone response to exercise increased with caffeine compared with placebo, as did cortisol response. It was concluded that caffeine increased voluntary workload in professional athletes, even more so under conditions of self-reported limited sleep. Caffeine may prove worthwhile when athletes are tired, especially in those identified as responders [12278].

Caffeine is the most widely used drug in the world, commonly ingested in coffee, tea, soda, and energy drinks. Its ability to enhance muscular work has been apparent since the early 1900s. Caffeine typically increases endurance performance; however, efficacy of caffeine ingestion for short-term high-intensity exercise is equivocal, which may be explained by discrepancies in exercise protocols, dosing, and subjects' training status and habitual caffeine intake found across studies. The primary aim of one review was to critically examine studies that have tested caffeine's ability to augment performance during exercise dependent on nonoxidative metabolism such as sprinting, team sports, and resistance training. A review of the literature revealed 29 studies that measured alterations in short-term performance after caffeine ingestion. Each study was critically analyzed using the Physiotherapy Evidence Database (PEDro) scale. The mean PEDro score was 7.76 ± 0.87. Eleven of 17 studies revealed significant improvements in team sports exercise and power-based sports with caffeine ingestion, yet these effects were more common in elite athletes who do not regularly ingest caffeine. Six of 11 studies revealed significant benefits of caffeine for resistance training. Some studies show decreased performance with caffeine ingestion when repeated bouts are completed. The exact mechanism explaining the ergogenic effect of caffeine for short-term exercise is unknown [10175].

Multiple studies corroborate the ergogenic properties of caffeine (CAF) for endurance performance, yet fewer investigations document the efficacy of acute caffeine intake for intense, short-term exercise. The aim of one study was to determine the ergogenic potential of caffeine during testing of muscular strength and endurance. Twenty-two resistance-trained men ingested CAF (6 mg/kg) or placebo (PL) 1 h pre-exercise in a randomized, double-blind crossover design. They refrained from caffeine intake and strenuous exercise 48 and 24 h, respectively, pre-visit. Initially, resting heart rate and blood pressure were obtained followed by one-repetition maximum (1-RM) testing on the barbell bench press and leg press. Upon determination of 1-RM, participants completed repetitions to failure at 60 percent 1-RM. Heart rate, blood pressure, and rating of perceived exertion (RPE) were measured after the final repetition. Compared to PL, there was no effect of caffeine on muscular strength, as 1-RM bench press and leg press were similar. Total weight lifted during the 60 percent 1-RM trial was 11 and 12 percent higher for the bench press and leg press with caffeine compared to placebo, yet did not reach significance. RPE was similar at the end of resistance exercise with CAF versus placebo. Acute caffeine intake does not significantly alter muscular strength or endurance during intense bench press or leg press exercise, yet the practical importance of the increased muscular endurance remains to be explored [07174].

**Effect of caffeine on upper-body anaerobic performance**

Peak power (PP) and mean power (MP) attained in upper body sprint performance test are considered important factors for competitive success in wrestling. This study aimed to determine whether acute caffeine ingestion would better maintain PP and MP across a simulated competition day in wrestling. In a double-blind, counterbalanced, crossover study,
14 trained wrestlers ingested either placebo or 5 mg/kg caffeine and completed four 6-min upper body intermittent sprint performance tests with 30-min recovery periods between consecutive tests. PP and MP were recorded during and blood lactate concentration was measured before and after each test. Ratings of perceived fatigue (RPF) and exertion (RPE) were recorded before and after each test, respectively. Heart rate (HR) was monitored across the whole testing period. Mean power decreased across four tests in both trials, but the reduction in PP (from 277 ± 35 W to 257 ± 45 W) only occurred in caffeine trial. Both pretest blood lactate concentration and HR were higher in caffeine than in placebo trial in the third and fourth tests. No between-trial differences occurred in RPF or RPE. It was concluded that acute caffeine ingestion has a partially detrimental effect on upper body intermittent sprint performance in trained wrestlers. Elevated HR and blood lactate levels observed between tests after caffeine ingestion suggest that caffeine may impair recovery between consecutive maximal efforts [13439, 13446].

**Effect on morning reduction in neuromuscular performance**

To investigate whether caffeine ingestion counteracts the morning reduction in neuromuscular performance associated with the circadian rhythm pattern 12 highly resistance-trained men underwent a battery of neuromuscular tests under three different conditions; i) morning (10:00 a.m.) with caffeine ingestion (i.e. 3 mg/kg; AM(CAFF) trial); ii) morning (10:00 a.m.) with placebo ingestion (AM(PLAC) trial); and iii) afternoon (18:00 p.m.) with placebo ingestion (PM(PLAC) trial). A randomized, double-blind, crossover, placebo controlled experimental design was used, with all subjects serving as their own controls. The neuromuscular test battery consisted in the measurement of bar displacement velocity during free-weight full-squat (SQ) and bench press (BP) exercises against loads that elicit maximum strength (75 % 1RM load) and muscle power adaptations (1 m/s load). Isometric maximum voluntary contraction (MVC(LEG)) and isometric electrically evoked strength of the right knee (EVOK(LEG)) were measured to identify caffeine's action mechanisms. Steroid hormone levels (serum testosterone, cortisol and growth hormone) were evaluated at the beginning of each trial (PRE). In addition, plasma norepinephrine (NE) and epinephrine were measured PRE and at the end of each trial following a standardized intense (85 % 1RM) 6 repetitions bout of SQ (POST). In the PM(PLAC) trial, dynamic muscle strength and power output were significantly enhanced compared with AM(PLAC) treatment (3.0-7.5 %). During AM(CAFF) trial, muscle strength and power output increased above AM(PLAC) levels (4.6-5.7 %) except for BP velocity with 1 m/s load. During AM(CAFF), EVOK(LEG) and NE (a surrogate of maximal muscle sympathetic nerve activation) were increased above AM(PLAC) trial. These results indicate that caffeine ingestion reverses the morning neuromuscular declines in highly resistance-trained men, raising performance to the levels of the afternoon trial. The electrical stimulation data, along with the NE values, suggest that caffeine increases neuromuscular performance having a direct effect in the muscle [12279].

**Effects on sprint**

One study examined the effects of 6 mg/kg caffeine ingestion in team-sport players (n=10) on repeated-sprint running performance (5 sets of 6 x 20 m) and reaction times, 60 min after caffeine or placebo ingestion. Best single sprint and total set sprint times, blood lactate and simple and choice reaction times were measured. Total sprint times across sets 1, 3 and 5 (departure every 25 s) were significantly faster after caffeine than placebo. Similarly, total sprint times across sets 2 and 4 (departure every 60 s), were significantly faster after caffeine than placebo. Significantly higher blood lactates were recorded in caffeine compared to placebo after set 3 and set 5. There were no significant effects on simple or choice reaction time, although effect sizes suggested improved post-exercise times after caffeine. It was concluded that caffeine ingestion 60 min prior to exercise can enhance repeated sprint running performance and is not detrimental to reaction times [08308].
Using a randomized double-blind research design, 21 physically active men ingested a gelatin capsule containing either caffeine (5 mg per kg body mass) or placebo (maltodextrin) 1 h before completing an indoor multiple sprint running trial (12 x 30 m; repeated at 35 second intervals). Venous blood samples were drawn to evaluate plasma caffeine and primary metabolite concentrations. Sprint times were recorded via twin-beam photocells, and earlobe blood samples were drawn to evaluate pretest and posttest lactate concentrations. Relative to placebo, caffeine supplementation resulted in a 0.06 second (1.4 %) reduction in fastest sprint time (95 % confidence interval 0.04 to 0.09 s), which corresponded with a 1.2 percent increase in fatigue (95 % confidence interval 0.3 to 2.2%). Caffeine supplementation also resulted in a 3.4 beat per minute increase in mean heart rate (95 % confidence interval 0.1 to 6.6) and elevations in pretest (+0.7 mmol per L; 95 % confidence interval 0.1 to1.3) and posttest (+1.8 mmol per L; 95 % confidence interval 0.3 to 3.2) blood lactate concentrations. It was concluded that although the effect of recovery duration on caffeine-induced responses to multiple sprint work requires further investigation, the results of the study showed that caffeine has ergogenic properties with the potential to benefit performance in both single and multiple sprint sports [08312].

Effect on anaerobe performance

One study investigated the effects of caffeine on repeated, anaerobic exercise using a double-blind, randomized crossover design. Seventeen subjects (five female) underwent cognitive (reaction time, number recall) and blood (glucose, potassium, catecholamines, lactate) testing before and after consuming caffeine (6 mg/kg), placebo, or nothing (control). An exercise test (two 60 s maximal cycling bouts) was conducted 90 min after caffeine/placebo consumption. Plasma caffeine concentrations significantly increased after caffeine ingestion, however, there were no positive effects on cognitive or blood parameters except a significant decrease in plasma potassium concentrations at rest. Potentially negative effects of caffeine included significantly higher blood lactate compared to control and significantly slower time to peak power in exercise bout 2 compared to control and placebo. Caffeine had no significant effect on peak power, work output, RPE, or peak heart rate. In conclusion, caffeine had no ergogenic effect on repeated, maximal cycling bouts and may be detrimental to anaerobic performance [06191].

Effects on upper-body resistance exercise

One double-blind, within-subjects experiment examined the effects of acute caffeine ingestion on perceptions of muscle pain following a bout of high-intensity, upper-body resistance exercise to failure. Moderately trained males (n=18) ingested a dose of caffeine (5 mg/kg) or placebo in a randomised and counterbalanced order and 1 hour later completed bench press exercise to failure at an intensity of 60 percent 1 repetition maximum. Repetitions completed was taken as a measure of performance, peak heart rate was determined via heart rate telemetry during the exercise bout, rating of perceived exertion (RPE) and upper body muscle pain was recorded immediately upon failure of the exercise task and peak blood lactate concentration was determined post-exercise. Caffeine resulted in improved repetitions to failure, greater peak blood lactate, and lower RPE compared to placebo. Muscle pain perception was also significantly lower in the caffeine condition compared to placebo. These results support prior studies using aerobic based exercise modes in suggesting that caffeine ingestion can dampen exercise-induced muscle pain. Specifically, caffeine ingestion enhances muscular strength performance and reduces upper body muscle pain perception immediately following a bout of high-intensity resistance exercise to failure [12282].

Effects of multi-task performance

1215
The purpose of one study was to examine the acute effects of a caffeine-containing supplement on upper- and lower-body strength and muscular endurance as well as anaerobic capabilities. Thirty-seven resistance-trained men (mean age: 21 years) volunteered to participate in this study. On the first laboratory visit, the subjects performed 2 Wingate Anaerobic Tests (WAnTs) to determine peak power (PP) and mean power (MP), as well as tests for 1 repetition maximum (1RM), dynamic constant external resistance strength, and muscular endurance (TOTV; total volume of weight lifted during an endurance test with 80 % of the 1RM) on the bilateral leg extension (LE) and free-weight bench press (BP) exercises. Following a minimum of 48 hours of rest, the subjects returned to the laboratory for the second testing session and were randomly assigned to 1 of 2 groups: a supplement group (SUPP; n=17), which ingested a caffeine-containing supplement, or a placebo group (PLAC; n=20), which ingested a cellulose placebo. One hour after ingesting either the caffeine-containing supplement or the placebo, the subjects performed 2 WAnTs and were tested for 1RM strength and muscular endurance on the LE and BP exercises. The results indicated that there was a significant increase in BP 1RM for the SUPP group, but not for the PLAC group. The caffeine-containing supplement had no effect, however, on LE 1RM, LE TOTV, BP TOTV, PP, and MP. Thus, the caffeine-containing supplement may be an effective supplement for increasing upper-body strength and, therefore, could be useful for competitive and recreational athletes who perform resistance training [06189].

Intermittent-sprint ability in team-sport
Caffeine can be a powerful ergogenic aid for the performance of prolonged, submaximal exercise. Little evidence, however, supports an ergogenic effect of caffeine on intermittent-sprint performance. Hence, one study was conducted to examine the effects of acute caffeine ingestion on prolonged intermittent-sprint performance. Using a double-blind, placebo-controlled design, 10 male team-sport athletes (amateur level) completed two exercise trials, separated by 7 d, 60 min after ingestion of either 6 mg/kg caffeine or placebo. The exercise trial was performed on a front-access cycle ergometer and consisted of 2 x 36-min halves, each composed of 18 x 4-s sprints with 2-min active recovery at 35 percent VO2peak between each sprint. Urinary caffeine levels were measured after exercise. The total amount of sprint work performed during the caffeine trial was 8.5 percent greater than that performed during the placebo trial in the first half, and was 7.6 percent greater in the second half. Similarly, the mean peak power score achieved during sprints in the caffeine trial was 7.0 percent greater than that achieved during the placebo trial in the first half, and was 6.6 percent greater in the second half. Urinary caffeine levels following the caffeine trial ranged from 3.5 to 9.1 microg/mL. The study revealed that acute caffeine ingestion can significantly enhance performance of prolonged, intermittent-sprint ability in competitive, male, team-sport athletes [06190].

Effects on skill performance
Popular use of caffeine is often at high concentrations (4-9 mg/kg) on the basis that these are more efficacious, but the proof of this is low with individual variability and consumption habits being the more dominant factors. While the ability of acute caffeine to address cognitive related sleep deficits is reasonably established, it is only recently that creatine has demonstrated similar properties. It has been suggested that sleep deprivation is associated with an acute reduction in high energy phosphates that in turn produces some degree of cognitive processing deficit. If sleep deprivation is associated with an energy deficit then errors in performance are perhaps more likely to occur when concentration demands are high and/or for prolonged periods of repeated task execution. Some evidence suggests that it is tasks of this nature that are most affected by acute sleep deprivation. Sleep deprivation is not uncommon around competition in sport particularly with the frequent demands of international travel. Assessing its effects on performance is however difficult, especially in
team sports where multiple physical and skill components are involved. While overt physical components such as power don't appear affected by acute deprivation a few studies do however suggest acute deprivation can affect certain sport skill and physical performance. Caffeine, for example, has been shown to improve both mood and mental function following sleep deprivation. The psychostimulant effects of caffeine appear to be related to the pre and post synaptic brakes that adenosine imposes on dopaminergic neurotransmission by acting on different adenosine receptor heteromers, although numerous mechanisms are likely to be involved. It is not known how much mood and other cognitive function, particularly motivation on repeat skill tasks, interact. The absorption of caffeine in plasma following consumption has been estimated at between 30 and 90 min with half life of several hours. Effective doses of caffeine (and their dose response nature) remain contentious in literature possibly reflecting larger inter-subject variability in responses and different sensitivities of various physical and behavioural expressions. It was thus investigated the effects of sleep deprivation with or without acute supplementation of caffeine or creatine on the execution of a repeated rugby passing skill. Ten elite rugby players completed 10 trials on a simple rugby passing skill test (20 repeats per trial), following a period of familiarisation. The players had between 7-9 h sleep on 5 of these trials and between 3-5 h sleep (deprivation) on the other 5. At a time of 1.5 h before each trial, they undertook administration of either: placebo tablets, 50 or 100 mg/kg creatine, 1 or 5 mg/kg caffeine. Saliva was collected before each trial and assayed for salivary free cortisol and testosterone. Sleep deprivation with placebo application resulted in a significant fall in skill performance accuracy on both the dominant and non-dominant passing sides. No fall in skill performance was seen with caffeine doses of 1 or 5 mg/kg, and the two doses were not significantly different in effect. Similarly, no deficit was seen with creatine administration at 50 or 100 mg/kg and the performance effects were not significantly different. Salivary testosterone was not affected by sleep deprivation, but trended higher with the 100 mg/kg creatine dose, compared to the placebo treatment. Salivary cortisol was significantly elevated with the 5 mg/kg dose of caffeine versus placebo. Thus, acute sleep deprivation affects performance of a simple repeat skill in elite athletes and this was ameliorated by a single dose of either caffeine or creatine. At the doses and administration time of caffeine use in this study there was, however, no evidence of an effect in non-sleep deprived subjects. Acute creatine use may help to alleviate decrements in skill performance in situations of sleep deprivation, such as transmeridian travel, and caffeine at low doses appears as efficacious as higher doses, at alleviating sleep deprivation deficits in athletes with a history of low caffeine use. Both options are without the side effects of higher dose caffeine use [11197].

*Effect on athletic agility*

Caffeine has been shown to improve sprint time, anaerobic power, and reaction time, all integral aspects of agility. The purpose of this study was to determine whether an acute caffeine dose would enhance agility and anaerobic power. Sixteen subjects participated in a randomized, double-blind experiment and performed the proagility run and the 30-second Wingate test 60 minutes after ingestion of caffeine (6 mg/kg) or placebo. No significant change was observed in the proagility run after caffeine ingestion compared with placebo. Also, no significant change was observed in peak power, mean power, or percent power decrease. Agility is an integral component of athletic skill and any reasonable method for enhancing agility would benefit active individuals. However, results from this study indicate that a 6 mg/kg dose of caffeine does not impact agility as measured by the proagility run test or power output as measured by the 30-second Wingate test in recreationally active young adult males who are not habituated to caffeine [06196].

*Effects on resistance training*
One study examined the placebo effect of caffeine on number of repetitions, rating of perceived exertion (RPE), blood pressure (BP), and peak heart rate (PHR) during resistance-training exercise with repetitions performed to volitional failure. Following determination of 1-rep maximum in single-leg leg extension, 15 males performed reps to failure at 60 percent 1-RM in 3 conditions: control, perceived caffeine condition, and perceived placebo condition presented in a randomized order. Participants were informed they would ingest 250 mL of solution that contained either 3 mg/kg body weight caffeine or 3 mg/kg body weight placebo 1 h before each exercise trial. A deceptive protocol was employed and subjects consumed a placebo solution in both conditions. During each condition, total reps, RPE for the active muscle and overall body, and PHR were recorded. Subjects completed 2 more repetitions when they perceived they had ingested caffeine. RPE was significantly lower in the perceived caffeine and control conditions and RPE for the active muscle was significantly higher across all conditions compared with RPE for the overall body. No substantial differences were evident in PHR across conditions. Results of this study are similar to studies of actual caffeine ingestion. However, the perception of consuming a substance that purportedly enhances performance is sufficient enough to enable individuals to complete a greater number of reps to failure during short-term resistance exercise [09253].

The purpose of one study was to evaluate the effects of caffeine ingestion before a resistance exercise session on markers of muscle damage (CK, LDH, ALT, AST) and leukocyte levels. Fifteen soccer athletes completed two resistance exercise sessions that differed only in the ingestion of caffeine or a placebo preworkout. CK concentration increased significantly following the caffeine session and the placebo session, with no significant differences between sessions. Similarly, LDH concentration increased significantly following the caffeine session and the placebo session, with no significant differences between sessions. Both sessions resulted in significant increases in the total leukocyte count, neutrophils, lymphocytes, and monocytes, with no significant differences between sessions. It was concluded that ingestion of caffeine at 4.5 mg/kg did not augment markers of muscle damage or leukocyte levels above that which occurs through resistance exercise alone [10181].

The primary aim of one study was to determine the efficacy of acute caffeine intake to enhance intense resistance training performance. Fourteen resistance-trained men (age and body mass = 23 ± 1 years and 83 ± 13 kg, respectively) who regularly consumed caffeine ingested caffeine (6 mg·kg) or placebo 1 hour before completion of 4 sets of barbell bench press, leg press, bilateral row, and barbell shoulder press to fatigue at 70-80 percent 1-repetition maximum. Two minutes of rest was allotted between sets. Saliva samples were obtained to assess caffeine concentration. The number of repetitions completed per set and total weight lifted was recorded as indices of performance. Compared to placebo, there was a small but significant effect of acute caffeine intake on repetitions completed for the leg press but not for upper-body exercise. Total weight lifted across sets was similar with caffeine vs placebo yet there were 9 “responders” to caffeine, represented by a meaningful increase in total weight lifted with caffeine versus placebo. Any ergogenic effect of caffeine on performance of fatiguing, total-body resistance training appears to be of limited practical significance. Additional research is merited to elucidate interindividual differences in caffeine-mediated improvements [11202].

**Effects of performance of chronic use**

The purpose of one study was to examine the effects of daily administration of a supplement that contained caffeine in conjunction with 8 weeks of aerobic training on VO\textsubscript{2peak}, time to running exhaustion at 90 percent VO\textsubscript{2peak}, body weight, and body composition. Thirty-six college students (14 men and 22 women, age 22 years) volunteered for this investigation and were randomized into either a placebo (n=18) or supplement group (n=18). The subjects
ingested 1 dose (3 pills = 201 mg of caffeine) of the placebo or supplement per day during the study period. In addition, the subjects performed treadmill running for 45 minutes at 75 percent of the heart rate at VO$_{2peak}$, three times per week for 8 weeks. All subjects were tested pretraining and posttraining for VO$_{2peak}$, time to running exhaustion (TRE) at 90 percent VO$_{2peak}$, body weight (BW), percentage body fat (%FAT), fat weight (FW), and fat-free weight (FFW). The results indicated that there were equivalent training-induced increases in VO$_{2peak}$ and TRE for the supplement and placebo groups, but no changes in BW, %FAT, FW, or FFW for either group. These findings indicated that chronic use of the caffeine-containing supplement in the present study, in conjunction with aerobic training, provided no ergogenic effects as measured by VO$_{2peak}$ and TRE, and the supplement was of no benefit for altering body weight or body composition [06195].

**Effects on cycling**

The primary aim of one study was to determine the repeatability of caffeine's ergogenic effects on cycling performance. It was hypothesized that improvements in performance would be similar when caffeine was ingested on 2 separate days. Nine endurance-trained men and women (mean age and maximal oxygen uptake, 27 years and 58 mL/kg/min) initially completed two familiarization trials. During 3 subsequent sessions separated by at least 48 hours, the subjects completed a 10-km cycling time trial preceded by ingestion of a drink containing caffeine (5 mg/kg) or placebo. Treatments were ingested using a randomized, single-blind, crossover design, and the subjects were deceived as to the specific content of all drinks. During exercise, heart rate, rating of perceived exertion, and time were recorded every 1.6 km. Repeated-measures analysis of variance was used to compare the differences in variables across distance and treatment. In both caffeine trials, caffeine increased, cycling performance by 1.6 and 1.9 percent versus placebo, and 7 of 9 subjects revealed improved performance. The mean performance improvement in the caffeine trials was similar across days. Heart rate during exercise was higher with caffeine versus placebo, although the rating of perceived exertion was similar. Data reveal that caffeine's ergogenic effects on cycling performance are repeatable across days, yet some individuals did not exhibit improved performance with caffeine [12293].

To investigate whether coinciding peak serum caffeine concentration with the onset of exercise enhances subsequent endurance performance it was performed a randomised, placebo-controlled, double-blind crossover study, with 14 male trained cyclists and triathletes who consumed 6 mg/kg caffeine or a placebo either 1h (C(1h)) prior to completing a 40 km time trial or when the start of exercise coincided with individual peak serum caffeine concentrations (C(peak)). C(peak) was determined from a separate 'caffeine profiling' session that involved monitoring caffeine concentrations in the blood every 30 min over a 4h period. Following caffeine ingestion, peak serum caffeine occurred 120 min in 12 participants and 150 min in 2 participants. Time to complete the 40 km time trial was significantly faster (2.0 %) in C(1h) compared to placebo. No statistically significant improvement in performance was noted in the C(peak) trial versus placebo (1.1 %). Whilst no differences in metabolic markers were found between C(peak) and placebo conditions, plasma concentrations of glucose, norepinephrine and epinephrine were higher in the C(1h) trial 6 min post-exercise versus placebo. Thus, in contrast to coinciding peak serum caffeine concentration with exercise onset, caffeine consumed 60 min prior to exercise resulted in significant improvements in 40 km time trial performance. The ergogenic effect of caffeine was not found to be related to peak caffeine concentration in the blood at the onset of endurance exercise [13465].

**Effects on muscles**
Caffeine (1,3,7-trimethylxanthine) has been implicated in the regulation of glucose and lipid metabolism including actions such as insulin-independent glucose transport, glucose transporter 4 expression, and fatty acid utilization in skeletal muscle. These effects are similar to the exercise-induced and 5’adenosine monophosphate-activated protein kinase (AMPK)-mediated metabolic changes in skeletal muscle, suggesting that caffeine is involved in the regulation of muscle metabolism through AMPK activation. It was explored whether caffeine acts on skeletal muscle to stimulate AMPK. Incubation of rat epitrochlearis and soleus muscles with Krebs buffer containing caffeine (≥3 mmol/L, ≥15 minutes) increased the phosphorylation of AMPKα Thr(172), an essential step for full kinase activation, and acetyl-coenzyme A carboxylase Ser(79), a downstream target of AMPK, in dose- and time-dependent manners. Analysis of isoform-specific AMPK activity revealed that both AMPKα1 and α2 activities increased significantly. This enzyme activation was associated with a reduction in phosphocreatine content and an increased rate of 3-O-methyl-d-glucose transport activity in the absence of insulin. These results suggest that caffeine has similar actions to exercise by acutely stimulating skeletal muscle AMPK activity and insulin-independent glucose transport with a reduction of the intracellular energy status [09252].

Effects of neural recovery

The purpose of one study was to test the hypothesis that prior caffeine ingestion would enhance neural recovery after isometric fatiguing maximal intermittent plantar flexions, and thus would enhance the recovery of voluntary muscle strength. After a familiarisation session, 13 males randomly participated in two experimental trials where they ingested either caffeine (approximately 6 mg/kg) or identical placebo pills 1 h prior to testing. Subjects were tested for electromyogram (EMG) activity and evoked V-waves in the soleus and gastrocnemius medialis muscles. These measurements were obtained during brief plantar flexion maximum voluntary isometric contractions (MVICs), and normalised by the superimposed maximal M-wave (EMG/M(SUP) and V/M(SUP), respectively), before and after (20 s, 10 min and 20 min) a fatigue protocol (seven 25 s MVICs, 5 s rest). There were no effects (P > 0.05) of caffeine ingestion on EMG/M(SUP), V/M(SUP), MVIC or M(SUP). The central neural modulation (EMG/M(SUP) and V/M(SUP)) and voluntary strength changes followed a similar time-course with a substantial reduction 20 s post-fatigue and a gradual return towards baseline values. Thus, there was no effect of prior caffeine ingestion on neuromuscular recovery after maximal fatiguing contractions [10178].

Effects in children

Both cognitive and physical performance can be viewed as potentially enhanceable, and arguments can be made that enhancement can serve two purposes: gaining an edge or keeping up with others (who may or may not have used performance-enhancing substances). Caffeine, a central nervous system and cardiac stimulant, is frequently used by children for both academic and athletic performance enhancement. In fact, the marketplace contains a plethora of caffeinated products marketed directly to children. One article examines safety and ethical issues associated with the use of caffeine by children and explores the question: Can cognitive performance enhancement be ethically permissible if sports performance enhancement is not? [07170].

Effects on tennis

To determine the effects of prolonged simulated tennis on performance and the ergogenic potential of caffeine, carbohydrates, and cooling. Twelve highly trained male tennis players
performed 4 simulated matches (2 h 40 min) against a ball machine on an indoor hard court. The counterbalanced experimental trials involved caffeine supplementation (3 mg/kg), carbohydrate supplementation (6 % solution), precooling and intermittent cooling, and placebo control. Physiological markers (core temperature, heart rate, blood lactate, and blood glucose), subjective responses (ratings of perceived exertion and thermal sensation), stroke velocity and accuracy, serve kinematics, and tennis-specific perceptual skill quantified the efficacy of interventions. Significant effects of time reflected increased physiological demand, reduced serve velocity and ground-stroke velocity and accuracy, and a slowing of the serve racket-arm acceleration phase. Caffeine increased serve velocity (165 ± 15 km/h) in the final set of the match compared with placebo (159 ± 15 km/h) and carbohydrate (158 ± 13 km/h) conditions. Carbohydrate and cooling conditions afforded physiological advantage (increased blood glucose, and reduced preexercise thermal sensation, but did not affect performance relative to the placebo condition. It was concluded that prolonged simulated tennis induced significant decrements in tennis skills. Caffeine supplementation partly attenuated the effects of fatigue and increased serve velocity. In contrast, carbohydrate and cooling strategies had little ergogenic effect on tennis performance [09257].

Effects on rugby

The aim of one study was to determine the effects of a caffeine-containing energy drink on physical performance during a rugby sevens competition. A second purpose was to investigate the post-competition urinary caffeine concentration derived from the energy drink intake. On two non-consecutive days of a friendly tournament, 16 women from the Spanish National rugby team (mean age and body mass 23 ± 2 years and 66 ± 7 kg) ingested 3 mg of caffeine per kg of body mass in the form of an energy drink (Fure(®)) or the same drink without caffeine (placebo). After 60 min for caffeine absorption, participants performed a 15-s maximal jump test, a 6 × 30 m sprint test, and then played three rugby sevens games against another national team. Individual running pace and instantaneous speed during the games were assessed using global positioning satellite devices. Urine samples were obtained pre and post-competition. In comparison to the placebo, the ingestion of the energy drink significantly increased muscle power output during the jump series, running pace during the games and pace at sprint velocity. However, the energy drink did not affect maximal running speed during the repeated sprint test. The ingestion of the energy drink resulted in a higher post-competition urine caffeine concentration than the placebo (3.3 ± 0.7 vs 0.2 ± 0.1 microg/mL). In summary, 3 mg/kg of caffeine in the form of a commercially available energy drink considerably enhanced physical performance during a women's rugby sevens competition [13441].

The purpose of one study was to investigate the effectiveness of a caffeine-containing energy drink in enhancing rugby players' physical performance during a simulated match. A second purpose was to determine the urinary caffeine excretion derived from the energy drink intake. In a randomized and counterbalanced order, 26 elite rugby players played 2 simulated rugby games (2 × 30 min) 60 min after ingesting 3 mg of caffeine per kilogram of body mass in the form of an energy drink (Fure(®)) or the same drink without caffeine (placebo). During the matches, the individual running distance and the instantaneous speed were measured, and the number of running actions above 20 km/h (i.e. sprints) were determined, using global positioning system devices. The number of impacts above 5 g during the matches was determined by accelerometry. The ingestion of the energy drink, compared with the placebo, increased the total distance covered during the match, the running distance covered at more than 20 km/h, and the number of sprints. The ingestion of the energy drink also resulted in a greater overall number of impacts and a higher postexercise urine caffeine concentration. The use of an energy drink with a caffeine dose
equivalent to 3 mg/kg considerably enhanced the movement patterns of rugby players during a simulated match [13442].

Investigation of various exercise parameters in situations devised to simulate the repeated bouts of exercise required in rugby, a high-intensity team sport. Subjects were given either placebo or a moderate dose of caffeine (6 mg/kg) that previously has been shown to demonstrate ergogenic effects in submaximal exercise situations. Participants were then put through a series of 14 exercise circuits divided into two 40-minute halves. A 10-minute rest period occurred between the two halves. The design was intended to simulate the conditions of an actual rugby game with a first half, halftime, and second half. Subjects taking caffeine showed improvement in a variety of skill tasks including sprint tasks, power tasks, and passing accuracy tasks [06183].

Effects on weight-lifting

The purpose of the present study was to examine the acute effects of a caffeine-containing supplement (SUPP) on 1 repetition maximum (1RM) bench press and leg extension strength, as well as time to exhaustion (TTE), during cycle ergometry at a power output that corresponded to 80 percent of VO$_{2peak}$. The study used a double-blinded, placebo-controlled, crossover design. Twenty-one untrained men were randomly assigned to take either the SUPP or placebo (PLAC) first. The SUPP contained 400 mg of caffeine, 66.7 mg of capsicum extract, 10 mg of bioperine, and 40 mg of niacin, and the PLAC was microcrystalline cellulose. Sixty minutes after taking either the SUPP or PLAC, the subjects were tested for 1RM bench press and leg extension strength, as well as TTE. After 1 week of rest, the subjects ingested the opposite substance (SUPP or PLAC) and were retested for 1RM bench press and leg extension strength, as well as TTE. The results indicated that the SUPP had no effect on 1RM bench press strength, 1RM leg extension strength, or TTE at 80 percent VO$_{2peak}$. These findings did not support the use of the caffeine-containing SUPP in the present study as an ergogenic aid in untrained individuals [10182].

Effects on rowing

To determine whether a dose-response relationship exists between caffeine and 2000-m rowing performance in a randomized, placebo-controlled, double-blind crossover study, 10 competitive male rowers consumed 2, 4, or 6 mg/kg caffeine or a placebo 60 min before completing a 2000-m time trial on a rowing ergometer. The trials were preceded by a 24-h standardized diet (including a light preexercise meal of 2 g/kg carbohydrates), and subjects were tested preexercise for hydration, caffeine abstinence, and blood glucose concentrations. Time trial performance was not significantly different across the three caffeine doses or placebo. After the three caffeine trials, postexercise plasma glucose and lactate concentrations were higher compared with the placebo trial. Plasma caffeine concentrations after 60 min of ingestion were lower than the values reported previously by others following the same dose, and there was considerable interindividual variation in plasma caffeine concentrations in response to the various caffeine doses. It was concluded that the large interindividual response to the caffeine doses suggests that individual characteristics need to be considered when administering caffeine for performance enhancement. In addition, preexercise feeding may significantly affect plasma caffeine concentrations and the potential for caffeine to improve performance [10180].

Effects on iron-man

One study assessed the knowledge, prevalence, and quantity of caffeine use by athletes
competing at the 2005 Ironman Triathlon World Championships. Caffeine-related questionnaires were self-administered to 140 (105 male and 35 female, 40 ± 11 years) athletes representing 16 countries. Fifty of these athletes further consented to immediate post-race blood samples for analysis of plasma caffeine and paraxanthine using high-performance liquid chromatography (HPLC). Seventy-two percent of 70 athletes correctly identified caffeine as being an unrestricted substance in triathlon. The majority of athletes (89 %) were planning on using a caffeinated substance immediately prior to or throughout the race. Cola drinks (78 %), caffeinated gels (42 %), coffee (usually pre-race) (37 %), energy drinks (13 %), and NoDoz tablets (9 %) were the most popular caffeinated choices. Mean ± standard deviation post race plasma caffeine and paraxanthine levels were 22 ± 20 micromol/L and 9 ± 6 micromol/L, respectively. Seven athletes (14 %) finished with plasma caffeine levels > 40 micromol/L. Plasma values from elite athletes did not differ from age group competitors. Despite the prevalence of its consumption and the training experience of this athletic group, over one quarter of athletes remained either confused or uninformed about caffeine’s legality. Levels of plasma caffeine taken immediately post race indicated that athletes typically finish with quantities of caffeine that have been shown to improve endurance performance (i.e. approximately 20 micromol/L or a dose of ± 3 mg/kg body weight) [06198].

Effect on field hockey

One study examined the impact of caffeine ingestion on field hockey skill performance following high-intensity fatigue. Thirteen male hockey players (mean age 21 years) performed hockey sprint dribble and ball handling tests at rest and after a bout of total body fatigue (90 % maximal capacity) following caffeine (5 mg/kg) or placebo ingestion. Sprint dribble times were slower postfatigue compared with rest but were significantly faster postfatigue with caffeine compared with postfatigue with placebo ingestion. Ball handling scores were higher at rest compared with postfatigue, but scores postfatigue were higher following caffeine than placebo ingestion. Rating of perceived exhaustion (RPE) was lower and readiness to invest physical and mental effort were significantly higher in the caffeine condition. Caffeine ingestion may therefore be effective in offsetting decrements in skilled performance associated with fatigue [12289].

Effect on sedentary men

It is not known if ergogenic effects of caffeine ingestion in athletic groups occur in the sedentary. To investigate this, it was used a counterbalanced, double-blind, crossover design to examine the effects of caffeine ingestion (6 mg/kg body-mass) on exercise performance, substrate utilisation and perceived exertion during 30 minutes of self-paced stationary cycling in sedentary men. Participants performed two trials, one week apart, after ingestion of either caffeine or placebo one hour before exercise. Participants were instructed to cycle as quickly as they could during each trial. External work (J/kg) after caffeine ingestion was greater than after placebo. Further, heart rate, oxygen uptake and energy expenditure during exercise were greater after caffeine ingestion; whereas ratings of perceived exertion and respiratory exchange ratio values did not differ between trials. The ability to do more exercise after caffeine ingestion, without an accompanying increase in effort sensation, could motivate sedentary men to participate in exercise more often and so reduce adverse effects of inactivity on health [12288].

Effects on basket
One study investigated whether performance enhancement from caffeine described by other researchers transfers to male basketball players. The effects of caffeine ingestion were studied in a maximal-effort test on a treadmill that was followed by a vertical-jump test. Five elite-level male basketball players completed a graded treadmill test that measured maximal oxygen uptake, blood lactate profiles, respiratory exchange ratio, and rating of perceived exertion at each 3-minute stage. After a 15-minute warm-down, the subjects performed 10 vertical rebound jumps. Each subject completed the test twice – once with a 3 mg/kg of body weight dose of caffeine and once with a placebo, with the dosage administered 60 minutes before commencement of exercise. The test was thus administered according to a double-blind protocol. No substantial trends were found between caffeine and control trials, regardless of trial order. The study showed that the specified dosage had negligible effects on the players' power and endurance performance and had no efficacy as an ergogenic aid for male basketball players [13464].

Coffeine in central fatigue

Strong or sustained contractions can fatigue muscles and reduce their capacity to generate maximal voluntary force. This impairment may result not only from reduced force from the muscle but also from reduced output from the spinal motoneuron pool. This is known as “central fatigue.” Demonstration of the suboptimal volitional output from the motoneuron pool is easily achieved using methods that interpolate an extra motor impulse via an external agency, such as a nerve stimulator. If a twitchlike increment in force is obtained with stimulation of the nerve innervating part of the contracting muscles, suboptimal motoneuron output is obvious. However, quantitation of the level of output to the muscle group is less easy. For example, whereas many motor nerves innervate the bulk of synergists in a particular task, they also innervate antagonists (e.g., stimulation of the common peroneal nerve contracts ankle dorsiflexors but also some plantar flexors, stimulation of the femoral nerve activates knee extensors but also two weak knee flexors), and hence the size of the superimposed twitch can be contaminated by unwanted force produced by antagonists, and voluntary activation is spuriously high. As supraspinal fatigue develops with exercise, there are dramatic changes within the motor cortex and also in corticospinal “connectivity” with motoneurons. For example, the silent period in the electromyogram (EMG) after cortical stimulation lengthens (a reflection of intracortical inhibition) and the initial excitatory EMG response (motor evoked potential, MEP) increases during fatiguing contractions, and there are depressions in MEPs and cervicomedullary evoked potentials (a test of corticomotoneuronal function) after exercise. It has been used caffeine ingestion to probe links between force and motor cortical output. It is argued that, if a decrease in “central excitability” causes central fatigue with its associated failure in voluntary activation of the muscle, then caffeine, which increases central excitability (as represented by the size of the MEP), should reduce the fatiguing decline in voluntary force. Sets of repeated knee extensor contractions reduced force by about 35 percent, and performance was measured in two sessions: one with, and one without prior caffeine administration (6 mg/kg). TMS was delivered during weak contractions between exercise sets. Femoral nerve stimulation was applied during and after maximal voluntary contractions (MVCs) to assess changes in the M wave and in voluntary activation. Before fatigue, caffeine increased voluntary activation in brief maximal efforts (by 2-3 %) and increased the baseline MEP during very weak contractions (3 % MVC). During fatiguing exercise, MEP size was elevated by caffeine compared with placebo, whereas maximal voluntary activation and force recovery were unaffected. That is, increased central excitability did not ameliorate the fatigue-related falls in voluntary activation and voluntary force. Furthermore, after caffeine, the MEP at the end of fatiguing exercise was not decreased compared with control values, so the impairment of
voluntary activation seen at this moment is not due to impaired central excitability [06197].

**Ratings of perceived exertion**

One study examined effects of caffeine on session ratings of perceived exertion (RPE) following 30 min constant-load cycling. Individuals (n=15) of varying aerobic fitness completed a max trial and two 30 min cycling bouts (double-blind, counterbalanced) following ingestion of 6 mL/kg of caffeine or matched placebo. RPE overall, legs and breathing were estimated every 5 min and session RPE was estimated 30 min post-exercise using the OMNI pictorial scale. Session RPE for caffeine and placebo trials were compared using paired t test. Between-trial comparisons of HR, RPE overall, RPE legs and RPE breathing were analyzed using an independent 2 (trial) × 6 (time point) repeated measures analysis of variance (ANOVA) for each dependent variable. Caffeine resulted in a significantly lower session RPE for caffeine versus placebo. Acute perceptual responses were significantly lower for caffeine for RPE overall (15, 20, 25, and 30 min), RPE breathing (15, 20, 25, and 30 min) and RPE legs (20 and 30 min). Survey responses post-exercise revealed greater feelings of nervousness, tremors, restlessness and stomach distress following caffeine versus placebo. Blunted acute RPE and survey responses suggest participants responded to caffeine ingestion. Caffeine decreased acute RPE during exercise which could partially account for lower session RPE responses. However, decreased session RPE could also reveal a latent analgesic affect of caffeine extending into recovery. Extending the understanding of session RPE could benefit coaches in avoiding overtraining when adjusting training programs [13447].

Caffeine containing energy drinks is commonly consumed in the belief that it will enhance the quality of an exercise session and enhance mood. However, studies examining their efficacy are sparse. The aim of this study was to examine the effect of a caffeinated energy drink on leg pain perception, perceived exertion, mood state and readiness to invest effort pre, during and post 60 min cycling exercise. Fourteen active individuals (7 males, 7 females, mean age 24 years), completed two 60 min cycling trials at an intensity of 60 percent VO$_2$ max preceded by ingestion of solutions containing either a caffeinated energy drink or placebo using a double-blind, deceptive, crossover design. During exercise, RPE (6-20 scale), leg pain (0-10 scale), heart rate (HR) and blood lactate (Bla) were recorded. Participants also completed measures of mood state and readiness to invest physical effort (RTIPE) pre- and post-exercise. Repeated measures analysis of variance was used to assess differences in all variables and across time and treatments, with gender used as a between subjects variable. Results indicate that HR was significantly higher from 30 to 60 min and RPE and pain perception were significantly lower from 20 to 60 min in the energy drink condition compared to placebo. Lactate was significantly higher in the last 15 min of the energy drink trial and RTIPE increased significantly more from pre-ingestion to pre-exercise post-ingestion in the energy drink condition compared to placebo. No gender differences were evident. The data revealed positive effects of energy drink ingestion on perception of exertion, leg muscle pain perception and readiness to invest effort during submaximal cycling in active adults [13448].

**Caffeine levels before and after the removal of caffeine from the doping list**

Caffeine concentrations were measured in the urine of 4633 athletes tested for doping control in the Ghent Doping Control Laboratory in 2004. Determination of these concentrations was done using an alkaline extraction with a mixture of dichloromethane and methanol (9 : 1; v/v) followed by high performance liquid chromatography and ultraviolet detection (HPLC-UV). The method was validated according to ISO 17 025 standards.
(International Organisation for Standardisation). Quantification was done by using a linear calibration curve in the range from 0 to 20 microg/mL. The limit of quantification (LOQ) was 0.10 microg/ml. Because the results were not normally distributed, transformation of the data was done to evaluate the difference in detected concentrations in several sports. This resulted in an overall average concentration of 1.12 ± 2.68 microg/mL. Comparison of the most frequently tested sports in 2004 demonstrated that caffeine concentrations in samples originating from power lifters are significantly higher in comparison to urines taken in other sports. Also, a significant difference between caffeine concentrations found in cycling and concentrations found in other sports, including athletics and some ball sports, was observed. A comparison was made between results obtained in 2004 and results obtained before the removal of caffeine from the WADA (World Anti-Doping Agency) doping list indicating that average caffeine concentrations decreased after the withdrawal of caffeine from the list of prohibited substances. The overall percentage of positive samples between the two periods remained the same although the percentage of positive samples noticed in cycling increased after the removal of caffeine from the doping list [06187].

Caffeine in diabetics

Caffeine is a substance that has been used in our society for generations, primarily for its effects on the central nervous system that causes wakefulness. Caffeine supplementation has become increasingly more popular as an ergogenic aid for athletes and considerable scientific evidence supports its effectiveness. Because of their potential to alter energy metabolism, the effects of coffee and caffeine on glucose metabolism in diabetes have also been studied both epidemiologically and experimentally. Predominantly targeting the adenosine receptors, caffeine causes alterations in glucose homeostasis by decreasing glucose uptake into skeletal muscle, thereby causing elevations in blood glucose concentration. Caffeine intake has also been proposed to increase symptomatic warning signs of hypoglycemia in patients with type 1 diabetes and elevate blood glucose levels in patients with type 2 diabetes. Other effects include potential increases in glucose counterregulatory hormones such as epinephrine, which can also decrease peripheral glucose disposal. Despite these established physiological effects, increased coffee intake has been associated with reduced risk of developing type 2 diabetes in large-scale epidemiological studies. One review paper highlighted the known effects of caffeine on glucose homeostasis and diabetes metabolism during rest and exercise [13437].

Several prospective epidemiologic studies over the past 4 years concluded that ingestion of caffeinated and decaffeinated coffee can reduce the risk of diabetes. This finding is at odds with the results of trials in humans showing that glucose tolerance is reduced shortly after ingestion of caffeine or caffeinated coffee and suggesting that coffee consumption could increase the risk of diabetes. This review discusses epidemiologic and laboratory studies of the effects of coffee and its constituents, with a focus on diabetes risk. Weight loss may be an explanatory factor, because one prospective epidemiologic study found that consumption of coffee was followed by lower diabetes risk but only in participants who had lost weight. A second such study found that both caffeine and coffee intakes were modestly and inversely associated with weight gain. It is possible that caffeine and other constituents of coffee, such as chlorogenic acid and quinides, are involved in causing weight loss. Caffeine and caffeinated coffee have been shown to acutely increase blood pressure and thereby to pose a health threat to persons with cardiovascular disease risk. One short-term study found that ground decaffeinated coffee did not increase blood pressure. Decaffeinated coffee, therefore, may be the type of coffee that can safely help persons decrease diabetes risk. However, the ability of decaffeinated coffee to achieve these effects is based on a limited number of studies, and the underlying biological mechanisms have yet to be elucidated [06188].
Combination with creatinine

Caffeine and creatine are 2 of the most widely available and used compounds in sport. Although the use of either is not considered a doping infraction, the evidence does suggest ergogenic potential in certain sports. The purpose of one paper was to review the pharmacology and potential mechanism(s) of action of caffeine and creatine as they pertain to possible use as an ergogenic aid in sport. Previous review articles on caffeine and creatine use in sport were screened for relevant information and references, and studies for review and recent articles (2007 onwards) were obtained and reviewed using a PUBMED search with the terms “caffeine AND exercise”, “creatine and creatine monohydrate AND exercise”, and appropriate linked articles were evaluated. Caffeine taken before (3-6 mg/kg) or during (1-2 mg/kg) endurance exercise enhances performance, through central nervous system and direct muscle effects. Creatine monohydrate supplementation at higher (approx. 20 g/day × 3-5 days) or lower (approx. 5 g/day × 30 days) doses increases skeletal muscle total and phosphocreatine by 10-20 percent. Creatine supplementation appears to minimally but significantly enhance high-intensity sport performance and the mass and possibly strength gains made during resistance exercise training over the first few months. Although caffeine and creatine appear to be ergogenic aids, they do so in a sport-specific context and there is no rationale for their simultaneous use in sport. Higher doses of caffeine can be toxic and appear to be ergolytic. There is no rationale for creatine doses in excess of the recommendations, and some athletes can get stomach upset, especially at higher creatine doses [11201].

Combination with ephedrine

Caffeine and ephedrine-related alkaloids recently have been removed from International Olympic Committee banned substances lists, whereas ephedrine itself is now permissible at urinary concentrations less than 10 mug.mL. The changes to the list may contribute to an increased use of caffeine and ephedra as ergogenic aids by athletes. Consequently, It was investigated the effects of ingesting caffeine (C) or a combination of ephedra and caffeine (C + E) on muscular strength and anaerobic power using a double-blind, crossover design. Forty-five minutes after ingesting a glucose placebo (P: 300 mg), C (300 mg) or C + E (300 mg + 60 mg), 9 resistance-trained male participants were tested for maximal strength by bench press (1 repetition maximum) and latissimus dorsi pull down (1 repetition maximum). Subjects also performed repeated repetitions at 80 percent of 1 repetition maximumon both activities until exhaustion. After this test, subjects underwent a 30-second Wingate test to determine peak anaerobic cycling power, mean power, and fatigue index. Although subjects reported increased alertness and enhanced mood after supplementation with caffeine and ephedra, there were no significant differences between any of the treatments in muscle strength, muscle endurance, or peak anaerobic power. The results do not support the contention that supplementation with ephedra or caffeine will enhance either muscle strength or anaerobic exercise performance [08316].

Caffeine versus pseudoephedrine

Caffeine (CAF) improves performance in both short- and long-duration running and cycling where performance relies on power output and endurance capacity of leg muscles. No studies have so far tested the effects of CAF while using the double-poling (DP) technique in
cross-country skiing. When using the DP technique, arm muscles provide the speed-generating force and therefore play an important role in performance outcome. The metabolism of arm muscles differs from that of leg muscles. Thus, results from studies on leg muscles and CAF may not be directly applicable to exercises while using the DP technique in cross-country skiing. The purpose of one study was therefore to investigate the effects of CAF on exercise performance in DP. Ten highly trained male cross-country skiers performed a placebo (PLA) and CAF trial using a randomized, double-blind, crossover design. Performance was assessed by measuring the time to complete an 8-km cross-country DP performance test (C-PT). CAF (6 mg/kg) or PLA was ingested 75 min before the C-PT. CAF ingestion reduced the time to complete the 8-km C-PT. The subjects maintained higher speed and HR throughout the C-PT, and lactate was higher immediately after the C-PT with CAF exposure compared with PLA. Subjects reported lower RPE at submaximal intensities during CAF compared with PLA, although HR was similar. It was concluded that CAF intake enhances endurance performance in an 8-km C-PT, where arm muscles limit performance. CAF ingestion allowed the participants to exercise with a higher HR and work intensity possibly by reducing perception of effort or facilitating motor unit recruitment [13473].

Both caffeine (CAF) and pseudoephedrine (PSE) are proposed to be central nervous system stimulants. However, during competition, CAF is a permitted substance, whereas PSE is a banned substance at urinary levels >150 microg/mL. As a result, one study aimed to compare the effect of CAF versus PSE use on cycling time trial (TT) performance to explore whether the legal stimulant was any less ergogenic than the banned substance. Here, 10 well-trained male cyclists or triathletes were recruited for participation. All athletes were required to attend the laboratory on four separate occasions – including a familiarization trial and three experimental trials, which required participants to complete a simulated 40 km (1,200 kJ) cycling TT after the ingestion of either 200 mg CAF, 180 mg PSE or a nonnutritive placebo (PLA). The results showed that the total time taken and the mean power produced during each TT was not significantly different between trials, despite a 1.3 percent faster overall time (57 s) after CAF consumption. Interestingly, the time taken to complete the second half of the TT was significantly faster in CAF as compared with PSE (by 99 s), with magnitude based inferences suggesting a 91 percent beneficial effect of CAF during the second half of the TT. This investigation further confirms the ergogenic benefits of CAF use during TT performances and further suggests this legal CNS stimulant has a better influence than a supra-therapeutic dose of PSE [13474].

Combination with albuterol

The main aim of one study was to evaluate the comparative and additive effects of caffeine and albuterol (short-acting beta2-agonist) on the severity of exercise induced bronchoconstriction (EIB). Ten asthmatic subjects with exercise-induced bronchoconstriction participated in a randomized, double-blind, double-dummy crossover study. One hour before an exercise challenge, each subject was given 0, 3, 6, or 9 mg/kg of caffeine or placebo mixed in a flavored sugar drink. Fifteen minutes before the exercise bout, an inhaler containing either albuterol (180 microg) or placebo was administered to each subject. Pulmonary function tests were conducted pre- and post-exercise. Caffeine at a dose of 6 and 9 mg/kg significantly reduced the mean maximum percentage fall in post-exercise FEV1 compared to the double-placebo and baseline. There was no significant difference in the post-exercise % fall in FEV1 between albuterol and the 9 mg/kg dose of caffeine. Interestingly, there was no significant difference in the post-exercise percentage fall in FEV1 between albuterol and albuterol with 3, 6 or 9 mg/kg of caffeine. Similar changes were observed for the post-exercise percentage fall in FVC, FEF (25-75 %) and PEF. These data
indicate that moderate (6 mg/kg) to high doses (9 mg/kg) of caffeine provide a significant protective effect against EIB. It is feasible that the negative effects of daily use of short-acting beta-agonists by asthmatic athletes could be reduced simply by increasing caffeine consumption prior to exercise [10177].

Combination with sodium bicarbonate

To determine the effects of ingesting caffeine (CAFF) and sodium bicarbonate (SB), taken individually and simultaneously, on 3-km cycling time-trial (TT) performance 10 well-trained cyclists, age 24 years, participated in this acute-treatment, double-blind, crossover study that involved four 3-km cycling TTs performed on separate days. Before each TT, participants ingested either 3 mg/kg body mass (BM) of CAFF, 0.3 g/kg BM of SB, a combination of the two (CAFF+SB), or a placebo (PLAC). They completed each 3-km TT on a laboratory-based cycle ergometer, during which physiological, perceptual, and performance measurements were determined. For statistical analysis, the minimal worthwhile difference was considered about 1 percent based on previous research. Pretrial pH and HCO₃ were higher in SB and CAFF+SB than in the CAFF and PLAC trials. Differences across treatments for perceived exertion and gastric discomfort were mostly unclear. Compared with PLAC, mean power output during the 3-km TT was higher in CAFF, SB, and CAFF+SB trials (2.4 %, 2.6 %, 2.7 % respectively), resulting in faster performance times (-0.9, -1.2, -1.2 % respectively). Effect sizes for all trials were small (0.21 - 0.24). Thus, when ingested individually, both CAFF and SB enhance high-intensity cycling TT performance in trained cyclists. However, the ergogenic effect of these 2 popular supplements was not additive, bringing into question the efficacy of coingesting the 2 supplements before short-duration high-intensity exercise. In this study there were no negative effects of combining CAFF and SB, 2 relatively inexpensive and safe supplements [12292].

The purpose of this study was to investigate the effects of sodium bicarbonate (NaHCO₃), caffeine, and their combination on repeated 200-m freestyle performance. Six elite male freestyle swimmers ingested sodium bicarbonate (0.3 g/kg), caffeine (6.2 ± 0.3 mg/kg), a combination of both, and placebo on 4 separate occasions before completing 2 maximal 200-m freestyle time trials separated by 30 min. No significant differences were observed for performance but drop-off in performance time from first to second trial, however, was significantly greater when caffeine was ingested than with bicarbonate or the combination. This is likely because of the lower blood pH and slower recovery of blood HCO₃ after caffeine ingestion. These findings suggest that the ergogenic benefit of taking caffeine alone for repeated 200-meter swimming performance appears limited. When combined with sodium bicarbonate, however, its negative impact on repeated maximal exercise performance is reversed [08317].

The purpose of this investigation was to determine the effect of ingested caffeine, sodium bicarbonate, and their combination on 2,000-m rowing performance, as well as on induced alkalosis (blood and urine pH and blood bicarbonate concentration, HCO₃⁻, blood lactate concentration, gastrointestinal symptoms, and rating of perceived exertion (RPE). In a double-blind, crossover study, 8 well-trained rowers performed 2 baseline tests and 4 × 2,000-m rowing-ergometer tests after ingesting 6 mg/kg caffeine, 0.3 g/kg body mass (BM) sodium bicarbonate, both supplements combined, or a placebo. Capillary blood samples were collected at preingestion, pretest, and posttest time points. Pairwise comparisons were made between protocols, and differences were interpreted in relation to the likelihood of exceeding the smallest worthwhile-change thresholds for each variable. A likelihood of >75 percent was considered a substantial change. Caffeine supplementation elicited a substantial
improvement in 2,000-m mean power, with mean (± SD) values of 354 ± 67 W versus placebo with 346 ± 61 W. Pretest bicarbonate reached 29.2 ± 2.9 mmol/L with caffeine + bicarbonate and 29.1 ± 1.9 mmol/L with bicarbonate. There were substantial increases in pretest bicarbonate and pH and posttest urine pH after bicarbonate and caffeine + bicarbonate supplementation compared with placebo, but unclear performance effects. It was concluded that rowers' performance in 2,000-m efforts can improve by about 2 percent with 6 mg/kg BM caffeine supplementation. When caffeine is combined with sodium bicarbonate, gastrointestinal symptoms may prevent performance enhancement, so further investigation of ingestion protocols that minimize side effects is required [11493].

### Combination with sodium citrate

The aim of one study was to investigate whether caffeine and/or sodium citrate have an ergogenic effect on the 1500 m exercise performance in elite wheelchair athletes. A placebo-controlled, randomized, cross-over and double-blind study design was conducted with the four treatments placebo, caffeine, sodium citrate and the combination of caffeine and sodium citrate. Nine healthy, elite wheelchair racing athletes (category T53/54) completed the study. All athletes were national team members, including several Paralympic Games, World and European Championship medalists. The athletes performed a 1500 m time trial four times on a wheelchair training roller. Time to complete 1500 m, pH, bicarbonate and sodium concentration as well as lactate concentration were measured. The time to complete 1500 m was not significantly different between the four treatments (placebo; caffeine; sodium citrate; combination. However, pH and bicarbonate concentrations were significantly increased with sodium citrate ingestion compared to placebo. Moreover, maximal lactate concentrations were significantly higher in the caffeine and the combination treatment compared to placebo. The supplementation with sodium citrate and/or caffeine did not provide an ergogenic effect on the 1500 m exercise performance in wheelchair elite athletes [13468].

### Combination with carbohydrates

Carbohydrate (CHO) and caffeine (CAF) both improve endurance performance. To determine by systematic literature review coupled with meta-analysis whether CAF ingested with CHO (CHO+CAF) improves endurance performance more than CHO alone databases were searched using the keywords caffeine, endurance, exercise, carbohydrate, and performance. Criteria for inclusion were studies that used human subjects performing an endurance-exercise performance task and included both a CHO and CHO+CAF condition. Effect sizes were calculated as the standardized mean difference. Twenty-one studies met the criteria for analysis. Effect sizes for individual studies ranged from -0.08 (trivial effect favoring CHO) to 1.01 (large effect favoring CHO+CAF). The overall ES equaled 0.26 (95% confidence interval 0.15 to 0.38), indicating that CHO+CAF provides a small but significant performance benefit over CHO. Effect size was not significantly related to CAF dose, exercise duration, or performance-assessment method. To determine whether effect size of CHO+CAF versus CHO was different than CAF compared with water (placebo), a subgroup meta-analysis compared 36 CAF versus placebo studies against the 21 CHO+CAF versus CHO studies. The overall effect sizes for the former group of studies was nearly 2-fold greater than in CHO+CAF versus CHO studies. CHO+CAF ingestion provides a significant but small effect to improve endurance performance compared with CHO alone. However, the magnitude of the performance benefit that CAF provides is less when added to CHO than when added to placebo [11204].
The aim of this study was to evaluate the effect of co-ingesting carbohydrate and caffeine (CHO+CAF) in comparison to carbohydrate (CHO) and placebo (PLA), during a reliable soccer-specific test. Eight university-standard soccer players ingested a PLA, a 6.4 percent CHO or 6.4 percent CHO and 160 mg CAF (CHO+CAF) solution on three occasions, in a double-blind randomized cross-over design, with each trial separated by 7 days. The protocol was 90 min in duration, made up of ten 6 min exercise blocks, each followed by soccer-specific skills tests (agility, dribbling, heading and kicking accuracy). Dependant variables (agility, dribbling, heading, kicking accuracy, glucose, lactate, HR and RPE) were analysed using one-way repeated measures ANOVA. Significant difference was found between CHO+CAF, CHO and PLA for each of the soccer-specific skill tests. Significant improvement was observed in agility time in CHO versus PLA trials, although no significant difference was reported for dribbling, heading and kicking accuracy. Blood glucose and lactate were significantly elevated with CHO+CAF supplementation over PLA, but there was no difference compared to CHO. Blood glucose increased significantly in the CHO trial compared to PLA, with no difference between CHO+CAF and CHO. No significant difference was reported for HR and RPE values across all trial conditions. Skill performance during simulated soccer activity improved with CHO+CAF supplementation in comparison to both CHO and PLA. CHO+CAF co-ingestion had no ergogenic benefit over CHO in the maintenance and availability of blood glucose however, CHO+CAF co-ingestion did allow players to sustain a higher work intensity as opposed to CHO and PLA beverages as shown by elevated blood lactate levels [11487].

The aim of one study was to test the hypothesis that adding caffeine to postexercise carbohydrate (CHO) feedings improves subsequent high-intensity interval-running capacity compared with CHO alone. In a repeated-measures design, 6 men performed a glycogen-depleting exercise protocol until volitional exhaustion in the morning. Immediately after and at 1, 2, and 3 hr postexercise, participants consumed 1.2 g/kg body mass CHO of a 15 percent CHO solution, a similar CHO solution but with addition of 8 mg/kg body mass of caffeine (CHO+CAFF), or an equivalent volume of flavored water only (WAT). After the 4-hr recovery period, participants performed the Loughborough Intermittent Shuttle Test (LIST) to volitional exhaustion as a measure of high-intensity interval-running capacity. Average blood glucose values during the 4-hr recovery period were higher in the CHO conditions than in the WAT trial (4.6 ± 0.3 mmol/L), although there was no difference between CHO (6.2 ± 0.8 mmol/L) and CHO+CAFF (6.7 ± 1.0 mmol/L). Exercise capacity during the LIST was significantly longer in the CHO+CAFF trial (48 ± 15 min) than in the CHO (32 ± 15 min) and WAT conditions (19 ± 6 min). All 6 participants improved performance in CHO+CAFF compared with CHO. The study provides novel data by demonstrating that adding caffeine to postexercise CHO feeding improves subsequent high-intensity interval-running capacity, a finding that may be related to higher rates of postexercise muscle glycogen resynthesis previously observed under similar feeding conditions [11488].

The aim of one study was to test the hypothesis that adding caffeine to postexercise carbohydrate (CHO) feedings improves subsequent high-intensity interval-running capacity compared with CHO alone. In a repeated-measures design, 6 men performed a glycogen-depleting exercise protocol until volitional exhaustion in the morning. Immediately after and at 1, 2, and 3 hr postexercise, participants consumed 1.2 g/kg body mass CHO of a 15 percent CHO solution, a similar CHO solution but with addition of 8 mg/kg body mass of caffeine (CHO+CAFF), or an equivalent volume of flavored water only (WAT). Average blood glucose values during the 4-hr recovery period were higher in the CHO conditions than in the WAT trial (4.6 ± 0.3 mmol/L), although there was no difference between CHO (6.2 ± 0.8 mmol/L) and CHO+CAFF (6.7 ± 1.0 mmol/L). Exercise capacity during the study was significantly
longer in the CHO+CAFF trial (48 ± 15 min) than in the CHO (32 ± 15 min) and WAT conditions (19 ± 6 min). All 6 participants improved performance in CHO+CAFF compared with CHO. The study provides novel data by demonstrating that adding caffeine to postexercise CHO feeding improves subsequent high-intensity interval-running capacity, a finding that may be related to higher rates of postexercise muscle glycogen resynthesis previously observed under similar feeding conditions [13348].

The importance of endogenous carbohydrate (CHO) availability for high-intensity exercise performance has been well described in the literature. Several studies have shown that performance during high-intensity exercise is impaired when endogenous CHO availability (i.e. muscle and liver glycogen stores) is reduced. For example, it was reported that after three days of a low-CHO diet (about 5 % CHO) the average power output measured during a 30 s Wingate test in healthy men not engaged in any competitive sport was significantly reduced (from 581 ± 7 to 533 ± 7 W) when compared with a normal diet (about 50 % CHO). According to these authors, the reduction in performance (9 %) with low CHO availability was due to a lower contribution of the anaerobic energy system. Similarly, it was found a reduction in the anaerobic work capacity of healthy, non-athletic men when exercise was performed after a muscle-glycogen-depletion protocol compared to a control condition (10.33 ±2. 41 vs 12.83 ± 2.21 kJ, respectively), suggesting that low CHO availability can reduce the anaerobic contribution to total energy expenditure during high-intensity exercise. In addition, reduction in self-selected power output during high-intensity interval training when performed with low endogenous CHO availability has been also reported in well-trained subjects, and it may be associated with a reduction in the anaerobic contribution. While low CHO availability seems to reduce the anaerobic contribution and impair performance during high-intensity exercise, acute ingestion of caffeine seems to have the opposite effect. Taken together, several studies suggest that acute ingestion of caffeine may improve performance during high-intensity exercise via an increase in the anaerobic contribution. The purpose one study was therefore to examine the effects of caffeine ingestion on performance and energy expenditure (anaerobic and aerobic contribution) during a 4 km cycling time trial (TT) performed after a carbohydrate (CHO) availability-lowering exercise protocol. After preliminary and familiarization trials, seven amateur cyclists performed three 4-km cycling TT in a double-blind, randomized and crossover design. The trials were performed either after no previous exercise (CON), or after a CHO availability-lowering exercise protocol (DEP) performed in the previous evening, followed by either placebo (DEP-PLA) or 5 mg/kg of caffeine intake (DEP-CAF) 1 hour before the trial. Performance was reduced (-2.1 %) in DEP-PLA versus CON. However, performance was restored in DEP-CAF (404.6±17.1 s) compared with DEP-PLA, while no differences were found between DEP-CAF and CON. The anaerobic contribution was increased in DEP-CAF compared with both DEP-PLA and CON, and this was more pronounced in the first 3 km of the trial. Similarly, total anaerobic work was higher in DEP-CAF than in the other conditions. The integrated electromyographic activity, plasma lactate concentration, oxygen uptake, aerobic contribution and total aerobic work were not different between the conditions. The reduction in performance associated with low CHO availability is reversed with caffeine ingestion due to a higher anaerobic contribution, suggesting that caffeine could access an anaerobic "reserve" that is not used under normal conditions [13459].

The mechanisms by which caffeine increases the anaerobic contribution and performance during high-intensity exercise is not fully understood, but it has been proposed that caffeine intake would promote an inhibitory action on adenosine receptors, which would increase the activity of the enzyme phosphofructokinase, thereby increasing anaerobic glycolysis. Alternatively, caffeine may act on the central nervous system leading to an increase in motivational drive and neuromuscular excitability, which, in turn, results in a lowered rating of perceived exertion (RPE) for a given workload and improved neuromuscular function, as
measured via electromyography activity (EMG). In addition, it has also been suggested that caffeine attenuates muscle sensory signals to the brain and decreases the threshold of activation of motor neurons. All of these central alterations could lead to an ability to produce more work anaerobically [13459].

Although several studies have investigated the isolated effects of both CHO availability and caffeine intake on anaerobic contribution and performance, no study has examined whether acute caffeine ingestion could counteract the negative effects of low CHO availability on both the anaerobic contribution and performance. This seems to be particularly important since many athletes perform two training sessions in the same day, or participate in multi-stage event races (e.g. tour de France), where the time to replenish endogenous CHO stores between sessions or races may not be sufficient. Furthermore, most studies with either caffeine or CHO availability have focused on investigating their effects during time-to-exhaustion tests. However, time trials (TT) appear to be more reliable and to have greater external validity compared to constant-workload tests until exhaustion. Furthermore, during a high-intensity TT, where athletes are free to vary power output, anaerobic metabolism seems to exert a decisive effect on both performance and the distribution of work [13459].

**Caffeine at low muscle glycogen availability**

Commencing selected workouts with low muscle glycogen availability augments several markers of training adaptation compared with undertaking the same sessions with normal glycogen content. However, low glycogen availability reduces the capacity to perform high-intensity (>85 % of peak aerobic power, VO$_2$ peak) endurance exercise. We determined whether a low dose of caffeine could partially rescue the reduction in maximal self-selected power output observed when individuals commenced high-intensity interval training with low (LOW) compared with normal (NORM) glycogen availability. Twelve endurance-trained cyclists/triathletes performed four experimental trials using a double-blind Latin square design. Muscle glycogen content was manipulated via exercise-diet interventions so that two experimental trials were commenced with LOW and two with NORM muscle glycogen availability. Sixty minutes before an experimental trial, subjects ingested a capsule containing anhydrous caffeine (CAFF, 3 mg/kg body mass) or placebo (PLBO). Instantaneous power output was measured throughout high-intensity interval training (8 × 5 min bouts at maximum self-selected intensity with 1min recovery). There were significant main effects for both preexercise glycogen content and caffeine ingestion on power output. LOW reduced power output by approximately 8 percent compared with NORM, whereas caffeine increased power output by 2.8 and 3.5 percent for NORM and LOW, respectively. It was concluded that caffeine enhanced power output independently of muscle glycogen concentration but could not fully restore power output to levels commensurate with that when subjects commenced exercise with normal glycogen availability. However, the reported increase in power output does provide a likely performance benefit and may provide a means to further enhance the already augmented training response observed when selected sessions are commenced with reduced muscle glycogen availability [13460].

**Caffeinated mouth-rinse**

The purpose of one study was to investigate if acute caffeine exposure via mouth-rinse improved endurance cycling time-trial performance in well-trained cyclists. It was hypothesised that caffeine exposure at the mouth would enhance endurance cycling time-trial performance. Ten well-trained male cyclists completed two experimental time-trials following 24h of dietary and exercise standardisation. A randomised, double-blind, placebo-controlled, cross-over design was employed whereby cyclists completed a time-trial in the
fastest time possible, which was equivalent work to cycling at 75 percent of peak aerobic power output for 60min. Cyclists were administered 25 mL mouth-rinses for 10 s containing either placebo or 35 mg of anhydrous caffeine eight times throughout the time-trial. Perceptual and physiological variables were recorded throughout. No significant improvement in time-trial performance was observed with caffeine compared to placebo mouth-rinse. No elevation in plasma caffeine was detected due to the mouth-rinse conditions. Caffeine mouth-rinse had no significant effect on rating of perceived exertion, heart rate, rate of oxygen consumption or blood lactate concentration. Eight exposures of a 35mg dose of caffeine at the buccal cavity for 10s does not significantly enhance endurance cycling time-trial performance, nor does it elevate plasma caffeine concentration [13461].

Effect on individuals with negative energy balance

The ingestion of carbohydrate (+CHO) and caffeine (+CAF) during exercise is a commonly used ergogenic practice. Investigations are typically conducted with subjects who are in a rested state after an overnight fast. However, this state of positive energy balance is not achieved during many work and exercise circumstances. The aim of one study was to evaluate the substrate use and performance effects of caffeine and carbohydrate consumed alone and in combination while participants were in negative energy balance. Male participants (n=9) completed 4 trials in random order: -CAF/-CHO, -CAF/+CHO, +CAF/-CHO, and +CAF/+CHO. Diet and exercise were prescribed for 2 days before each trial to ensure negative energy balance. For each trial, before and after 2 h of cycling at 50 percent of maximal watts, a saliva sample and a muscle biopsy (vastus lateralis) were obtained. A simulated 20 km time trial was then performed. The respiratory exchange ratio was higher in +CHO trials and lower in the +CAF/+CHO trial than in the -CAF/+CHO trial. Salivary cortisol response was significantly higher in the +CAF/-CHO trial than in any of the other trials. Muscle glycogen and heart rates were similar in all trials. Performance in the 20 km time trial was significantly better in the -CAF/+CHO trial than in the -CAF/-CHO trial, but the +CAF/+CHO trial was no better than the +CAF/-CHO trial or any of the other trials. When co-ingested with carbohydrate, caffeine increased fat use and decreased nonmuscle glycogen carbohydrate use over carbohydrate alone when participants are in negative energy balance; however, caffeine had no effect on the 20 km cycling time trial performance [09254].

Combination with epigallocatechin

Different outcomes of the effect of catechin-caffeine mixtures and caffeine-only supplementation on energy expenditure and fat oxidation have been reported in short-term studies. Therefore, a meta-analysis was conducted to elucidate whether catechin-caffeine mixtures and caffeine-only supplementation indeed increase thermogenesis and fat oxidation. First, English-language studies measuring daily energy expenditure and fat oxidation by means of respiration chambers after catechin-caffeine mixtures and caffeine-only supplementation were identified through PubMed. Six articles encompassing a total of 18 different conditions fitted the inclusion criteria. Second, results were aggregated using random/mixed-effects models and expressed in terms of the mean difference in 24 h energy expenditure and fat oxidation between the treatment and placebo conditions. Finally, the influence of moderators such as BMI and dosage on the results was examined as well. The catechin-caffeine mixtures and caffeine-only supplementation increased energy expenditure significantly over 24 h (4.7 % and 4.8 %, respectively). However, 24 h fat oxidation was only increased by catechin-caffeine mixtures. A dose-response effect on 24 h energy expenditure and fat oxidation occurred with a mean increase of 0.53 kJ/mg and 0.02 g/mg for catechin-caffeine mixtures and 0.44 kJ/mg and 0.01 g/mg(-1) for caffeine-only. In conclusion,
catechin-caffeine mixtures or a caffeine-only supplementation stimulates daily energy expenditure dose-dependently by 0.4-0.5 kJ/mg administered. Compared with placebo, daily fat-oxidation was only significantly increased after catechin-caffeine mixtures ingestion [13349].

The aim of one study was to evaluate the combined effects of a 10-week exercise program with ingestion of caffeine and epigallocatechin-3-gallate (EGCG) on body composition, cardiovascular fitness, and strength in overweight and obese women. In a double-blind, placebo-controlled approach, overweight and obese women (n=27) were randomly assigned to treatment groups with exercise (an active-supplementing group with exercise (EX-Act) and a placebo group with exercise (EX-PL)) or without exercise (an active-supplementing group without exercise (NEX-Act) and a placebo group without exercise (NEX-PL)). All participants consumed 1 drink per day for 10 weeks; EX-Act and EX-PL participated in a concurrent endurance and resistance training program. Changes in body composition were assessed using a 4-compartment model. Changes in muscle mass (MM) were evaluated using a DXA-derived appendicular lean-soft tissue equation. There was a significant time × treatment interaction for MM and total cholesterol (TC), and a significant time × training interaction for peak oxygen consumption and upper-body and lower-body strength. Significant differences between the EX groups and NEX groups for percentage change in MM and peak oxygen consumption, and upper-body and lower-body strength, were revealed. Clinical markers for hepatic and renal function revealed no adverse effects. TC significantly decreased for the active-supplementing groups (EX-Act, NEX-Act). The current study suggests that implementing a caffeine-EGCG-containing drink prior to exercise may improve MM, fitness, and lipid profiles in overweight women [10502].

Combination with taurine

Consumption of energy drinks is common among athletes; however, there is a lack of research on the efficacy of these beverages for short-duration, intense exercise. The purpose of one research was to investigate the acute effects of a low-calorie caffeine-taurine energy drink (AdvoCare Spark) on repeated sprint performance and anaerobic power in National Collegiate Athletic Association Division I football players. Twenty football players (age 20) participated in a double-blind, randomized crossover study in which they received the energy drink or an isoenergetic, isovolumetric, non-caffeinated placebo in 2 trials separated by 7 days. The Running Based Anaerobic Sprint Test, consisting of six 35-m sprints with 10 s of rest between sprints, was used to assess anaerobic power. Sprint times were recorded with an automatic electronic timer. The beverage treatment did not significantly affect power or sprint time. However, there was a significant interaction effect between caffeine use and the beverage for sprint times as well as for anaerobic power, indicating a confounding effect. In conclusion, a caffeine-taurine energy drink did not improve the sprint performance or anaerobic power of college football players, but the level of caffeine use by the athletes likely influenced the effect of the drink [12283].

Combination with ecstasy

Concomitant consumption of caffeine with recreational psychostimulant drugs of abuse can provoke severe acute adverse reactions in addition to longer term consequences. The mechanisms by which caffeine increases the toxicity of psychostimulants include changes in body temperature regulation, cardiotoxicity and lowering of the seizure threshold. Caffeine also influences the stimulatory, discriminative and reinforcing effects of psychostimulant...
drugs. In this review, we consider our current understanding of such caffeine-related drug interactions, placing a particular emphasis on an adverse interaction between caffeine and the substituted amphetamine, 3,4-methylenedioxymethamphetamine (MDMA, “ecstasy”), which has been most recently described and characterized. Co-administration of caffeine profoundly enhances the acute toxicity of MDMA in rats, as manifested by high core body temperature, tachycardia and increased mortality. In addition, co-administration of caffeine enhances the long-term serotonergic neurotoxicity induced by MDMA. Observations to date support an interactive model of drug-induced toxicity comprising MDMA-related enhancement of dopamine release coupled to a caffeine-mediated antagonism of adenosine receptors in addition to inhibition of PDE. These experiments are reviewed together with reports of caffeine-related drug interactions with cocaine, d-amphetamine and ephedrine where similar mechanisms are implicated. Understanding the underlying mechanisms will guide appropriate intervention strategies for the management of severe reactions and potential for increased drug-related toxicity, resulting from concomitant caffeine consumption [12284].

Caffeine versus theobromine

The combination of theobromine and caffeine, methylxanthines found in chocolate, has previously been shown to improve mood and cognition. However, it is unknown whether these molecules act synergistically. This study tested the hypothesis that a combination of caffeine and theobromine has synergistic effects on cognition, mood and blood pressure in 24 healthy female subjects. The effects of theobromine (700 mg), caffeine (120 mg) or the combination of both, or placebo were tested on mood (the Bond-Lader visual analog scale), psychomotor performance (the Digit Symbol Substitution Test) and blood pressure before and at 1, 2 and 3 h after administration. Theobromine alone decreased self-reported calmness 3h after ingestion and lowered blood pressure relative to placebo 1 h after ingestion. Caffeine increased self-reported alertness 1, 2 and 3h after ingestion and contentedness 1 and 2 h after ingestion, and increased blood pressure relative to placebo (at 1 h). The combination of caffeine+theobromine had similar effects as caffeine alone on mood, but with no effect on blood pressure. There was no treatment effect on performance. Together these results suggest that theobromine and caffeine could have differential effects on mood and blood pressure. It was tentatively concluded that caffeine may have more CNS-mediated effects on alertness, while theobromine may be acting primarily via peripheral physiological changes [11494].

Caffeine in asthma

The main aim of one study was to evaluate the comparative and additive effects of caffeine and albuterol (short-acting beta2-agonist) on the severity of EIB (exercise-induced bronchoconstriction). Ten asthmatic subjects with EIB participated in a randomized, double-blind, double-dummy crossover study. One hour before an exercise challenge, each subject was given 0, 3, 6, or 9 mg/kg of caffeine or placebo mixed in a flavored sugar drink. Fifteen minutes before the exercise bout, an inhaler containing either albuterol (180 microg) or placebo was administered to each subject. Pulmonary function tests were conducted pre- and post-exercise. Caffeine at a dose of 6 and 9 mg/kg significantly reduced the mean maximum percentage fall in post-exercise FEV₁ compared to the double-placebo and baseline. There was no significant difference in the post-exercise % fall in FEV₁ between albuterol (plus caffeine) and the 9 mg/kg dose of caffeine. Interestingly, there was no significant difference in the post-exercise percentage fall in FEV₁ between albuterol (plus
caffeine) and albuterol with 3, 6 or 9 mg/kg of caffeine. Similar changes were observed for the post-exercise percentage fall in FVC, FEF (25-75 %) and PEF. These data indicate that moderate (6 mg/kg) to high doses (9 mg/kg) of caffeine provide a significant protective effect against EIB. It is feasible that the negative effects of daily use of short-acting beta2-agonists by asthmatic athletes could be reduced simply by increasing caffeine consumption prior to exercise [10183].

Influence on circadian rhythms

Although caffeine alters sleep in many animals, whether or not it affects mammalian circadian clocks remains unknown. It was found that incubating cultured mammalian cell lines, human osteosarcoma U2OS cells and mouse fibroblast NIH3T3 cells, with caffeine lengthened the period of circadian rhythms. Adding caffeine to ex vivo cultures also lengthened the circadian period in mouse liver explants from Per2::Luciferase reporter gene knockin mice, and caused a phase delay in brain slices containing the suprachiasmatic nucleus, where the central circadian clock in mammals is located. Furthermore, chronic caffeine consumption ad libitum for a week delayed the phase of the mouse liver clock in vivo under 12 h light-dark conditions and lengthened the period of circadian locomotor rhythms in mice under constant darkness. The results showed that caffeine alters circadian clocks in mammalian cells in vitro and in the mouse ex vivo and in vivo [13342].

Influence on biomonitoring data

Smoking appears to enhance the body's clearance of dioxins and dioxin-like polychlorinated biphenyls (PCB) by inducing CYP1A2 activity based on studies with a limited number of participants. This hypothesis was evaluated by using data from National Health and Nutrition Examination Survey. Specifically, adult participants were identified and the sums of their serum lipid-adjusted concentrations of 12 polychlorinated dibenzo-p-dioxins/polychlorinated dibenzofurans (PCDD/PCDF) congeners, 33 PCB (total), 26 non-dioxin-like PCB, and 6 mono-ortho (dioxin-like) PCB were determined. In addition to evaluating the association of smoking, the association of caffeine consumption and the interaction between them was evaluated. Data analysis included regression models that were fitted with age, gender, race/ethnicity, and body mass index (BMI). Smokers had significantly lower concentrations of total PCDD/PCDF than nonsmokers. New to this study, a significant interaction between caffeine consumption and smoking for total PCB was found. When caffeine was consumed less than once a day, smokers had higher concentrations of total PCB than nonsmokers. However, when caffeine was consumed at least once a day, smokers had lower concentrations than nonsmokers. A significant interaction between age and caffeine consumption frequency for each of the PCB groups was also observed. The differences in concentration between younger and older age groups were greater when caffeine was consumed at least once a day than when caffeine was consumed less frequently. Smoking and caffeine consumption need to be considered in the interpretation of human biomonitoring data because they appear to affect the serum concentrations of these chemicals [13345].

Impact on pain perception

Caffeine has been shown to reduce leg-muscle pain during submaximal cycle ergometry, as well as in response to eccentric exercise. However, less is known about its analgesic properties during non-steady-state, high-intensity exercise. The primary aim of one study
was to examine the effect of 2 doses of caffeine on leg pain and rating of perceived exertion (RPE) during repeated bouts of high-intensity exercise. Fifteen active men (age 26 ± 4 year) completed 2 bouts of 40 repetitions of "all-out" knee extension and flexion of the dominant leg at a contraction velocity equal to 180°/s. Before each trial, subjects abstained from caffeine intake and intense exercise for 48 hr. Over 3 days separated by 48 hr, subjects ingested 1 of 3 treatments (5 mg/kg or 2 mg/kg of anhydrous caffeine or placebo) in a randomized, single-blind, counterbalanced, crossover design. Leg-muscle pain and RPE were assessed during and after exercise using established categorical scales. Across all treatments, pain perception was significantly increased during exercise, as well as from bout 1 to 2, yet there was no effect of caffeine on pain perception or RPE. Various measures of muscle function were improved with a 5-mg/kg caffeine dose versus the other treatments. In the 5-mg/kg trial, it is plausible that subjects were able to perform better with similar levels of pain perception and exertion [11203].

This experiment examined the effect of a moderate dose of caffeine on quadriceps muscle pain during a bout of high-intensity cycling in low- versus high-caffeine-consuming males. College-age men who were low (< 100 mg/day; n=12) or high (> 400 mg/day; n=13) habitual caffeine consumers ingested caffeine (5 mg/kg body weight) or a placebo in a counterbalanced order and 1 hr later completed 30 min of cycle ergometry at 75-77 percent of peak oxygen consumption. Perceptions of quadriceps muscle pain, as well as oxygen consumption, heart rate, and work rate, were recorded during both bouts of exercise. Caffeine ingestion resulted in a statistically significant and moderate reduction in quadriceps muscle-pain-intensity ratings during the 30-min bout of high-intensity cycle ergometry compared with placebo ingestion in both low and high caffeine consumers. The results suggest that caffeine ingestion is associated with a moderate hypoalgesic effect during high-intensity cycling in college-age men who are low or high habitual caffeine consumers, but future work should consider better defining and differentiating pain and effort when examining the effects of caffeine during acute exercise [09256].

Impact on testosterone levels

Interest in the use of caffeine as an ergogenic aid has increased since the International Olympic Committee lifted the partial ban on its use. Caffeine has beneficial effects on various aspects of athletic performance, but its effects on training have been neglected. To investigate the acute effect of caffeine on the exercise-associated increases in testosterone and cortisol in a double-blind crossover study 24 professional rugby-league players ingested caffeine doses of 0, 200, 400, and 800 mg in random order 1 hr before a resistance-exercise session. Saliva was sampled at the time of caffeine ingestion, at 15-min intervals throughout each session, and 15 and 30 min after the session. Data were log-transformed to estimate percent effects with mixed modeling, and effects were standardized to assess magnitudes. Testosterone concentration showed a small increase of 15 percent (90 % confidence limits ± 19 %) during exercise. Caffeine raised this concentration in a dose-dependent manner by a further small 21 percent (± 24 %) at the highest dose. The 800-mg dose also produced a moderate 52 percent (± 44 %) increase in cortisol. The effect of caffeine on the testosterone:cortisol ratio was a small decline (14 %; ± 21 %). It was concluded that caffeine has some potential to benefit training outcomes via the anabolic effects of the increase in testosterone concentration, but this benefit might be counteracted by the opposing catabolic effects of the increase in cortisol and resultant decline in the testosterone:cortisol ratio [08306].

Impact in hot environments
Caffeine is regarded as a diuretic despite evidence that hydration is not impaired with habitual ingestion. The purpose of one study was to determine whether a caffeinated sports drink impairs fluid delivery and hydration during exercise in warm, humid conditions (29 degrees C, 60 % relative humidity). Sixteen cyclists completed 3 trials: placebo (P), carbohydrate-electrolyte (CE), and caffeinated (195 mg/L) sports drink (CAF+CE). Subjects cycled for 120 min at 60-75 percent VO2max followed by 15 min of maximal-effort cycling. Heart rate and rectal temperature were similar until the final 15 min, when these responses and exercise intensity were higher with CAF+CE than with CE and P. Sweat rate, urine output, plasma-volume losses, serum electrolytes, and blood deuterium-oxide accumulation were not different. Serum osmolality was higher with CAF+CE vs. P but not CE. The authors conclude that CAF+CE appears as rapidly in blood as CE and maintains hydration and sustains cardiovascular and thermoregulatory function as well as CE during exercise in a warm, humid environment [07173].

To investigate the effects of caffeine ingestion on thermoregulation and fluid-electrolyte losses during prolonged exercise in the heat seven endurance-trained (VO2max 61 ± 8 mL/kg.min) heat-acclimated cyclists pedaled for 120 min at 63 percent VO2max in a hot-dry environment (36 degrees C; 29 % humidity) on six occasions: 1) without rehydration (NF); 2) rehydrating 97% of sweat losses with water (WAT); 3) rehydrating the same volume with a 6% carbohydrate-electrolytes solution (CES); or combining these treatments with the ingestion of 6 mg caffeine/kg body weight 45 min before exercise, that is, 4) CAFF + NF; 5) CAFF + WAT; and 6) CAFF + CES. Without fluid replacement (NF and CAFF + NF), final rectal temperature reached 39.4 ± 0.1 degrees C, whereas it remained at 38.7 ± 0.1 degrees C during WAT (CES and CAFF + WAT. Caffeine did not alter heat production, forearm skin blood flow, or sweat rate. However, CAFF + carbohydrate-electrolytes solution tended to elevate rectal temperature above CES alone (38.9 ± 0.1 degrees C vs 38.6 ± 0.1 degrees C). Caffeine ingestion increased sweat losses of sodium, chloride, and potassium (approximately 14 %) and enlarged significantly urine flow (28 %). The authors concluded that caffeine ingested alone or in combination with water or a sports drink was not thermogenic or impaired heat dissipation. Caffeine increased urine flow and sweat electrolyte excretion, but these effects are not enough to affect dehydration or blood electrolyte levels when exercising for 120 min in a hot environment [08313].

**Impact on immunology**

One study investigated the effect of a high and low dose of caffeine on antigen-stimulated natural killer (NK) cell (CD3- CD56+) activation after prolonged, strenuous cycling, as assessed by the early-activation molecule CD69. In a randomized crossover design, 12 healthy male endurance-trained cyclists cycled for 90 min at 70 percent VO2peak 60 min after ingesting either 0 (PLA), 2 (2CAF), or 6 (6CAF) mg/kg body mass of caffeine. Whole blood was stimulated with Pediacel (5 in 1) vaccine. A high dose of caffeine (6CAF) significantly increased the number of CD3-CD56+ cells in the circulation immediately postexercise compared with PLA. For both 2CAF and 6CAF, the geometric mean fluorescence intensity (GMFI) of CD69+ expression on unstimulated CD3-CD56+ cells was significantly higher than with PLA. When cells were stimulated with antigen, the GMFI of CD69 expression remained significantly higher with 2CAF than with PLA 1 hr postexercise. Although not achieving statistical significance, 6CAF also followed a similar trend when stimulated. There were no differences in GMFI of CD69 expression between 2CAF and 6CAF. These results suggest that a high (6 mg/kg) dose of caffeine was associated with the recruitment of NK cells into the circulation and that both a high and low (2 mg/kg) dose of caffeine increased unstimulated and antigen-stimulated NK-cell activation 1 hr after high-intensity exercise.
Furthermore, there does not appear to be a dose-dependent effect of caffeine on NK-cell activation 1 hr after prolonged intensive cycling [11199].

Several studies investigating the effect of caffeine on immune function following exercise have used one large bolus dose of caffeine. However, this does not model typical caffeine consumption. Therefore, the purpose of one study was to investigate whether small repeated doses of caffeine ingested throughout the day would elicit a similar response as one large bolus dose ingested 1 h prior to exercise on antigen-stimulated NK cell CD69 expression following strenuous intermittent exercise. In a randomized cross-over design, 15 healthy males completed six 15 min blocks of intermittent running consisting of maximal sprinting interspersed with less intense running and walking. Participants had ingested either 0 (PLA), 2 mg/kg body mass (BM) caffeine on three separate occasions during the day (3 × CAF) or one dose of 6 (1 × CAF) mg/kg BM caffeine, 1 h before exercise. At 1-h post-exercise, the number of antigen-stimulated CD3(-)CD56(+) cells expressing CD69 was lower on 1 × CAF compared with PLA, with values on 1 × CAF at this time point remaining close to pre-supplement. 1 × CAF tended to attenuate the exercise-induced increase in geometric mean fluorescence intensity of CD69 expression on antigen-stimulated CD3(-)CD56(+) cells 1-h post-exercise. These findings suggest that although one large bolus dose of caffeine attenuated the exercise-induced increase in antigen-stimulated NK cell CD69 expression 1 h following strenuous intermittent exercise, this attenuation at no point fell below pre-supplement values and caffeine does not appear to depress NK cell CD69 expression [13347].

Immunoendocrine effects

One study investigated the effect of caffeine consumed with and without carbohydrate (CHO) on immunoendocrine responses after exercise. On four occasions, 12 recreational male cyclists cycled for 2 h at 65 percent VO$_{2\text{max}}$. Sixty minutes before exercise, participants ingested 6 mg.kg(-1) body mass of caffeine (CAF) or placebo (PLA), then during exercise they consumed a 6 percent CHO or placebo (PLA) drink, providing CAF/CHO, PLA/CHO, CAF/PLA, and PLA/PLA conditions. f-MLP-stimulated neutrophil oxidative burst responses were significantly higher after exercise on CAF/CHO and PLA/CHO than PLA/PLA when expressed as a percentage of baseline value. The response on CAF/PLA tended to be higher than PLA/PLA at this point. No significant differences between CAF/CHO, PLA/CHO, and CAF/PLA were observed after exercise; however, only PLA/CHO showed no significant postexercise decline. Coingestion of CAF/CHO significantly attenuated epinephrine and IL-6 responses that occurred after ingestion of CAF alone (CAF/PLA) and significantly attenuated the transient alterations in circulating leukocyte and neutrophil counts. Plasma cortisol concentration was significantly lower on PLA/CHO than CAF/PLA and PLA/PLA after exercise. Perceived exertion during exercise was significantly lower on CAF/CHO than the other three trials. Taken together, this suggests that coingestion of caffeine and CHO has greater influence on immunoendocrine responses than neutrophil functional responses to prolonged exercise [07169].

Effect on hydration

Acute and chronic caffeine intakes have no impact on hydration status [Maughan RJ, Griffin J. J Hum Nutr Diet 2003; 16: 411-20], although no research has been conducted to analyze the effects using dilution techniques on total-body water (TBW) and its compartments. Therefore, the aim of this study was to investigate the effects of a moderate dose of caffeine on TBW, extracellular water (ECW), and intracellular water (ICW) during a 4-day period in
active males. Thirty men, nonsmokers and low caffeine users (<100 mg/day), aged 20-39 years, participated in this double-blind, randomized, crossover trial. The study included 2 conditions (5 mg/kg/day of caffeine and placebo (malt-dextrin)) of 4 days each, with a 3-day washout period. TBW and ECW were assessed by deuterium oxide and sodium bromide dilution, respectively, whereas ICW was calculated as TBW minus ECW. Body composition was assessed by dual-energy X-ray absorptiometry. Physical activity was assessed by accelerometer and water intake was assessed by dietary records. Repeated-measures analysis of variance (ANOVA) was used to test main effects. No changes in TBW, ECW, or ICW and no interaction between the randomly assigned order of treatment and time were observed. TBW, ECW, and ICW were unrelated to fat-free mass, water ingestion, and PA. These findings indicate that a moderate caffeine dose, equivalent to approximately 5 espresso cups of coffee or 7 servings of tea, does not alter TBW and fluid distribution in healthy men, regardless of body composition, PA, or daily water ingestion [13451].

**Effect on urea formation**

It was investigated the effects of caffeine on the ammonia and amino acid metabolism of elite soccer players. In a double-blind randomized study, athletes (n=19) received 5 mg/kg caffeine or lactose (LEX, control) and performed 45 min of intermittent exercise followed by an intermittent recovery test (Yo-Yo IR2) until exhaustion. The caffeine-supplemented athletes were divided into two groups (CEx and SCEx) depending on their serum caffeine levels (<900 % and >10,000 %, respectively). Data were analyzed by ANOVA and Tukey post hoc test. Caffeine supplementation did not significantly affect the performance. Exercise changed the blood concentrations of several amino acids and increased the serum concentrations of ammonia, glucose, lactate, and insulin. The LEx group showed an exercise-induced increase in valine (29 %), which was inhibited by caffeine. Higher serum caffeine levels abolished the exercise-induced increase (24%-27 %) in glutamine but did not affect the exercise-induced increase in alanine (110 % - 160 %) and glutamate (42 % - 61 %). In response to exercise, the SCEx subjects did not exhibit an increase in urea and showed a significantly lower increase in their serum arginine (15 %), citrulline (16 %), and ornithine concentrations. The data suggest that caffeine might decrease systemic urea by decreasing the glutamine serum concentration, which decreases the transportation of ammonia to the liver and thus urea synthesis [13452].

**Caffeine with carbohydrates**

One study compared the effects of three carbohydrate-hydration strategies on blood glucose concentration, exercise performance and hydration status throughout simulated soccer match-play. A randomized, double-blind and cross-over study design was employed. After familiarization, 14 recreational soccer players completed the soccer match simulation on three separate occasions. Participants consumed equal volumes of 9.6 percent carbohydrate-cafeine-electrolyte (6 mg/kg BW caffeine) solution with carbohydrate-electrolyte gels (H-CHO), 5.6 percent carbohydrate-electrolyte solution with electrolyte gels (CHO) or electrolyte solution and electrolyte gels (PL). Blood samples were taken at rest, immediately before exercise and every 15 min during exercise (first half: 15, 30, 45 min; second half: 60, 75, 90 min). Supplementation influenced blood glucose concentration, however, none of the supplementation regimes were effective in preventing a drop in blood glucose at 60 min. Mean sprint speed was 3 ± 1 percent faster in H-CHO when compared with PL. Supplementation caused a 2.3 ± 0.5 percent increase in plasma osmolality in H-CHO without change in CHO or PL. Similarly, mean sodium concentrations were 2.1 ± 0.4
percent higher in H-CHO when compared with PL. It was concluded that combining high carbohydrate availability with caffeine resulted in improved sprint performance and elevated blood glucose concentrations throughout the first half and at 90 min of exercise; however, this supplementation strategy negatively influenced hydration status when compared with 5.6 percent carbohydrate-electrolyte and electrolyte solutions [13453].

Caffeine with phosphatidylserine

Phosphatidylserine (PS) may attenuate the adverse effects of physical fatigue. Therefore, it was investigated the effects of a multi-ingredient supplement containing 400 mg/d PS and 100 mg/d caffeine (supplement, SUP) for 2 weeks on measures of cognitive function (CF), reaction time (RT), and mood (MD) following an acute exercise stress. It is hypothesized that PS will maintain preexercise CF and RT scores, while attenuating postexercise fatigue. Participants completed 2 acute bouts of resistance exercise (T1 and T2) separated by 2-week ingestion of SUP or control (CON). Outcome measures were assessed pre- and postexercise. When collapsed across groups, a significant decrease in RT performance was seen in the 60-second reaction drill from pre- to postexercise at T1. All other RT tests were similar from pre- to postexercise at T1. Reaction time was not significantly changed by PS. When collapsed across groups, a significant increase in performance of the serial subtraction test was seen. A significant increase (8.9 % and 7.1 %) in the number of correct answers and a significant decrease (8.0 % and 7.5 %) in time to answer were seen from pre- to postworkout at T1 and T2, respectively. A significant increase in total MD score from pre- to postworkout was observed for CON but not for PS at T2. Phosphatidylserine significantly attenuated pre- to postexercise perception of fatigue compared to CON. Ingestion of SUP for 14 days appears to attenuate postexercise MD scores and perception of fatigue, but does not affect CF or RT, in recreationally trained individuals [13454].

Lack of effect on oxidative stress

Coffee has been reported to be rich in antioxidants, with both acute and chronic consumption leading to enhanced blood antioxidant capacity. High-fat feeding is known to result in excess production of reactive oxygen and nitrogen species, promoting a condition of postprandial oxidative stress. It was tested the hypothesis that coffee intake following a high-fat meal would attenuate the typical increase in blood oxidative stress during the acute postprandial period. On 3 different occasions, 16 men and women consumed a high-fat milk shake followed by either 16 ounces of caffeinated or decaffeinated coffee or bottled water. Blood samples were collected before and at 2 and 4 hours following intake of the milk shake and analyzed for triglycerides (TAG), malondialdehyde (MDA), hydrogen peroxide (H2O2), and Trolox equivalent antioxidant capacity (TEAC). Values for TAG and MDA, as well as for H2O2, increased significantly following milk shake consumption, with values higher at 4 hours compared with 2 hours post consumption for TAG and H2O2. TEAC was unaffected by the milk shake consumption. Coffee had no impact on TAG, MDA, H2O2, or TEAC, with no condition or interaction effects noted for any variable. It was concluded that acute coffee consumption following a high-fat milk shake has no impact on postprandial oxidative stress [13472].

Coffee has been reported to be rich in antioxidants, with both acute and chronic consumption leading to enhanced blood antioxidant capacity. High-fat feeding is known to result in excess production of reactive oxygen and nitrogen species, promoting a condition of postprandial oxidative stress. It was tested the hypothesis that coffee intake following a high-fat meal
would attenuate the typical increase in blood oxidative stress during the acute postprandial period. On 3 different occasions, 16 men and women consumed a high-fat milk shake followed by either 16 ounces of caffeinated or decaffeinated coffee or bottled water. Blood samples were collected before and at 2 and 4 hours following intake of the milk shake and analyzed for triglycerides (TAG), malondialdehyde (MDA), hydrogen peroxide ($H_2O_2$), and Trolox equivalent antioxidant capacity (TEAC). Values for TAG and MDA, as well as for $H_2O_2$, increased significantly following milk shake consumption, with values higher at 4 hours compared with 2 hours post consumption for TAG and $H_2O_2$. TEAC was unaffected by the milk shake consumption. Coffee had no impact on TAG, MDA, $H_2O_2$, or TEAC, with no condition or interaction effects noted for any variable. Thus, acute coffee consumption following a high-fat milk shake has no impact on postprandial oxidative stress [13470].

**Modulation of oxidative stress markers in the liver of trained rats**

Caffeine has been widely used in sports competitions due to its ergogenic effects. Most of the studies regarding caffeine and exercise have focused on muscle and plasma adaptations, while the impact on the liver is scarcely described. The aim of one study was to analyze the effects of caffeine and exercise training on oxidative stress markers and injury-related parameters in the liver. Rats were divided into sedentary/saline, sedentary/caffeine, exercise/saline, and exercise/caffeine groups. Exercise groups underwent 4 weeks of swimming training, and caffeine (6 mg/kg, p.o.) was supplemented throughout the training protocol. Injury-related liver parameters were assessed in plasma, while redox status and oxidative stress markers were measured on liver homogenates. Exercise training increased muscle citrate synthase activity in the muscle, while in caffeine decreased its activity in both sedentary and trained rats. Aspartate transaminase levels were increased after training, and caffeine intake suppressed this elevation. Caffeine also diminished alanine transaminase levels in both sedentary and exercised rats. Exercise training induced a significant increase on the activity of the enzymes superoxide dismutase and glutathione peroxidase, as an increase on thiobarbituric acid-reactive substances levels was also reached; caffeine intake blunted these alterations. Caffeine intake also suppressed liver catalase activity in both sedentary and exercise groups. The data suggest that caffeine modified the hepatic responses associated to exercise-induced oxidative stress without affecting the performance, exerting different actions according to the tissue. However, further studies are needed to better understand caffeine’s role on liver under exercise training [13475].

**Impact on the inflammatory response**

The objective of the study was to determine the effects of caffeine supplementation on the inflammatory response (IL-6 and IL-10 levels and leukocyte numbers) induced by a 15-km run competition and to examine the effect of caffeine supplementation on the energetic metabolites as well as on the exercise-induced oxidative stress. A double-blinded study of supplementation with caffeine was performed. Athletes participating in the study (n=33) completed a 15 km run competition. Before competition, athletes took 6 mg/kg body weight of caffeine (caffeine group, n=17) or a placebo (placebo group, n=16). Blood samples were taken before and after competition (immediately and after 2-h recovery). Leukocyte numbers were determined in blood. Concentrations of oxidative stress markers, antioxidants, interleukins (IL-6 and IL-10), caffeine, adrenaline, and energetic metabolites were measured in plasma or serum. Caffeine supplementation induced higher increases in circulating total leukocytes and neutrophils, with significant differences between groups after recovery. Adrenaline, glucose, and lactate levels increased after exercise, with higher increases in the
caffeine group. Exercise induced significant increases in IL-6 and IL-10 plasma levels, with higher increases in the caffeine group. Caffeine supplementation induced higher increases in oxidative stress markers after the competition. In conclusion, caffeine supplementation induced higher levels of IL-6 and IL-10 in response to exercise, enhancing the anti-inflammatory response. The caffeine-induced increase in adrenaline could be responsible for the higher increase in IL-6 levels, as well as for the increased lactate levels. Furthermore, caffeine seems to enhance oxidative stress induced by exercise [13471].

**Impact on glycogen accumulation**

It was determined the effect of coinestion of caffeine with carbohydrate (CHO) on rates of muscle glycogen resynthesis during recovery from exhaustive exercise in seven trained subjects who completed two experimental trials in a randomized, double-blind crossover design. The evening before an experiment subjects performed intermittent exhaustive cycling and then consumed a low-CHO meal. The next morning subjects rode until volitional fatigue. On completion of this ride subjects consumed either CHO (4 g/kg body mass) or the same amount of CHO + caffeine (8 mg/kg) during 4 hours of passive recovery. Muscle biopsies and blood samples were taken at regular intervals throughout recovery. Muscle glycogen levels were similar at exhaustion and increased by a similar amount (approximately 80%) after 1 hour of recovery. After 4 hours of recovery caffeine resulted in higher glycogen accumulation. Accordingly, the overall rate of resynthesis for the 4-hour recovery period was 66 percent higher in caffeine compared with CHO. After 1 hour of recovery plasma caffeine levels had increased to $31 \pm 11$ microM, which was a significant difference, and at the end of the recovery reached $77 \pm 11$ microM with caffeine. Phosphorylation of CaMK(Thr286) was similar after exercise and after 1 hour of recovery, but after 4 hour CaMK(Thr286) phosphorylation was significantly higher in caffeine than CHO. Phosphorylation of AMP-activated protein kinase (AMPK)(Thr172) and Akt(Ser473) was similar for both treatments at all time points. It was provided the first evidence that in trained subjects coingestion of large amounts of caffeine (8 mg/kg) with CHO has an additive effect on rates of postexercise muscle glycogen accumulation compared with consumption of CHO alone [08314].

**Impact on ventilation**

The purpose of one project was to determine whether a moderate dosage of caffeine, a common ventilatory stimulant, could augment resting ventilatory responsiveness, exercise ventilation, end-tidal $O_2$ partial pressure ($P_{etO_2}$), and arterial oxyhemoglobin saturation ($HbSaO_2$) in athletes with exercise-induced hypoxemia. Eight highly trained males who demonstrated exercise-induced hypoxemia, ingested in a randomized design a placebo or caffeine (8 mg/kg body wt) 1 hour before testing. Ventilatory responsiveness at rest was assessed via the isocapnic hypoxic and hyperoxic hypercapnic ventilatory responses (HVR and HCVR, respectively). The failure of $HbSaO_2$ to increase at despite an increase in ventilation suggests that mechanisms influencing $HbSaO_2$ other than an inadequate hyperventilatory response may operate to different degrees across individuals as $VO_{2max}$ is approached [08315].

The effects of caffeine on exercise performance have been well documented, with most reviews focusing on the metabolic, hormonal, and/or central nervous system effects. However, caffeine's effects on ventilation and pulmonary function are often overlooked. Studies have shown that caffeine is a strong ventilatory stimulant, increasing the sensitivity of the peripheral chemoreceptors in untrained subjects and increasing exercise ventilation at all
workloads in highly trained endurance athletes. The consequences of increased exercise ventilation could hold either positive or negative effects for exercise performance. Anti-inflammatory and bronchoprotective effects of caffeine are great enough to consider its efficacy as a possible prophylactic antiasthma treatment. Although an upper urinary concentration limit exists for caffeine with international sports doping control agencies, caffeine's universal accessibility in the marketplace has resulted in its daily use being increasingly more socially acceptable as an ergogenic substance for sport and exercise [09250].

Impact on sweating

It was assessed the effect of caffeine on sudomotor activity and sweating sensitivity during physical loading. Both physiological responses could occur due to energy expenditure. Subjects were 13 athletically trained males (22 ± 4 years old, 174 ± 5 cm tall, and weighing 71 ± 5 kg, with maximal oxygen consumption (VO$_{2\text{max}}$) of 54 ± 4 mL/kg/minute). The study involved a within-subject, random, crossover design. Tests were performed following the ingestion of 3 mg/kg caffeine. The physical loading involved running for 30 minutes at 60 percent VO$_{2\text{max}}$ (24 ± 0.5°C, 40 ± 3 % relative humidity). Tympanic temperature (TYMP) was significantly higher in the caffeine-consuming group (Caffe-I) at pre-exercise (40 minutes after caffeine intake and immediately before running). Mean body temperature (mT$_b$) was significantly higher in the Caffe-I group at pre- and post-exercise (30 min after start of running). Onset time of localized sweating was significantly shorter in the Caffe-I group, but localized sweat volume and active sweat gland output (per single gland) was significantly higher in the Caffe-I group. Activated sweat gland density was significantly increased in the Caffe-I group on the abdomen and thigh. In conclusion, caffeine ingestion caused not only increases in TYMP and mT$_b$ through thermogenesis, but also an increased sweating sensitivity via changes in sudomotor activity [11492].

Impact on delayed-onset muscle soreness

One double-blind, placebo-controlled, repeated-measures experiment examined the effects of a 5 mg/kg body weight dose of caffeine on delayed-onset muscle pain intensity and force loss in response to 64 eccentric actions of the dominant quadriceps induced by electrical stimulation. Low caffeine-consuming college-aged females (n=9) ingested caffeine or placebo 24 and 48 hours following electrically stimulated eccentric exercise of the quadriceps. One hour after ingestion, maximal voluntary isometric contractions (MVIC) and submaximal voluntary eccentric actions were used to determine force loss during activation of damaged quadriceps and whether caffeine attenuates muscle pain intensity. Pain intensity was measured using a 0 to 100 visual analog scale. Caffeine produced a large (12.7 raw visual analog scale, VAS, units), statistically significant hypoalgesia during the MVIC. The reduction in pain scores during submaximal voluntary eccentric movements was smaller as was the increase in MVIC force. Thus, eccentric exercise occurs when skeletal muscles produce force while being lengthened. For example, the biceps brachii muscles act eccentrically when a cup of coffee is lowered from the mouth to a tabletop. This experiment found that caffeine (equal to approximately 2 cups of brewed coffee) could produce a large reduction in pain resulting from eccentric exercise-induced, delayed-onset muscle injury. This finding may improve the quality of life of individuals who experience skeletal muscle pain after engaging in unaccustomed, eccentrically biased exercise [06200].
Impact on postexercise oxygen consumption

This study investigated the effect of acute caffeine (CAF) intake on postexercise oxygen consumption (EPOC) after intense resistance training. Fourteen strength-trained men (mean ± SD age and mass =23 ± 4 years and 83 ± 13 kg, respectively) who were caffeine users initially completed one-repetition maximum testing (1-RM) of four exercises: bench press, leg press, lat row, and shoulder press. On each of two days separated by one week, they completed four sets of each exercise to fatigue at 70-80 percent 1-RM, which was preceded by ingestion of CAF (6 mg/kg) or placebo. Pre-exercise, indirect calorimetry was used to assess energy expenditure for 35 min; this was repeated for 75 min postexercise while subjects remained seated in a quiet lab. Results revealed that EPOC was significantly higher with CAF (27 ± 4. L) compared to placebo (23 ± 4 L). With CAF ingestion, oxygen uptake was significantly higher from 10 min pre-exercise to 70 min postexercise. Respiratory exchange ratio was significantly different with CAF versus placebo. Caffeine intake increased total energy expenditure by 15 percent, but the additional calories burned was minimal (+27 kcal). Caffeine ingestion in individuals regularly completing rigorous resistance training significantly increases EPOC and energy expenditure pre- and post-exercise, yet the magnitude of this effect is relatively small [11207].

Impact on potassium levels

There was one report of severe hypokalemia in two young bicycle riders due to massive caffeine intake [10184].

Impact on glutamine acid

It was investigated the effects of caffeine on the ammonia and amino acid metabolism of elite soccer players. In the double-blind, randomized study, the athletes (n=19) received 5 mg·kg caffeine or lactose (LEX, control) and performed 45 min of intermittent exercise followed by an intermittent recovery test (Yo-Yo IR2) until exhaustion. The caffeine-supplemented athletes were divided into two groups (CEx and SCEx) depending on their serum caffeine levels (< 900 % and > 10,000 %, respectively). The data were analyzed by ANOVA and Tukey's post hoc test. Caffeine supplementation did not significantly affect the performance. Exercise changed the blood concentrations of several amino acids and increased the serum concentrations of ammonia, glucose, lactate, and insulin. The LEx group showed an exercise-induced increase in valine (29 %), which was inhibited by caffeine. Higher serum caffeine levels abolished the exercise-induced increase (24-27 %) in glutamine but did not affect the exercise-induced increase in alanine (110-160 %) and glutamate (42-61 %). In response to exercise, the SCEx subjects did not exhibit an increase in uremia and showed a significantly lower increase in their serum arginine (15 %), citrulline (16 %), and ornithine (ND) concentrations. The data suggest that caffeine might decrease systemic urea by decreasing the glutamine serum concentration, which decreases the transportation of ammonia to the liver and thus urea synthesis [12285].

Impact on sex-hormone binding globulin

Findings from observational studies suggest that sex hormone-binding globulin (SHBG) and endogenous sex hormones may be mediators of the putative relation between coffee consumption and lower risk of type 2 diabetes. The objective of one study was to evaluate
the effects of caffeinated and decaffeinated coffee on SHBG and sex hormone levels. After a two-week run-in phase with caffeine abstention, we conducted an 8-week parallel-arm randomized controlled trial. Healthy adults (n=42) were recruited from the Boston community who were regular coffee consumers, nonsmokers, and overweight. Participants were randomized to five 6-ounce cups of caffeinated or decaffeinated instant coffee or water (control group) per day consumed with each meal, mid-morning, and mid-afternoon. The main outcome measures were SHBG and sex hormones [i.e., testosterone, estradiol, dehydroepiandrosterone sulfate]. No significant differences were found between treatment groups for any of the studied outcomes at week 8. At 4 weeks, decaffeinated coffee was associated with a borderline significant increase in SHBG in women, but not in men. At week 4, we also observed several differences in hormone concentrations between the treatment groups. Among men, consumption of caffeinated coffee increased total testosterone and decreased total and free estradiol. Among women, decaffeinated coffee decreased total and free testosterone and caffeinated coffee decreased total testosterone. The data do not indicate a consistent effect of caffeinated coffee consumption on SHBG in men or women, however results should be interpreted with caution given the small sample size. This is the first randomized trial investigating the effects of caffeinated and decaffeinated coffee on SHBG and sex hormones and our findings necessitate further examination in a larger intervention trial [12286].

Effects after a withdrawal period

In one study, it was investigated the impact of a controlled 4-day caffeine withdrawal period on the effect of an acute caffeine dose on endurance exercise performance. Twelve well-trained and familiarized male cyclists, who were caffeine consumers (from coffee and a range of other sources), were recruited for the study. A double-blind placebo-controlled cross-over design was employed, involving four experimental trials. Participants abstained from dietary caffeine sources for 4 days before the trials and ingested capsules (one in the morning and one in the afternoon) containing either placebo or caffeine (1.5 mg/kg body weight/day). On day 5, capsules containing placebo or caffeine (3 mg/kg body weight) were ingested 90 min before completing a time trial, equivalent to one hour of cycling at 75 percent peak sustainable power output. Hence the study was designed to incorporate placebo-placebo, placebo-caffeine, caffeine-placebo, and caffeine-caffeine conditions. Performance time was significantly improved after acute caffeine ingestion by 1:49 ± 1:41 min (3.0 %) following a withdrawal period (placebo-placebo vs placebo-caffeine), and by 2:07 ± 1:28 min (3.6 %) following the non-withdrawal period (caffeine-placebo vs caffeine-caffeine). No significant difference was detected between the two acute caffeine trials (placebo-caffeine vs caffeine-caffeine). Average heart rate throughout exercise was significantly higher following acute caffeine administration compared with placebo. No differences were observed in ratings of perceived exertion between trials. A 3 mg/kg dose of caffeine thus significantly improves exercise performance irrespective of whether a 4-day withdrawal period is imposed on habitual caffeine users [11208].

It has been traditional in caffeine research or in actual competition use to withdraw people from caffeine use for 24-48 h prior to the study or event (i.e. remove their habituation to repeated use). However, there does not seem to be a consistent difference in the performance effects of caffeine between regular users and non-users of caffeine, or as a result of withdrawal from regular caffeine use. Rather there may be several disadvantages to avoiding or withdrawing caffeine prior to a performance trial. Caffeine withdrawal can be associated with side effects such as headaches and fatigue. In fact, it has been suggested that the benefits of caffeine seen in controlled studies may be overstated, and may actually
be explained as the reversal of adverse withdrawal symptoms rather than an ergogenic effect of caffeine per se. It can also increase the risk, with subsequent caffeine intake, of the negative effects often seen with large caffeine doses (irritability, tremor, heart rate increases) [10174].

Effects on arousal

Studies indicate that the change from closed to open eyes in a resting condition results in an increase in skin conductance level (SCL) and a global decrease in EEG alpha activity, both indicative of increased arousal. Other studies show that ingestion of caffeine also produces SCL increase and alpha reduction. One study investigated the additivity of the effects of these two independent arousing variables. EEG activity and SCL were recorded from 22 university students during both eyes-closed and eyes-open resting conditions, under the action of both caffeine and placebo, in a counterbalanced randomised double-blind study. SCL increased significantly from eyes-closed to eyes-open conditions, and from placebo to caffeine, with no interaction. Global reductions in EEG alpha amplitude were apparent with opening of the eyes and caffeine ingestion; again, there was no interaction. Caffeine had a larger effect than opening the eyes on SCL, but their relative effect sizes were reversed in alpha. The two dependent measures showed the predicted negative correlation in both eyes-closed placebo and eyes-open caffeine conditions, with the latter substantially reduced relative to the former. It was concluded that caffeine and opening the eyes have additive effects on two measures of arousal, increasing SCL and reducing global EEG alpha. However, the independent variable effects are not equivalent, suggesting that one or both measures reflect additional non-arousal processes. As caffeine is widely used by both children and adults, knowledge of the additivity of arousal effects of caffeine and opening the eyes is important in controlling participant state in EEG studies [13344].

Moderated effect of anxiety

One experiment examined the effect of a moderate dose of caffeine on perceptions of leg-muscle pain during a bout of high-intensity cycling exercise and the role of anxiety sensitivity in the hypalgesic effect of caffeine on muscle pain during exercise. Sixteen college-age women ingested caffeine (5 mg/kg body weight) or a placebo and 1 hour later completed 30 min of cycling on an ergometer at 80 percent of peak aerobic capacity. The conditions were completed in a counterbalanced order, and perceptions of leg-muscle pain were recorded during the bouts of exercise. Caffeine resulted in a large reduction in leg-muscle pain-intensity ratings compared with placebo, and the reduction in leg-muscle pain-intensity ratings was larger in those with lower anxiety-sensitivity scores than those with higher anxiety-sensitivity scores. The results support that caffeine ingestion has a large effect on reducing leg-muscle pain during high-intensity exercise, but the effect is moderated by anxiety sensitivity [08318].

Psychological effects

Caffeine's metabolic and performance effects have been widely reported. However, caffeine's effects on affective states during prolonged exercise are unknown. Therefore, this was examined in one study. Following an overnight fast and in a randomised, double-blind, counterbalanced design, twelve endurance trained male cyclists performed 90 min of exercise at 70 percent of VO₂max 1h after ingesting 6 mg/kg body weight of caffeine (CAF) or
placebo (PLA). Dimensions of affect and perceived exertion were assessed at regular intervals. During exercise, pleasure ratings were better maintained in the CAF trial compared to the PLA trial with significantly higher ratings at 15, 30 and 75 min. Perceived exertion increased throughout exercise and values, overall, were significantly lower in the CAF trial compared to the PLA trial. Perceived arousal was elevated during exercise but did not differ between trials. Overall, the results suggest that a moderate dose of CAF ingested 1h prior to exercise maintains a more positive subjective experience during prolonged cycling. This observation may partially explain caffeine's ergogenic effects [13346].

**Psychological effects**

One study examined the effect of coffee ingestion on physiological responses and ratings of perceived exertion (RPE) during submaximal endurance exercises by 10 healthy young adults. Participants performed a submaximal endurance cycling exercise corresponding to 60% of maximum oxygen uptake capacity for 60 min. They drank either caffeinated coffee with a caffeine content of 6 mg/kg body-mass of each participant (Caf) or a decaffeinated coffee (Dec) 60 min. before starting exercise. Participants participated in the blind design experiment under both conditions at a one-week interval. Oxygen uptake, respiratory exchange ratio, heart rate, RPE, and plasma lactate concentration were measured during the endurance exercise. The RPE under the Caffeinated coffee condition during the last 60 min. of endurance exercise was significantly lower than that in the Decaffeinated coffee condition. However, no significant differences in any physiological response were observed between conditions. Thus, caffeine ingestion 60 min. before starting exercise had an insignificant effect on the physiological responses, except for RPE during submaximal endurance exercises for 60 min. Caffeine ingestion before endurance exercise of relatively low intensity may have a beneficial effect on psychological responses [07168].

General Factor of Personality (GFP) research is an emergent field in personality research. This paper uses a theoretical mathematical model to predict the short-term effects of a dose of a stimulant drug on GFP and reports the results of an experiment showing how caffeine achieves this. This study considers the General Factor of Personality Questionnaire (GFPQ) a good psychometric approach to assess GFP. The GFP dynamic mechanism of change is based on the Unique Trait Personality Theory (UTPT). This theory proposes the existence of GFP which occupies the apex of the hierarchy of personality, and extends from an impulsiveness-and-aggressiveness pole (approach tendency) to an anxiety-and-introversion pole (avoidance tendency). An experiment with 25 volunteers was performed. All the participants completed the GFPQ and the Sensation-Seeking Scale list of adjectives from the trait version of MAACL-R (Multiple Affect Adjective Checklist Revised) on an empty stomach. The participants in the experimental group (20) received 330 mg of caffeine. All the participants filled in a state version form with the sensation-seeking adjectives every 4.5 minutes. This study considers that the Sensation-Seeking Scale list of adjectives from the MAACL-R, available in both trait and state versions, is a good psychometric approach to assess GFP. The results show that GFP is modified by a single dose of caffeine in the direction predicted by the UTPT [11489].

*Caffeine choices prospectively predicts positive subjective effects d-amphetamine*

Individuals vary in their subjective and behavioral response to psychomotor stimulants and these differences may be associated with the likelihood of developing problematic use of these drugs. The present study sought to determine whether individual differences in caffeine choice prospectively predict subjective response to acute doses of caffeine and d-amphetamine. In phase 1, Choosers and Nonchoosers of caffeine were identified using 10 independent choice trials in which subjects repeatedly chose between caffeine (200 mg/70 kg) and placebo. Choosers were defined as those who chose caffeine over placebo on ≥7 of
the 10 trials; Nonchoosers were those who chose placebo on ≥7 trials. In Phase 2, Choosers and Nonchoosers were compared in their subjective response to caffeine (100, 200, 400 mg/70 kg) and d-amphetamine (5, 10, 20 mg/70 kg). Of the 22 participants completing the study, 11 met criteria for being a caffeine Chooser and 8 were Nonchoosers. In phase 1, Choosers reported higher ratings of positive (i.e., pleasant) and lower ratings of negative (i.e. unpleasant) effects of caffeine during the sampling sessions. In phase 2, caffeine Choosers reported more positive subjective effects and fewer negative effects of caffeine and d-amphetamine, particularly at the highest doses examined. It was concluded that individual differences in caffeine reinforcement predicted subsequent subjective response to both d-amphetamine and caffeine. This observation may have clinical utility for identifying individuals who are vulnerable to the reinforcing effects of abused psychomotor stimulants [11490].

**Caffeinated versus decaffeinated coffee**

One study examined the effect of coffee ingestion on physiological responses and ratings of perceived exertion (RPE) during submaximal endurance exercises by 10 healthy young adults. Participants performed a submaximal endurance cycling exercise corresponding to 60 percent of maximum oxygen uptake capacity for 60 min. They drank either caffeinated coffee with a caffeine content of 6 mg/kg body-mass of each participant or a decaffeinated coffee 60 min before starting exercise. Participants participated in the blind design experiment under both conditions at a one-week interval. Oxygen uptake, respiratory exchange ratio, heart rate, RPE, and plasma lactate concentration were measured during the endurance exercise. The RPE under the caffeinated coffee condition during the last 60 min of endurance exercise was significantly lower than that in the decaffeinated coffee condition. However, no significant differences in any physiological response were observed between conditions. Thus, caffeine ingestion 60 min before starting exercise had an insignificant effect on the physiological responses, except for RPE during submaximal endurance exercises for 60 min. Caffeine ingestion before endurance exercise of relatively low intensity may have a beneficial effect on psychological responses [08319].

Although coffee is largely consumed by adults in Western countries, controversy exists about its impact on the cardiovascular system. It was recently demonstrated that caffeinated and decaffeinated espresso coffee have different acute effects on endothelial function in healthy subjects, measured using flow-mediated dilation of the brachial artery. In one study, it was measured the anti-oxidant capacity of two coffee substances in terms of free stable radical 2,2-diphenyl-1-picryl-hydrazyl 50 percent inhibition (I50 DPPH). The caffeinated coffee had a slightly higher anti-oxidant capacity than decaffeinated espresso coffee. It was suggested that the unfavourable effects observed after caffeinated coffee ingestion are due to caffeine and that the antioxidant activity is responsible for the increased FMD observed after decaffeinated coffee ingestion. Further clinical and epidemiological studies are needed to understand the chronic effects of coffee consumption on health [10499].

**Hematological side effects**

To evaluate the effect of caffeine on white cell distribution and muscle injury markers in professional soccer players during exercise 22 male athletes completed a placebo controlled double blind test protocol to simulate a soccer match, followed by a Yo-Yo intermittent recovery test. Exercise caused an increase in packed cell volume that was enhanced by caffeine. Caffeine and exercise had a synergistic effect on the blood lymphocyte count, which
increased by about 38 percent after exercise, and by an additional 35 percent when combined with caffeine. Caffeine promoted an exercise independent rise in circulating monocytes, and a synergistic action of exercise and caffeine was observed on segmented neutrophils. Caffeine promoted thrombocytosis. Plasma adenosine deaminase, aspartate aminotransferase, and lactate dehydrogenase concentrations were enhanced by exercise, and alanine transaminase concentration was enhanced in both groups, with a synergistic effect of caffeine. It was concluded that the pronounced increase in the white cell count in the group receiving caffeine appeared to be caused by greater muscle stress and consequently more intense endothelial and muscle cell injury. The use of caffeine may augment the risk of muscle damage in athletes [07176].

Experimental

Caffeine and taurine

Caffeine enhances endurance performance; however, its effect on accumulated lactate remains unclear. Conversely, taurine, which also enhances endurance performance, decreases accumulated lactate. In one study, the effect of combination of caffeine and taurine on endurance performance was assessed. Mice ran on a treadmill, and the accumulated lactate was measured. In addition, muscle fibers from the gastrocnemius muscle of the mice were stained with ATPase and analyzed. The use of caffeine and taurine over a 2 week period enhanced endurance performance. Moreover, taurine significantly decreased the accumulated concentration of lactate over long running distances. However, the diameter of the cross-sections and ratios of Types I, IIA, and IIB muscle fibers were not affected [09258].

Interaction with amitriptylin

The interaction of caffeine (1 mg/kg) and amitriptyline (15 mg/kg) on the immobility time during Porsolt's forced swimming test was investigated in female Wistar rats. Vehicle-treated animals had a significant increase of immobility time during the second day of the test. Amitriptyline only prevented the increase of immobility time during the second session. While caffeine alone prevented the increase of immobility time in both groups, the methylxanthine abolished the effect of amitriptyline, leaving the antidepressant action. These results suggest that the anti-immobility effect of amitriptyline is mediated in part by endogenous adenosine [08320].

Muscle metabolism

Caffeine (1,3,7-trimethylxanthine) has been implicated in the regulation of glucose and lipid metabolism including actions such as insulin-independent glucose transport, glucose transporter 4 expression, and fatty acid utilization in skeletal muscle. These effects are similar to the exercise-induced and 5'adenosine monophosphate-activated protein kinase (AMPK)-mediated metabolic changes in skeletal muscle, suggesting that caffeine is involved in the regulation of muscle metabolism through AMPK activation. It was explored whether caffeine acts on skeletal muscle to stimulate AMPK. Incubation of rat epitrochlearis and soleus muscles with Krebs buffer containing caffeine (≥3 mmol/L, ≥15 minutes) increased the phosphorylation of AMPK-alpha Thr(172), an essential step for full kinase activation, and acetyl-coenzyme A carboxylase Ser(79), a downstream target of AMPK, in dose- and time-dependent manners. Analysis of isoform-specific AMPK activity revealed that both AMPKalpha1 and alpha2 activities increased significantly. This enzyme activation was
associated with a reduction in phosphocreatine content and an increased rate of 3-O-methyl-d-glucose transport activity in the absence of insulin. These results suggest that caffeine has similar actions to exercise by acutely stimulating skeletal muscle AMPK activity and insulin-independent glucose transport with a reduction of the intracellular energy status [09259].

Caffeine activates 5'AMP-activated protein kinase (AMPK), a signalling intermediary implicated in the regulation of glucose, lipid and energy metabolism in skeletal muscle. Skeletal muscle expresses two catalytic α subunits of AMPK, alpha1 and alpha2, but the isoform specificity of caffeine-induced AMPK activation is unclear. The aim of this study was to determine which α isoform is preferentially activated by caffeine in vitro and in vivo using rat skeletal muscle. Rat epitrochlearis muscle was isolated and incubated in vitro in the absence or presence of caffeine. In another experiment, the muscle was dissected after intravenous injection of caffeine. Isoform-specific AMPK activity, the phosphorylation status of AMPKalpha Thr(172) and acetyl-CoA carboxylase (ACC) Ser(79), the concentrations of ATP, phosphocreatine (PCr) and glycogen, and 3-O-methyl-d-glucose (3MG) transport activity were estimated.

Incubation of isolated epitrochlearis muscle with 1 mm of caffeine for 15 min increased AMPKα1 activity, but not AMPKα2 activity; concentrations of ATP, PCr and glycogen were not affected. Incubation with 3 mm of caffeine activated AMPKα2 and reduced PCr and glycogen concentrations. Incubation with 1 mm of caffeine increased the phosphorylation of AMPK and ACC and enhanced 3MG transport. Intravenous injection of caffeine (5 mg/kg) predominantly activated AMPKalpha1 and increased 3MG transport without affecting energy status. The results suggest that of the two alpha isoforms of AMPK, AMPKalpha1 is predominantly activated by caffeine via an energy-independent mechanism and that the activation of AMPKalpha1 increases glucose transport and ACC phosphorylation in skeletal muscle [11205].

Effect of fat free weight

The influences of creatine and caffeine supplementation associated with power exercise on lean body mass (LBM) composition are not clear. The purpose of this research was to determine whether supplementation with high doses of creatine and caffeine, either solely or combined, affects the LBM composition of rats submitted to vertical jumping training. Male Wistar rats were randomly divided into 8 groups: sedentary (S) or exercised (E), placebo (Pl), creatine (Cr), caffeine (Caf) or creatine plus caffeine (CrCaf). The supplemented groups received creatine (load: 0.430 g/kg of body weight for 7 days; and maintenance: 0.143 g/kg of body weight for 35 days), caffeine (15 mg/kg of body weight for 42 days) or creatine plus caffeine. The exercised groups underwent a vertical jump training regime (load: 20 to 50 % of body weight, 4 sets of 10 jumps interspersed with 1 min resting intervals), 5 days/wk, for 6 weeks. LBM composition was evaluated by portions of water, protein and fat in the rat carcass. Exercised animals presented a lower carcass weight (11 %), as compared to sedentary animals. However, no effect of supplementation was observed on carcass weight. There were no significant differences among the groups for percentage of water in the carcass. The percentage of fat in the group SCr was higher than in the groups SCaf and ECr. A higher percentage of protein was observed in the groups EPI and ECaf when compared to the groups SPI and SCaf. The percentage of fat in the carcass decreased, while those of water and protein increased in exercised animals, compared to sedentary animals. Caffeine groups presented reduced percentage of fat when compared to creatine supplemented groups. It was concluded that high combined doses of creatine and caffeine does not affect the LBM composition of either sedentary or exercised rats, however, caffeine supplementation alone reduces the percentage of fat. Vertical jumping training increases the percentages of water and protein and reduces the fat percentage in rats [11206].

Practical recommendations
The ergogenic effects of caffeine on athletic performance have been shown in many studies, and its broad range of metabolic, hormonal, and physiologic effects has been recorded, as one review of the literature shows. However, few caffeine studies have been published to include cognitive and physiologic considerations for the athlete. The following practical recommendations consider the global effects of caffeine on the body: lower doses can be as effective as higher doses during exercise performance without any negative coincidence; after a period of cessation, restarting caffeine intake at a low amount before performance can provide the same ergogenic effects as acute intake; caffeine can be taken gradually at low doses to avoid tolerance; and caffeine can improve cognitive aspects of performance, such as concentration, when an athlete has not slept well. Athletes and coaches also must consider how a person's body size, age, gender, previous use, level of tolerance, and the dose itself all influence the ergogenic effects of caffeine on sports performance [08321].

The position of the International Society of Sports Nutrition regarding caffeine supplementation and sport performance is summarized by the following seven points [10176]:

- caffeine is effective for enhancing sport performance in trained athletes when consumed in low-to-moderate dosages (about 3-6 mg/kg) and overall does not result in further enhancement in performance when consumed in higher dosages (≥9 mg/kg)
- caffeine exerts a greater ergogenic effect when consumed in an anhydrous state as compared to coffee
- it has been shown that caffeine can enhance vigilance during bouts of extended exhaustive exercise, as well as periods of sustained sleep deprivation
- caffeine is ergogenic for sustained maximal endurance exercise, and has been shown to be highly effective for time-trial performance
- caffeine supplementation is beneficial for high-intensity exercise, including team sports such as soccer and rugby, both of which are categorized by intermittent activity within a period of prolonged duration
- the literature is equivocal when considering the effects of caffeine supplementation on strength-power performance, and additional research in this area is warranted
- the scientific literature does not support caffeine-induced diuresis during exercise, or any harmful change in fluid balance that would negatively affect performance

Caffeinated “energy shots”

Caffeine (1,3,7-trimethylxanthine) is widely used among athletes, and it was in 2007 found that 73 percent of 140 athletes surveyed at the 2005 Ironman Triathlon World Championships believed caffeine improved performance. Via ingestion of coffee, capsules, or anhydrous powder, caffeine improves performance of moderate to high intensity endurance exercise. However, most studies examining caffeine utilized anhydrous caffeine, which is not readily accessible to coaches and athletes. Additionally, most researchers utilize doses relative to body weight instead of the absolute doses commonly found in commercially available caffeine products. While it could be argued that weighing out a relative dose may be plausible for elite athletes, who have access to dietitians and other trained staff, most track and field/cross country running coaches in the United States have large numbers of athletes to supervise, and this is relatively impractical. Energy drink usage among athletes is also quite widespread, and it was reported 48 percent of 401 collegiate athletes regularly consumed energy drinks. Thus, a coach is far more likely to tell an athlete to “Drink this” prior
to a competition instead of calculating a target caffeine dose for each athlete. Recent research has examined effects of more accessible forms of caffeine, such as energy drinks, on exercise performance in athletes. A, yet to be evaluated, caffeine supplement is the energy "shot" which is smaller in volume (generally 59-88 mL), as it lacks the large amounts of sugars, carbohydrates, and/or carbonated water of energy drinks containing caffeine. This low volume and energy content may make their intake practical for runners, who typically avoid supplements due to the onset of gastrointestinal disturbances, as running has a higher occurrence of GI symptoms than cycling. Despite the large amount of literature examining the ergogenic properties of caffeine, few studies have evaluated the efficacy of caffeine ingestion on running performance using ecologically valid assessments, such as time trials. Energy shots may prove to be a viable pre-competition supplement for runners. Six male runners (mean ± SD age 22.5 ± 1.8 years) completed three trials [placebo (PLA; 0 mg caffeine), Guayaki Yerba Maté Organic Energy Shot™ (YM; 140 mg caffeine), or Red Bull Energy Shot™ (RB; 80 mg caffeine)]. Treatments were ingested following a randomized, placebo-controlled crossover design. Participants ran a five kilometer time trial on a treadmill. No differences in performance were detected with RB or YM ingestion compared to placebo. Thus, ingestion of two commercially available energy shots with differing levels of caffeine does not alter treadmill five kilometer time-trial performance, RPE, or physiological variables in well-trained runners, compared to a placebo. The results must be considered preliminary due to the small sample size, and further studies should examine the effects of energy shot ingestion on performance in a variety of sport and field settings. While some research has been conducted on energy drinks, this is the first study to examine the efficacy of energy shots on exercise performance. Therefore, additional study is needed to examine their long-term effects on body composition and health, in addition to athletic performance, before recommendations about their usage can be provided to coaches and athletes [13438].

Caffeinated chewing gum

One investigation reports the effects of caffeinated chewing gum on fatigue and hormone response during repeated sprint performance with competitive cyclists. Nine male cyclists completed four high-intensity experimental sessions, consisting of four sets of 30 s sprints (5 sprints each set). Caffeine (240 mg) or placebo was administered via chewing gum following the second set of each experimental session. Testosterone and cortisol concentrations were assayed in saliva samples collected at rest and after each set of sprints. Mean power output in the first 10 sprints relative to the last 10 sprints declined by 5.8 ± 4.0 percent in the placebo and 0.4 ± 7.7 percent in the caffeine trials, respectively. The reduced fatigue in the caffeine trials equated to a 5.4 percent performance enhancement in favour of caffeine. Salivary testosterone increased rapidly from rest (53 %) and prior to treatments in all trials. Following caffeine treatment, testosterone increased by a further 12 ± 14 percent relative to the placebo condition. In contrast, cortisol concentrations were not elevated until after the third exercise set; following the caffeine treatment cortisol was reduced by 21 ± 31 percent relative to placebo. The acute ingestion of caffeine via chewing gum attenuated fatigue during repeated, high-intensity sprint exercise in competitive cyclists. Furthermore, the delayed fatigue was associated with substantially elevated testosterone concentrations and decreased cortisol in the caffeine trials [10389].

Low-dose caffeine administered in chewing gum does not enhance cycling to exhaustion. The purpose of the current investigation was to examine the effect of low-dose caffeine (CAF) administered in chewing gum at 3 different time points during submaximal cycling exercise to exhaustion. Eight college-aged (26 ± 4 years), physically active (46 ± 6 mL/kg/min) volunteers participated in 4 experimental trials. Two pieces of caffeinated
chewing gum (100 mg per piece, total quantity of 200 mg) were administered in a double-blind manner at 1 of 3 time points (-35, -5, and +15 minutes) with placebo at the other 2 points and at all 3 points in the control trial. The participants cycled at 85 percent of maximal oxygen consumption until volitional fatigue and time to exhaustion (TTE) were recorded in minutes. Venous blood samples were obtained at -40, -10, and immediately postexercise and analyzed for serum-free fatty acid and plasma catecholamine concentrations. Oxygen consumption, respiratory exchange ratio, heart rate, glucose, lactate, ratings of perceived exertion, and perceived leg pain measures were obtained at baseline and every 10 minutes during cycling. The results showed that there were no significant differences between the trials for any of the parameters measured including TTE. These findings suggest that low-dose CAF administered in chewing gum has no effect on TTE during cycling in recreational athletes and is, therefore, not recommended [12290].

Research has shown that standard chewing gum can affect aspects of both attention and memory. One study examined the effects of Think Gum®, a caffeinated-herbal chewing gum, on both concentration and memory using a series of paper-based and online testing. Compared to standard chewing gum and a no-gum control, chewing caffeinated-herbal gum during testing improved aspects of memory, but did not affect concentration. The findings suggest that caffeinated-herbal chewing gum is an effective memory aid [13350].

The purpose of this study was to determine the most efficacious time to administer caffeine (CAF) in chewing gum to enhance cycling performance. Eight male cyclists participated in 5 separate laboratory sessions. During the first visit, the subjects underwent a graded exercise test to determine maximal oxygen consumption (VO\textsubscript{2max}). During the next 4 visits, 3 pieces of chewing gum were administered at 3 time points (120-minute precycling, 60-minute precycling, and 5-minute precycling). In 3 of the 4 visits, at 1 of the time points mentioned previously, 300 mg of CAF was administered. During the fourth visit, placebo gum was administered at all 3 time points. The experimental trials were defined as follows: trial A (-120), trial B (-60), trial C (-5), and trial D (Placebo). After baseline measurements, time allotted for gum administration, and a standard warm-up, the participants cycled at 75% VO\textsubscript{2max} for 15 minutes then completed a 7kJ/kg cycling time trial. Data were analyzed using a repeated measures analysis of variance. Cycling performance was improved in trial C (-5), but not in trial A (-120) or trial B (-60), relative to trial D (Placebo). CAF administered in chewing gum enhanced cycling performance when administered immediately prior, but not when administered 1 or 2 hours before cycling [13466].

**Caffein gel**

It was investigated the effects of ingesting carbohydrate gels with and without caffeine on a 90 minute, four blocks intermittent sprint test (IST), in 12 recreationally trained male athletes. Using a cross-over design, one 70 ml dose of gel containing either 25 g of carbohydrate with (CHOCAF) or without (CHO) 100 mg of caffeine, or a non-caloric placebo (PL) was ingested on three occasions: one hour before, immediately prior to and during the IST. Blood glucose, rating of perceived exertion (RPE) and fatigue index (FI) were analysed. Glucose showed significantly higher values for both CHOCAF and CHO at the first, second and third blocks when compared with PL, while only CHOCAF was significantly different to PL at the fourth block. CHOCAF showed an improved FI compared with CHO and PL, a significantly lower RPE compared with PL and a trend in respect of CHO after the third block. In conclusion, ingesting CHOCAF one hour before, prior to and during an IST is effective at transiently reducing fatigue and RPE whilst maintaining higher glucose levels at the final stages of the exercise [13455].
Guarana

Guarana (*Paullinia cupana*), a climbing plant in the maple family, native to the Amazon basin and especially common in Brazil, contains a high amount of guaranine, a chemical substance with the same characteristics as caffeine. Guaranine, a synonym for caffeine, is defined only as the caffeine chemical in guarana and is identical to the caffeine chemical derived from other sources (e.g. coffee, tea, maté). Guarana features large leaves, clusters of flowers, and a fruit similar in size to the coffee bean. As a dietary supplement, guarana is a useful caffeine source with guarana seeds containing approximately twice the amount of caffeine (2-4.5 %) compared with 1-2 percent for coffee beans. Guarana, alongside other natural sources of caffeine, also contains varying mixtures of other xanthine alkaloids such as theobromine and theophylline. Guarana is generally recognised as an acceptable ingredient and can be found in drinks, “energy shots”, herbal teas or capsules. Consequently, guarana is best known for its stimulatory properties, providing similar benefits to caffeine, such as reducing fatigue, increasing alertness, and as an ergogenic aid in the athletic arena. The maximal ergogenic benefits of caffeine and guarana can be seen at small to moderate caffeine doses (2-3 mg/kg). Theoretically, it is possible to overdose on caffeine or guarana, with the fatal dose being estimated at a single dose of 10 g pure caffeine/guaranine [11150].
OTHER STIMULANTS

While the extent of explicitly named substances among S.6 of WADA's prohibited list remained nearly unchanged in 2011 compared to the preceding year, the growing number of new designer stimulants in addition to earlier abandoned and now re-discovered agents with stimulating properties (e.g. mephedrone, naphyrone, methylene, methedrone, flephedrone) has required more comprehensive screening efforts and attention by doping control laboratories [12016].

Central nervous system (CNS) stimulants may be used to reduce tiredness and increase alertness, competitiveness, and aggression. Central nervous system (CNS) stimulants were originally used by athletes to improve performance on the day of competition. Although there was evidence that these drugs might be linked with sudden collapse or death, usually from cardiac or respiratory arrest, particularly during competition, the long term side effects of addiction and physiological damage to the body were regarded as minor or were not mentioned. The class of stimulants includes psychomotor stimulants, sympathomimetics, and miscellaneous CNS stimulants – for example, caffeine, amphetamines, ephedrines, and cocaine. These substances are either prohibited or monitored, previously by the International Olympic Committee (IOC) and now by the World Anti-Doping Agency (WADA), and are screened for daily by accredited laboratories. There are several potential dangers involving their misuse in contact sports. One paper reviewed the three main CNS stimulants, ephedrine, amphetamine, and cocaine, in relation to misuse in sport. CNS stimulants have psychotropic effects that may be perceived to be ergogenic. Some are prescription drugs, such as Ephedra alkaloids, and there are issues regarding their appropriate therapeutic use. Recently attention has been given to their widespread use by athletes, despite the lack of evidence regarding any ergogenic or real performance benefit, and their potentially serious side effects. Recreational drugs, some of which are illegal (cocaine, amphetamines), are commonly used by athletes and cause potential ergolytic effects. Overall, these drugs are important for their frequent use and mention in anti-doping laboratories statistics and the media, and their potentially serious adverse effects. Doping with CNS stimulants is a real public health problem and all sports authorities should participate in its prevention. Dissemination of information is essential to prevent doping in sport and to provide alternatives. Adequate training and education in this domain should be introduced [06171].

Stimulants are banned in-competition for all categories of sports by the World Anti-Doping Agency. A simple liquid chromatography-tandem mass spectrometry (LC-MS/MS) assay employing electrospray ionisation in positive mode was developed in that work for the quantification in urine specimens of 4-methyl-2-hexanamine, a primary amine exhibiting sympathomimetic properties. Following a simple pretreatment procedure, the analyte was separated using a gradient mobile phase on reverse phase C8 column. Selected reaction monitoring m/z 116.2-->57.3 was specific for detection of 4-methyl-2-hexanamine and the assay exhibited a linear dynamic range of 50-700 ng/mL. The validated method has been successfully applied to analyze the target compound in food supplements as well as in urine specimens. The administered drug (40 mg) was detected at the level of 350 ng/mL in the urine up to 4 days [09249].

Stimulants have been frequently detected in doping control samples and represent a structurally diverse class of compounds. Comprehensive sports drug-testing procedures have been developed using gas or liquid chromatography combined with mass spectrometric detection, and they have revealed various adverse analytical findings, as demonstrated with 2 examples, 4-methylhexan-2-amine and methoxyphenamine. Moreover, the necessity of
controlling the use or misuse of stimulating agents is outlined by means of pseudoephedrine, a compound that was prohibited in sports until the end of 2003. Since the ban was lifted, monitoring programs proved a significant increase in pseudoephedrine applications as determined from urine samples collected in competition. As a consequence, a reimplementation of this drug in future doping controls was decided [10185].

Stimulants have been frequently detected in doping control samples and represent a structurally diverse class of compounds. Comprehensive sports drug-testing procedures have been developed using gas or liquid chromatography combined with mass spectrometric detection, and they have revealed various adverse analytical findings, as demonstrated with 2 examples, 4-methylhexan-2-amine and methoxyphenamine. Moreover, the necessity of controlling the use or misuse of stimulating agents is outlined by means of pseudoephedrine, a compound that was prohibited in sports until the end of 2003. Since the ban was lifted, monitoring programs proved a significant increase in pseudoephedrine applications as determined from urine samples collected in competition. As a consequence, a reimplementation of this drug in future doping controls was decided [10186].

The evidence for the ergogenic properties of the most potent stimulants, amphetamines, cocaine and ephedrine, is mostly insubstantial. Low doses of amphetamines may aid performance where effects of fatigue adversely affect higher psychomotor activity. Pseudoephedrine, at high doses, has been suggested to improve high intensity and endurance exercise but phenylpropanolamine has not been proven to be ergogenic. Only caffeine has substantial experimental backing for being ergogenic in exercise. The mode of action of these stimulants centres on their ability to cause persistence of catecholamine neurotransmitters, with the exception of caffeine which is an adenosine receptor antagonist. By these actions, the stimulants are able to influence the activity of neuronal control pathways in the central (and peripheral) nervous system. Rodent models suggest that amphetamines and cocaine interact with different pathways to that affected by caffeine. Caffeine has a variety of pharmacological effects but its affinity for adenosine receptors is comparable with the levels expected to exist in the body after moderate caffeine intake, thus making adenosine receptor blockade the favoured mode of ergogenic action. However, alternative modes of action to account for the ergogenic properties of caffeine have been supported in the literature. Biochemical mechanisms that are consistent with more recent research findings, involving proteins such as DARPP-32 (dopamine and cAMP-regulated phosphoprotein), are helping to rationalize the molecular details of stimulant action in the central nervous system [08292].

One review examined the pharmacology of stimulants prohibited by the World Anti-Doping Agency. Stimulants that increase alertness and reduce fatigue or activate the cardiovascular system can include drugs like ephedrine available in many over-the-counter medicines. Others such as amphetamines, cocaine and hallucinogenic drugs, available on prescription or illegally, can modify mood. A total of 62 stimulants (61 chemical entities) are listed in the WADA List, prohibited in competition. Athletes may have stimulants in their body for one of three main reasons: inadvertent consumption in a propriety medicine; deliberate consumption for misuse as a recreational drug and deliberate consumption to enhance performance. The majority of stimulants on the list act on the monoaminergic systems: adrenergic (sympathetic, transmitter noradrenaline), dopaminergic (transmitter dopamine) and serotonergic (transmitter serotonin, 5-HT). Sympathomimetic describes agents, which mimic sympathetic responses, and dopaminomimetic and serotoninomimetic can be used to describe actions on the dopamine and serotonin systems. However, many agents act to mimic more than one of these monoamines, so that a collective term of monoaminomimetic may be useful. Monoaminomimetic actions of stimulants can include blockade of re-uptake of neurotransmitter, indirect release of neurotransmitter, direct activation of monoaminergic
receptors. Many of the stimulants are amphetamines or amphetamine derivatives, including agents with abuse potential as recreational drugs. A number of agents are metabolized to amphetamine or metamphetamine. In addition to the monoaminomimetic agents, a small number of agents with different modes of action are on the list. A number of commonly used stimulants are not considered as "Prohibited Substances" [08293].

Stimulatory substances applied during competition possess a reasonable potential as performance enhancing agents and their misuse in elite sport has been frequently reported during the last few decades. An analytical method for the qualitative determination of selected stimulants containing a primary or secondary amine moiety in human urine for doping control purposes was developed. A rapid and highly specific procedure based on a sample preparation using weak cation exchange solid phase extraction (SPE-XCW) followed by liquid chromatography-tandem mass spectrometry (LC-MS/MS) with a C6-Phenyl analytical column allowed the unambiguous identification of the target analytes down to low concentration levels. Validation provided recovery rates of better than 75 percent, precisions of less than 20 percent and a linear approximation in the required working range (10-750 ng/mL) were obtained for 19 different target compounds. This method provides a rugged and highly specific alternative to the established method utilising gas or liquid chromatography after liquid-liquid extraction [08294].

One study tested the related hypotheses that acute fatigue reduces +Gz tolerance and endurance, and that stimulant can partially reverse this impact. To determine the effect of fatigue on +Gz tolerance and the impact of stimulant use, 10 male centrifuge subjects, mean age 32, were tested in a repeated measures study under five nighttime conditions following an average of 22 h of sustained wakefulness during their circadian nadir. Using a within-subject design, subjects received placebo, dextroamphetamine 10 mg, modafinil 200 mg, methylphenidate 10 mg, and pemoline 37.5 mg at night, and were tested during a daytime control session. No difference in +Gz tolerance or endurance was detected among conditions. The cognitive/performance tests also did not detect any differences. Subject perception that anti-G straining maneuver (AGSM) difficulty was greater during the night placebo condition than during the daytime control, methylphenidate and modafinil night conditions reached statistical significance [08295, 08296].

The objective of one study was to determine the prevalence of asthma-like symptoms and asthma and the use of asthma medication in Danish elite athletes. A cross-sectional questionnaire survey of Danish elite athletes was conducted in 2006. All elite athletes (n=418) financially supported by the national organization of elite athletes comprised the study group; 329 (79 %) completed the questionnaire concerning their sport, asthma-like symptoms, asthma and use of asthma medication. Asthma-like symptoms at rest were reported by 41 percent of respondents; 55 percent reported asthma-like symptoms at rest or at exercise. Physician-diagnosed asthma was present in 16 percent and 14 percent had current asthma. Asthma medication was taken by 7 percent of the athletes, of whom 79 percent used inhaled corticosteroids and 21 percent used inhaled beta2-agonists only. Athletes participating in endurance sports had significantly higher prevalences of current asthma (24 %) and use of asthma medication (15 %) than all other athletes. Athletes participating in endurance sports have a higher prevalence of asthma and use of asthma medication. The frequency of asthma medication is lower than the prevalence of current asthma indicating that there is no overuse of asthma medication among Danish elite athletes [08297].

One paper reviewed the prevalence of legal and illegal stimulants in relation to doping-control analysis. Stimulants are among the oldest classes of doping agents, having been used since ancient times. Despite the ease with which they can be detected and the
availability of sensitive detection methods, stimulants are still popular among athletes. Indeed, they remain one of the top three most popular classes of prohibited substances. Because the list of legal and illegal stimulants is extensive only a selection is discussed in detail. The compounds selected are caffeine, ephedrines, amphetamine and related compounds, methylphenidate, cocaine, strychnine, modafinil, adrafinil, 4-methyl-2-hexaneamine, and sibutramine. These compounds are mainly prevalent in sport or are of therapeutic importance. Because stimulants are the oldest doping class the first detection methods were for this group. Several early detection techniques including GC-NPD, GC-ECD, and TLC are highlighted. The more novel detection techniques GC-MS and LC-MS are also discussed in detail. In particular, the last technique has been shown to enable successful detection of stimulants difficult to detect by GC-MS or for stimulants previously undetectable. Because stimulants are also regularly detected in nutritional (food) supplements a section on this topic is also included [11192].

Because stimulants are also regularly detected in nutritional (food) supplements a section on this topic is also included [11193].

Ergonomic effects

The actual ergonomic benefits of amphetamines, cocaine, and ephedrines are unclear, but all are banned or monitored to varying degrees by different sporting federations and associations in relation with their real side effects in sport practice. This discrepancy between actual benefit and banned status highlights the difficulty sport physicians have in advising athletes, parents, coaches, and the sporting community about the proper approach to monitoring, education, and testing for these drugs. Together, they should take action in the areas of education, scientific research, and social and health measures to protect athletes, harmonise standards and coordinate the legislation in relation to doping [06171].

Theobromine

The effects of theobromine in man are underresearched, possibly owing to the assumption that it is behaviourally inert. Toxicology research in animals may appear to provide alarming results, but these cannot be extrapolated to humans for a number of reasons. Domestic animals and animals used for racing competitions need to be guarded from chocolate and cocoa-containing foods, including foods containing cocoa husks. Research ought to include caffeine as a comparative agent, and underlying mechanisms need to be further explored. Of
all constituents proposed to play a role in our liking for chocolate, caffeine is the most convincing, though a role for theobromine cannot be ruled out. Most other substances are unlikely to exude a psychopharmacological effect owing to extremely low concentrations or the inability to reach the blood-brain barrier, whilst chocolate craving and addiction need to be explained by means of a culturally determined ambivalence towards chocolate [11209].

**Theobromine and theophylline**

Theobromine and theophylline are methylxanthine alkaloids originally identified from the chocolate or cocoa plant Theobroma cacao L. (Malvaceae, syn. Sterculiaceae), but subsequently identified in tea, cola, guarana and many other plants. Theobromine and theophylline are isomers of one another and paraxanthine. All three are structurally similar to caffeine and all three are metabolites of caffeine in the human body, although paraxanthine is much more so. Both theobromine and theophylline have been used in energy- or metabolism-enhancing sports supplements for their stimulant effects. Beyond their presence in foods, beverages and sports supplements where they may work as stimulants, pure theophylline is widely prescribed as an antiasthmatic, and is under investigation as a treatment for other cardiorespiratory diseases. Theophylline is an alleged ergogenic aid, though studies both support and refute this capacity. One study found no effect of theophylline (serum concentrations 10–20 mg/L) on VO\textsubscript{2max}, muscle or lung measures, or reaction time in nonasthmatic athletes, concluding it was not ergogenic. In contrast, two other groups dosed athletes with 4.5 mg/kg theophylline/body mass and reported improved time-to-exhaustion when athletes cycled either at 80 percent of their VO\textsubscript{2max} or intermittently (1 min cycling at 120 percent VO\textsubscript{2max} alternating with 3 min rest) and concluded it was ergogenic. Although a more thorough review exists elsewhere, this sample of studies demonstrates why the potential ergogenic effects of theophylline are still being questioned. Similar studies of theobromine could not be found. Both body mass and exercise are known to influence the metabolism of both compounds and, given current reports, it is likely that both may act additively or synergistically with other compounds. For example, theophylline is known to augment the effects of ephedrine, another stimulant discussed previously in this series. Both theobromine and theophylline have proven anti-inflammatory actions at cellular and molecular levels, including abilities to regulate reactive oxygen species (ROS), as well as to modulate the behaviours of inflammatory cells. The past (International Olympic Committee and World Anti-Doping Association) and present (National Collegiate Athletic Association) restrictions on high doses of caffeine intake by athletes in competition has created some discussion on whether theobromine and theophylline should also be regulated. Antidoping agencies have never placed restrictions on the use of these compounds, though one research team argued during the period when urinary caffeine concentrations were restricted to <12 microg/mL, that urinary levels of 5 μg/ml for theophylline and a theophylline/paraxanthine ratio of 0.50 should be used for doping standards. Quantities of theobromine and theophylline in commercially available products are probably too low to elicit any ergogenic benefits when such products are consumed in typical or even tolerable quantities, and pure theophylline is only available by prescription in many countries. Available data suggest that current policies regarding these compounds should be maintained but not cemented [12300].

**Ephedrine**

Echinacea and ephedra are herbs used by athletes worldwide. Echinacea is believed to strengthen the immune system against upper respiratory infections, while ephedra is supposed to promote alertness, endurance and strength. Purported bioactive molecules
include alk(yl)amides, caffeic acid derivatives and polysaccharides from echinacea, and alkaloids (ephrine, pseudoephedrine, phenylpropanolamine) from ephedra. Supplements are made from echinacea roots or flowering tops and ephedra stems. Taxonomically, Echinacea is an American angiosperm genus of nine species, whereas Ephedra is a global gymnosperm genus of about 50 species. Vernacularly, “echinacea” commonly refers to three species (Echinacea angustifolia, Echinacea pallida and Echinacea purpurea), whereas “ephedra” often refers to one Asian species (Ephedra sinica, Ma Huang) or sometimes a supplement containing one isolated alkaloid. Supplements from both plants may be purchased over the counter; additionally, ephedra alkaloids are components in cough syrups, decongestants and diet aids. Ephedra sympathomimetic alkaloids are structurally similar to methamphetamine, releasing catechoalamines and acting on cellular alpha and beta receptors and adrenoreceptors; these actions increase cardiovascular variables. Studies have looked at ergogenic effects of ephedra by dosing athletes with isolated alkaloids (usually pseudoephedrine, usually up to 120 mg) and together have reported non-significant and often heterogeneous results, reviewed elsewhere. One study that supplemented athletes with a whole herb supplement found no effect of 60 mg of ephedra when used in conjunction with 300 mg of caffeine on strength or power. Despite widespread public belief, ephedra does not have ergogenic properties in applicable contexts. However, it does carry serious adverse effect risks. The World Anti-Doping Agency (WADA) prohibits urinary concentrations of ephedrine and methylephedrine of >10 μg/ml and pseudoephedrine >150 μg/ml. Clinical studies of echinacea supplements typically utilise commercial whole herb formulations from above-ground parts and focus on immune enhancing outcomes. Research on athletes given echinacea supplements (doses varied or not given) reported upper respiratory tract infection prophylaxis and good tolerability with few adverse effects. Echinacea is a relatively modern remedy, studied first in the late 19th century as opposed to those herbs studied for centuries. Ephedra has been used in Chinese medicine for thousands of years. It became widely used in the late 1920s when its apparent ergogenic properties were observed. Despite several attributed fatalities and many adverse events, it was only after a notorious sporting fatality in 2003 that ephedra was banned [10391].

In recent years, the use of herbal preparations containing Ephedra has increased and so has the number of reported negative health effects. Ephedra products are used as a slimming aid, (sports) performance enhancer, stimulant during long working hours and as a plant-based ecstasy-surrogate in the party scene. The health effects caused by the use of Ephedra products are mainly restlessness, agitation, tachycardia and palpitations. The most important risk factors are the relatively high amounts of Ephedra alkaloids in the preparations available, the varying concentrations within different batches of the same product, the relatively high risk of voluntary overdosing in order to improve results and the occurrence of interactions with the concurrent use of other stimulants and medicines [10503].

Ephedrine is a stimulant with a chemical structure closely related to amphetamine. It is derived from ephedra herbs also known as ma huang. It possesses alpha and beta adrenergic agonistic effects, enhances the release of norepinephrine, and stimulates the central nervous system. Pseudoephedrine is closely related and also possesses central nervous system stimulant properties in addition to being a popular decongestant. Previously available ephedrine compounds in the US included such brands as Metabolife356 and Ripped Fuel. Before being banned in 2004, the FDA recommended that daily ephedra alkaloid intake remain under 25 mg and not be continued longer than 1 week. Pseudoephedrine in cold remedies is taken in maximal amount at 60 mg. Combining ephedrine with caffeine or its herbal form guarana poses significant risk and was prohibited by the FDA in the 1980s [06003].
The sympathomimetic drug ephedrine is used to treat symptoms of infection with the cold virus. It was originally prescribed as a bronchodilator for asthma, although it is now regarded as less suitable for this use since it has been linked with cardiac arrhythmia. Ephedrine is likely to be misused for its stimulant effect, but can also be ingested inadvertently because of its widespread availability in over-the-counter medicines [06171].

One study examined trends in stimulant use and attitudes toward use among American collegiate hockey athletes. All 139 players in one college hockey conference completed a comprehensive questionnaire. Over half of the athletes (52 %) confirmed stimulant use before a hockey game or practice. About half of the respondents (49 %) reported having used ephedra at least one time to improve athletic performance. Additionally, 17 percent reported using pseudoephedrine to improve performance in the 30 days prior to survey administration. Over half (55 %) were aware of the recent national ban on ephedra. Fifty-nine percent stated the national ban made them less likely to use ephedra products. The majority of athletes began use prior to college. Coaches, athletic trainers, and team physicians should be aware of athletes' patterns of stimulant use. Improved educational efforts directed at younger athletes are necessary to deter abuse of metabolic stimulants [06177].

Ephedra alkaloids, which are popular components of many nutritional supplements, are naturally occurring CNS stimulants obtained from several Ephedra species. Historically, Ephedra alkaloids have been used for both asthma and allergies in China for more than 5000 years. Currently, it is found in various pharmaceuticals, mainly as a decongestant, and in numerous nutritional and dietary supplements as an energy stimulant and anorexic agent. Pseudoephedrine can be found in prescription and over-the-counter preparations for respiratory infections or allergies (mostly for the treatment of congestion). Until its recent voluntary removal from the market because of reports of increased risk for stroke in women, phenylpropanolamine was also used similarly to pseudoephedrine and in over-the-counter diet pills. Purified forms of these substances include ephedrine, pseudoephedrine, norephedrine, methylephedrine, norpseudoephedrine and methylpseudoephedrine. Phenylpropanolamine is a synthetic compound functionally similar to the ephedra alkaloids in effect and use. Ephedrine, which is now also produced by chemical synthesis, is closely related in structure to metamfetamine, although its CNS actions are much less potent but longer acting than those of the amphetamines. Its peripheral stimulant actions are similar to, but less powerful than, those of adrenaline (epinephrine), a hormone produced in the body by the adrenal glands [06171].

**Chinese preparations**

Sho-seiryu-to is one of the most common Traditional Chinese Medicine preparations for the attenuation of colds. Ephedrae Herba is one of the prescriptions of Sho-seiryu-to. The major ingredients of Ephedrae Herba, ephedrines, are banned substances on the WADA list. The purpose of one study was to investigate the elimination of urinary ephedrines after administering Sho-seiryu-to preparation and to determine the possibility of positive ephedrines test results in urine. Six healthy volunteers took a single 2.5-g dose of concentrated Sho-seiryu-to preparation. All urine was collected for 48 h. The concentrations of urinary ephedrines were analyzed by high-performance liquid chromatography and the elimination half-life of the ephedrines was estimated. The results show that ephedrine and cathine (norpseudoephedrine), the prohibited substances of the WADA, were excreted in the urine after taking a single dose of Sho-seiryuto preparation. The peak concentration of ephedrine was 3.9 ± 1.9 mg/mL, which was lower than the WADA permitted value (10 mg/mL). The estimated elimination half-lives of ephedrine, norephedrine, pseudoephedrine, and norpseudoephedrine following administration of this preparation were 5.3 ± 1.2, 4.9 ±
The study concluded that the urine would not violate the antidoping rules after administering a single dose of Sho-seiryu-to preparation. Nevertheless, an applied multiple-dose study upon administering the preparation for three times per day for three days showed a positive urine ephedrine result (13.7 mg/mL). Athletes should be careful when taking more than a single dose of Sho-seiryu-to preparation [09261].

Kakkon-to is one of the most common traditional Chinese medicine preparations for the attenuation of colds. Ephedrae Herba is one of the prescriptions of Kakkon-to. The major ingredients of Ephedrae Herba, ephedrines, are banned substances on the WADA list. The purpose of one study was to investigate the elimination of urinary ephedrines after administering Kakkon-to and to determine the possibility of urinary positive ephedrine test results. Six healthy volunteers took one single dose of 2.5 g Kakkon-to extract granules. The concentrations of urinary ephedrines were analyzed by high-performance liquid chromatography. The result showed that ephedrine and norpseudoephedrine were excreted in the urine after taking one single dose of Kakkon-to. However, the highest amount of ephedrines in urine was ephedrine and the peak concentration was $4.4 \pm 1.8$ microg/mL, which was lower than the WADA permitted value (10 microg/mL). The estimated elimination half-lives of ephedrine, norephedrine, pseudoephedrine, and norpseudoephedrine following administration of this preparation were: $5.2 \pm 1.2$, $4.2 \pm 1.3$, $4.2 \pm 0.9$, and $6.5 \pm 2.8$ h, respectively. The study concluded that the urine would not violate the rule of doping after administering a single dose of Kakkon-to. Nevertheless, a further study on administering the preparation for 3 times per day for 3 days showed a positive ephedrine result. Athletes should be careful when taking more than a single dose of Kakkon-to [08303].

**Use in women**

Ephedra is a dietary supplement used for performance enhancement due to its stimulant effects. Ephedra contains the alkaloids ephedrine and pseudoephedrine. It is a sympathomimetic and has a chemical structure close to amphetamine. Its use as a performance-enhancing supplement was popularized due to reported improvement in weight loss, energy levels, and athletic performance. Ephedra and ephedra-containing products were removed from the market in 2004 in the US; ephedra is the only dietary supplement that has been removed since the creation of the Dietary Supplement Health and Education Act in 1994. Nonetheless, the ban has not stopped its use by athletes 07[086].

**Prevalence**

The NCAA study of substance use habits of college student-athletes found that ephedra use increased in female athletes from 2001 to 2005 despite highly publicized adverse health effects. Prevalence of ephedrine use increased from 3.2 to 11.9 percent in women's ice hockey and 0.3 to 2.7 percent in lacrosse from 2001 to 2005, while prevalence increased or stayed the same in women's basketball, softball, and tennis. It was found that, of 270 high school athletes, 26 percent of girls and 12 percent of boys have tried ephedrine products [07086].

**Legal affairs**

In 2004, ephedrine was the first supplement removed from the US market by the FDA since the 1994 supplement act. However, in April 2005 a US District Court judge ruled to overturn the ban, stating that the FDA had not proved that a 10-mg dose was dangerous. She ruled that “[the prior ban] would be directly contrary to the statutory language placing the burden of proof on the government…. ” It is likely that this legal battle will continue with possible appeals by the FDA, although this ruling may open the door to ephedrine's return to the
supplement marketplace. The International Olympic Committee, NCAA, Major League Baseball, National Basketball Association, and National Football League all have banned the systemic use of ephedrine products [06003].

Physiological effects

Ephedrine traditionally has been used by athletes to provide quick energy and to aid in fat loss, consequently improving speed and appearance. The majority of studies that are available show no change in athletic performance with ephedrine use. A few investigations have reported improvements in quadriceps strength or stationary cycling, but these have involved high doses of ephedra compounds and sometimes were combined with caffeine, which poses significant risk to the athlete [06003].

Ephedrine is the most potent thermogenic of the Ephedra alkaloids. It is a mixed sympathomimetic agent which acts as a CNS stimulant by enhancing the release of noradrenaline from sympathetic neurones and stimulating alpha and beta receptors. Ephedrine not only stimulates the heart rate and thereby increases cardiac output, but also causes peripheral constriction, resulting in an increase in peripheral resistance, which can lead to a sustained rise in blood pressure. Ephedrine has moderately potent bronchial smooth muscle relaxant properties, and is used as a decongestant and for temporary relief of shortness of breath caused by asthma. Ephedrine is excreted in the urine largely unchanged and the usual elimination half-life is three to six hours which can be prolonged with increased urine pH [06171].

Side effects

It has been reported that ephedra accounted for 0.82 percent of herbal product sales but was implicated in 64 percent of adverse herbal reactions in the United States in 2001. Adverse reactions are wide ranging and include hypertension, arrhythmias, anxiety, tremors, insomnia, seizures, paranoid psychoses, cerebral vascular accident, myocardial infarction, and death. In fact, in athletic performance studies, the most consistent finding is increased heart rate. In 2000 critically it was evaluated the 140 adverse events reported to the FDA from 1997 to 1999 and concluded that 62 percent of the adverse events reported were definitely or possibly related to the drug. In that series, 10 users were younger than 18 years, and there were 10 deaths and 13 cases of permanent disability. These included a 22-year-old man who was taking Ripped Force and sustained a cardiac arrest and was left with a permanent neurologic disability and a 15-year-old girl who was taking Ripped Fuel and sustained a fatal arrhythmia [06003].

The common side effects of ephedrine are qualitatively similar to those produced by amfetamines but are generally milder: headache, dizziness, irritability, anxiety, tremor, and psychosis. Higher doses (overdose) can cause restlessness and anxiety, dizziness, insomnia, tremor, rapid pulse, sweating, respiratory difficulties, confusion, hallucinations, delirium, and convulsions. The most dangerous symptoms of overdose are abnormally high blood pressure and rapid, irregular heartbeat. A dose of ephedrine only two or three times the therapeutic maximum can cause a significant increase in blood pressure. Finally, a number of instances of psychosis, clinically similar to amphetamine psychosis, have resulted from chronic high-dose misuse. There are serious doubts concerning the safety of food supplements containing ephedra alkaloids. Because supplements are not considered therapeutic, they are not held to the same level of rigor in claiming efficacy and safety as that required of prescribed and over-the-counter medicines. Since the 1994 deregulation, an increased number of reports of adverse events, including hypertension, arrhythmia,
myocardial infarction, seizure, cerebrovascular accidents and death, has prompted the US Food and Drug Administration to recommend a limit on the use of ephedra alkaloids. Furthermore, joint use of ephedrine and caffeine can augment adverse cardiovascular and CNS effects [06171].

To evaluate ephedra's effects on weight loss, athletic performance, and adverse events, it was conducted a meta-analysis of trials using ephedra and similar compounds. They concluded that, compared with placebo, ephedra had a weight loss of 0.6 kg/months (95% confidence interval 0.2 to 1.0). Seven trials using different exercise type and outcome measures did not show significant improvement on exercise performance. This conclusion was supported by another study where it was concluded that standard ephedra doses did not have a performance-enhancing effect. Safety data from 50 trials produced an estimated risk 2.2 to 3.6 times that of developing psychiatric, autonomic, or gastrointestinal symptoms, and heart palpitations. No clinical trials have been specifically performed in women athletes to evaluate ephedrine's performance-enhancing effect [07086].

Much of the literature has focused on ephedra's adverse effects related to the cardiovascular and central nervous systems. In one study it was examined 140 cases submitted to the US Food and Drug Administration (FDA) between 1997 and 1999. Adverse effects included hypertension, arrhythmia, myocardial infarction, hemorrhagic stroke, seizure, and death. Thirty-one percent of cases were definitely or probably related to ephedra substances, while another 31 percent were possibly related. In many cases, ephedra was combined with caffeine [07086].

Heart
These are usually found through the internet or on the sports black market under names like “ma-huang”, “herbal Ecstasy”, and so on. Very frequent cardiovascular complications have been described as a result of their use, such as arrhythmias, hypertension, acute myocardial infarction, stroke, myocarditis, dilated cardiomyopathy, and sudden death. The pathophysiological mechanism of action is similar to that of the other sympathomimetic amines [12126].

Little has been done by way of measuring both the acute/chronic effects of stimulant use/abuse on a range of CV risk factors. While significant CV events are associated with their use, the effect on long-term atherosclerotic risk even with moderate usage, through negative alterations in known CV risk factors is worthy of further examination. All stimulants structurally related to amphetamine can cause catecholamine-mediated cardiotoxicity. Increased catecholamine levels can lead to vasoconstriction, vasospasm, tachycardia and hypertension and it is as a result of these responses that oxygen supply to the heart is compromised and hypertrophy, fibrosis and necrosis can result. Clearly, such conditions develop over time, as a consequence of chronic exposure and the repercussions may include myocardial infarction, aortic dissection and sudden cardiac death. There have been numerous reported cases of serious adverse cardiovascular (CV) events, including fatalities, linked with the use of ephedrines. The use of ephedrine has also been linked to cardiomyopathy and stroke while pseudoephedrine use has also been linked with stroke and coronary artery spasm with myocardial infarction. Further, there are numerous case reports of significant cardiovascular events following the administration of over-the-counter stimulants. As with AS use, the interpretation of such case reports is difficult, since it may be that serious adverse events are as a consequence of preexisting medical conditions combined with drug use. What case studies do promote is further experimental study. For example, doses equivalent to three to four times greater than the recommended therapeutic dose of pseudoephedrine have raised diastolic blood pressure above 90 mm Hg. These results were in accord with two other studies: it was reported significant increases in heart
rate and systolic blood pressure following relatively high doses of pseudoephedrine (120 and 180 mg), and noted that doses of 120 and 180 mg produced statistically significant increases in both pulse and systolic blood pressure. The clinical relevance of these blood pressure changes is not known. Reports of the CV effects of sympathomimetics in therapeutic doses have been conflicting. It was observed that a single dose of ephedrine (25 mg) significantly elevated both heart rate and systolic blood pressure while a single therapeutic dose of pseudoephedrine (60 mg) significantly elevated only systolic arterial blood pressure. However, it was noted little change in CV function following therapeutic doses. Increased blood pressure has been demonstrated in cases whereby ephedrines have been co-administered with a moderate dose of caffeine. Caffeine is thought to exacerbate the action of ephedrine's since it too may cause vasoconstriction through antagonism of adenosine and release of catecholamines [12114].

**Ephedrine in sport**

With their stimulant properties and sympathomimetic actions, ephedra alkaloids have been perceived as products that can potentially be used to enhance athletic performance and lending unfair advantages to athletes, even if used in supplement forms. Research has shown that the isolated use of ephedrine, pseudoephedrine and phenylpropanolamine alone at usual dosages has an inconsistent, and probably insignificant, ergogenic benefit for power, endurance, strength, or speed. Other studies looking at the use of ephedrine combined with vitamins, minerals, or caffeine have supported potential ergogenic effects. Indeed, many athletes use food supplements containing ephedra alkaloids because of perceived benefits of increased energy, decreased time to exhaustion and potential thermogenic properties with increased metabolism, increased fat loss, and improved muscle strength. In particular, a series of studies evaluated the effects of ephedrine in combination with caffeine showing an increased time to exhaustion and decreased rating of perceived exhaustion on cycle ergometry compared with either drug alone or placebo. The medical use of ephedrine is tolerated by WADA and IOC at therapeutic levels. Nevertheless, urine concentrations of greater than 10 microg/ml are considered positive. Ephedrine is a category S6 prohibited substance [06171].

**Side effects of ephedrine in relation to sport**

The recent highly publicised tragedies have prompted various athletic associations to focus on further evaluations of the use of these substances and on trying to educate athletes about potential health risks associated with their use. Continued evaluation of the use of these substances is necessary, as is continued education of athletes, parents, coaches, and trainers regarding the health risks associated with ephedrine alkaloids and corresponding supplements [06171].

**Fatal effect**

Ephedrine or ephedra herbal products have occasionally been used to enhance sports performance and energy or to aid weight loss. The most serious side effects are those on cardiovascular function, including acute myocardial infarction, severe hypertension, myocarditis and lethal cardiac arrhythmias. A 19-year-old woman was taking ephedrine to enhance her sports performance. After 10 days of this medication she developed hemodynamically unstable ventricular tachycardia resistant to cardioversion and amiodarone treatment. She converted to sinus rhythm 60 hours later, presumably when the plasma ephedrine level had sufficiently decreased. In an electrophysiological study the ventricular tachycardia could be induced and successfully ablated. There were no recurrences during follow-up of more than a year. The use of ephedrine carries a risk of development of life-threatening arrhythmias. Ephedrine alone cannot be considered as the ultimate cause of tachycardia in our patient; however, it is highly probable that ephedrine triggered the
tachycardic attack. The proarrhythmic effect most likely occurred because of underlying idiopathic left ventricular tachycardia. Although the patient could have developed her first attack of ventricular tachycardia at any time in her life, it is highly improbable that the attack following the ephedrine abuse was purely coincidental. The experience with the reported patient shows that ephedrine alone, or in combination with substances that increase its effects on the cardiovascular system, may also trigger paroxysms of non-ischemic ventricular tachycardia. The use of ephedrine carries a risk of development of life-threatening arrhythmias and should be discouraged [06178].

Dietary supplements containing ephedrine and other alkaloids related to ephedrine are largely consumed in various countries, with the purpose of energetic stimulation and weight loss. Despite the fact that it is not approved for marketing in Brazil, these products may be freely purchased over the Internet or at gyms/fitness centers. It was reported a case of a young athlete with no risk factors for cardiovascular disease who experienced a myocardial infarction during the period in which he used an ephedrine-rich supplement [06179].

**Laboratory technique**

The separation and quantification of hydrophilic basic compounds continues to challenge reversed-phase chromatography. Ephedrines are an example where the optimal separation of their isomers and related substances is complicated due to both their hydrophilicity and basic nature. Here we study two potential ultra-high pressure liquid chromatography (UHPLC) methods and present the merits and limitations of a high pH reversed-phase and a hydrophilic interaction liquid chromatography (HILIC) approach for the separation and quantification of ephedrines for doping control analysis. The study compares a hybrid silica material used for the HILIC separations with a C18 reversed-phase material produced from the same hybrid silica. While both analytical approaches provide good retention and resolution, HILIC offers benefits in terms of peak shape, sample loading capacity and enhanced sensitivity with electrospray ionisation-mass spectrometry (ESI-MS). HILIC permits favourable kinetic performance owing to the low viscosity mobile phase and hence better mass transfer characteristics. Common problems associated with HILIC including retention shifts and undesirable peak shapes are investigated and overcome using a suitable re-equilibration time and injection solvent. Matrix effects were shown to have a negligible effect on ionisation variability in each mode, with inter-day retention times also being repeatable (<0.17 % RSD). HILIC gave increased sensitivity with ESI-MS, giving a 6-fold increase in signal over the RPLC approach. In this application, we demonstrate the use of UHPLC technology coupled with a hybrid quadrupole time-of-flight (QToF) mass analyser. This approach provides fast scanning medium-resolution accurate mass detection for reliable identification and quantification purposes [13476].

Among the stimulants prohibited by WADA, four (cathine, ephedrine, pseudoephedrine, and methylephedrine) are not considered as anti-doping rule violation when their urinary concentration remains below their respective threshold level. Hence, quantitation is required, and Gray et al. compared the performance of reversed-phase and hydrophilic interaction LC in combination with a medium-resolution (ca. 10 000 FWHM) TOF MS set-up concerning separation capability and general fitness-for-purpose for doping control analyses. Urine samples were prepared for analysis by a 45-fold dilution in mobile phase followed by another dilution step (1:1, v/v) with a volume containing the isotopically labelled internal standard. Subsequently, the samples were analyzed on either a C-18 (2.1 x 50 mm, particle size 1.7 µm) or a HILIC (2.1 x 100 mm, particle size 1.7 microm) column, connected via ESI to a Q/TOF MS operated in positive ionization mode. Both approaches allowed baseline separation of the target analytes within 5 min and fulfilled the desired criteria in terms of sensitivity, accuracy, precision, and specificity [13009].
A simple method for the determination of ephedrine alkaloids: ephedrine (EF), pseudoephedrine (PE), norpseudoephedrine (NPE), norephedrine (NE) and methylpseudoephedrine (MPE) in dietary supplements by gas chromatography-mass spectrometry is described. After the addition of 3,4-methylenedioxypropylamphetamine as internal standard, a liquid-liquid extraction procedure in alkaline conditions with chloroform/isopropanol (9:1, v/v) was applied to the samples prior to analysis. Chromatography was performed on a fused capillary column and analytes, derivatized with pentafluoropropionic anhydride, were determined in the selected-ion-monitoring (SIM) mode. The method was validated in the range 0.3-10 microg/mg for EP, 0.06-2.5 microg/mg for PE and NPE and 0.04-1 microg/mg NE and MPE. Mean recovery ranged between 66 and 81 percent for the different analytes in dietary supplements. The quantification limits were 0.3 microg/mg for EP, 0.06 microg/mg for PE, 0.04 microg/mg for NE and MPE. The method was applied to analysis of various dietary supplements containing Ma-huang (Ephedra Sinica) and Sida Cordifolia plant extracts promoted for aiding weight control and boosting sports performance and energy [06180].

Ephedrine (EPH), pseudoephedrine (PEPH), phenylpropanolamine (PPA), methylephedrine (MEPH) and cathine are sympathomimetic amines. These drugs are commonly found in over-the-counter (OTC) cold medicines and some dietary supplements. In Taiwan, the misuse of these drugs has resulted in an increase in athletic violations. Excretion studies of the ephedrine-related drugs have been performed to better understand the metabolic yields of ephedrines in urine. After consuming a single clinical dose of each of these drugs, urine samples from volunteers (n=3 for each drug) were subjected to tert-butyl-methyl-ether (TBME) extraction and trifluoroacetic acid (TFAA) derivatization before gas chromatography-mass spectrometry (GC-MS) analysis. Most ephedrines were excreted unchanged in urine, including EPH (41 %), PEPH (72 %), and PPA (59 %). However, only a relatively small amount of MEPH (16 %) was excreted unchanged in urine. In addition, an trace amount of PPA (2 %) and cathine (1 %) was found to be the metabolites of EPH and PEPH, respectively. Urinary EPH, PEPH, and PPA reached peaks at 2-6h and disappeared in urine at approximately 24-48 h post-administration. For MEPH, the peaks of excretion extended from 4 to 12h post-administration and were undetectable at approximately 48 h. A single clinical dose of EPH (25 mg) may exceed threshold level (10 microg/mL) in sport drug testing if the urine samples are tested within approximately 8h post-administration. However, a single dose of MEPH (20 mg) never reached the threshold value (10 microg/mL) [06181].

A rapid and simple liquid chromatography tandem mass spectrometry method was developed and validated for the simultaneous determination of L-ephedrine, pseudosephedrine, and caffeine in male Fisher-344 rat plasma at nanogram-per-milliliter concentrations for use in support of toxicology studies. Only 25 μL of plasma is required, and extraction is performed using a simple, single-step protein precipitation. The method was validated over a range of 2.09 to 5460 ng/mL for L-ephedrine, 2.09 to 5050 ng/mL for pseudoeephydine and 2.03 to 5340 ng/mL for caffeine. The method was evaluated for linearity, recovery, precision, accuracy, and stability, and it was successfully applied in toxicokinetic studies of ephedrine, administered alone, in combination with caffeine, and in the herbal source Ma Huang [11210].

The compound 3,4-dimethyl-5-phenyl-1,3-oxazolidine can appear as an artifact during the gas chromatographic analysis of ephedrines. Its presence is a risk for doping control and forensic analyses. An evaluation about the consequences of its formation showed the possibility of a false positive for ephedrine, a false negative for pseudophedrine and increased uncertainty in the quantitative approach. Misinterpretations can be avoided with the observation of fragments m/z 56 and 71 in the ephedrine mass spectrum during GC-MS.
analysis and also by the formation of N-TFA-O-TBDMS derivatives prior to GC analysis. These N-TFA-O-TBDMS derivatives lead to an increase in the number and mass of diagnostic ions, meet the identification criteria, and provide an improvement in chromatographic resolution, allowing the separation of the ephedrines [11211].

A simple, rapid and sensitive CE-ESI-MS method for the simultaneous analysis of seven stimulants and narcotics (amphetamine, ephedrine, methadone, pethidine, tetracaine, codeine and heroin) was developed. The CE-ESI-MS experimental conditions were optimized as follows: 20 mmol/L ammonium acetate with pH 9.0 as running buffer, the separation voltage of 22 kV and the sheath liquid of isopropanol/water (1:1 v/v) containing 7.5 mmol/L acetic acid with 3.0 μL/min flow rate. Under the optimized conditions, the stimulants and narcotics were well separated within 4.6 min using a 70-cm length fused-silica capillary (50 μm id). The detection limits (S/N=3) of the CE-ESI-MS analysis were in the range of 0.40-1.0 ng/mL. Method repeatability of intra-day and inter-day was satisfactory. The recoveries obtained from the analysis of spiked urine samples were between 84.1 and 108%. The developed method was successfully applied for the simultaneous analysis of methadone, pethidine and codeine and their in vitro metabolites [11212].

A simple and sensitive HPLC technique was developed for the qualitative determination of ephedrine and pseudoephedrine (ephedrines), used as precursors of clandestine d-methamphetamine hydrochloride of high purity. Good separation of ephedrines from bulk d-methamphetamine was achieved, without any extraction or derivatization procedure on a CAPCELLPACK C(18) MGII (250 × 4.6 mm) column. The mobile phase consisted of 50 mM KH₂PO₄-acetonitrile (94:6 v/v %) using an isocratic pump system within 20 min for detecting two analytes. One run took about 50 min as it was necessary to wash out overloaded methamphetamine for column conditioning. The analytes were detected by UV absorbance measurement at 210 nm. A sample (20 mg) was simply dissolved in 1 mL of water, and a 50 μL aliquot of the solution was injected into the HPLC. The detection limits for ephedrine and pseudoephedrine in bulk d-methamphetamine were as low as 3 ppm each. This analytical separation technique made it possible to detect ephedrine and/or pseudoephedrine in seven samples of high-purity d-methamphetamine hydrochloride seized in Japan. The presence of trace ephedrines in illicit methamphetamine may strongly indicate a synthetic route via ephedrine in methamphetamine profiling. This method is simple and sensitive, requiring only commonly available equipment, and should be useful for high-purity methamphetamine profiling [11213].

Solvent systems for use with LC-MS often result in a compromise between chromatographic performance and mass spectrometric detection, exemplified here by a LC-MS/MS method development for the analysis of ephedrines in doping control. Ephedrines, frequently found in therapeutic and nutritional preparations, are among the most commonly administered doping agents in competitive sport. Improved separation of these hydrophilic, basic compounds, some of which are diastereoisomers, is achieved in reversed-phase LC by the use of a high pH mobile phase in order to suppress analyte ionisation, and thus alter their polarity, resulting in reduced peak tailing and enhanced retention. However, when coupled to an ESI-MS detector, this eluent composition generated a non-linear and poorly reproducible signal. APCI yielded greater stability and reproducibility and is here presented as an ion source for the analysis of basic compounds under conditions that suppress their ionisation. Errors as large as 49 percent were observed with ESI, compared with 15 percent generated using APCI, for pseudoephedrine over the calibration range (25-400 μg/mL) in urine with a simple dilution and injection of samples. These data highlight the importance of suitable MS conditions for stable performance, necessary for accurate quantification, without undue compromise to the LC separation [11214].
In one paper, a fast and economical HPLC method (on a Phenomenex Polar-RP column with a solution of phosphoric acid:triethylamine:diisobutylamine:water and methanol) was developed, and applied for the determination of norephedrine, norpseudoephedrine, ephedrine (E), pseudoephedrine (PE) and methylephedrine (ME) in 64 samples of three species from main habitats in China. Quantitation data showed that total alkaloid content in Ephedra equisetina Bge. is higher than that in Ephedra sinica Stapf. and Ephedra intermedia Schrenk et C. A. Mey., but the range of total alkaloid content in each species is so wide that the ranges of the three species greatly overlap. The contents of E, PE and ME are different among the three species. The ratio E/total alkaloid content and ratio E/PE as well as E and ME contents can be used for identification of Ephedra sinica, Ephedra intermedia and Ephedra equisetina from one another [11215].

Ephedrines are sympathomimetic amines which have central nervous system stimulating properties and, for this reason, some of them are forbidden in sport by the World Anti-Doping Agency. The amines are screened and quantitated in urine by several published techniques and confirmed by gas chromatography/mass spectrometry (GC/MS). In one paper, a simple and easy confirmation procedure for norpseudoephedrine, norephedrine, ephedrine and pseudoephedrine in human urine by GC/electron ionization (EI)-MS was described. After the addition of diphenylamine as internal standard, a liquid-liquid extraction procedure under alkaline conditions with tert-butyl methyl ether was applied to the samples. The analytes were derivatized with acetone and pyridine to form the correspondent oxazolidine derivatives (acetonide). The EI mass spectra of all the studied substances have many diagnostic ions with relative abundance in accordance with WADA requirements and show great structural information [08302].

One article described a method for the detection and quantitation of cathine, pseudoephedrine, ephedrine, and methylephedrine in urine, using their deuterated analogues as internal standards and derivatization to form the corresponding trimethylsilyl derivatives after a simple liquid-liquid extraction. The study was designed to evaluate whether the urinary cutoff values set by the World Anti-Doping Agency for the banned ephedrines (cathine >5 microg/mL, ephedrine and methylephedrine >10 microg/mL) can be exceeded after the normal self-administration of common over-the-counter medicaments containing nonbanned ephedrines. The present method, after validation, has been applied on real urine samples obtained from 9 healthy volunteers taking different doses of over-the-counter preparations containing ephedrines. Results obtained from excretion studies show high interindividual differences in the urinary concentrations of both pseudoephedrine and cathine, not dependent on body weight or sex nor, in some instances, on the administered dose. The same typical therapeutic dose of pseudoephedrine (60 mg) produced a urinary concentration of more than 5 microg/mL for cathine and of more than 100 microg/mL for pseudoephedrine in 2 of 9 subjects only. When a dose of 120 mg was administered, cathine concentration exceeded 5 microg/mL in 4 of 7 subject, and also concentrations of pseudoephedrine above 100 microg/mL. After administration of 5 x 120 mg of pseudoephedrine (120 mg administered every 7 days for 5 weeks) to one of the subjects exceeding the urinary threshold values, the urinary concentration of cathine and pseudoephedrine exceeded 5 microg/mL (peak concentration 14.8 microg/mL) and 100 microg/mL (peak concentration 275 microg/mL), respectively. When the same subject took 180 mg of pseudoephedrine, the urinary concentration values were below 5 microg/mL for ephedrine and 100 microg/mL for pseudoephedrine. In the case of ephedrine administration in a sustained-release formulation containing 12 mg of ephedrine, 2 of 3 subjects exceeded the urinary cutoff value of 10 microg/mL. The high interindividual variability is still significant even if the urinary concentration values are adjusted by specific gravity and/or creatinine. These results confirm a high interindividual variability in the urinary concentration of ephedrines after the administration of the same therapeutic dose of a preparation [09260].
A novel capillary electrophoresis (CE) method coupled with monolithic molecular imprinted polymer (MIP) fiber based solid phase microextraction (SPME) was developed for selective and sensitive determination of ephedrine (E) and pseudoephedrine (PE). With in situ polymerization in a silica capillary mold and E as template, the MIP fibers could be produced in batch reproducibly and each fiber was available for 50 extraction cycles without significant decrease in extraction ability. Using the MIP fiber under optimized extraction conditions, CE detection limits of E and PE were greatly lowered from 0.20 to 0.00096 microg/mL and 0.12 to 0.0011 microg/mL, respectively. Analysis of urine and serum samples by the MIP-SPME-CE method was also performed, with results indicating that E and PE could be selectively extracted. The recoveries and relative standard deviations (RSDs) for sample analysis were found in the range of 91-104 percent and 3.8-9.1 percent, respectively [11496].

In one study, hollow fiber liquid phase microextraction (HF-LPME) based on pH gradient and electromembrane extraction (EME) coupled with high-performance liquid chromatography (HPLC) was compared for the extraction of ephedrine from biological samples. The influences of fundamental parameters affecting the extraction efficiency of ephedrine were studied and optimized for both methods. Under the optimized conditions, preconcentration factors of 120 and 35 for urine and 51 and 8 for human plasma were obtained using EME and HF-LPME, respectively. The calibration curves showed good linearity for urine and plasma samples by both methods with the coefficient of estimations higher than 0.98. The limits of detection were obtained 5 and 10 ng/mL using EME and 60 and 200 ng/mL by HF-LPME for urine and plasma samples respectively. The relative standard deviations of the analysis were found in the range of 5.2-8.6 percent (n=3). The results showed that in comparison with HF-LPME based on pH gradient, EME is a much more effective transport process, providing high extraction efficiencies in very short time [11497].

In oral fluid
One study was designed to optimize a method for the identification and quantification of ephedrines in oral fluid (OF) and for its application to subjects taking different doses of pseudoephedrine. Ephedrines use by athletes is banned by World Anti-Doping Agency (WADA), only "in competition" if their concentration in urine exceeds the cutoff limit. The study aimed to establish if there is a correlation in terms of times of elimination and of concentration trends of ephedrine in OF and urine after administration of therapeutic doses of pseudoephedrine to various subjects. Results obtained from excretion studies performed on eight subjects showed reproducible times of disappearance of ephedrines from OF. Pseudoephedrine was generally at low concentrations or undetectable in oral fluid samples 12 h after administration, whereas urine samples collected in the same period of time showed higher ephedrine concentrations and exceeding cutoff values generally between 8 and 24 h after administration of the drug. Within- and between-individual variability was observed in terms of concentrations of pseudoephedrine in OF following the administration of the same dose. Only in the case of sustained-release drugs were constant pseudoephedrine concentrations achieved in OF [10187].

Pseudoephedrine
Since the re-introduction of pseudoephedrine as a banned stimulant in 2010, an adverse analytical finding is to be reported by doping control laboratories when urinary concentrations greater 150 microg/ml are determined. This threshold value was deduced from two studies with healthy subjects receiving a total of 240 mg of pseudoephedrine within 24 or 48 h using different administration regimens and drug formulations. Peak concentrations were found between 100 and 175 microg/mL [13012].
Pseudoephedrine is an over-the-counter drug to relieve nasal and sinus congestion. Although it has been suggested that pseudoephedrine could be a stimulant and ergogenic aid, pseudoephedrine was recently removed from the banned substance list by the International Olympic Committee and placed on the monitoring program (from January 2004). It was felt that evidence was lacking for an ergogenic effect, although few studies have investigated the effects of pseudoephedrine on exercise performance. One study, therefore, aimed to investigate the effects of pseudoephedrine on 1500-m running performance. In a double-blind, randomized crossover design, seven male athletes completed two 1500-m running trials on an outdoor track after having completed a familiarization trial. All trials were 7 d apart. After a 12-h overnight fast, subjects reported to the laboratory and received a standardized breakfast (energy asymptotically equal to 500 kcal 50% CHO). Subjects were given either 2.5 mg/kg bw pseudoephedrine or 2.5 mg/kg bw maltodextrins (placebo) in gelatin capsules 70 min before the start of the warm-up, which started 20 min before they ran 1500 m all-out. Pre- and postexercise blood samples were collected and analyzed for lactate and glucose concentrations, partial pressure of oxygen (PO$_2$) and carbon dioxide (PCO$_2$), and percent oxygen saturation. Pseudoephedrine significantly decreased time to completion of 1500-m time trials in the present study by 2 percent with no reported side effects. No changes in the measured blood parameters were found, suggesting a central effect of pseudoephedrine rather than a metabolic effect. It was concluded that the finding was that 2.5 mg/kg bw pseudoephedrine ingested 90 min preexercise improves 1500-m running performance [06182].

The Drug Enforcement Administration (DEA) is removing the thresholds for importation, exportation, and domestic distributions of the List I chemicals pseudoephedrine and phenylpropanolamine. This rulemaking is being conducted as part of DEA's implementation of the Combat Methamphetamine Epidemic Act of 2005 and is needed to implement the Act's requirements for import and production quotas and to address the potential diversion of these chemicals. DEA is also clarifying that all transactions of drug products containing ephedrine, pseudoephedrine, and phenylpropanolamine, except retail transactions, are considered to be regulated transactions [10392].

The aim of one study was to investigate the effect of 180 mg of pseudoephedrine (PSE) on cycling time-trial (TT) performance. Six well-trained male cyclists and triathletes underwent two performance trials in which they completed a 25-min variable-intensity (50-90 % maximal aerobic power) warm-up, followed by a cycling TT in which they completed a fixed amount of work (7 KJ/kg body mass) in the shortest possible time. Sixty minutes before the start of exercise, they orally ingested 180 mg of PSE or a cornstarch placebo (PLA) in a randomized, crossover, double-blind manner. Venous blood was sampled immediately pre- and postexercise for the analysis of pH plus lactate, glucose, and norepinephrine (NE). PSE improved cycling TT performance by 5 percent (95 % confidence interval 0 to 10 %) compared with PLA. There was a significant Treatment x Time interaction for NE, with NE increasing during the PSE trial only. Similarly, blood glucose also showed a trend for increased levels postexercise in the PSE trial. The ingestion of 180 mg of PSE 60 min before the onset of high-intensity exercise improved cycling TT performance in well-trained athletes. It is possible that changes in metabolism or an increase in central nervous system stimulation is responsible for the observed ergogenic effect of PSE [10188].

Two studies were conducted to characterize multiple-dose pharmacokinetics and potential drug interactions of ibuprofen and pseudoephedrine combined in a suspension and to evaluate safety of this combination in children with common cold, flu, or sinusitis. In the pharmacokinetic study, 24 healthy children aged 4-11 years were administered ibuprofen - pseudoephedrine suspension at 7.5 and 1.125 mg/kg, respectively, every 6 hours for 5 doses. Serial blood samples were drawn over 6 hours after final dose for assessment of
steady-state pharmacokinetics. In the open-label, multicenter safety study, more than 100 children aged 2-11 years experiencing symptomatic rhinitis were enrolled. Ibuprofen-pseudoephedrine suspension was administered as needed at similar mg/kg doses every 6-8 hours for up to 3 days. Subjects enrolled in the pharmacokinetic study showed no accumulation of either drug; their weight-adjusted clearances were independent of age, and results were comparable with those from previous single-ingredient studies. In the safety study, adverse events were reported for 18 percent of subjects; most were mild to moderate intensity. There was little difference in incidence of adverse events among different age and weight groups. In conclusion, administration of combined ibuprofen and pseudoephedrine in children demonstrated similar pharmacokinetics when compared with reports of the pharmacokinetics for the single-ingredient products, consistent with no apparent drug interactions. The combination suspension was generally well tolerated [10393].

Due to its stimulatory effects on the central nervous system, and its structural similarity to banned stimulants such as ephedrine and methamphetamine, pseudoephedrine (PSE) at high doses is considered as an ergogenic aid for boosting athletic performance. However, the status of PSE in the International Standard of the Prohibited List as established under the World Anti-Doping Code has changed over the years, being prohibited until 2003 at a urinary cut-off value of 25 microg/mL, and then subsequently removed from the Prohibited List during the period 2004-2009. The re-consideration of this position by the World Anti-Doping Agency (WADA) List Expert Group has led to the reintroduction of PSE in the Prohibited List in 2010. In this manuscript, we present the results of two WADA-sponsored clinical studies on the urinary excretion of PSE and its metabolite cathine (CATH) following the oral administration of different PSE formulations to healthy individuals at therapeutic regimes. On this basis, the current analytical urinary threshold for the detection of PSE as a doping agent in sport has been conservatively established at 150 microg/mL [11216].

During recent years, a syndrome of hypokinesia, dysarthria, dystonia, and postural impairment, related to intravenous use of a "designer" psychostimulant derived from pseudoephedrine using potassium permanganate as the oxidant, has been observed in drug addicts in several countries in Eastern Europe with some cases also in Western countries. A levodopa unresponsive Parkinsonian syndrome occurs within a few months of abusing the homemade drug mixture containing ephedrine (methcathinone) and manganese. The development of this neurological syndrome has been attributed to toxic effects of manganese, but the role of the psychostimulant ephedrone is unclear. This paper describes the clinical syndrome, results of neuroimaging, and therapeutic attempts [11217].

Since the re-introduction of pseudoephedrine as a banned stimulant in 2010, an adverse analytical finding is to be reported by doping control laboratories when urinary concentrations greater 150 mg/mL are determined. This threshold value was deduced from two studies with healthy subjects receiving a total of 240 mg of pseudoephedrine within 24 or 48 h using different administration regimens and drug formulations. Peak concentrations were found between 100 and 175 mg/mL [12017].

Pseudoephedrine (PSE) is an over-the-counter decongestant that might have ergogenic effects. The World Anti-Doping Agency has prohibited large doses (>150 microg/mL) of PSE, while the National College Athletic Association (NCAA) does not include it on their banned-substance list. One study examined the effect of body-weight dosing of PSE on 800-m-run times of NCAA female runners. Fifteen NCAA female track athletes volunteered to participate in the randomized, double-blind, crossover design. Participants were given 2.5 mg/kg PSE or placebo in trials separated by a week. Ninety minutes postingestion, participants completed an 800-m individual time trial on an indoor track. Finishing time was recorded with an automated video timing device. Heart rate and anxiety state scores were recorded
immediately after each trial. Fourteen runners completed both trials, and 1 was an outlier: n=13. Despite the dose being well above normal therapeutic levels (144 ±1.7 mg), there was no significant difference in 800-m times between PSE and placebo trials, in postexercise heart rate or in anxiety-state levels. A 2.5-mg/kg dose of PSE had no effect on 800-m performance for female NCAA runners [12295].

Due to its stimulatory effects on the central nervous system, and its structural similarity to banned stimulants such as ephedrine and methamphetamine, pseudoephedrine (PSE) at high doses is considered as an ergogenic aid for boosting athletic performance. However, the status of PSE in the International Standard of the Prohibited List as established under the World Anti-Doping Code has changed over the years, being prohibited until 2003 at a urinary cut-off value of 25 microg/mL, and then subsequently removed from the Prohibited List during the period 2004-2009. The re-consideration of this position by the World Anti-Doping Agency (WADA) List Expert Group has led to the reintroduction of PSE in the Prohibited List in 2010. In this manuscript, we present the results of two WADA-sponsored clinical studies on the urinary excretion of PSE and its metabolite cathine (CATH) following the oral administration of different PSE formulations to healthy individuals at therapeutic regimes. On this basis, the current analytical urinary threshold for the detection of PSE as a doping agent in sport has been conservatively established at 150 micro/mL [12296].

Dose-response in cycling

The purpose of one study was to examine a possible dose-response between pre-exercise pseudoephedrine intake and cycling time trial performance. Ten trained male endurance cyclists (26.5 ± 6.2 years, 75.1 ± 5.9 kg, 70.6 ± 6.8 mL/kg/min) undertook three cycling time trials in which a fixed amount of work (7 kJ/kg body mass) was completed in the shortest possible time. Sixty minutes before the start of exercise, subjects orally ingested either 2.3 mg/kg or 2.8 mg/kg body mass of pseudoephedrine or a placebo in a randomised and double-blind manner. Venous blood was sampled at baseline, pre- and post-warm up and post-exercise for the analysis of pH and lactate and glucose concentrations; plasma catecholamine and pseudoephedrine concentrations were measured at all times except post-warm up. Cycling time trial performance (30 min) was not enhanced by pseudoephedrine ingestion. Plasma pseudoephedrine concentration increased from pre-warm up to post-exercise in both treatment conditions, with the 2.8 mg/kg body mass dose producing the highest concentration at both time points (2.8 mg/kg >2.3 mg/kg >placebo). It was concluded that there was large individual variation in plasma pseudoephedrine concentration between subjects following pseudoephedrine administration. A number of factors clearly influence the uptake and appearance of pseudoephedrine in the blood and these are not yet fully understood. Combined with subsequent differences in plasma pseudoephedrine between individuals, this may partially explain the present findings and also the inconsistencies in performance following pseudoephedrine administration in previous studies [13477].

Influence of preexercise food intake

One study examined the influence of preexercise food intake on plasma pseudoephedrine (PSE) concentrations and subsequent high-intensity exercise. In addition, urinary PSE concentrations were measured under the same conditions and compared with the present threshold of the World Anti-Doping Agency (WADA). Ten highly trained male cyclists and triathletes undertook four cycling time trials (TT), each requiring the completion of a set amount of work (7 kJ/kg BM) in the shortest possible time. Participants were randomized into a fed or nonfed condition and orally ingested 2.8 mg·kg BM of PSE or a placebo (PLA) 90 min before exercise; in the fed trials, they consumed a meal providing 1.5 g·kg BM of CHO.
Venous blood was sampled at 30, 50, and 70 min and pre-warm-up and postexercise for the analysis of plasma PSE and catecholamine concentrations, and urine was also collected for the analysis of PSE concentration. Independent of the preexercise meal, 2.8 mg/kg BM of PSE did not significantly improve cycling TT performance. The fed trials resulted in lower plasma PSE concentrations at all time points compared with the nonfed trials. Both plasma epinephrine and blood lactate concentrations were higher in the PSE compared with the PLA trials, and preexercise and postexercise urinary PSE concentrations were significantly higher than the threshold (150 microg/mL) used by WADA to determine illicit PSE use. It was concluded that irrespective of the preexercise meal, cycling TT performance of approximately 30 min was not improved after PSE supplementation. Furthermore, 2.8 mg/kg BM of PSE taken 90 min before exercise, with or without food, resulted in urinary PSE concentrations exceeding the present WADA threshold.

Methylephedrine

A simple and effective method of capillary electrophoresis-amperometric detection (CE-AD) coupled with transient isotachophoresis (tITP) was developed for the trace determination of doping substances. Compared with the conventional capillary electrophoresis method, the maximum enhancement factor in terms of peak heights was up to 5500-fold when the tITP technique was adopted. Under the optimum conditions, the detection limit for methylephedrine (MDP), celiprolol (CEL), sotalol (SOT) and indapamide (IDP) were $4.2 \times 10^{-14}$, $6.3 \times 10^{-13}$, $5.8 \times 10^{-14}$ and $9.5 \times 10^{-13}$ mol/L, respectively. The RSDs of four analytes were 1.0-2.3 percent for migration time and 2.6-3.8 percent for peak current, respectively. The proposed method was successfully applied to determine the contents of SOT and IDP in real urine sample, and the excretion curve of IDP within 48 h was also investigated. The recoveries of the four doping in urine ranged 90-102 percent.

Synephrine

The occurrence of some cases of positive results in anti-doping analysis of octopamine requires clarification as to whether its methylated derivative synephrine could be a metabolic precursor of octopamine itself. Synephrine is a natural phenylethylamine derivative present in some food supplements containing Citrus aurantium, permitted in sport regulations. A simulative laboratory study had been done using a photocatalytic process, to identify all possible main and secondary transformation products, in a clean matrix; these were then sought in biological samples obtained from three human volunteers and four rats treated with synephrine: the parent compound and its new potential metabolic products were investigated in human urine and rat plasma samples. The transformation of synephrine and octopamine and the formation of intermediate products were evaluated, adopting titanium dioxide as photocatalyst. Several products were formed and characterized using the HPLC-HRMS(n) technique. The main intermediates identified in these experimental conditions were compared with the major synephrine metabolites found in in vivo studies on rats and humans. Some more oxidized species, already formed in the photocatalytic process, were also found in urine and plasma samples of treated animals. These new findings could be of interest in further metabolism studies. The main photocatalytic pathway involving synephrine appears to be N-demethylation to give octopamine. On the contrary, it was demonstrate the inconsistency of this reaction in both rat and human in vivo determinations, resulting in forensic importance.
Prenylamine

Prenylamine is a vasodilator of phenylalkylamine structure and was used for the treatment of angina pectoris, until reports of undesirable effects including ventricular tachycardia led to a decreasing use of the drug in the 1980s. Metabolic N-dealkylation of orally ingested prenylamine can liberate amphetamine in humans and cause positive findings for amphetamine in doping and forensic analysis. In 2010, the World Anti-Doping Agency (WADA) classified prenylamine as a non-specified stimulant according to the 2010 Prohibited List, thus banning its use in sports in-competition. Supporting the development of a liquid chromatography-tandem mass spectrometry (LC-MS/MS) based detection method, a post-administration urine sample following a single oral prenylamine ingestion (Segontin® 60 mg) was analyzed for urinary metabolites. The LC-separated analytes were ionized in positive electrospray ionization (ESI) mode and detected as protonated ions using an AB Sciex TripleTOF 5600 quadrupole-time-of-flight hybrid mass spectrometer. Over 40 phase I metabolites were detected, including previously unknown mono- bis-, tris- and tetra-hydroxylated prenylamine, several hydroxylated and methoxylated prenylamine metabolites and (hydroxylated) diphenylpropylamine. Investigation of the collision-induced dissociation behaviours of the metabolites by high resolution/high accuracy mass spectrometry allowed for the assignment of the nature and the site of observed metabolic transformations. The most abundant phase I metabolite was confirmed as p-hydroxy-prenylamine by chemical synthesis and stable isotope labelling of reference material. An existing routine screening assay based on direct injection and LC-MS/MS analysis of urine was modified and validated according to common guidelines, in order to allow for the detection of p-hydroxy-prenylamine in sports drug testing. The assay demonstrated the ability to detect the target metabolite at 0.1 ng/ml at intra- and inter-day imprecisions below 10 percent [12298].

Octopamine

The biogenic amine octopamine [4-(2-amino-1-hydroxyethyl)phenol] is prohibited in sports owing to its stimulating and performance-enhancing properties. Adverse analytical findings in athletes' doping control samples commonly result from surreptitious applications; however, the occurrence of octopamine in nutritional supplements and in selected invertebrates as well as the assumption that its N-methylated analog synephrine [4-(1-hydroxyethyl-2-methylamino)phenol, not banned by anti-doping authorities but currently monitored in prevalence studies) might be converted in-vivo into octopamine have necessitated a study to investigate the elimination of synephrine and octopamine present in over-the-counter products. Urine samples collected after administration of nutritional supplements containing octopamine and/or synephrine as well as urine samples collected after therapeutic application of octopamine- or synephrine-containing drugs were analyzed using a validated solid-phase extraction-based procedure employing a weak cation exchange resin and liquid chromatographic/tandem mass spectrometric detection with electrospray ionization and multiple reaction monitoring. In the case of therapeutic octopamine application, the urinary concentration of the target compound increased from baseline levels below the lower limit of detection to 142 microg/mL, while urine samples collected after synephrine as well as dietary supplement administration did not yield any evidence for elevated renal excretion of octopamine [12299].
Dopamine

In one work, a highly sensitive and selective biomimetic electrochemical sensor for the amperometric detection of trace dopamine (DA) in human serums was achieved by gold nanoparticles (AuNPs) doped molecularly imprinted polymers (MIPs). Functionalized AuNPs (F-AuNPs), a novel functional monomer bearing aniline moieties on the surface of the AuNPs, were prepared via a direct synthesis method and then used to fabricate the conductive MIPs film on the modified electrode by electropolymerization method in the presence of DA and p-aminobenzenethiol (p-ATP). The obtained electrochemical sensor based on the conductive film of AuNPs doped MIPs (AuNPs@MIPs) could effectively minimize the interferences caused by ascorbic acid (AA) and uric acid (UA). The linear range for amperometric detection of DA was from 0.02 micromol/L to 0.54 micromol/L with the detection limit of 7.8 nmol/L. Furthermore, the AuNPs@MIPs modified electrode (AuNPs@MIES) was successfully employed to detect trace DA in different human serums [13481].

Phenylethylamine

The drug scene is constantly changing and evolving. Traditionally, drugs of abuse are associated with popular street drugs such as marijuana, heroin, cocaine, and methamphetamine. In the 1990s, several other drugs were added to this list, including the so-called “club drugs”: ecstasy, ketamine, and gamma hydroxybutyric acid. In more recent years, “designer drugs” have emerged, which are either chemically altered natural substances or completely synthetic molecular structures that have psychotropic effects. Due to the widespread use of the Internet, information regarding synthesis of and access to novel compounds is more accessible than ever. This poses new challenges to the medical community in terms of treatment as well as identification of the abused substance, especially in patients unable to communicate. In recent years, access to information regarding acquisition and synthesis of newer designer drugs has been at an all-time high due largely to the Internet. As these drugs have become more prevalent, laboratory techniques have been developed and refined to identify and screen for this burgeoning population of drugs. This provides a unique opportunity for learning about many of these methods. Laboratory testing techniques and instrumentation are obscure to many health care professionals, yet their results are crucial. Here, it was presented a case of an overdose of an uncommon designer drug (2C-E) and discuss the basics of liquid chromatography and mass spectrometry, two important techniques used in isolating and identifying the drug. Although often overlooked and taken for granted, these techniques can play a pivotal role in the diagnosis and subsequent management of select patients. Here it was presented a case of a fatal overdose of the designer drug known as 2C-E (4-ethyl-2, 5-dimethoxy-b-phenethylamine), a phenethylamine derivative [13538].

Modafinil

Modafinil was originally introduced in the clinical literature as a wake-promoting agent in 1988. Modafinil was first approved by the US Food and Drug Administration (FDA) in 1998 and marketed as the racemic mixture of R- and S-enantiomers and later as a formulation containing only the R-enantiomer, which is pharmacokinetically distinct from the S-enantiomer in humans as described later. It has been viewed throughout its history as a “novel” wake-promoting therapeutic, and apparently is still viewed in the same manner to this day. The fact that this mainstream therapeutic agent is still thought of as novel presumably
stems from some unique pharmacological and clinically relevant properties of modafinil relative to other wake-promoting agents. Modafinil, in its two clinical formulations (Provigil® and Nuvigil®), is a widely prescribed wake-promoting therapeutic agent. It binds competitively to the cell-membrane dopamine (DA) transporter and is dependent on catecholaminergic (dopaminergic and adrenergic) signaling for its wake-promoting effects. The clinical spectrum of effects for modafinil is distinct from the effects seen with other catecholaminergic agents. Relative to other commonly used agents that act through catecholaminergic mechanisms, modafinil has a relatively low abuse potential, produces wakefulness with an attenuated compensatory sleep recovery thereafter, and does not ameliorate cataplexy in narcolepsy. These clinically relevant phenomenological differences between modafinil and agents such as amphetamines and cocaine do not eliminate catecholaminergic effects as a possible mediator of its wake-promoting action; they merely reflect its unique pharmacological profile.

Modafinil is an exceptionally weak, but apparently very selective, DA transporter inhibitor. The pharmacodynamic response to modafinil, as measured by DA levels in brain microdialyzate, is protracted relative to other agents that act via catecholaminergic mechanisms. The conformational constraints on the interaction of modafinil with the DA transporter – and probably, as a consequence, its effects on trace amine receptor signaling in the catecholaminergic cell – are unique among catecholaminergic agents. These unique pharmacological properties of modafinil should be considered both in seeking to thoroughly understand its putatively elusive mechanism of action and in the design of novel therapeutic agents [13479].

Like many compounds, modafinil was found to be clinically useful long before its pharmacological target was known. Still, as with any new wake-promoting agent, a number of potential targets came to mind in the search for its mechanism of action. Among the potential targets for modafinil were the cell-membrane monoamine transporters. These monoamine-selective transporters serve, in a non-selective fashion, to clear the monoamines dopamine (DA), noradrenaline (NE), and serotonin (5-HT) from the extracellular space surrounding the neurons that release them. The transporters are named for the neurochemical identity of the cells that express them at the highest levels – the dopamine transporter (DAT), the noradrenaline transporter (NET), and the serotonin transporter (SERT). Despite this nomenclature, they are not truly selective for their namesake neuromodulators. For instance, the Michaelis constant (K_m) for DA uptake by the NET is lower than the K_m for NE uptake by the NET – at least in genetically engineered cells expressing NET under an exogenous construct – indicating a higher affinity for DA. This fact, and the promiscuity among catecholaminergic (dopaminergic and adrenergic) receptors in responding to both DA and NE, may lead to some confusion with regard to modafinil’s mechanism of action. At the time when modafinil’s wake-promoting effect was discovered, various agents that bind to and inhibit the activity of monoamine transporters, such as cocaine and amphetamines, were known to also promote wakefulness. Thus, it was reasonable to hypothesize that modafinil might act through monoamine transporter inhibition to produce wakefulness. The first indication that modafinil binds competitively to a monoamine transporter, specifically DAT, came in 1994. In that study, modafinil competitively displaced the binding of radiolabeled (−)-2-beta-carbomethoxy-3-beta-(4-fluorophenyl) tropane (abbreviated beta-CFT, also known as WIN 35,428), a known DAT ligand, in extracts of a tissue enriched for DAT, the striatum, with a concentration that inhibits 50 percent (IC_{50}) value of 3.19 μM. The ability of modafinil to displace SERT and NET ligands was investigated in the same study and no effect was detected [13479].

Psychostimulants have been used to treat many symptoms associated with advanced cancer. The primary role of psychostimulants in such cases is the treatment of symptoms such as cancer-related fatigue, opioid-induced sedation, depression, and cognitive dysfunction associated with malignancies. These uses for psychostimulants came after approval for treatment of disorders such as attention deficit disorder. Modafinil, a new
psychostimulant, is following a similar path after its approval for use in attention deficit disorder in 1998. Modafinil has been used to treat fatigue associated with neurodegenerative disorders such as multiple sclerosis and amyotrophic lateral sclerosis. It is now being increasingly used for cancer-related symptoms targeted by psychostimulants. Preliminary evidence from literature review suggests that modafinil is efficacious in improving opioid-induced sedation, cancer-related fatigue, and depression. There is no evidence to support its use in the treatment of cognitive dysfunction related to cancer or to support its having analgesic properties. Well-designed, randomized, controlled clinical trials are still needed to further elucidate the precise role of this drug in the care of patients with cancer. Specifically, large placebo-controlled trials with modafinil must be conducted in patients with cancer, with specific attention paid to pain control, depression, cognitive function, and adverse effects.

Modafinil is a novel wake-promoting agent that has US Food and Drug Administration approval for narcolepsy and shift work sleep disorder and as adjunctive treatment of obstructive sleep apnea/hypopnea syndrome. Modafinil has a novel mechanism and is theorized to work in a localized manner, utilizing hypocretin, histamine, epinephrine, gamma-aminobutyric acid, and glutamate. It is a well-tolerated medication with low propensity for abuse and is frequently used for off-label indications. The objective of this study was to systematically review the available evidence supporting the clinical use of modafinil. The search term modafinil OR Provigil was searched on PubMed. Selected articles were mined for further potential sources of data. Abstracts from major scientific conferences were reviewed. Lastly, the manufacturer of modafinil in the United States was asked to provide all publications, abstracts, and unpublished data regarding studies of modafinil. There have been 33 double-blind, placebo-controlled trials of modafinil. Additionally, numerous smaller studies have been performed, and case reports of modafinil's use abound in the literature. It was concluded that modafinil is a promising drug with a large potential for many uses in psychiatry and general medicine. Treating daytime sleepiness is complex, and determining the precise nature of the sleep disorder is vital. Modafinil may be an effective agent in many sleep conditions. To date, the strongest evidence among off-label uses exists for the use of modafinil in attention-deficit disorder, postanesthetic sedation, and cocaine dependence and withdrawal and as an adjunct to antidepressants for depression.

Modafinil (Provigil@) is an example of a drug operating on state variables that is widely discussed with regard to cognitive enhancement. The compound was first marketed nearly 20 years ago in Europe as an agent to offset excessive sleepiness associated with narcolepsy; it was approved by the Food and Drug Administration for this use and for the treatment of certain sleep disorders. While the effects of modafinil on sleep and its EEG correlates are well-documented only a few studies have examined its effects on locomotor activity. This is surprising given that the drug is often referred to as a psychostimulant. In any event, modafinil causes a marked increase in activity in mice but only modest effects in rats or on daytime locomotion by monkeys. The reasons for these discrepancies are an important topic for future work, but the results as they stand indicate that the psychological state variables affected by modafinil are quite different from those targeted by Ritalin@. There is a large and often conflicting literature on the effects of modafinil on components of cognition. Some studies obtained a clear improvement in sustained attention in healthy human subjects but others failed to find such effects. Similar discrepancies occur in the literature on animals.

The FDA has approved modafinil to improve wakefulness in adult patients with excessive sleepiness associated with sleep apnea, shift work disorder, and narcolepsy. Despite seeming acceptance of modafinil for PESA purposes, the FDA has not approved modafinil for additional indications, so physicians prescribing modafinil to patients for other conditions...
occurs off-label. Studies have shown that modafinil serves as a countermeasure for sleep loss and sustains continued wakefulness to improve attention, alertness, spatial planning, and visual pattern recognition memory. A recent, multi-factorial analysis provided convincing evidence that moderate doses of modafinil improve attention in healthy middle-aged rats without affecting motivation or locomotor activity. Importantly, these effects became evident only as attentional demands were increased. In all, it seems reasonable at this point to conclude that modafinil's effects on basic psychological state variables – wakefulness – can translate into selective improvements in attention. There is also a sizable literature suggesting that the above conclusion can be extended to memory encoding. An intriguing aspect of these studies in rodents and humans is that they generally point to a drug influence on working memory as opposed to the encoding of long-term memory for specific information. For example, the above noted work on middle-aged rats found no evidence for accelerated acquisition of a visual discrimination problem, with minimal demands on working memory, despite clear improvements in attention. There are, however, studies showing that modafinil accelerates the acquisition of simple rules (“win-stay”), a spatial learning protocol, and a non-match to position problem in rodents. It is tempting to speculate that we are here seeing hierarchical effects of modafinil such that enhanced wakefulness produces greater attention that in turn improves both working memory and simple rule learning. By far the greater part of the human studies with modafinil involves subjects with impairments to performance (sleep deprivation) or psychiatric disorders. A retrospective analysis of several studies led to the conclusion that modafinil does not produce a "global" enhancement of cognition. Uncertainties about the cellular effects of modafinil limit the utility of the neurobiological dimension in evaluating the drug's likely effects on cognition. Recent work has reinforced earlier arguments that modafinil binds to forebrain dopamine transporters in rats, monkeys, and humans, and that this is accompanied by the expected increases in extracellular dopamine concentrations. There is also evidence for binding to norepinephrine transporters in human thalamus. These effects would be expected to promote wakefulness via mechanisms engaged by classical stimulants. But then the question arises as to why modafinil's behavioral profile (e.g. locomotor activity) differs so clearly from those for amphetamine, methylphenidate, and cocaine. One possibility is that the dopamine effects are less potent than seen with the stimulants but are supplemented by other, more unusual actions. Studies have established that modafinil activates the perifornical region and the tuberomammillary nucleus of the hypothalamus, two areas that are of primary importance to sleep-wakefulness. The first of these contains orexin synthesizing neurons that have been directly implicated in narcolepsy while the latter region is the exclusive location of wake-promoting histaminergic neurons. Modafinil still causes wakefulness as well as its other behavioral, EEG, and Fos expression effects in orexin null mice and so is not likely to produce its major effects via the sleep suppressing peptide. It does however increase extracellular histamine levels in the posterior hypothalamus and there is considerable evidence that histamine plays an important role in maintaining the vigilant, wakeful state. It seems reasonable then to assume that modafinil, at moderate doses, exerts its effects via a combined activation of histaminergic and catecholaminergic projections into telencephalon. With regard to cortical networks, modafinil is a compound that enhances inputs that are diffusely distributed and whose terminal populations are vastly outnumbered by the glutamatergic endings generated by the cortical neurons themselves. These arrangements are suggestive of a modulatory role wherein the activated inputs change global parameters of networks as opposed to discrete changes in communication patterns within and between networks, or in the various synaptic plasticity effects used to store information. It is also highly likely that the pertinent lower brain areas focus some component of their projections on subcortical areas that exert strong effects on particular cortical areas. For example, the histaminergic cells in posterior hypothalamus give rise to projections to the relatively small medial septum; it can be imagined that this results in a strong histaminergic influence over
cholinergic and GABAergic septal projection neurons that regulate hippocampal rhythms [11434].

One paper examined the social construction of the new wakefulness-promoting drug Modafinil (brand name Provigil) in the British press. Key themes in this newspaper coverage include the potential "uses" and "abuses" of this drug in relation to: (i) medical conditions; (ii) lifestyle choices; (iii) military operations; and (iv) sporting competition. The British press played a dual role in reporting on these trends and developments: on the one hand constructing this as something of a "wonder drug" in relation to the treatment of a number of medical complaints or conditions, on the other hand articulating and amplifying a range of cultural concerns and anxieties about the non-medical "uses" and "abuses" of this drug, both now and in the future. These issues, it is argued, are best interpreted in terms of media concerns over the pharmaceuticalisation rather than the medicalisation of everyday/night life. The paper concludes with some further thoughts and reflections on these issues, including the potential reworking of notions of "pharmaceutical Calvinism" and the spirit of (bio)capitalism [08298].

Previous research has demonstrated cognitive-enhancing effects of modafinil in humans and generated evidence for its therapeutic potential in psychiatric disorders. The neurochemical basis of these effects remains unresolved although a role for alpha1-adrenoceptors has been hypothesised. In one within-subject, double-blind, placebo-controlled study, 12 healthy male adults received modafinil (300 mg), the alpha1-adrenoceptor antagonist prazosin (3 mg), both together and placebo on separate occasions at least 5 days apart. Cognitive effects were assessed using a well-validated testing battery focusing on executive and working memory functions. Blood pressure, heart rate and salivary alpha-amylase were measured at hourly intervals. Cognitive effects of modafinil and prazosin were identified at the difficult levels of the One-Touch Stockings of Cambridge (OTSOC) planning task. Prazosin antagonized the error-reducing effect of modafinil when the agents were given together. In contrast, the combined agents acted synergistically to increase time taken to complete OTSOC problems compared with placebo. The tachycardic and amylase-elevating effects of prazosin were also potentiated by concurrent modafinil administration. The current data suggest that the cognitive effects of modafinil on performance accuracy and latency are dissociable in terms of their neurochemical mechanisms. The findings support the hypothesised involvement of alpha1-adrenoceptors in some of the cognitive-enhancing effects of modafinil [09263].

Modafinil is a non-amphetamine wakefulness-promoting agent used for the treatment of various sleep disorders characterized by excessive daytime sleepiness. There is little information in the medical literature with respect to supratherapeutic doses of this medication. It was performed a retrospective review of the California Poison Control System database for all cases of single-substance ingestion of modafinil with follow-up to a known outcome for the time period 1998-2008. Data collected included age, gender, dose ingested, clinical effects, and medical outcome. There were a total of 87 patients, 53 (61 %) of which were female. Patient ages ranged from 1 to 72 years with a mean of 30 years; 17 (20 %) patients were aged 6 years or less. Thirty-three (38 %) were intentional overdoses. Most commonly reported effects were tachycardia (n=23), agitation (n=14), anxiety (n=11), headache (n=8), hypertension (n=6), dystonia/tremor (n=6), and dizziness (n=5). Forty-nine patients (56 %) were managed at home, and 38 (44 %) were managed in a healthcare setting. Therapies administered included activated charcoal (n=8), benzodiazepines (n=7), antihistamines (n=2), intravenous fluids (n=2), haloperidol (n=2), and beta-blockers (n=1). Effects were classified as none (n=22), minor (n=54), and moderate (n=11). No major effects and no deaths occurred. Effects of modafinil overdose appear to be mild in most cases, with
tachycardia and CNS symptoms predominating. Clinically significant effects requiring treatment occurred in a small number of patients [10381].

Modafinil, a wake-promoting drug used to treat narcolepsy, is increasingly being used as a cognitive enhancer. Although initially launched as distinct from stimulants that increase extracellular dopamine by targeting dopamine transporters, recent preclinical studies suggest otherwise. To measure the acute effects of modafinil at doses used therapeutically (200 mg and 400 mg given orally) on extracellular dopamine and on dopamine transporters in the male human brain. In this pilot study, modafinil blocked dopamine transporters and increased dopamine in the human brain (including the nucleus accumbens). Because drugs that increase dopamine in the nucleus accumbens have the potential for abuse, and considering the increasing use of modafinil, these results highlight the need for heightened awareness for potential abuse of and dependence on modafinil in vulnerable populations [09264].

Adrafinil and modafinil have received wide publicity and have become controversial in the sporting world when several athletes were discovered allegedly using these drugs as doping agents. By acknowledging the facts, the World Anti-Doping Agency (WADA) banned these drugs in sports since 2004. One study explored the possibility of differentiating adrafinil and modafinil and their major metabolites under electron impact ionization in gas chromatograph-mass spectrometer (GC-MSD) and electrospray ionization in liquid chromatograph-mass spectrometer (LC-MS/MS) by studying the fragmentation pattern of these drugs. Adrafinil, modafinil and their major metabolite, modafinilic acid were analyzed on EI-GC-MSD and ESI-LC-MS/MS using various individual parameters on both the instruments. The results show that adrafinil, modafinil and their major metabolite modafinilic acid could be detected as a single artifact without differentiation under EI-GC-MSD analysis. However, all drugs could be detected and differentiated under ESI-LCMS/MS analysis without any artifaction. The GC-MSD analysis gives a single artifact for both the drugs without differentiation and thus can be used as a marker for screening purposes. Further, the Multiple Reaction Monitoring (MRM) method developed under LC-MS/MS is fit for the purpose for confirmation of suspicious samples in routine sports testing and in forensic and clinical analysis [09265].

Stimulant medications appear effective at restoring simple alertness and psychomotor vigilance in sleep deprived individuals, but it is not clear whether these medications are effective at restoring higher order complex cognitive capacities such as planning, sequencing, and decision making. After 44 hours awake, participants received a double-blind dose of one of 3 stimulant medications or placebo. After 45-50 hours awake, participants were tested. Participants were randomly assigned to 1 of 3 stimulant medication groups, including caffeine, 600 mg (n=12), modafinil, 400 mg (n=12), dextroamphetamine, 20 mg (n=16), or placebo (n=14). At the doses tested, modafinil and dextroamphetamine groups completed the task in significantly fewer moves than the placebo group, and the modafinil group demonstrated greater deliberation before making moves. In contrast, subjects receiving caffeine completed the task in fewer moves than all 3 of the other groups, although speed of completion was not influenced by the stimulants. Finally, the modafinil group outperformed all other groups on indices of perseverative responding and perseverative errors. Although comparisons across tasks cannot be made due to the different times of administration, within-task comparisons suggest that, at the doses tested here, each stimulant may produce differential advantages depending on the cognitive demands of the task [09266].

A new and reliable two-step liquid chromatography/tandem mass spectrometry (LC/MS/MS) method in combination with gas chromatography/mass spectrometry (GC/MS) for the screening and confirmation of adrafinil and its major metabolites, modafinil and modafinil acid, in human urine has been developed and validated. The method involved reversed-
phase C18 solid-phase extraction cartridge extraction and MS analysis by means of LC/MS/MS and GC/MS. The study illustrated that the ESI capillary temperature played a key role in the formation of the protonated molecule. The limits of detection (LODs) of the developed method for the three compounds were lower than the minimum required performance limit (MRPL) of the World Anti-Doping Agency (WADA). The human urine samples obtained after the oral administration of modafinil and from the Beijing 2008 Olympic Games were analyzed by using the described method, which has also been successfully applied to routine analyses and the WADA Proficiency Test [09267].

Sports and military environments have many common features – intense physical activity, rigorous physical environment (heat, cold, high or low pressure, hypoxia, acceleration...), specific psychosocial atmosphere, team spirit. If combined with jet lag syndrome, these specific conditions can favor altered physical and mental performance. There is always the temptation to use drugs as a simple way to reduce the penalizing effects. The available compounds known to affect sleep and wakefulness include hypnotics, benzodiazepines and non benzodiazepines such as temazepam, zolopidem, and zopiclone, stimulants such as amphetamine and amphetamine-like agents, adrafinil, modafinil, caffeine and chronobiotics substances such as melatonin and, more recently, slow release caffeine. In the sports area, all of these substances except caffeine are on the list of forbidden products, although special authorizations linked to known disease conditions are allowed. In the military setting, the environment may be similar, but the context of use is very different. In the context of a rescue mission, the current practice in the French military organization is to place modafinil pills in the ejection seat of fight planes and in rescue boats. A second context is the use of anti-sleep agents under orders; the debate continues on this and the appropriate recommendations in this context. Self-medication is a third condition, in which case no rules have been defined [07178].

The neuro-enhancement Modafinil promises to dramatically increase users' waking hours without much sacrifice to clarity of thought and without serious side effects (inducing addiction). For Modafinil to be advantageous, its usage must enable access to goods that themselves improve the quality of one's life. I draw attention to a variety of conditions that must be met for an experience, activity or object to improve the quality of one's life, such as positional, relational, and saturation conditions, as well as it's being good for its own sake. I discuss and describe the contexts in which widespread usage (legal or not) of Modafinil would undermine these conditions being met, and thus users would fail to significantly improve the quality of their lives and would in fact potentially make both themselves and nonusers worse off in important respects thus far overlooked by critics. In the right contexts, where free time is protected and prolonged, Modafinil does have a variety of potential benefits including, most interestingly, a distinctive form of agency possible only in free time. The potential disadvantages and advantages highlighted in this article are relevant not only to public institutions deciding whether to legalize Modafinil's use as an enhancement but also to individuals deciding whether to use it illegally, as well as to the questions of how and whether to alter key features of one's context (e.g. regulating work hours or extending social services) rather than, or in addition, to regulating the use of enhancement drugs such as Modafinil [12301].

Combined with cocaine

Modafinil is a wake-promoting drug effective at enhancing alertness and attention with a variety of approved and off-label applications. The mechanism of modafinil is not well understood but initial studies indicated a limited abuse potential. A number of recent publications, however, have shown that modafinil can be rewarding under certain conditions. The present study assessed the reinforcing properties of modafinil using conditioned place
preference and locomotor sensitization in mice. Experiment 1 examined a high dose of modafinil (75 mg/kg) as well as its interactions with cocaine (15 mg/kg). Cocaine alone and modafinil co-administered with cocaine induced sensitization of locomotor activity; modafinil alone showed little or no locomotor sensitization. Animals given modafinil alone, cocaine alone, and modafinil plus cocaine exhibited a strong and roughly equivalent place preference. When tested for sensitization using a low challenge dose of modafinil, cross-sensitization was observed in all cocaine-pretreated mice. Experiment 2 examined a low dose of modafinil that is similar to the dose administered to humans and has been shown to produce cognitive enhancements in mice. Low dose modafinil (0.75 mg/kg) did not produce conditioned place preference or locomotor sensitization. Together, these results suggest that modafinil has the potential to produce reward, particularly in cocaine addicts, and should be used with caution. However, the typical low dose administered likely moderates these effects and may account for lack of addiction seen in humans [12302].

Combined with cannabis

Marijuana (cannabis) is the most widely used illicit substance globally, and cannabis use is associated with a range of adverse consequences. Currently, no medications have been proven to be effective for the treatment of cannabis addiction. The goals of this study were to examine the safety and efficacy of a potential treatment medication, modafinil, in combination with oral delta9-tetrahydrocannabinol (THC). Twelve male and female occasional cannabis users participated in an outpatient double-blind, placebo-controlled, crossover study. Across four sessions, participants were randomly assigned to a sequence of four oral treatments: (1) 400 mg modafinil+placebo, (2) 15 mg THC+placebo, (3) 400 mg modafinil+15 mg THC, or (4) placebo+placebo. Outcome measures included heart rate, blood pressure, performance on the Rapid Visual Information Processing (RVIP), and the Hopkins Verbal Learning Test (HVLT), and subjective measures. Oral THC increased heart rate, and produced increased subjective ratings of feeling "high" and "sedated," as well as increased ratings of euphoria. Modafinil alone increased the Profiles of Mood States (POMS) subscales of vigor and tension. These findings support the safety of modafinil in combination with THC. The effects of modafinil in combination with a range of doses of THC need to be determined in future studies [11196].

Adrafinil

A new and reliable two-step liquid chromatography/tandem mass spectrometry (LC/MS/MS) method in combination with gas chromatography/mass spectrometry (GC/MS) for the screening and confirmation of adrafinil and its major metabolites, modafinil and modafinil acid, in human urine has been developed and validated. The method involved reversed-phase C18 solid-phase extraction (SPE) cartridge extraction and MS analysis by means of LC/MS/MS and GC/MS. The study illustrated that the ESI capillary temperature played a key role in the formation of the protonated molecule. The limits of detection (LODs) of the developed method for the three compounds were lower than the minimum required performance limit (MRPL) of the World Anti-Doping Agency (WADA). The human urine samples obtained after the oral administration of modafinil and from the Beijing 2008 Olympic Games were analyzed by using the described method, which has also been successfully applied to routine analyses and the WADA Proficiency Test [09268].

Armodafinil

Armodafinil, a non-amphetamine, wakefulness-promoting medication, is the R- and longer-lasting isomer of racemic modafinil. Armodafinil has been shown to improve wakefulness in
patients with excessive sleepiness associated with treated obstructive sleep apnoea, shift work disorder or narcolepsy. In comparison with modafinil, armodafinil maintains higher plasma concentrations later in the day in healthy subjects. The objective of this analysis was to characterize the pharmacokinetic parameters related to those higher concentrations. Data from three randomized studies in healthy adult subjects receiving single doses of either armodafinil (50, 100, 200, 250, 300 or 400 mg) or modafinil (400 mg) were pooled, and subsequently dose-normalized to a 200 mg dose for each drug. Non-compartmental pharmacokinetic parameters were assessed. Armodafinil and modafinil both had a mean single-dose terminal elimination half-life of approximately 13 hours, with similar mean maximum plasma drug concentration ($C_{\text{max}}$) and median time to $C_{\text{max}}$ values. After reaching $C_{\text{max}}$, plasma concentrations appeared to decline in a monophasic manner with armodafinil, but in a biphasic manner with modafinil due to the initial rapid elimination of its S-isomer. As a result, mean area under the plasma drug concentration versus time curve (AUC) from time zero to the time of the last measurable concentration and AUC from time zero to infinity values were 33 percent and 40 percent higher, respectively, with armodafinil compared with modafinil on a milligram-to-milligram basis. Despite similar half-lives, plasma concentrations following armodafinil administration are higher late in the day than those following modafinil administration on a milligram-to-milligram basis [09269].

Armodafinil is the R-enantiomer of modafinil, a wake-promoting agent, that primarily affects areas of the brain involved in controlling wakefulness. Once-daily armodafinil was effective in improving wakefulness in adult patients with excessive sleepiness associated with obstructive sleep apnoea/hypopnoea syndrome (despite treatment of the underlying condition), narcolepsy or shift work sleep disorder in four large (n >195), double-blind, multinational trials of 12 weeks' duration. Compared with placebo, mean sleep latency (coprimary endpoint) was significantly improved with armodafinil 150 or 250 mg once daily in patients with obstructive sleep apnoea/hypopnoea syndrome (or narcolepsy, and with armodafinil 150 mg once daily in patients with shift work sleep disorder, as assessed by the Multiple Sleep Latency Test or the Maintenance of Wakefulness Test. Furthermore, a significantly higher proportion of armodafinil than placebo recipients achieved a response (at least a minimal improvement) on the Clinical Global Impressions of Change scale at study end in these four trials (coprimary endpoint). Once-daily armodafinil was generally well tolerated in adult patients with excessive sleepiness associated with obstructive sleep apnoea/hypopnoea syndrome (despite treatment of the underlying condition), narcolepsy or shift work sleep disorder [09270].

Armodafinil (R-modafinil) is the R- and longer-lasting isomer of the racemic compound modafinil, a wakefulness-promoting medication. Armodafinil is eliminated approximately three times more slowly than the S-isomer of racemic modafinil. Published studies have demonstrated the efficacy of armodafinil for treating excessive sleepiness associated with obstructive sleep apnoea, shift work disorder and narcolepsy. The objectives of one study were to describe the pharmacokinetic profile, tolerability and safety of armodafinil in healthy subjects. Pooled pharmacokinetic data from three separate randomized studies in 119 healthy subjects who received single or multiple (once daily for up to 14 days) oral doses of armodafinil ranging between 50 and 400 mg were analysed. The impact of food on the single-dose pharmacokinetic profile of armodafinil was also assessed in subjects following an overnight fast and after the consumption of a standard fatty meal. Armodafinil was readily absorbed and exhibited linear pharmacokinetics over the 50-400 mg dose range. Peak plasma concentrations were reached around 2 hours after administration in the fasted state. Food had no effect on the overall bioavailability of armodafinil; however, the peak concentration was delayed by approximately 2-4 hours. In the multiple-dose study, dose proportionality was confirmed by linear regression analyses of the log-transformed area under the plasma concentration versus time curve and maximum plasma concentration.
values as a function of dose. After reaching the peak, plasma concentrations of armodafinil declined in a monophasic manner, with a mean elimination half-life of approximately 15 hours. Steady state appeared to be reached within 7 days. At steady state, the systemic exposure to armodafinil was 1.8 times that observed after single-dose administration. Armodafinil was generally well tolerated, the most frequent adverse events being headache, dizziness and nausea. While food affected the rate but not the extent of absorption, peak plasma concentrations were reached in approximately 2 hours when the drug was taken on an empty stomach. With once-daily dosing, steady state appeared to be reached within 7 days. After reaching peak plasma levels, concentrations of armodafinil declined monophasically, with a mean elimination half-life of around 15 hours. Armodafinil was generally well tolerated [09271].

Experimental

Modafinil has been shown to promote wakefulness and some studies suggest the drug can improve cognitive function. Because of many similarities, the mechanism of action may be comparable to classical psychostimulants, although the exact mechanisms of modafinil's actions in wakefulness and cognitive enhancement are unknown. One study aimed to further examine the effects of modafinil as a cognitive enhancer on hippocampus-dependent memory in mice. A high dose of modafinil (75 mg/kg ip) given before training improved acquisition on a Morris water maze. When given only before testing, modafinil did not affect water maze performance. It was also examined modafinil (0.075 to 75 mg/kg) on Pavlovian fear conditioning. A low dose of pretraining modafinil (0.75 mg/kg) enhanced memory of contextual fear conditioning (tested off-drug 1 week later) whereas a high dose (75 mg/kg) disrupted memory. Pretraining modafinil did not affect cued conditioning at any dose tested, and immediate posttraining modafinil had no effect on either cued or contextual fear. These results suggest that modafinil's effects of memory are more selective than amphetamine or cocaine and specific to hippocampus-dependent memory [09272].

Methylphenidate

Methylphenidate (Ritalin®), a much-discussed compound with regard to the usage of enhancers by healthy individuals, is a good example of a drug whose actions can be classified with regard to psychological variables. Its effects on arousal are extensively documented beginning with a marked, amphetamine-like increase in rat exploratory behavior. Differences between Ritalin's influence on behavior relative to classical stimulants are subtle at best. That a drug whose primary effect is to increase arousal would produce positive effects on components of cognition, including attention and memory encoding, would not be surprising given the long history of work pointing to an inverted U-curve relationship between arousal levels and performance on complex problems. But whether Ritalin does in fact produce such effects in the absence of disturbances to other aspects of cognition, the latter a possibility inherent in the inverted U, is debatable. In large measure this reflects the fact that the great majority of animal and human studies on Ritalin are concerned with its effects on attention deficit hyperactivity disorder and other psychiatric problems; a much smaller number of experiments deal with control animals or healthy humans. Surveys of the older literature indicate that Ritalin and other stimulants increase attention or vigilance, although a recent study did not obtain this result in a test in which human subjects were required to discriminate significant stimuli from distracters. It seems likely that Ritalin's positive effects on attention are most apparent in relatively simple tasks requiring sustained engagement and less evident for more difficult problems requiring selective attention. There is also evidence that Ritalin can improve spatial working memory in healthy humans under
some but not all conditions. Specifically, performance was improved on novel spatial problems but impaired in repeat tests. Other studies confirmed the improvements in spatial working memory but found them to be evident only in subjects with low baseline scores the latter point, as it happens, also arises in discussions of modafinil’s effects on cognitive operations. Ritalin is also reported to improve digit span test score in healthy individuals, so its influence on working memory is not restricted to spatial problems. There is, however, little evidence for a positive effect on the encoding of long-term episodic or data memory. An early paper found that low to moderate doses have no effect on retention of various types of information on tests carried out 24 h post-learning, while the highest concentration tested produced an impairment. Others provided evidence for improved scores shortly after learning but not at later time points. In all, a limited set of results suggest that Ritalin's pronounced effects on arousal can facilitate the attentional and working memory components of cognition but that these effects are situation- and perhaps subject-dependent. Processes are generally negative. An interesting study using a complex video game that requires the evolution of strategies for optimizing performance found that Ritalin disrupted normally occurring improvements in scores. Ritalin appears to have little effect on verbal fluency, set shifting decision making or selecting shapes to fit within a matrix (Raven's test). Perhaps a fair, though necessarily tentative, conclusion for this collection of findings is that enhancing arousal and some components of cognition do not produce positive outcomes on integrated cognitive operations in fully engaged subjects. Ritalin also provides an illustrative case with regard to neurobiological mechanism of action. It increases the concentration of dopamine and noradrenaline at synapses by blocking their reuptake an action that fits well with its generalized effects on arousal. The drug thus belongs to a sizable group of therapeutically useful compounds acting on diffuse, ascending biogenic amine systems (ACh, 5-HT, NE, and DA). As implied by the name, these projections originate from a relatively small number of cells in the lower brain that generate widely branching projections to broad areas of the forebrain. Such anatomical arrangements constitute a convergent/divergent system in which multiple inputs innervate relatively small targets (the biogenic amine nuclei) that disperse their outputs across much larger target regions. However, dopaminergic projections may exert one type of effect in cortical, particularly frontal, areas where they are comparatively sparse and another in the striatum where they are present in high numbers [11434].

Attention can be readily measured in experimental animal models. Animal models of attention have been used to better understand the neural systems involved in attention, how attention is impaired, and how therapeutic treatments can ameliorate attentional deficits. One review focused on the ways in which animal models are used to better understand the neuronal mechanism of attention and how to develop new therapeutic treatments for attentional impairment. Several behavioral test methods have been developed for experimental animal studies of attention, including a 5-choice serial reaction time task (5-CSRTT), a signal detection task (SDT), and a novel object recognition (NOR) test. These tasks can be used together with genetic, lesion, pharmacological and behavioral models of attentional impairment to test the efficacy of novel therapeutic treatments. The most prominent genetic model is the spontaneously hypertensive rat (SHR). Well-characterized lesion models include frontal cortical or hippocampal lesions. Pharmacological models include challenge with the NMDA glutamate antagonist dizocilpine (MK-801), the nicotinic cholinergic antagonist mecamylamine and the muscarinic cholinergic antagonist scopolamine. Behavioral models include distracting stimuli and attenuated target stimuli. Important validation of these behavioral tests and models of attentional impairments for developing effective treatments for attentional dysfunction is the fact that stimulant treatments effective for attention deficit hyperactivity disorder (ADHD), such as methylphenidate (Ritalin®), are effective in the experimental animal models. Newer lines of treatment including nicotinic agonists, alpha4beta2 nicotinic receptor desensitizers, and histamine H₃ antagonists, have also been found to be effective in improving attention in
these animal models. Good carryover has also been seen for the attentional improvement caused by nicotine in experimental animal models and in human populations. Animal models of attention can be effectively used for the development of new treatments of attentional impairment in ADHD and other syndromes in which have attentional impairments occur, such as Alzheimer's disease and schizophrenia [11355].

The primary purpose of one study was to examine the extent to which two of the three sources of risk-taking – dispositional and ecological – in adolescence and demographic variables were related to Ritalin®, tranquilizer and narcotics misuse. The secondary aim of the study was to distinguish subgroups of Ritalin®, tranquilizer, and narcotics misusers using dispositional, ecological and demographic variables. An archival dataset containing 1672 participants (11-18 years old) was used. Ritalin®, tranquilizer, and narcotics misuse were dichotomized and hierarchical logistic regressions were computed for dispositional and ecological sources of risk-taking and demographics. To distinguish subgroups of misusers, hierarchical multinomial regressions were computed. Dispositional, ecological, and demographic variables were related to Ritalin®, tranquilizer, and narcotics misuse and distinguished among non-users, experimenters/occasional misusers, and frequent misusers. Prescription drug prevention programs should incorporate demographic, dispositional, and ecological variables and should parallel the guidelines currently used for developing effective substance abuse prevention programs [11356].

Acute bupropion (dopamine/noradrenaline reuptake inhibitor) administration significantly improved time trial performance and increased core temperature in the heat (30 degrees C). One study was performed to examine the effect of a dopaminergic reuptake inhibitor on exercise capacity and thermoregulation during prolonged exercise in temperate and warm conditions. Eight healthy well-trained male cyclists participated in this study. Subjects ingested either placebo (20 mg) or methylphenidate (Ritalin 20 mg) 1 h before the start of exercise in temperate (18 degrees C) or warm (30 degrees C) conditions and cycled for 60 min at 55 percent Wmax, immediately followed by a time trial to measure exercise performance. It was shown that Ritalin has a clear ergogenic effect that was not apparent in 18 degrees C. The combination of a dopamine reuptake inhibitor and exercise in the heat clearly improved performance and caused hyperthermia without any change in the perception of effort or thermal stress compared with the placebo trial. This response may potentially increase the risk of developing heat illness during exercise in individuals taking drugs of this nature [08299].

Psychostimulants are effective treatments for attention-deficit/hyperactivity disorder (ADHD) but may be associated with euphoric effects, misuse/diversion, and adverse effects. These risks are perceived by some clinicians to be greater in substance-abusing adolescents relative to non-substance-abusing adults. The present study evaluates the subjective effects, misuse/diversion, and adverse effects associated with the use of osmotic-release oral system methylphenidate (OROS-MPH), relative to placebo, for treating ADHD in adolescents with a substance use disorder (SUD) as a function of substance use severity and compared these risks with those associated with the treatment of ADHD in adults without a non-nicotine SUD. Datasets from two randomized placebo-controlled trials of OROS-MPH for treating ADHD, one conducted with 303 adolescents (13-18) with at least one non-nicotine SUD and one with 255 adult smokers (18-55), were analyzed. Outcome measures included the Massachusetts General Hospital Liking Scale, self-reported medication compliance, pill counts, and adverse events. Euphoric effects and misuse/diversion of OROS-MPH were not significantly affected by substance use severity. The euphoric effects of OROS-MPH did not significantly differ between the adolescent and adult samples. Adults rated OROS-MPH as more effective in treating ADHD, whereas adolescents reported feeling more depressed when taking OROS-MPH. The adolescents lost more pills relative to the adults regardless of
treatment condition, which suggests the importance of careful medication monitoring. Higher baseline use of alcohol and cannabis was associated with an increased risk of experiencing treatment-related adverse events in OROS-MPH, but baseline use did not increase the risk of serious AEs or of any particular category of AE and the adolescents did not experience more treatment-related AEs relative to the adults [11503].

Methylphenidate (MPH) is an amphetamine-like psychostimulant drug approved for the treatment of attention-deficit-hyperactivity-disorder (ADHD) and narcolepsy. An increase in MPH abuse has been observed in the United States in recent years. MPH is abused for recreational purposes with the aim of inducing feelings of euphoria. However, the use of MPH as so-called cognitive enhancer to boost performance has become a focus of concern. Data from poison centres suggest only mild or moderate toxicity in most cases of MPH abuse. Non-medical use of methylphenidate is increasing. Little is known about potential acute medical complications associated with recreational use of methylphenidate. Retrospective case series of methylphenidate abuse cases presenting to an inner city emergency department. It was identified 14 cases of methylphenidate abuse between 2003 and 2010. Ten of these patients abused methylphenidate alone while four co-ingested other drugs, mainly alcohol. The route of ingestion was oral in nine patients, nasal in one and intravascular in four. Severe toxicity was exclusively observed in users who injected the drug. Two cases involved accidental intra-arterial injection and resulted in tissue necrosis leading to the amputation of a forearm and of fingertips, respectively. Clinical findings in the non-serious cases included mild to moderate symptoms and signs of sympathetic nervous stimulation such as agitation, tachycardia, hypertension, anxiety, hallucination, headache, tremor and dizziness. Nine of the fourteen patients were taking methylphenidate as a prescribed drug. Eight patients were former or current multiple substance abusers. It was concluded that methylphenidate misuse is not a significant burden for emergency departments in Switzerland. Oral and nasal administration of methylphenidate did not result in severe toxicity. However, injection of crushed methylphenidate pills lead to serious local toxicity. Most patients with methylphenidate abuse had a prescription for the drug indicating deviation from medical use. A history of multiple substance use may be a risk factor for non-medical use of methylphenidate [11504].

Transdermal

An 8-week, open-label trial assessed the efficacy of methylphenidate transdermal system in 14 adult individuals diagnosed with ADHD and with a history of stimulant misuse, abuse, or dependence. The primary efficacy endpoint was the Wender-Reimherr Adult ADHD Scale, and secondary efficacy endpoints included the Clinical Global Impression ratings and substance abuse as quantified by urine drug screens and self-reported use. Significant improvements from baseline were found on both the measurements. No abuse of the study medication was observed. The findings suggested that methylphenidate transdermal system may improve ADHD symptoms in adults with a history of stimulant misuse; however, there were limitations. The study data showed the need for subsequent randomized studies that further explore findings made in this study [11505].

Laboratory technique

A novel electrophoric derivatisation procedure using o-(pentafluorobenzylxyloxy carbonyl)-2,3,4,5-tetrafluorobenzoyl chloride for the quantitative determination of methylphenidate in human plasma is described. The drug can be quantitatively measured down to 0.006 pg/mL plasma due to the extraordinary sensitivity of the derivatives under negative ion chemical ionisation mass spectrometry. Plasma samples were made alkaline with carbonate buffer
and treated with extraction solvent (n-hexane) and reagent solution for 15 min, which, after concentration was measured by GC-NICI-MS. The method is rapid as extraction and derivatisation occur in one single step. A stable isotope labelled internal standard was used. Validation data are given to demonstrate the usefulness of the assay, including selectivity, linearity, accuracy and precision, autosampler stability, aliquot analysis, robustness, and prospective analytical batch size accuracy. The method has been successfully applied to pharmacokinetic profiling of the drug after oral administration [11357].

A validated, accurate and sensitive LC-MS/MS method for determination of racemic methylphenidate and its metabolite ritalinic acid has been developed. The analytes were quantified by tandem mass spectrometry operating in positive electrospray ionization mode with multiple reaction monitoring. Blood, plasma and oral fluid samples of 100μL were prepared by simple precipitation with 200μL of an aqueous solution of zinc sulphate in methanol. Corresponding deuterated internal standards were used for quantification. Calibrations for methylphenidate and ritalinic acid were linear within the selected range of 0.2-30 ng/mL and 10-1500 ng/mL in blood or plasma and in the range of 1-500 ng/mL and 0.25-125 ng/mL in oral fluid, respectively. The method was successfully applied for the analysis of samples from patients treated with methylphenidate in the dose range of 36-72 mg/day and some representative ante mortem and post mortem samples from clinical and forensic toxicological investigations. A three to fourfold higher concentration of methylphenidate was found in oral fluid compared with blood while for ritalinic acid the concentrations were about 25-fold lower in oral fluid [11358].

**Amphetamine**

Methamphetamine- or amphetamine-type stimulants are the second most frequently used illicit drug worldwide, second only to cannabis. Behavioural treatments are efficacious, but their impact is limited underscoring the need for other treatment options, notably, pharmacotherapy. A review of randomised controlled trials of pharmacotherapies for methamphetamine- or amphetamine-type stimulants was performed using PubMed and Google Scholar databases. Evidence for efficacy of medications is reported. Clinical trials have yielded no broadly effective pharmacotherapy. Promising signals have been observed for methylphenidate, naltrexone, bupropion and mirtazapine in subgroups of patients in reducing stimulant use (e.g. patients with less severe dependence at baseline and men who have sex with men), though none has produced an unambiguous, replicable signal of efficacy. Problems in phase II trials, including high dropout rates, missing data and a lack of agreement on outcomes, complicate efforts to find a broadly effective pharmacotherapy for amphetamine-type stimulant disorders. Efforts to address these problems include calls for better validation of pharmacological target exposure, receptor binding and functional modulation. As well, there is a need for agreement in using findings from preclinical and early phases of the medication development process for selecting better pharmacotherapy candidates. After over 20 years of efforts worldwide to develop a broadly effective medication for dependence on methamphetamine- or amphetamine-type stimulants, no candidate has emerged. This highlights the need for new compounds, consistent and stringent research methods, better integration between preclinical and clinical stages of medication development, and improved collaboration between government, industry and researchers [13482].

Amphetamine (AP) and amphetamine-type stimulants, methamphetamine (MA) and N,N-dimethylamphetamine (DMA), are known as central nervous system stimulants, and their abuse throughout the world has recently increased. Since it is difficult to physically
distinguish among AP, MA and DMA, analysts may not be aware of what abusers have administered. In one study, following the detection of specific metabolites of AP, MA and DMA as biomarkers in abuser urines, a rapid and sensitive method was developed for the identification and classification of AP-type stimulants abusers. After the simple filtration of the urine samples, the samples were directly analyzed using a liquid chromatography/tandem mass spectrometry system with selected reaction monitoring (SRM)-triggered quantitation-enhanced data-dependent MS/MS (QED-MS/MS) for the simultaneous qualitative and quantitative analysis of p-hydroxy AP, p-hydroxy MA, p-hydroxy DMA, AP, MA, DMA and DMA N-oxide. The determination of p-hydroxy AP, p-hydroxy MA, AP, MA, DMA and DMA N-oxide was accurate and reproducible, with the limits of quantitation of 5 ng/mL in urine. When applied to the urine samples of suspected AP-type stimulants abusers, the abused drugs were precisely identified between MA and DMA abusers [10488].

Epidemiological studies on all types of illicit drug use among athletes are essential for both the sport community and drug control achievements. Here, it was investigated the prevalence and associated factors of amphetamine use in body builders in Tehran, Iran, 2007. One study is a secondary analysis of a substance use survey done in 103 randomly selected gymnasia in Tehran (capital city of Iran). The survey was conducted from 2007 to 2008 and included 843 randomly selected bodybuilders (aged 40 years or less). By interviews via questionnaires the following data were obtained: age, job, marital status, education level, housing status, average monthly family income, number of family members, gymnasion area (m²), number of trainers, number of gymnasion members, initiation time (months), weekly duration of the sporting activity (h), monthly cost of the sporting activity, purpose of participating in sporting activity, and history of anabolic steroid and amphetamine use. One hundred twenty (13 %) body builders reported a history of amphetamine use. According to the results of regression analysis, being married and participating in body building to enhance self-esteem or to enhance sport performance had protective effects on amphetamine use. However, having university qualifications using anabolic steroids and participating in sport to maintain fitness were linked to increased risk of amphetamine use. I was concluded that well-educated bodybuilders were more likely to use amphetamines, and why this is so needs to be discovered. If further studies show that they are not aware of the dangers associated with amphetamine use, providing them with information should be considered [12294].

Amphetamines are controlled substances under general drugs legislation, although they have been prescribed as appetite suppressants and for the treatment of narcolepsy. They are known to produce dependence, often in increasing doses. Athletes are likely to use amphetamines to sharpen reflexes and reduce tiredness. However, athletes have died as a result of amphetamine misuse, since the increase in blood pressure combined with increased physical activity and peripheral vasoconstriction makes it difficult for the body to cool down. If the body overheats, it dehydrates and blood circulation decreases, and the heart and other organs are unable to work normally [06171].

Amphetamine was synthesised in 1920 and was used to reduce fatigue and increase alertness during the second world war. Since then, many derivatives have been elaborated – for example, methamphetamine, dimethylamphetamine, methylendioxyamphetamine (MDA), methylendioxydimethylamphetamine (MDMA, “ecstasy”), and selegiline—and they are all forbidden in the practice of sport. Amphetamine was prescribed unsuccessfully as a nasal decongestant, antidepressant, and appetite suppressant, but soon appeared to be a powerful CNS stimulant. It acts primarily by enhancing the brain activity of noradrenaline and dopamine, intensifying psychological sensations of alertness, concentration, and self-confidence. Amphetamine is readily absorbed, mainly from the small intestine, and the plasma concentration peaks one to two hours following administration. Absorption is usually
complete in two and a half to four hours and is accelerated by food intake. The metabolism of amfetamine has been difficult to investigate because of the wide variation among species with regard to its metabolic effects. The principal amfetamine metabolites are p-hydroxy ephedrine and p-hydroxy amfetamine. Amfetamine is lost from the body by renal filtration. For detection of amfetamine use in sport, urine is analysed for the parent compound amfetamine. After a single dose of amfetamine, it has been shown that it can be detected in urine in the first urine void for at least 48 hours after the intake of the drug. The peak concentration in urine is strongly dependent on the individual, but occurs between 3 hours and 12 hours after the intake of the drug. Amfetamine excretion is enhanced by an acidic urine, and treatments that increase the acidity of urine enhance amfetamine loss – a reaction that is useful in the treatment of amfetamine overdose [06171].

**Physiologic effects of amphetamine**

The positive effects of amphetamine include an increase in physical energy, mental aptitude, talkativeness, restlessness, excitement, and good humour. Subjects taking amfetamine also report that they feel confident, efficient, ambitious, and that their food intake is reduced. Some negative effects of amphetamine (that can be dose dependent) are anxiety, indifference, slowness in reasoning, irresponsible behaviour, irritability, dry mouth, tremors, insomnia, and, following withdrawal, depression. Tolerance develops rapidly to many of the effects of the amfetamines. Tolerance is said to be present when, over a period of time, increasing doses of a drug are required to maintain the same response. There is much evidence to show that amfetamines induce drug dependence and the amfetamine dependent person may become psychotic, aggressive, and antisocial. Withdrawal of amfetamines is associated with mental and physical depression [06171].

**Side effects**

The major side effects of amfetamine use include confusion, delirium, sweating, palpitations, dilation of the pupil, and rapid breathing, as well as hypertension, tachycardia, tremors, and muscle and joint pain. Long term administration of amfetamine is associated with myocardial pathology and with growth retardation in adolescents. In most cases, the personality changes induced by chronic low doses of amfetamine are reversed gradually after the drug is stopped. High chronic doses may lead to a variety of persistent personality changes, paranoid delusions, and tactile hallucinations called “amphetamine psychosis” [06171].

**Heart**

Amphetamine is one of the oldest substances used in doping. Many cardiovascular disorders have been described, even SCD, from both their acute and chronic use. Specifically, they can cause coronary artery spasm, resulting in acute myocardial infarction, and or diffuse vasospasm. Their long-term use leads to arterial and pulmonary hypertension, stroke, and cardiomyopathy. Also common is the appearance of rhythm disturbances. Amphetamines are believed to increase levels of intracellular cyclic adenosine monophosphate and sympathetic nervous system tone. Thus, they favour the development of arrhythmias, especially in athletes with myocardial hypertrophy and heterogeneity of ventricular repolarisation [12126].

Atrial fibrillation (AF) is the most frequent cause of prolonged palpitations in young competitive athletes, even including those performing elite sport activity. This arrhythmia may occasionally affect impair athletes’ ability to compete thus leading to non-eligibility at prequalification screening. Competitive sport has a significant impact on the autonomous nervous system. In fact, long-term regular intense physical training determines an increase in
vagal tone leading to resting bradycardia. During physical activity, particularly in the setting of competition, a marked release of catecholamines occurs as a result of both the intense physical effort and emotional stress. Both of these adaptive phenomena may precipitate AF. Furthermore, in several athletes with AF an association with sick sinus syndrome has been found, even though the pathophysiological basis of this finding is not clear. This picture is further complicated by the increasingly intake of illicit substances, whose arrhythmogenic effect has been shown both at the ventricular and atrial levels. Moreover, the use of recreational drugs, such as amphetamines, ecstasy, alcohol, cannabinoids, cocaine and so called new drugs in clubs has dramatically increased, with several cases of drug-induced arrhythmic events. These effects are often exacerbated by the combined use of different drugs, especially in situations such as sports competitions, in which the adrenergic system is already hyperactivated. No data have been published on the efficacy of antiarrhythmic therapy in athletes with AF, but it has been reported that athletes are more predisposed to the development of pro-arrhythmic effects induced by antiarrhythmic drugs when compared to general population. Most recently, radiofrequency catheter ablation involving electrical disconnection of the pulmonary veins in athletes with AF limiting their normal training activity and participation in sports competitions has proven highly effective to restore stable sinus rhythm and enable subsequent re-eligibility [10489].

Amfetamine in sport

The action of amfetamine on sporting performance was first investigated in 1959. It has since been concluded that amfetamines enhanced anaerobic performance while having little or no effect on aerobic performance. Amfetamines may enhance sports performance from a supplemental mental stimulant effect as well as the effects on physical power derived from all three human energy systems – the ATP-CP, lactic acid, and oxygen energy systems. Depending on the type of effect or effort the athlete has to do, the dosage might be important for the user. Aggressiveness seems to increase with high dosage, whereas alertness is stimulated by lower doses. To summarise, amfetamines may:

- improve reaction time when fatigued
- increase muscular strength and endurance
- increase acceleration
- raise lactic acid levels at maximal exercise
- increase aerobic endurance capacity
- stimulate metabolism by inducing a loss of body fat

All amfetamines are banned by the WADA and IOC codes. Laboratory analysis is qualitative only, verifying presence of metabolites in urine. This is sufficient to demonstrate the presence of the substance in the urine and declare the case as an analytical adverse finding. The presence of amfetamine in urine can be described as a severe doping offence because amfetamines are no longer used therapeutically. Many countries prohibit its use because of the adverse effects. Amfetamines are part of the category S6 of the prohibited substances in competition [06171].

Side effects of amfetamine in relation to sport

Side effects of amfetamine, besides headaches, sleeplessness and anxiety, are particularly important to athletes. Indeed, amfetamine use may carry significant health risks for the sportsperson as evidenced by several amfetamine-linked deaths in sport. Two of the major risks are amfetamine induced heatstroke and cardiac arrest, which have resulted in several fatalities among cyclists during arduous effort. Amfetamines obscure pain from injuries and have enabled athletes in some sports to continue to compete and thus exacerbated their injuries. The side effects of amfetamine with regard to behaviour also are important in sport.
The euphoriant effects of amphetamine – taken to promote aggression and lower fatigue – has led in misjudgments and major fouls on the pitch [06171].

In hair

In the preparation of a reference material (RM) for quality assurance, both homogeneity and stability studies are integral parts. In the present study, both homogeneity and stability of a candidate RM for the determination of methamphetamine and amphetamine in hair were examined by an isotope dilution gas chromatography/mass spectrometry (GC/MS) method, which is not only one of the analytical methods validated in our previous study but also one of the primary methods for the preparation of a certified reference material (CRM). Additionally, homogeneity was monitored using a different method: micropulverized extraction followed by high performance liquid chromatography-tandem mass spectrometry (HPLC-MS/MS), which was fully validated in the previous study. In order to demonstrate the suitability of the method as an isotope dilution with mass spectrometry (IDMS), the extraction efficiency was also determined according to time. The results showed that the current method, i.e., agitating hair with isotope internal standards in the extraction solvent for 20 h followed by GC-MS, was accepted as an IDMS. No significant difference was observed between bottles of the candidate CRM. The statistical results also showed no significant trends in stability for 92 days at room temperature and 4 degrees C. An inter-laboratory quality assurance program was also performed successfully using this material. The candidate CRM developed in the present study demonstrated its suitability for quality assurance in hair drug analysis. Even though a RM is necessity as a quality control tool, it is not always easy to have an authentic RM containing target drugs and metabolites. Even when an in-house quality control material is used, both homogeneity and stability should be investigated [10490].

Famprofazone

During a sport competition event in Taiwan, one urine specimen was found positive for both methamphetamine (2688 ng/mL) and amphetamine (462 ng/mL). The specimen donor claimed that she had taken Gewolen (a nonprescription drug manufactured in Taiwan) for treating abdominal pain and the medication was presented. Laboratory investigation confirmed that Gewolen contains famprofazone, which is known to metabolize to methamphetamine and amphetamine and is included in the prohibited list of the World Anti-Doping Agency. Study on the excretion profiles of three volunteers ingesting 50 mg famprofazone produced the following patterns similar to that observed in the case specimen: the ratio of methamphetamine to amphetamine was approximately 6 to 1, and d- and l-enantiomers of both methamphetamine and amphetamine were present, while the amount of l-methamphetamine was 3-4-fold greater than its counterpart. The data suggested that famprofazone (as the ingredient of Gewolen) was likely the source of the prohibited drugs found in the case specimen [07179].

Laboratory techniques

A selective and sensitive method for the qualitative screening of urine samples for 27 amphetamine and amphetamine-type drugs in the field of doping analysis is described. The method consists of a liquid-liquid extraction with diethyl ether at pH 14 and analysis of the extracts with a LCQ-Deca mass spectrometer equipped with an atmospheric pressure chemical ionisation interface, operated in positive ionisation mode. The total run time was 15 min. All compounds were analysed in MS2 or MS3. The detection limit for all compounds was lower than 25 ng/mL except for chlorphentermine (detection limit: 250 ng/mL) [06174].
In Japan, a wide variety of designer drugs became popular among juveniles because of their availability via the Internet and mobile phones. Hence, it is necessary to develop simple and rapid screening methods for these drugs. A rapid screening method for 30 abused drugs, including amphetamines, amphetamine-, piperazine-, tryptamine-, and phenethylamine-derived designer drugs and opiates in human urine was devised. The urine sample was digested with urease, and the drugs were analyzed by gas chromatography-mass spectrometry in the scan mode after solid-phase extraction with a Focus column and acetylation. The retention time obtained with the use of a retention time locking technique and three qualifier ions were used to obtain positive results. As the Focus column requires only simple extraction steps and can retain various drugs of a wide range of polarity, screening of 30 abused drugs was feasible within 3 h. The calibration curves were linear in the concentration range of 100-5,000 ng/mL in most drugs with correlation coefficients exceeding 0.99. The absolute recoveries for all drugs in urine samples were 6.9-125.4 percent at the concentration 1,000 ng/mL. This method will be most useful to confirm the presence of many abused drugs in urine in clinical and forensic cases [06175].

The purpose of one study was to evaluate the gas chromatographic-mass spectrometric method (GC-MS) for assay of stimulants of amphetamine type: amphetamine (AMP), methamphetamine (MAMP), ephedrine (EPH), norephedrine (NOREPH), and the amphetamine-derived designer drugs 3,4-methylenedioxyamphetamine (MDA), 3,4-methylenedioxymethamphetamine (MDMA, ecstasy), 3,4-methylenedioxy-N-ethylamphetamine (MDEA) and N-methyl-benzodioxolylbutanamine (MBDB) in urine. These drugs are often encountered in forensic and clinical toxicological analysis. GC-MS method after mixed-mode solid-phase extraction (SPE) and derivatization with heptafluorobutyric anhydride (HFBA) is presented for quick and reliable screening as well as identification and quantification of amphetamines and amphetamine derived designer drugs in urine. The measurement of calibration dependence allowed to determine the extent of linearity in the concentration range from 10 to 2,000 ng/mL for all amphetamines except AMP and for all amphetamine-derived designer drugs with correlation coefficients exceeding 0.98. Detection limits were established at 5 ng/ml and quantification limits at 10 ng/mL for all analytes, except AMP. LOD for AMP was established at 20 ng/ml and LOQ at 50 ng/mL. Extraction efficiency for all analytes at concentration levels 50 and 500 ng/ml (n=6) was established in the range 60-99 percent. Repeatability was measured at concentration levels 50 and 500 ng/mL (n=6), relative standard deviations (RSDs) were under 10% for all analytes. It was concluded that the GC-MS method after mix-mode solid-phase extraction and derivatization with heptafluorobutyric anhydride is presented for screening followed by identification and quantification of AMP, MAMP, EPH, NOREPH, MDA, MDMA, MDEA, and MBDB. The applicability of the GC-MS method was proven by analyzing authentic urine samples [06176].

A fast and selective ultra-performance liquid chromatography-tandem mass spectrometry (UPLC-MS-MS) method for the determination of amphetamines (amphetamine, methamphetamine, methylenedioxymethamphetamine, methylenedioxymethamphetamine, methylenedioxyethyamphetamine, ephedrine, and p-methoxyamphetamine) in plasma has been developed and validated. Sample preparation was performed by liquid-liquid extraction using ethyl acetate. For optimized chromatographic performance with repeatable retention times, narrow and symmetrical peaks, and focusing all analytes at the column inlet, a gradient start, with acid mobile phase consisting of 0.1 percent formic acid and methanol was chosen. Positive electrospray ionization MS-MS detection was performed with two multiple reaction monitoring transitions for each analyte. Deuteriumlabeled internal standards were used for five of the analytes. The limit of detection was in the range 0.25-1.25 ng/mL, and the limit of quantification was fixed at the lowest calibrator of 2.5 ng/mL for all of the compounds.
The RSD values of the intra- and interassay precision and accuracy were lower than 11% at four concentration levels, including two external quality controls. No or only minor matrix effects were observed, and the extraction method presented recoveries higher than 93 percent for all the compounds. Total run time, including equilibration, was 12 min. The method is routinely used at the National Institute of Criminalistics and Criminology for quantitative determination of the main amphetamines in plasma from forensic and driving under the influence cases [11498].

Capillary electrophoresis, CE, methods with capacitively coupled contactless conductivity detection (C(4)D) were developed for the enantiomeric separation of the following stimulants: amphetamine (AP), methamphetamine (MA), ephedrine (EP), pseudoephedrine (PE), norephedrine (NE) and norpseudoephedrine (NPE). Acetic acid (pH 2.5 and 2.8) was found to be the optimal background electrolyte for the CE-C(4)D system. The chiral selectors, carboxymethyl-beta-cyclodextrin (CMBCD), heptakis(2,6-di-O-methyl)-beta-cyclodextrin (DMBCD) and chiral crown ether (+)-[(18-crown-6)-2,3,11,12-tetra-carboxylic acid (18C6H(4))], were investigated for their enantioseparation properties in the BGE. The use of either a single or a combination of two chiral selectors was chosen to obtain optimal condition of enantiomeric selectivity. Enantiomeric separation of AP and MA was achieved using the single chiral selector CMBCD and (hydroxypropyl)methyl cellulose (HPMC) as the modifier. A combination of the two chiral selectors, CMBCD and DMBCD and HPMC as the modifier, was required for enantiomeric separation of EP and PE. In addition, a combination of DMBCD and 18C6H₄ was successfully applied for the enantiomeric separation of NE and NPE. The detection limits of the enantiomers were found to be in the range of 2.3-5.7 micromol/L. Good precisions of migration time and peak area were obtained. The developed CE-C(4)D method was successfully applied to urine samples of athletes for the identification of enantiomers of the detected stimulants [11499].

The detection of 11 sympathomimetic alkylamines in urine was presented with a focus on human doping control is proposed using liquid chromatography tandem mass spectrometry (LC-QqQ) and high resolution mass spectrometry (LC-HRMS) as a screening tool after a dilute-and-shoot (DS) approach. For the LC-HRMS analyses, several compounds exhibited better limits of detection (LOD) than the LC-QqQ. However, due to their small differences in structure, co-elution among the alkylamines was observed. Therefore, the chemical conversion of the alkylamines into an appropriate derivative for the confirmation analyses using gas chromatography-mass spectrometry (GC-MS) was evaluated. Five derivatization approaches were evaluated in an attempt to increase the analytical response and the confidence of the identification. The choice of the appropriated derivative for each alkylamine makes their spectra more easily interpretable, fulfills the WADA’s rather strict identification criteria and enables the unequivocal identification of alkylamines in urine [13480].

A microwave-assisted fluorescence labeling method for use in CE-LIF (capillary electrophoresis-laser induced fluorescence) is described. Six amphetamine-like designer drugs, namely, α-, m-, p-chloro- and o-, m-, p-fluoro-amphetamine derivatives, were synthesized and used as model compounds. FITC (fluorescein isothiocyanate isomer I) and a blue-laser were used as the fluorescent labeling reagent and excitation source, respectively. When a microwave oven was used, the reaction was complete within 5 min, while the classical method required at least 20 h (usually, an overnight reaction). A mimic oral fluid sample was obtained by spiking oral fluid from a volunteer with the six standards, and after liquid-liquid extraction and microwave-derivatization, it was possible to process the analytes by CE-LIF within a period of 10 min; the wavelength of the blue-laser used was 473 nm. For comparison, data obtained using classical methods, including CZE-UV (capillary zone electrophoresis-UV absorbance detection), sweeping-MEKC-UV (micellar electrokinetic chromatography-UV absorbance detection) and LC-Q-TOFMS (liquid chromatography/
Electrospray ionization quadrupole time-of-flight mass spectrometry) are also reported [13483].

In the context of driving ability diagnostics in Germany, administrative cutoffs for various drugs and pharmaceuticals in urine have been established. Two liquid chromatography-tandem mass spectrometry methods for simultaneous detection and quantification of amphetamines, designer amphetamines, benzylecgonine, benzodiazepines, opiates, and opioids in urine were developed and validated. A 500-microL aliquot of urine was diluted and fortified with an internal standard solution. After enzymatic cleavage, online extraction was performed by an ion-exchange/reversed-phase turbulent flow column. Separation was achieved by using a reversed-phase column and gradient elution. For detection, a Thermo Fisher TSQ Quantum Ultra Accurate Mass tandem mass spectrometer with positive electrospray ionization was used, and the analytes were measured in multiple-reaction monitoring mode detecting two transitions per precursor ion. The total run time for both methods was about 15 min. Validation was performed according to the guidelines of the Society of Toxicological and Forensic Chemistry. The results of matrix effect determination were between 78 and 116 percent. The limits of detection and quantification for all drugs, except zopiclone, were less than 10 ng/mL and less than 25 ng/mL, respectively. Calibration curves ranged from 25 to 200 ng/mL for amphetamines, designer amphetamines, and benzylecgonine, from 25 to 250 ng/mL for benzodiazepines, from 12.5 to 100 ng/mL for morphine, codeine, and dihydrocodeine, and from 5 to 50 ng/mL for buprenorphine and norbuprenorphine. Intraday and interday precision values were lower than 15 percent, and bias values within ± 15 percent were achieved. Turbulent flow chromatography needs no laborious sample preparation, so the workup is less time-consuming compared with gas chromatography-mass spectrometry methods. The methods are suitable for quantification of multiple analytes at the cutoff concentrations required for driving ability diagnostics in Germany [13484].

**Methamphetamine**

Methamphetamine (MA) use is a worldwide problem. Abusers can have cognitive deficits, monoamine reductions, and altered magnetic resonance spectroscopy findings. Animal models have been used to investigate some of these effects, however many of these experiments have not examined the impact of MA on the stress response. For example, numerous studies have demonstrated (+)-MA-induced neurotoxicity and monoamine reductions, however the effects of MA on other markers that may play a role in neurotoxicity or cell energetics such as glucose, corticosterone, and/or creatine have received less attention. In this experiment, the effects of a neurotoxic regimen of (+)-MA (4 doses at 2 h intervals) on brain monoamines, neostriatal GFAP, plasma corticosterone, creatinine, and glucose, and brain and muscle creatine were evaluated 1, 7, 24, and 72 h after the first dose. In order to compare MA’s effects with stress, animals were subjected to a forced swim test in a temporal pattern similar to MA administration (i.e. 30 min/session 4 times at 2 h intervals). Methamphetamine increased corticosterone from 1-72 h with a peak 1 h after the first treatment, whereas glucose was only increased 1 h post-treatment. Neostriatal and hippocampal monoamines were decreased at 7, 24, and 72 h, with a concurrent increase in GFAP at 72 h. There was no effect of MA on regional brain creatine, however plasma creatinine was increased during the first 24 h and decreased by 72 h. As with MA treatment, forced swim increased corticosterone more than MA initially. Unlike MA, forced swim reduced creatine in the cerebellum with no change in other brain regions while plasma creatinine was decreased at 1 and 7 h. Glucose in plasma was decreased at 7 h. It was concluded that methamphetamine and forced swim increase demand on energy substrates.
Methamphetamine (MA) has been implicated in cognitive deficits in humans after chronic use. Animal models of neurotoxic MA exposure reveal persistent damage to monoaminergic systems but few associated cognitive effects. Since questions have been raised about the typical neurotoxic dosing regimen used in animals and whether it adequately models human cumulative drug exposure, these experiments examined two different dosing regimens. Rats were treated with one of the two regimens: one based on the typical neurotoxic regimen (4 x 10 mg/kg every 2 h) and one based on pharmacokinetic modeling designed to better represent accumulating plasma concentrations of MA as seen in human users. On markers of neurotoxicity, methamphetamine showed decreased dopamine (DA) and 5-HT, increased glial fibrillary acidic protein, and increased corticosterone levels regardless of dosing regimen 3 days post-treatment. Behaviorally, methamphetamine-treated groups, regardless of dosing regimen, showed hypoactivity, increased initial hyperactivity to a subsequent MA challenge, impaired novel object recognition, impaired learning in a multiple water maze test of path integration, and no differences on spatial navigation or reference memory in the Morris water maze. After behavioral testing, reductions of DA and 5-HT remained. It was concluded that methamphetamine treatment induces an effect on path integration learning not previously reported. Dosing regimen had no differential effects on behavior or neurotoxicity.

Recently "detox" agents have been popularly used as forms of diets or nutritional supplements. Especially, several cases have been reported that these detox agents have been used to mask drug tests among drug abusers. In the present study, capsule and drink types of detox agents were evaluated for their ability to alter the elimination of methamphetamine in rats. For this study, methamphetamine and its major metabolite, amphetamine in urine samples were determined using LC-tandem mass spectrometry after administration of the detox agents to methamphetamine-treated rats. As a result, significant differences were not shown between control and detox-dosed groups in the amounts of methamphetamine and amphetamine excreted into urine as well as the volume of excreted urine. This result suggests that the detox agents tested may not affect the metabolism or elimination of methamphetamine and further might have minimal effect on narcotics detection in the urine samples of drug abusers.

One of the most notable trends in illegal substance use among Americans over the past decade is the dramatic growth and spread of methamphetamine use. In response to the dramatic rise in methamphetamine use and its associated burden, a broad range of legislations has been passed to combat the problem. In one paper, it was assessed the impact of retail-level laws intended to restrict chemicals used to manufacture methamphetamine (methamphetamine precursor laws) in reducing indicators of domestic production, methamphetamine availability, and the consequences of methamphetamine use. Specifically, we examine trends in these indicators of methamphetamine supply and use over a period spanning the implementation of the US federal Methamphetamine Anti-Proliferation Act (MAPA) (October 2000) and a more stringent state-level restriction enacted in California (January 2000). The results are mixed in terms of the effectiveness of legislative efforts to control methamphetamine production and use, depending on the strength of the legislation (California Uniform Controlled Substances Act versus federal MAPA), the specification of the comparison group, and the particular outcome of interest. Some evidence suggests that domestic production was impacted by these legislative efforts, but there is also evidence that prices fell, purities rose, and treatment episodes increased.

Methamphetamine is a highly addictive stimulant and long-term exposure leads to reductions in dopamine. One therapeutic strategy is to develop and test compounds that normalize...
dopamine. The primary aim of this study was to determine the safety of modafinil treatment during methamphetamine exposure in a controlled clinical setting. Methamphetamine-dependent volunteers (n=13), who were not seeking treatment, were randomized to receive either modafinil (200 mg) or matching placebo over three days (days 1-3 or days 8-10). On day 1, subjects were randomized to modafinil or placebo in the morning, and then 3 and 6 hours later received infusions of methamphetamine (0 and 30 mg, intravenously), after which cardiovascular and subjective effects were assessed. On day 3, participants completed intravenously self-administration sessions during which they made 10 choices for low doses of methamphetamine (3 mg) or saline. Days 4-7 were used as a washout period. On day 8 participants were assigned to the alternate study medication (placebo or modafinil), and the same testing procedures were repeated through day 10. The data reveal that modafinil treatment was well-tolerated and not associated with increased incidence of adverse events. In general, modafinil reduced by approximately 25 percent ratings of methamphetamine-induced “Any Drug Effect”, “High”, and “Want Methamphetamine”, and reduced total number of choices for methamphetamine and monetary value of methamphetamine, though none of these measures reached statistical significance. Given these encouraging, though non-significant trends, the primary conclusion is that it appears safe to proceed with modafinil in further clinical evaluations of therapeutic efficacy [09274].

Following more than two decades of generally increasing trends in the use and abuse of methamphetamine in certain parts of the country, prevalence indicators for the drug began to decrease in the mid-2000’s-but was this decrease signaling the end of the “meth problem”? one paper has compiled historical and recent data from supply and demand indicators to provide a broader context within which to consider the changes in trends over the past half decade. Data suggest supply-side accommodation to changes in precursor chemical restrictions, with prevalence indicators beginning to attenuate in the mid-2000’s and then increasing again by 2009-2010. Results support the need for continuing attention to control and interdiction efforts appropriate to the changing supply context and to continuing prevention efforts and increased number of treatment programs [11500].

To assess the effectiveness of methamphetamine precursor regulations in reducing illicit methamphetamine supply and use a systematic review of 12 databases was used to identify studies that had evaluated the impact of methamphetamine precursor regulations on methamphetamine supply and/or use. The guidelines of the Effective Practice and Organization of Care Group of The Cochrane Collaboration were used to determine which study designs were included and assess their quality. Ten studies met the inclusion criteria. These studies evaluated 15 interventions (13 regulations and two related interdiction efforts), all of which were located in North America. Interventions had consistent impacts across various indicators of methamphetamine supply and use. Seven of the 15 interventions produced reductions in methamphetamine indicators (ranging from 12 % to 77 %). Two of the largest impacts were seen following interdiction efforts, involving the closure of rogue pharmaceutical companies. There was no evidence of a shift into other types of drug use, or injecting use, although the impact on the synthetic drug market was not examined. Null effects were related largely to the existence of alternative sources of precursor chemicals or the availability of imported methamphetamine. It was concluded that methamphetamine precursor regulations can reduce indicators of methamphetamine supply and use. Further research is needed to determine whether regulations can be effective outside North America, particularly in developing countries, and what impact they have on the broader synthetic drug market. Improved data on precursor diversion are needed to facilitate the evaluation of precursor regulations [11501].

Heart rate variability (HRV) reflects a healthy autonomic nervous system and is increased with physical training. Methamphetamine dependence (MD) causes autonomic dysfunction
and diminished HRV. It was compared recently abstinent MD participants with age-matched, drug free controls (DF) and also investigated whether HRV can be improved with exercise training in the MD participants. In 50 participants (MD=28; DF=22) resting heart rate (R-R intervals) was recorded over 5 min while seated using a monitor affixed to a chest strap. Previously reported time-domain (SDNN, RMSSD, pNN50) and frequency-domain (LFnu, HFnu, LF/HF) parameters of HRV were calculated with customized software. MD were randomized to thrice weekly exercise training (ME=14) or equal attention without training (MC=14) over 8 weeks. Groups were compared using paired and unpaired t-tests. Participant characteristics were matched between groups: age 33 ± 6 years; body mass 83 ± 12 kg, BMI 27 ± 4 kg/min. Compared with DF, the MD group had significantly higher resting heart rate, LFnu, and LF/HF as well as lower SDNN, RMSSD, pNN50 and HFnu. At randomization, HRV indices were similar between ME and MC groups. However, after training, the ME group significantly increased SDNN (+15 ± 2 ms, +34 %), RMSSD (+20 ± 4 ms, +63 %), pNN50 (+23 ± 3 %, +173 %), HFnu (+14 ± 2, +60 %) and decreased HR (-5 ± 1 beats/min, -7 %), LFnu (-10 ± 2, -16 %) and LF/HF (-0.7 ± 0.3, -19 %). These measures did not change from baseline in the MC group. It was concluded that HRV, based on several conventional indices, was diminished in recently abstinent, methamphetamine dependent individuals. Moreover, physical training yielded a marked increase of HRV representing increased vagal modulation or improved autonomic balance [13485].

**Treatment of dependence**

Individuals who are methamphetamine dependent exhibit higher rates of cognitive dysfunction than healthy people who do not use methamphetamine, and this dysfunction may have a negative effect on the success of behavioral treatments for the disorder. Therefore, a medication that improves cognition, such as modafinil (Provigil), may serve as a useful adjunct to behavioral treatments for methamphetamine dependence. Although cognitive-enhancing effects of modafinil have been reported in several populations, little is known about the effects of modafinil in methamphetamine-dependent individuals. It was thus sought to evaluate the effects of modafinil on the cognitive performance of methamphetamine-dependent and healthy individuals. Seventeen healthy subjects and 24 methamphetamine-dependent subjects participated in this randomized, double-blind, placebo-controlled, crossover study. Effects of modafinil (200 mg, single oral dose) were assessed on participants’ performance on tests of inhibitory control, working memory, and processing speed/attention. Across subjects, modafinil improved performance on a test of sustained attention, with no significant improvement on any other cognitive tests. However, within the methamphetamine-dependent group only, participants with a high baseline frequency of methamphetamine use demonstrated a greater effect of modafinil on tests of inhibitory control and processing speed than those participants with low baseline use of methamphetamine. It was concluded that although modafinil produced limited effects across all participants, methamphetamine-dependent participants with a high baseline use of methamphetamine demonstrated significant cognitive improvement on modafinil relative to those with low baseline methamphetamine use. These results add to the findings from a clinical trial that suggested that modafinil may be particularly useful in methamphetamine-dependent subjects who use the drug frequently [11502].

**L-methamphetamine**

L-methamphetamine (the non-abused isomer of methamphetamine) is banned in athletic competition because it may improve athletic performance, but there are no studies assessing its effects on performance. In the United States L-methamphetamine is formulated in the
non-prescription Vick’s Vapor Inhaler nasal decongestant. Vick’s Vapor sold elsewhere contain similar inactive ingredients (menthol, camphor and Siberian pine oil) but no L-methamphetamine. One study tested the effects of inhaled L-methamphetamine delivered from a widely available non-prescription product on athletic performance. In a 2-session double-blind placebo-controlled study 12 participants (ages 14-17) were dosed with 4 (session 1) and 12 (session 2) inhalations from Vick’s Vapor with (USA) or without (UK) L-methamphetamine and then performed two 20 minute rides on a stationary bike with rides separated by a 30 minute rest. After about 16 μg L-methamphetamine distance travelled was 5.26 miles versus 5.30 with placebo. After about 48 μg L-methamphetamine distance travelled was not either significantly different. Modest doses of inhaled L-methamphetamine probably do not improve athletic performance but do minimally raise diastolic blood pressure [09275].

Methylamphetamine

The illicit drug methylamphetamine is often prepared from the precursor ephedrine or pseudoephedrine, which in turn are obtained by three processes: extraction from the Ephedra plant (“natural”), via fermentation of sugars (“semi-synthetic”), and by a “fully synthetic” route from propiophenone. We report the first method to differentiate between the three industrial routes used to produce the precursors ephedrine and pseudoephedrine by measurement of stable isotope ratios of nitrogen (delta^{15}N), hydrogen (delta^{2}H), and carbon (delta^{13}C). Analysis of 782 samples of seized methylamphetamine allowed classification into three groups using k-means clustering or the expectation-maximization algorithm applied to a Gaussian mixture model. By preparation of 30 samples of ephedrine by the “fully synthetic” industrial process and measuring their delta^{15}N, delta^{2}H, and delta^{13}C values, it was observed that ^{15}N becomes significantly depleted compared to the methylamine starting material. Conversion of ten ephedrine samples to methylamphetamine showed that this depletion is maintained in the final drug product, of which the delta^{15}N, delta^{2}H, and delta^{13}C values were distinct from those of ephedrine and methylamphetamine samples of a semi-synthetic (fermentation pathway) origin. Combining modeling analysis with the new experiments and published information on the values of delta^{2}H gave a definitive assignment of the three model groups, and equations to obtain probabilities for the precursor origin of any new sample. A simple rule of thumb is also presented. Making an assignment using delta values is particularly useful when no other chemical profiling information is available [13486].

Mephentermine

The urine specimens of numerous athletes were found to be positive for mephentermine both in-competition and out-of-competition in Taiwan. The donor of one specimen claimed she had only taken Mucaine (contains oxethazaine) for relieving symptomatic peptic ulcer and gastritis. Oxethazaine is not included in the prohibited list of the World Anti-Doping Agency; however, its metabolized compounds, mephentermine and phentermine, are included in that list. This study applied LC-MS-MS to analyze the excretions of three volunteers who ingested oxethazaine and presented positive results for mephentermine and/or phentermine. Thus, oxethazaine is the source of mephentermine and phentermine. Moreover, the results showed that 48 brands of gastric medicines containing oxethazaine were legally imported or locally manufactured in Taiwan, information which could be useful for limiting the misuse of oxethazaine by athletes. The data suggested that the sports associations should warn athletes about the risks of taking oxethazaine [09276].
Mephentermine and phentermine, substances prohibited in sports by the World Anti-Doping Agency, were found for the first time in urine specimens following the administration of a therapeutic medication, oxethazaine. In a recent sporting event, a urine specimen donor who tested positive for mephentermine and phentermine claimed consumption of Mucaine® for treating stomach pain was the reason for testing positive. Five volunteers were administrated oxethazaine (a topical anesthetic found in the multi-ingredient medication Mucaine and its generic equivalent, both of which are available in Taiwan), mephentermine, and phentermine. Excretion profiles of mephentermine and phentermine following the administration of these drugs were found to be similar. However, the mephentermine/phentermine ratios found in urine specimens collected at different time points following the administration of oxethazaine and mephentermine were found to be characteristically different [10190].

Metamfepramone

The sympathomimetic agent metamfepramone (2-dimethylamino-1-phenylpropan-1-one, dimethylpropion) (Dimethycathinone, Dimethylpropion) is a stimulant drug related to cathinone and methcathinone and used for the treatment of the common cold or hypotonic conditions, although first evaluated as an appetite suppressant. Due to its stimulating properties and its rapid metabolism resulting in major degradation products such as methylpseudoephedrine and methcathinone, it has been considered relevant for doping controls by the World Anti-Doping Agency (WADA). The rapid degradation of the active drug complicates the detection of metamfepramone itself but the metabolites methylpseudoephedrine and methcathinone can be monitored, and the finding of the latter in particular allows the inference of a metamfepramone administration. In order to improve sports drug testing procedures, metamfepramone, methylpseudoephedrine and methcathinone were characterized using electrospray ionization-high resolution/high accuracy mass spectrometry, and a method employing liquid chromatography/tandem mass spectrometry was established that allowed the analysis of these three analytes by direct injection of 2 microL of urine specimens. The assay was validated with regard to specificity, lower limits of detection (2-10 ng/mL), intraday and interday precision (3-17 %) and ion suppression/enhancement effects. The developed procedure has been used to verify or falsify suspicious signals observed in routine screening procedures based on gas chromatography/mass spectrometry and yielded an adverse analytical finding concerning a metamfepramone administration in an authentic doping control sample. Although the active drug was not detected, the indicative metabolites methylpseudoephedrine and methcathinone were considered sufficient to infer the application of the prohibited drug [09406].

The sympathomimetic agent metamfepramone (2-dimethylamino-1-phenylpropan-1-one, dimethylpropion) is widely used for the treatment of the common cold or hypotonic conditions. Due to its stimulating properties and its rapid metabolism resulting in major degradation products such as methylpseudoephedrine and methcathinone, it has been considered relevant for doping controls by the World Anti-Doping Agency (WADA). The rapid degradation of the active drug complicates the detection of metamfepramone itself but the metabolites methylpseudoephedrine and methcathinone can be monitored, and the finding of the latter in particular allows the inference of a metamfepramone administration. In order to improve sports drug testing procedures, metamfepramone, methylpseudoephedrine and methcathinone were characterized using electrospray ionization-high resolution/high accuracy mass spectrometry, and a method employing liquid chromatography/tandem mass spectrometry was established that allowed the analysis of these three analytes by direct
injection of 2 microL of urine specimens. The assay was validated with regard to specificity, lower limits of detection (2-10 ng/mL), intraday and interday precision (3-17 %) and ion suppression/enhancement effects. The developed procedure has been used to verify or falsify suspicious signals observed in routine screening procedures based on gas chromatography/mass spectrometry and yielded an adverse analytical finding concerning a metamfepramone administration in an authentic doping control sample. Although the active drug was not detected, the indicative metabolites methylpseudoephedrine and methcathinone were considered sufficient to infer the application of the prohibited drug [09277].

Cathinones

A new group of recreational drugs, popularly known as "bath salts", "plant feeders" or "plant food", has recently emerged in numerous countries. Although various products are labeled with warnings "not for human consumption" or "not tested for hazards or toxicity", they are intended to produce a high similar to that obtained with illegal stimulants, such as MDMA, methamphetamine or cocaine. The active compounds in "bath salts" are cathinone derivatives continuously developed and modified by drug designers to avoid detection or legal scrutiny. Around 2010 the most prevalent were mephedrone (4-methylmethcathinone) and MDPV (3,4-methylenedioxypyrovalerone). One review surveyed the current state of knowledge regarding the pharmacotoxicological properties of synthetic cathinones, the prevalence and pattern of their use. Special emphasis is given to the negative consequences of using these products including, among others, cardiovascular, psychiatric and neurologic symptoms, dehydration, rhambdomyolysis, renal and liver failure. Case reports on synthetic cathinones-related fatalities are also presented [13501].

The abuse of synthetic cathinones, widely known as bath salts, has been increasing since the mid-2000s. These substances are derivatives of the naturally occurring compound cathinone, which is the primary psychoactive component of khat. The toxicity of synthetic cathinones includes significant sympathomimetic effects, as well as psychosis, agitation, aggression, and sometimes violent and bizarre behavior. Mephedrone and methylenedioxypyrovalerone are currently the predominantly abused synthetic cathinones [13502].

Designer beta-keto-amphetamines (e.g. cathinones, “bath salts” and “research chemicals”) have become popular recreational drugs, but their pharmacology is poorly characterized. It was determined the potencies of cathinones to inhibit DA, NA and 5-HT transport into transporter-transfected HEK 293 cells, DA and 5-HT efflux from monoamine-preloaded cells, and monoamine receptor binding affinity. Mephedrone, methylone, ethylone, butylone and naphyrone acted as non-selective monoamine uptake inhibitors, similar to cocaine. Mephedrone, methylone, ethylone and butylone also induced the release of 5-HT, similar to 3,4-methylenedioxymethamphetamine (MDMA, ecstasy) and other entactogens. Cathinone, methcathinone and flephedrone, similar to amphetamine and methamphetamine, acted as preferential DA and NA uptake inhibitors and induced the release of DA. Pyrovalerone and 3,4-methylenedioxypyrovalerone (MDPV) were highly potent and selective DA and NA transporter inhibitors but unlike amphetamines did not evoke the release of monoamines. The non-β-keto amphetamines are trace amine-associated receptor 1 ligands, whereas the cathinones are not. All the cathinones showed high blood-brain barrier permeability in an in vitro model; mephedrone and MDPV exhibited particularly high permeability. It was concluded that cathinones have considerable pharmacological differences that form the basis of their suggested classification into three groups. The predominant action of all
cathinones on the DA transporter is probably associated with a considerable risk of addiction [13503].

A rapid, reproducible and sensitive reversed phase liquid chromatography-mass spectrometry method was developed and validated for the identification and semi-quantitative confirmation of stimulants in urine. The method is capable of separating compounds such as cocaine and metabolites, amphetamines, substituted cathinones and other designer drugs, with a total run time of 11 min. The method was subsequently used to confirm the presence of these stimulants in the urine of patients attending the Drug Treatment Centre Board Ireland over the period in which legislation banning some named cathinones was introduced in Ireland. Substituted cathinones were the predominant drug of choice, outside of cocaine use. Mephedrone was the most widely detected cathinone in 2010, whereas 3,4-methylenedioxypyrovalerone featured more prevalently in screenings in 2011. The appearance of adverse effects increases during multi-stimulant use related to synergistic pharmacological combinations, and this method has benefits in identifying multi-drug use between next generation designer drugs and commonly used stimulants [13504].

Laboratory techniques

Recently, clandestine drug lab operators have attempted to bypass controlled substances laws and regulations with "designer" compounds chemically and pharmacologically similar to controlled substances. For example, "bath salts" have erupted onto the scene as "legal highs" containing cathinone analogs that have produced severe side effects in users worldwide. These products have sparked concern among law enforcement agencies, and emergency bans have been placed on the sale of such items. Despite the increasing number of designer drugs available, there are few comprehensive screening techniques for their detection and quantification in biological specimens. The liquid chromatography triple quadrupole tandem mass spectrometry (LC-QQq-MS/MS) method presented here encompasses over thirty important compounds within the phenethylamine, tryptamine, and piperazine designer drug classes. Analytes were determined by LC-QQq-MS/MS in the multiple-reaction monitoring mode after mixed-mode solid-phase extraction. The bioanalytical method was fully validated according to recommended international guidelines. The assay was selective for all analytes with acceptable accuracy and precision. Limits of quantification were in the range of 1-10 ng/mL for each compound with limits of detection near 10 pg/mL. In order to evaluate its applicability in a forensic toxicological setting, the validated method was used to analyze post-mortem specimens from two cases that were suspected of containing designer drugs. The method was able to identify and quantify seven of these compounds at concentrations as low as 11 ng/mL. The method should have wide applicability for rapid screening of important new drugs of abuse at high sensitivity in both post- and ante-mortem forensic analysis [13513].

Methylenedioxypyrovalerone (MDPV)

3,4-Methylenedioxypyrovalerone (MDPV) is a psychoactive, synthetic analog of the central nervous system stimulant cathinone. Its recent popularity as a recreational drug in the United States has led to numerous reports to poison control centers across the country. As with other synthetic cathinones, the recreational use of MDPV has resulted in death. MDPV is thought to exert its pharmacologic effects by inhibiting the reuptake of dopamine and norepinephrine. This report describes the case of an exposure of a 39-year-old male to MDPV, which resulted in his death. Postmortem concentrations of MDPV in various tissues
were measured. The detection of MDPV in tissues and fluids was accomplished using gas chromatography-mass spectrometry analysis after solid-phase extraction. Blood analysis also demonstrated therapeutic levels of lamotrigine, fluoxetine, risperidone, benztropine, pseudoephedrine and ibuprofen. The detection of cathinones in hair was conducted using high-performance liquid chromatography-tandem mass spectrometry after solid-phase extraction. MDPV was uniformly distributed among multiple tissues (blood, brain, muscle, cerebrospinal fluid and lung) at concentrations of approximately 0.4 to 0.6 microg/mL. Tissue and fluids responsible for detoxification/excretion had higher concentrations of MDPV (kidney, liver and bile > 0.8 microg/mL). A blood concentration ≥ 0.4 microg/mL was judged sufficient to cause death. The cause of death was ruled MDPV intoxication resulting in cardiac arrhythmia [13509].

It was identified six synthetic cathinones, commonly found in bath salt products, in 43 cases. Thirty-two cases will be reviewed here, including all of the postmortem cases, all of the human performance cases that had blood specimens submitted, and one urine-only human performance case. The following compounds have been confirmed: 3,4-methylenedioxy-pyrovalerone (MDPV), 3,4-methylenedioxymethcathinone (methylene), pyrovalerone, pentylone, alpha-pyrolidinopentiophenone (alpha-PVP) and methedrone. The method also screens for mephedrone, butylone and 3-fluoromethcathinone. Case demographics show 42 white males and females ranging in age from 19 to 53 years. The remaining case was that of a 34-year-old Hispanic male. The 43 cases represent 17 driving under the influence, two domestic violence, four suicides, 12 overdoses, six accidents, one drug-facilitated assault and one homicide. Data will be presented on the distribution of some of these cathinones in various matrices. After review, blood concentration does not appear to predict outcome regarding fatalities or impairment. The highest MDPV concentration occurred in a suicide by hanging and the highest methylene concentration was in a driver. The confirmation method is a liquid-liquid extraction with detection by liquid chromatography triple quadrupole mass spectrometry using electrospray ionization in multiple reaction monitoring mode [13510].

The analysis of designer drugs, including those in the synthetic cathinone and piperazine classes, may be complicated by the poor stability of these compounds in biological specimens. The stability of four of these compounds was investigated: 3,4-methylenedioxy-pyrovalerone, 4-methyl-N-methylcathinone (mephedrone), N-benzylpiperazine and 1-[3-(trifluoromethyl)phenyl]piperazine. Compound stability was monitored in three different biological matrices when each matrix was stored under three different conditions. These matrices and conditions included human whole blood, human serum and human urine, each stored at -20, 4 and 22°C for a period of 14 days in the dark in a sealed glass container. Analysis by liquid chromatography-tandem mass spectrometry was performed on Day 1 to establish the initial concentration for each drug in each specimen type, and then the samples were divided into three parts for storage under the various conditions. Analysis was performed in triplicate on Days 2, 4, 7 and 14 for each specimen type under each storage condition and the results were compared to those obtained on Day 1. Following analysis of the data, it became clear that mephedrone was not stable, and that care must be taken following specimen receipt to ensure minimal degradation [13511].

**Sudden death**

The rise in popularity of "bath salts" as safe alternatives to MDMA (3,4-methylenedioxy-methamphetamine), methamphetamine, and other illicit substances has resulted in increased scrutiny of the contents and toxicology associated with these products. It was reported a case of sudden death related to the synthetic cathinone methylene (3,4-methylenedioxy-N-methylcathinonomethyl) in a previously healthy 19-year-old man. Although several fatal case reports have been published involving methylene and other synthetic cathinones, this is
the first reported case of sudden cardiac death associated with methylone use. Although lack of published data prevented a comparison of blood methylone concentrations between the case and existing reports, the amount of methylone that was detected postmortem (0.07 mg/dL) is below those reported in MDMA-related fatalities. The report suggests that methylone toxicity has been greatly underestimated by users of this synthetic cathinone [13512].

Mephedrone

New natural and synthetic compounds are continuously introduced into the illicit drug market. Their origin, composition, main and side-effects are often not exactly known by the users themselves. Thus, the control of these substances is extremely difficult. In year 2008, a new synthetic drug called mephedrone (2-metilamino-1-(4-metilfenil) propan-1-on) appeared in Hungary (also known as: Mct, 4-MMC, MM-Cat, Meow, 4-methylmethcathinone. It was summarized its frequency in biological samples investigated for illicit drugs, and experiences of the medical examination of mephedrone-users. Toxicological analyses of biological samples (urine and/or blood) were carried out by GC-MS. Altogether 5386 samples were analyzed in 2010 (4922 in Budapest and 464 in Szeged), and mephedrone was identified in 363 cases (7 %). At present it is not sufficient experience with its long-term effects, tolerance, addiction, withdrawal symptoms or toxic dose. Thus, it is difficult to establish whether addiction and/or mental disorder occurred [11367].

To assess the patterns of use, subjective effect profile and dependence liability of mephedrone, supported by corroborative urine toxicology a cross-sectional structured telephone interview of UK-based drug users associated with the dance music scene was performed. A total of 100 mephedrone users were recruited through their involvement with the dance music scene. Assessment of pattern of use, acute and after effects, DSM dependence used criteria and gas chromatography-mass spectrometry urinalysis. Mephedrone consumption results in typical stimulant-related subjective effects: euphoria, increased concentration, talkativeness, urge to move, empathy, jaw clenching, reduced appetite and insomnia. Thirty per cent of the sample potentially met criteria for DSM-IV dependence and there was evidence of a strong compulsion to use the drug (47 % had used the drug for 2 or more consecutive days). Self-reported recent consumption of mephedrone was confirmed by toxicological analysis in all of the 14 participants who submitted a urine sample. Mephedrone has a high abuse and health risk liability, with increased tolerance, impaired control and a compulsion to use, the predominant reported dependence symptoms [11506].

One study sought to collect information on the former legal-high “mephedrone” using a web-based survey targeted at mephedrone users. The survey was advertised on websites frequented by drug users. Individuals were invited to complete the survey if they had taken mephedrone on at least one occasion in the past. One thousand and six completed forms were received from declared users, making this the largest survey on mephedrone to date. Results showed that mephedrone users consider its effects to compare best with those of MDMA, and while MDMA was considered marginally safer and its effects more pleasurable, mephedrone's appeal lay in its availability, low price and reliable purity [11507].

Mephedrone (4-methylmethcathinone) is the beta-keto analogue of 4-methylmethamphetamine. Before its control in April 2010, it became popular as a legal high in the United Kingdom, displacing methylenedioxyamphetamine as the stimulant drug of choice. The drug has stimulant and psychoactive properties, and therefore has forensic significance
in criminal and morbid toxicology. The purpose of one study was to survey casework involving the drug (impaired driving and sudden death). The cases were received in the laboratory for analysis between late 2009 and the end of 2010. Analysis of blood samples for mephedrone was conducted by liquid chromatography-mass spectrometry (LC-MS). Routine screening for alcohol and a range of other pharmaceuticals and drugs of abuse was conducted using a combination of enzyme-linked immunoassay, gas chromatography (GC) headspace, GC-MS and high-performance liquid chromatography with diode array detection. Mephedrone was detected in a total of 12 fatal cases. Most of these cases involved death by mechanical means; in two cases, death was attributed directly to mephedrone intoxication (blood concentrations of 2.1 and 1.94 mg/L). Mephedrone was detected in a total of 32 impaired driving cases. Blood concentrations ranged up to 0.74 mg/L (mean 0.21, median 0.10). The casework evidence in this study indicated that recreational use of the drug can produce blood levels as high as 0.74 mg/L, although the most common value encountered is likely to lie between 0.2 and 0.3 mg/L [13505].

“Bath salts” are stimulants with high abuse potential that are known to contain agents such as 3,4-methylenedioxypyrovalerone and 4-methylmethcathinone (mephedrone). They are marketed locally and through online retailers as legitimate products in order to evade legal control and facilitate widespread distribution. They have been present in Europe since 2007 but are now becoming a burgeoning presence in American hospitals. Though preliminary efforts are underway in the United States to restrict their usage and distribution, there remains a general unawareness on the part of physicians regarding the drugs' physiological effects. While they mimic the effects of other known stimulants, they are not detected on standard urine screens. It was presented a clinical case that illustrates a typical pattern of usage along with a description of their basic chemistry, appearance, methods of delivery, withdrawal and intoxication characteristics, treatment recommendations, and areas for further research [13506].

**Long-term effects**

The use of cathinone-derivative designer drugs methylene and mephedrone has increased rapidly in recent years. The aim of one study was to investigate the possible long-term effects of these drugs on a range of behavioral tests in mice. Further, it was investigated the long-term effects of these drugs on brain neurochemistry in both rats and mice. It was treated animals with a binge-like regimen of methylene or mephedrone (30 mg/kg, twice daily for 4 days) and, starting 2 weeks later, we performed behavioral tests of memory, anxiety and depression and measured brain levels of dopamine (DA), serotonin (5-HT), their metabolites and norepinephrine (NE). 5-HT and DA transporter (5-HTT and DAT) levels were also measured in rats by 3H-paroxetine and 3H-mazindol binding. Mephedrone reduced working memory performance in the T-maze spontaneous alternation task but did not affect neurotransmitter levels aside from a 22 percent decrease in striatal homovanillic acid (HVA) levels in mice. Methylene had little effect on behavior or neurotransmitter levels in mice but produced a widespread depletion of 5-HT and 5-HTT levels in rats. It was concluded that both methylene and mephedrone appeared to have a long-term effect on either behavioral or biochemical gauges of neurotoxicity in rodents [13507].

**A fatal case**

A death caused by a new designer drug, 4-methylmethcathinone (mephedrone), is reported. Eight small plastic bags containing white powder were found in the jacket of a young dead male. Spot tests conducted by the police officer indicated the presence of 4-bromo-2,5-dimethoxyphenethylamine (2C-B) in the powders. Laboratory routine screening analyses of blood and vitreous humor did not reveal any positive results; therefore, 2C-B was excluded.
Analysis of powders was conducted using gas chromatography-mass spectrometry and high-pressure liquid chromatography with diode array detection. The purity of mephedrone found in all powder samples was in the range of 80-87 percent. In connection with these findings, blood and vitreous humor samples were analyzed for mephedrone. Analyses were conducted using liquid chromatography-tandem mass spectrometry. Mephedrone was found in blood and vitreous humor at the concentrations of 5.5 and 7.1 µg/mL, respectively, revealing that this was a fatal mephedrone intoxication [13508].

Tuaminoheptane

Since January 2007, the list of prohibited substances established by the World Anti-Doping Agency includes the sympathomimetic compound tuaminoheptane (1-methyl-hexylamine, 2-heptylamine). Primarily used as nasal decongestant drug it has been considered relevant for sports drug testing due to its stimulating properties. A confirmatory gas chromatographic-mass spectrometric procedure was developed including liquid-liquid extraction and imine formation of tuaminoheptane employing various aldehydes and ketones such as formaldehyde, acetaldehyde, benzaldehyde and acetone. Extraction and derivatisation conditions were optimised for utmost efficiency, and characteristic fragment ions obtained after electron ionisation allowed for a sensitive and selective analytical assay, which was validated with regard to recovery (50 %), lower limit of detection (20 ng/mL) as well as interday- and intraday precision (<15 %). The applicability to authentic urine samples was demonstrated using administration study specimens obtained from two male persons using Rhinofluimucil (tuaminoheptane hemisulfate) for intranasal application. The administered drug was detected up to 46 h after repeated topical instillation of a total of approximately 3 mg [07180].

Mesocarb

The synthesis and method of analysis of hydroxylated mesocarb metabolites were described. Six potential hydroxylated mesocarb metabolites were prepared, characterized, and compared with the mesocarb metabolites synthesized enzymatically in vitro using human liver proteins and also compared with metabolites extracted from human urine after oral administration of mesocarb. p-Hydroxymesocarb was the most prevalent metabolite (conjugated and non-conjugated) observed. With respect to doping analysis, synthesis of p-hydroxymesocarb, the main urinary metabolite of mesocarb, and its availability as a reference material is important [09262].

The objective of one study was to investigate mesocarb metabolism in humans. Samples obtained after administration of mesocarb to healthy volunteers were studied. The samples were extracted at alkaline pH using ethyl acetate and salting-out effect to recover metabolites excreted free and conjugated with sulfate. A complementary procedure was applied to recover conjugates with glucuronic acid or with sulfate consisting of the extraction of the urines with XAD-2 columns previously conditioned with methanol and deionized water; the columns were then washed with water and finally eluted with methanol. In both cases, the dried extracts were reconstituted and analyzed by ultra-performance liquid chromatography-tandem mass spectrometry. Chromatographic separation was carried out using a C18 column (100 mm x 2.1 mm i.d., 1.7 microm particle size) and a mobile phase consisting of water and acetonitrile with 0.01% formic acid with gradient elution. The chromatographic system was coupled to a mass spectrometer with an electrospray ionization source working in positive mode. Metabolic experiments were performed in multiple-reaction monitoring mode by
monitoring one transition for each potential mesocarb metabolite. Mesocarb and 19 metabolites were identified in human urine, including mono-, di-, and trihydroxylated metabolites excreted free as well as conjugated with sulfate or glucuronic acid. All metabolites were detected up to 48 h after administration. The structures of most metabolites were proposed based on data from reference standards available and molecular mass and product ion mass spectra of the peaks detected. The direct detection of mesocarb metabolites conjugated with sulfate and glucuronic acid without previous hydrolysis has been described for the first time. Finally, a screening method to detect the administration of mesocarb in routine antidoping control analyses was proposed and validated based on the detection of the main mesocarb metabolites in human urine (p-hydroxymesocarb and p-hydroxymesocarb sulfate). After analysis of several blank urines, the method demonstrated to be specific. Extraction recoveries of 100 ± 1 and 106 ± 11 (n=4), and limits of detection of 0.5 and 0.1 ng/mL were obtained for p-hydroxymesocarb sulfate and p-hydroxymesocarb [10382]

**Sydnocarb**

Sydnocarb is a psychomotor stimulant structurally similar to d-amphetamine (D-AMPH) and is used in Russia for the treatment of a variety of neuropsychiatric comorbidities. The nature of sydnocarb-induced facilitation of dopamine (DA) neurotransmission (DA release versus DA transporter, DAT, inhibition) is not clear. One study characterized the pharmacological actions and behavioral effects of intraperitoneal sydnocarb in male Sprague-Dawley rats. Where relevant, comparisons were made with intraperitoneal D-AMPH. Unlike D-AMPH, which causes release of DA from rat synaptosomes, sydnocarb (up to 100 microM) did not. Sydnocarb potently blocked recombinant human DAT expressed in Chinese hamster ovary-K1 cells and less potently blocked the norepinephrine transporter. Sydnocarb at 10 microM did not bind to 64 other targets. In rats, 10 and 30 mg/kg sydnocarb showed a 2-fold longer half-life in plasma and brain and a 5-fold lower brain-to-plasma ratio compared with 0.3 and 1 mg/kg D-AMPH. In the Irwin assay, sydnocarb was well tolerated up to 30 mg/kg; D-AMPH-like stereotypic behaviors were evident at 100 mg/kg. Behavioral effects of 30 mg/kg sydnocarb and 0.3 mg/kg D-AMPH were comparable. In a sleep/wake assay, 10 mg/kg sydnocarb and 1 mg/kg D-AMPH increased wakefulness comparably; however, sydnocarb (up to 30 mg/kg) did not induce D-AMPH-like rebound hypersomnolence (RHS). Like D-AMPH, sydnocarb enhanced theta power, an electrophysiological measure of cognitive function. In conclusion, sydnocarb is a selective and potent DAT inhibitor that produces robust increases in the wake state without RHS, and with potential cognitive-enhancing properties [11219].

**Strychnine**

A simple, rapid, sensitive and low-cost method using capillary electrophoresis (CE) coupled with field-amplified sample stacking (FASS) has been developed and validated for the simultaneous determination of strychnine and brucine residues in human urine. Before sample loading, a water plug (3.5 kPa, 3 s) was injected to contain sample cations and to permit FASS. Electrokinetic injection at a voltage (20 kV, 25 s) was then used to introduce cations. Separation was performed using 20 mM acetate buffer (pH 3.8) with an applied voltage of 20 kV. The calibration curves were linear over a range of 8.00 x 10^2 ng/mL for strychnine and 10.0-3.20 x 10^2 ng/mL for brucine. Extraction recoveries in urine were greater than 80 and 83 percent for strychnine and brucine, respectively, with an RSD of less than 4.9 percent. The detection limits (signal-to-noise ratio 3) for strychnine and brucine
were 2.00 and 2.50 ng/mL, respectively. A urine sample from one healthy female volunteer (26 years old, 50 kg) was pretreated and analyzed. Strychnine and brucine levels in urine could be detected 24 h after administration. On these grounds, this method was feasible for application to preliminary screening of trace levels of abused drugs for both doping control and forensic analysis [09280].

A simple, rapid, sensitive and low-cost method using capillary electrophoresis (CE) coupled with field-amplified sample stacking (FASS) has been developed and validated for the simultaneous determination of strychnine and brucine residues in human urine. Before sample loading, a water plug (3.5 kPa, 3 s) was injected to contain sample cations and to permit FASS. Electrokinetic injection at a voltage (20 kV, 25 s) was then used to introduce cations. Separation was performed using 20 mM acetate buffer (pH 3.8) with an applied voltage of 20 kV. The calibration curves were linear over a range of 8.00-2.56 x 10^2 ng/mL for strychnine and 10.0-3.20 x 10^2 ng/mL for brucine. Extraction recoveries in urine were greater than 80 and 83 percent for strychnine and brucine. The detection limits (signal-to-noise ratio 3) for strychnine and brucine were 2.00 and 2.50 ng/mL, respectively. A urine sample from one healthy female volunteer (26 years old, 50 kg) was pretreated and analyzed. Strychnine and brucine levels in urine could be detected 24 h after administration. On these grounds, this method was feasible for application to preliminary screening of trace levels of abused drugs for both doping control and forensic analysis [10191].

Benfluorex

Benfluorex [1-(m-trifluoromethylphenyl)-2-(β-benzoyloxyethyl)aminopropane] has been widely used for the treatment of atherogenic metabolic disorders and impaired carbohydrate metabolism (particularly in obese type-II diabetic patients) as well as an anorectic drug. Due to its potentially performance-enhancing properties, benfluorex has been added to the list of prohibited compounds and methods of doping by the World Anti-Doping Agency (WADA) in 2010, necessitating the implementation of the drug as well as its major metabolites into routine doping control procedures. In one study, human urinary metabolites of benfluorex were characterized by gas chromatography-electron ionization-mass spectrometry (GC-EI-MS) as well as liquid chromatography-electrospray ionization-high resolution/high accuracy tandem mass spectrometry (LC-ESI-MS/MS). Commonly employed sports drug testing approaches consisting of liquid-liquid extraction followed by GC-MS or urine dilution and immediate LC-MS/MS analysis were expanded and validated with regard to specificity, recovery (48-54 %, GC-MS only), intra- and interday precision (<25 %), limits of detection (5-8 ng/mL for LC-MS/MS and 80 ng/mL for GC-MS), and ion suppression (for LC-ESI-MS/MS only) to allow the detection of benfluorex metabolites 1-(m-trifluoromethylphenyl)-2-(2-hydroxyethyl)aminopropane (M1), 1-(m-trifluoromethylphenyl)-2-(2-carboxymethyl)aminopropane (M2), and 1-(m-trifluoromethylphenyl)-2-aminopropane (M3) as well as the glucuronic acid conjugate of M1 [11435].

Laboratory techniques

A liquid-chromatography-tandem-mass-spectrometry method using pneumatically assisted electrospray ionisation (LC-ESI-MS/MS) was developed for the simultaneous determination of cathinone, methcathinone, ethcathinone, amfepramone, mephedrone, flephedrone, methedrone, methylene, butylone, cathine, norephedrine, ephedrine, pseudoephedrine, methylephedrine and methylpseudoephedrine in human live and post-mortem whole blood. The blood proteins were precipitated by the addition of methanol, and the extract was
purified by ultrafiltration. The separation of diastereomeric ephedrines was achieved on an ethyl-linked phenyl column. Matrix-matched calibrants combined with the isotope dilution of selected substances were used for quantitative analysis. The relative intra-laboratory reproducibility standard deviations were generally better than 7 percent at concentrations of 20 microg/L, and the mean true recoveries were 87-106 percent in the concentration range of 10-250 microg/L. The detection limits were in the range of 0.5-3 microg/L. The cathinones were unstable in whole blood and sample extracts under neutral conditions, but the stability could be improved by the acidification of the sample matrix [11194].

A novel method for the determination of propranolol hydrochlorid (PRO) in human urine was developed using capillary electrophoresis coupled with electrochemiluminescence detection (CE-ECL). The parameters that affected the separation and detection were optimized. Under the optimal conditions, the linear range for PRO was from 0.003 to 2 µg/mL and the detection limit was 1.3 ng/mL (S/N=3). The method was successfully applied to the study of the pharmacokinetics of PRO in human urine. The relative standard deviations of ECL intensity and migration time were 2.6 and 2.1 percent, respectively (1.0 µg/mL PRO, n=6). The recovery was between 97 and 97 percent. The peak excretion rate in urine was observed during the 0.5-1 h after oral administration of a 10-mg PRO tablet and the urinary excretion ratio of PRO was 14 percent within 12 h. The method was simple, rapid, economical and sensitive, and may improve the detection of PRO as a doping agent in sports [11195].

A method for the simultaneous screening and confirmation of the presence of fourteen tertiary amine stimulants in human urine by gas chromatography-mass spectrometry (GC-MS) in combination with liquid chromatography-tandem mass spectrometry (LC-MS/MS) has been developed and validated. Solid phase extraction (SPE) and liquid-liquid extraction (LLE) approaches were utilized for the pre-treatment of the urine samples. The study indicated that the capillary temperature played a significant role in the signal abundances of the protonated molecules of cropropamide and crotethamide under positive ion electrospray ionization (ESI) conditions. In addition, comparison studies of two different pre-treatment approaches as well as the two ionization modes were conducted. The LODs of the developed method for all the analytes were lower than the minimum required performance limit (MRPL) as set forth in the World Anti-Doping Agency (WADA) technical document for laboratories. The human urine sample obtained after oral administration of prolintane. HCl was successfully analyzed by the developed method, which demonstrated the applicability and reliability of
SIBUTRAMINE

Sibutramine (trade name Meridia in the US and Canada, Ectiva in South Africa, Reductil in Europe and most other countries), usually as sibutramine hydrochloride monohydrate, is an orally administered agent for the treatment of obesity, as an appetite suppressant. It is a centrally-acting serotonin-norepinephrine reuptake inhibitor structurally related to amphetamines, although its mechanism of action is distinct A method for identifying the metabolites of sibutramine 1-(4(chlorophenyl)-N,N-dimethyl-alpha-(2-methylpropyl)) cyclobutanemethanamine) in urine, utilizing a double derivatization strategy, with N-methyl-N-(trimethylsilyl)-trifluoroacetamide and N-methyl-bis-(trifluoroacetamide), in gas chromatography/mass spectrometry was proposed. This methodology results in mass spectra with at least three fragments in abundance superior to 20 percent, attending the World Anti-Doping Agency identification criteria for qualitative assays. Sibutramine was administered to five volunteers and the excretion profile followed for 92 h. Routine analytical, hydroxy-cyclobutane-bis-nor-sibutramine which becomes the more abundant metabolite in the first 10 h and hydroxy-isopropyl-bis-nor-sibutramine which becomes the most abundant after 40 h, were proposed for doping monitoring [09278].

A method for identifying the metabolites of sibutramine (Reductil®, Meridia® and Sibutrex®) 1-(4(chlorophenyl)-N,N-dimethyl-alpha-(2-methylpropyl))cyclobutanemethanamine) in urine, utilizing a double derivatization strategy, with N-methyl-N-(trimethylsilyl)-trifluoroacetamide and N-methyl-bis-(trifluoroacetamide), in gas chromatography/mass spectrometry was proposed. This methodology results in mass spectra with at least three fragments in abundance superior to 20 percent, attending the World Anti-Doping Agency identification criteria for qualitative assays. The characterization of the derivatives was obtained through two ionization modes: Chemical Ionization and Electron Impact ionization, both in full scan mode. Sibutramine was administered to 5 (five) volunteers and the excretion profile followed for 92 h. Routine analytical, hydroxy-cyclobutane-bis-nor-sibutramine which becomes the more abundant metabolite in the first 10h and hydroxy-isopropyl-bis-nor-sibutramine which becomes the most abundant after 40h, were proposed for doping monitoring [09279].

A gas chromatographic/mass spectrometric (GC/MS) study aimed at identifying the metabolites of sibutramine (1-(4-chlorophenyl)-N,N-dimethyl-alpha-(2-methylpropyl)cyclobutanemethanamine) in urine is described. Urinary excretion of sibutramine metabolites following the oral administration of a single dose of sibutramine was followed by GC/MS analysis. After identification of the chromatographic signals corresponding to the six main urinary metabolites, the fragmentation pattern was studied in electron ionization (EI) mode after derivatization to the corresponding methyl and trimethylsilyl derivatives. Urine samples were pretreated according to a reference procedure (liquid/liquid separation, enzymatic hydrolysis, pre-concentration under a stream of nitrogen and derivatization, either under thermal incubation or by microwave irradiation). All sibutramine metabolites were excreted as glucuroconjugates, and retain the chiral carbon present in the sibutramine skeleton. The metabolites identified included mono-desmethyIsibutramine (nor-sibutramine), bi-desmethyIsibutramine (nor-nor-sibutramine), and the corresponding hydroxylated compounds, the hydroxylation taking place either on the cyclobutane or on the isopropyl chain. The excretion profiles of the different metabolites were also evaluated. From an analytical point of view, the method can be applied to different fields of forensic analytical toxicology, including anti-doping analysis. Although the lack of certified reference materials does not allow a precise determination of the limits of detection (LODs) of all the sibutramine metabolites, an estimation taking into account the response factor of similar compounds ensures that all metabolites are still clearly detectable in a range of concentrations between
10 and 50 ng/mL, thus satisfying the minimum required performance limits (MRPLs) of the World Anti-Doping Agency (WADA) [07200].

Since January 2006, the list of prohibited substances established by the World Anti-Doping Agency includes the antidepressant and anti-obesity drug Sibutramine. Due to its rapid degradation to its active metabolites N-desmethyl and N-bisdesmethyl Sibutramine, reference compounds were synthesized and included into an existing screening assay to allow the unambiguous determination of these metabolic products in human urine using liquid-liquid extraction followed by liquid chromatography/tandem mass spectrometry. Characteristic product ions, obtained after electrospray ionization and collision-induced dissociation, were elucidated using high resolution/high accuracy mass measurements with a hybrid linear ion trap/orbitrap mass analyzer. Based on diagnostic product ions, the extended screening procedure was validated for both Sibutramine metabolites using a triple quadrupole mass spectrometer. Items such as lower limits of detection (6-40 ng/mL), recoveries (39-42 %), intraday precision (low: 5.5-10.6%, medium: 4.9-5.9%), high: 12.8-16.4%) and interday precision (low: 15.0-22.8 %, medium: 17.7-18.6 %), high: 16.5-25.6 %) were evaluated, and a clinical spot urine sample was analyzed to demonstrate the applicability of the developed assay in sports drug testing [06219].

Adulteration of botanical food supplements with undeclared synthetic drugs is a common problem. One of the most affected product groups are the slimming agents. There are no analytical protocols for the detection of synthetic adulterants from these products. The present study aimed at the development of a multistep analytical method for the quick and reliable determination of sibutramine, one of the most common adulterants among botanical food supplements. The extract of a sibutramine-containing slimming formula was analysed by colour tests, TLC, HPLC-DAD, MS and NMR. The multistep method proposed by the authors allows the quick identification of sibutramine in counterfeit samples in laboratories with different instrumentation [13563].

A suspected sibutramine analogue was detected in a slimming functional food by an ultra performance liquid chromatography-electrospray ionisation-time of flight mass spectrometry (UPLC-ESI-TOF/MS) method. The ultraviolet (UV) spectrum of this suspected compound showed close similarity to that of sibutramine. The sample was extracted with 70 percent MeOH and isolated by semi-preparative column chromatography. The structure of this compound was identified by spectroscopic analyses (nuclear magnetic resonance [NMR] technique, mass and tandem mass etc.). The structure of the unknown compound was demonstrated to be [([+]-dimethyl-1-[1-(3,4-dichlorophenyl)cyclobutyl]-N,N,3-trimethylbutan-1-amine (molecular formula C17H25NCl2) and named as chloro-sibutramine. Compared with sibutramine, it has one more chlorine atom than the 3-chlorophenyl group so was switched to 3,4-dichlorophenyl. Until now, chloro-sibutramine was isolated for the first time from the undeclared ingredient included in dietary supplements. Although the safety of chloro-sibutramine is unknown, there is a potential health risk to consumers because of a similar skeleton to sibutramine. For public health, this sibutramine analogue has been included in the inspection list of illegal adulterants in Korea [13564].
Asthma, a chronic inflammatory airway disorder, is one of the most frequently occurring chronic diseases. Its prevalence in adults is about 5 percent. Among athletes, however, it is assumed to be 10-20 percent. Inhaled beta-2 agonists are the drug of choice for treatment of asthma. However, beta-2 agonists are prohibited for non-asthmatic athletes according to the most recent list of prohibited substances released by the World Anti-Doping Agency (WADA). The main reason for prohibition in non-asthmatic athletes is its claimed ergogenic potential. Beta-2 agonists have received recent attention from the International Olympic Committee (IOC) and the World Anti-Doping Agency. At the 1992 Barcelona Olympic Games, two US athletes tested positive for the beta-2 agonist clenbuterol and were subsequently disqualified. Controversy at the Olympics about clenbuterol raised questions as to whether beta-2 agonists could affect muscle mass and function. Numerous studies have demonstrated that administration of some beta-2 agonists such as clenbuterol to a variety of species caused muscle growth and alteration in body composition. However, the anabolic effects of salbutamol remain equivocal. In animal studies, the anabolic effect of salbutamol on skeletal muscle was only found after intravenous administration with implanted minipumps, but never after oral administration. Oral administration of slow-release preparation of salbutamol (Volmax, Glaxo, Greenford, UK), caused increases in quadricep and hamstring muscle strength, but did not affect lean body mass in healthy men [07185].

The potential ergogenic effects of asthma medication in athletes have been controversially discussed for decades. The prevalence of asthma is higher in elite athletes than in the general population. The highest risk for developing asthmatic symptoms is found in endurance athletes and swimmers. In addition, asthma seems to be more common in winter-sport athletes. Asthmatic athletes commonly use inhaled beta2-agonists to prevent and treat asthmatic symptoms. However, beta2-agonists are prohibited according to the "Prohibited List of the World Anti-Doping Agency" (WADA). Until the end of 2009 an exception was only allowed for the substances formoterol, salbutamol, salmeterol, and terbutaline by inhalation, as long as a so-called therapeutic use exemption has been applied for and was granted by the relevant anti-doping authorities. From 2010 salbutamol and salmeterol are allowed by inhalation requiring a so called declaration of use [10166].

Respiratory symptoms in relationship to exercise, bronchial hyperresponsiveness (BHR), and exercise-induced asthma (EIA) are very common in elite winter athletes. Symptom-based screening for BHR would facilitate selection of athletes with possible EIA. The aim of one study was to evaluate the diagnostic accuracy of self-reported symptoms as predictors of BHR in an unselected population of adult elite cross-country skiers. Forty-six Swedish adult skiers competing at national or international level were included. They had a mean (SD)
training volume in the past 12 months of 593 (122) hours. Twenty-four subjects had previous physician-diagnosed asthma. The European Community Respiratory Health Survey questionnaire was used to evaluate the presence of respiratory symptoms. BHR was defined as bronchoconstriction to either eucapnic voluntary hyperventilation, dry powder mannitol or methacholine provocation. The “classical” EIA symptom of shortness of breath post-exercise was reported by 17 percent of all skiers. Eight subjects (17 %) had BHR. None of the self-reported respiratory symptoms had high positive predictive values. However, symptoms caused by grass or pollen had high negative predictive values. It was concluded that EIA in elite winter athletes cannot accurately be based only on self-reported symptoms but requires verification with objective testing of BHR. Bronchoprovocation of elite winter athletes reporting respiratory symptoms in rest or because of exercise will probably reveal a high proportion of athletes without BHR [10372].

One study was aimed at defining the prevalence of airway hyperresponsiveness (AHR) and exercise-induced bronchoconstriction (EIB) in swimmers and winter sport athletes according to the previously recommended regulatory sport agencies criteria, the relationship between respiratory symptoms and AHR/EIB, the impact of the chosen cutoff value for AHR on its prevalence, and the effect on the prevalence of the positive eucapnic voluntary hyperpnea (EVH) test of using the highest vs the lowest spirometric post-EVH values to calculate the magnitude of the airway response. It was compared the prevalence of respiratory symptoms with responses to methacholine challenge and EVH in 45 swimmers, 45 winter sport athletes, and 30 controls. Two methacholine challenge cutoffs for AHR were analyzed: < 4 mg/mL (the sport agencies' criteria for AHR) and < 16 mg/mL. Sixty percent of swimmers, 29 percent of winter sport athletes, and 17 percent of controls had evidence of EIB or AHR (with the < 4 mg/mL criteria). Among athletes with a methacholine provocative concentration inducing a 20% decrease in the FEV₁ between 4 and 16 mg/mL, 43 percent of swimmers and 100 percent of winter sport athletes were symptomatic. Prevalence of positive EVH tests were 39 percent in swimmers, 24 percent in winter sport athletes, and 13 percent in controls when the highest FEV₁ value measured at each time point post-EVH was used to identify maximal response for calculation of airway response, although these prevalences were higher if we used the lowest value. This study suggests that AHR/EIB is frequent in swimmers, whereas the frequently reported respiratory symptoms in winter sport athletes are often not related to AHR/EIB. Furthermore, the choice of methods for assessing methacholine challenge and EVH responses influences the prevalences of airway hyperresponsiveness and exercise-induced bronchoconstriction [10373].

The International Olympic Committee-Medical Commission (IOC-MC) accepts a number of bronchial provocation tests for the diagnosis of exercise-induced bronchoconstriction (EIB) in elite athletes, none of which have been studied in elite swimmers. With the suggestion of a different pathogenesis involved in the development of EIB in swimmers, there is a possibility that the recommended test for EIB in elite athletes, the eucapnic voluntary hyperpnoea (EVH) challenge, may be missing the diagnosis in elite swimmers. The aim of one study was to assess the effectiveness of the EVH challenge, the field swim challenge and the laboratory cycle challenge in the diagnosis of EIB in elite swimmers. Thirty-three elite swimmers were evaluated on separate days for the presence of EIB using three different bronchial provocation challenge tests: an 8 minute field swim challenge, a 6 minute laboratory EVH challenge, and an 8 minute laboratory cycle challenge. It was decided that a fall in FEV₁ from baseline of ≥ 10 percent post challenge was diagnostic of EIB. Only 1 of the 33 subjects (3 %) had a positive field swim challenge with a fall in FEV₁ of 16 percent from baseline. Eighteen of the 33 subjects (55 %) had a positive EVH challenge, with a mean fall in FEV₁ of 20 (SD 12) percent from baseline. Four of the subjects (12 %) had a positive laboratory cycle challenge, with a mean fall in FEV₁ of 15 ± 5 percent from baseline. Only 1 of the 33 subjects was positive to all 3 challenges. These results suggest that the EVH challenge is a highly
sensitive challenge for identifying EIB in elite swimmers, in contrast to the laboratory and field-based exercise challenge tests, which significantly underdiagnose the condition. The EVH challenge, a well-established and standardised test for EIB in elite winter and summer land-based athletes, should thus be used for the diagnosis of EIB in elite swimmers, as recommended by the IOC-MC [10374].

Two groups of substances which stimulate the adrenergic system are listed as prohibited by the World Anti-Doping Agency. Stimulants are prohibited in-competition only and beta2-agonists are prohibited in- and out-of-competition. While beta2-agonists act directly on the target receptors, sympathomimetic amines can exert their action directly and indirectly. Due to differences in pharmacology but mainly due to differences in administered dose, differences in detection methods between both groups of substances exist although preparation is similar and consists of an extraction at basic pH. Gas chromatography coupled to mass spectrometry has been the detection methodology of choice for several decades. However, the importance of liquid chromatography-mass spectrometry as a preferred detection methodology is rapidly increasing, especially for the detection of beta2-agonists and new stimulants [10168].

Beta-2 Agonists bronchodilators (salbutamol, salmeterol, formoterol and terbutaline), as well as inhaled corticoids, are prohibited in sports unless the participant follows the procedure known as Therapeutic Use Exemption (TUE). An abbreviated form (ATUE) was accepted until December 2008, but a revised version of International Standard for TUE (approved by the World Anti-Doping Agency (WADA) Executive Committee on 10 May 2008) came into effect on 1 January 2009. In this version, the concept of an ATUE has been abolished. With the abbreviated form, the athlete could start (or continue) the treatment while the formal process was in progress (taking into account that this process used to be very long), while with the standard form, treatment can only start after receiving the authorisation notice. It is the International Olympic Committee Medical Commission who established the criteria for accepting the use of inhaled beta-2 agonists late in 2001 for the Salt Lake City Winter Olympic Games. Due to the success of its application, these criteria were renewed in January 2004 for the Athens Summer Olympic Games and assumed by WADA. These criteria require an athlete to prove the existence of bronchial hyper-responsiveness and the measures of forced expiratory volume in 1 s (FEV1) at rest, as well as changes in FEV1 in response to either an inhaled bronchodilator or to a bronchial provocation test. These are the essential criteria that must be completed on the TUE form for β-2 agonists. To review the methacholine tests performed in our laboratory up until 2008, to compare them with previously reported data in 2006, and to examine if the anti-doping rules are meeting the needs of asthmatic athletes who really need bronchodilator treatment 89 high-level athletes were examined in laboratory in order to obtain an abbreviated therapeutic use exemption for beta-2 agonists between 2004 and 2008. Of these, 50 men (23 years) and 23 women (21 years) performed a methacholine inhalation test with increasing concentrations of methacholine (0.025, 0.25, 2.5, 5, 10 and 25 mg/ml) until a fall of 20 percent in forced expiratory volume in 1 s (FEV1) was achieved. Thirty-one candidates (43 %) had a provocative concentration causing a 20 percent fall in FEV1 (PC20) <2 mg/ml; 12 (16 %) were between 2 and 4 mg/ml; 8 (11 %) between 4.1 and 8 mg/ml and 22 candidates (30 %) had a PC20 >8 mg/ml. Seven of the 73 candidates had an obstructive pattern in the spirometry at rest, demonstrated by a FEV1% <70 % but with a FEV1 >70 % of the reference value. It was concluded that the anti-doping regulations with respect to beta-2 agonists need to be reviewed, and measures should be adopted to include a fall of 70 percent in FEV1% as an obstruction criterion to indicate a bronchodilation test and to extend the criterion for a positive methacholine test to a PC20 of 8 mg/ml [11361].

Asthma, a chronic inflammatory disorder of the airways is associated with variable
obstruction to the airways and is provoked by many triggers including exercise. The management of asthma is primarily pharmacological, but exercise, despite causing bronchoconstriction in almost all asthmatics, is an important adjunct to treatment. With adequate control of the hyperresponsive airways obtained with inhaled corticosteroids (ICS) and inhaled beta 2 agonists (IBA), used as both a pre-exercise preventive agent and a reliever if necessary, all asthmatics should benefit from an exercise program. Some have realised this benefit with such success as to become Olympic and world champions in many sports. Exercise programs should be individually tailored, follow established guidelines and result in similar benefits to those obtained by non-asthmatics. However asthmatics must try to avoid or minimise triggers whenever possible. A specific benefit of a physical training program is that it allows asthmatics to exercise with less bronchoconstriction at the same exercise stress, although it does not abolish or reduce airway hyper responsiveness (AHR) [11362].

In COPD, improvements in lung mechanics following bronchodilator, measured using the forced oscillation technique (FOT), are more sensitive than spirometry at detecting improvement in lung function following bronchodilator. The relationship between these improvements in lung mechanics and improvements in functional outcomes, such as exertional dyspnoea, following bronchodilator, in COPD is unknown. Seventeen COPD subjects were recruited into a double blind placebo controlled randomised cross over study. Dyspnoea was induced using a standardised six-minute walk test (6 MWT), and measured by Borg score throughout the test. Measurement of respiratory system conductance, respiratory system reactance, inspiratory capacity and spirometry were made at baseline and 1 h after a single dose of either 18 microg of tiotropium bromide plus 200 microg salbutamol, or placebo. Subjects had a mean baseline FEV1 of 46 ± 11 percent predicted. The bronchodilator induced reduction in exertional dyspnoea correlated significantly with the increase in respiratory system conductance and approached significance with FEV1 but not with FVC, respiratory system reactance or inspiratory capacity. Increase in respiratory system conductance was the best and sole predictor of reduction in exertional dyspnoea, explaining 41 percent of the variance. There was no additional contribution to the model from the increase in FEV1 or inspiratory capacity. It was concluded that bronchodilator induced improvements in exertional dyspnoea in moderate to severe COPD are predicted by improvements in respiratory system conductance, measured by FOT, independent of improvements in spirometry or hyperinflation. The findings suggest that FOT may be useful for measuring response to bronchodilator in COPD [11363].

For the past 40 years, beta-blockers have been widely used in cardiovascular medicine, reducing morbidity as well as mortality. Beta-blockers are currently used in a number of cardiovascular conditions such as systolic heart failure, postmyocardial infarction, and in prevention and treatment of arrhythmias. They are not recommended as the first line antihypertensive therapy, particularly in the elderly, unless there are specific indications. Despite the benefits of beta-blockers, tolerability concerns in patients with co-morbidities have limited their use. Some of these problems were overcome with the discovery of cardioselective beta-blockers. The third generation beta-blockers have additional properties of vasodilatation and advantages in terms of minimizing the adverse effects of beta-blockers. Some of the advantages include improvement of insulin resistance, decrease in cholesterol as well as alleviation of erectile dysfunction. Acute treatment with beta-blockers modifies local muscular metabolic properties and impairs endurance exercise capacity whereas the influence of chronic is debated controversially [13403].

Beta2-adrenergic agonists, or beta2-agonists, are considered essential bronchodilator drugs in the treatment of bronchial asthma, both as symptom-relievers and, in combination with inhaled corticosteroids, as disease-controllers. The use of beta2-agonists is prohibited in
sports by the World Anti-Doping Agency (WADA) due to claimed anabolic effects, and also, is prohibited as growth promoters in cattle fattening in the European Union. One paper reviewed the last seven-year (2006-2012) literature concerning the development of novel beta2-agonists molecules either by modifying the molecule of known beta2-agonists or by introducing moieties producing indole-, adamantyl- or phenyl urea derivatives. New emerging beta2-agonists molecules for future therapeutic use are also presented, intending to emphasize their potential use for doping purposes or as growth promoters in the near future.

Impact of WADA regulations

To investigate how changes to the World Anti-Doping Agency (WADA) guidelines on asthma medication requests have impacted the management of asthmatic athletes in Portugal a retrospective analysis of asthma medication requests submitted in 2008 to 2010 was performed. Yearly changes in number of asthma medication requests and diagnostic procedures was analyzed in 326 requests: 173 abbreviated Therapeutic Use Exemptions (TUEs) in 2008 (objective tests not required), 9 Declaration of Use (DoU) and 76 TUEs in 2009, and 39 DoU and 29 TUEs in 2010. Spirometry was performed in 87 and 37 percent of athletes in 2009 and 2010, respectively; the corresponding figures for bronchoprovocation were 59 and 16 percent, almost all positive in both years. Applications for inhaler use have decreased by approximately half since objective asthma testing became mandatory. The findings show that WADA guidelines have an impact on asthmatic athletes care: In 2009 a more rigorous screening was possible, leading to withdrawal of unnecessary medication. Constant changes, however, jeopardize this achievement and nowadays introduce safety issues stemming from the unsupervised use of inhaled beta2-agonists.

Finland

The class of beta2-agonists has been subject of numerous studies related to sports drug testing. In Finland, a considerable increase in using asthma medications (including corticosteroids and beta2-agonists) was recognized over the last few years; however, the increase was observed among elite athletes only and not the general public. The reason(s) for this are yet unclear and might not or not entirely be due to assumed performance-enhancing effects in the light of recent data indicating no improvement in aerobic capacity or oxygen intake in endurance-trained athletes having received supra-therapeutic doses of inhaled salbutamol. Nevertheless, it was questioned how especially exercise-induced asthma in elite athletes is to be managed and treated, concluding that individual therapies as with any non-elite athlete are recommended, starting with actions preventing inflammatory response of lung tissue (e.g. heat masks for winter sport) and combined beta2-agonist and corticosteroid treatment. In order to enable high-profile athletes, being subject of doping controls, the adequate therapy for bronchoconstriction, WADA's Prohibited List allows the use of selected beta2-agonists up to defined amounts (and resulting urinary threshold levels) with limitations concerning the route of administration.

Therapy or doping?

Asthma, exercise-induced bronchoconstriction, and airway hyper-responsiveness are often found in elite athletes, perhaps as a consequence of their sport or maybe because asthma is a common disorder in young adults. Inhaled beta2-agonists (IBA) are frequently used in elite
athletes, but due to regulations introduced by the International Olympic Committee, the use of anti-asthmatic therapy might change. Drugs that make ergogenic effect persist are prohibited in all athletes, whether or not they take part in competitions and systemic steroids and beta₂-agonists are among such drugs. On the other hand, opinion is more divided about the use of inhaled corticosteroids (ICS) and IBA. In humans, no effect has been found on the oxygen uptake, performance or distance run with therapeutic doses of IBA, either in asthmatics or non-asthmatics, whereas others report an ergogenic effect and better lung function of high doses of a beta₂-agonist in non-asthmatics. Anti-asthmatic treatment is necessary for asthmatics, but should not be used by non-asthmatic elite athletes due to both possible systemic effects and furthermore, side effects of both ICS and IBA [07186].

**Improves swim ergometer sprint performance?**

There is a high prevalence of asthma and airway hyperresponsiveness (AHR) in elite athletes, which leads to a major use of beta₂-agonists. In a randomized double-blinded crossover study, it was investigated the effects of combined inhalation of beta₂-agonists (salbutamol, formoterol, and salmeterol), in permitted doses within the World Anti-Doping Agency 2013 prohibited list, in elite swimmers with (AHR, n=13) or without (non-AHR, n=17) AHR. Maximal voluntary isometric contraction of m. quadriceps (MVC), sprint performance on a swim ergometer and performance in an exhaustive swim test at 110% of VO₂max were determined. Venous plasma interleukin-6 (IL-6) and interleukin-8 (IL-8) were measured post-exercise. No improvement was observed in the exhaustive swim test, but swim ergometer sprint time was improved in both groups from 57 ± 1.7 to 56 ± 1.8 s in AHR and 58.3 ± 1 to 57.4 ± 1 s in non-AHR. MVC and post-exercise plasma IL-6 increased with beta₂-agonists in both groups, whereas IL-8 only increased in AHR. In summary, inhalation of beta₂-agonists, in permitted doses, did not improve swim performance in elite swimmers. However, swim ergometer sprint performance and MVC were increased, which should be considered when making future anti-doping regulations [13406].

**Doping efficiency of beta₂-agonists**

The question whether beta-2-agonists (or beta₂-agonists) should be considered performance-enhancing or not has not yet been answered. A meta-analysis was conducted aiming for the assessment of the effects of beta₂-agonists on physical performance in healthy, non-asthmatic subjects when administered either via inhalation or systemically. Considering scientific data published up to August 2009, a total of 26 studies concerning inhaled beta₂-agonists was evaluated and no significant effects on endurance, strength or sprint performance in healthy athletes were observed. With systemically administered salbutamol (predominantly orally), endurance time to exhaustion (at 80-85% VO₂(max)) was found to be significantly increased while the same parameter at 70 percent VO₂(max) together with two additional recorded parameters including VO₂(max) and power output at 90 percent VO₂(max) were not influenced. Overall, the advantageous effect of beta₂-agonists on the performance of healthy athletes was considered modest. The controversy concerning the general use of beta₂-agonists in cases of exercise-induced asthma was further kindled by suggestions to substitute these therapeutics by inhaled corticosteroids in acute situations [12016].

**Physiology**

Traditional views of the determinants of physical performance in healthy individuals
document the importance of oxygen transport to the working skeletal muscles. It is also viewed that the capacity of the pulmonary system (respiratory muscles, airways and lung parenchyma) is more than adequate to meet the demands for ventilation and gas exchange. However, in top athletes, years of training have increased the capacity of cardiac and skeletal muscles to deliver and use oxygen such that the demands placed on the airways, chest wall and alveoli to maintain gas exchange cannot be met. During heavy exercise at sea level, in many healthy, highly trained endurance athletes, arterial oxygen concentration can fall precipitously from normal levels to values seen in patients with chronic obstructive lung disease. This is reflected in the development of exercise-induced arterial hypoxemia, which occurs transiently in about 50 percent of athletes during peak exercise [08323].

Changes in exercise-induced arterial hypoxemia have a measurable effect on maximal aerobic capacity in highly trained athletes. On average, the effect is about a 1 percent decrement in maximal aerobic capacity for each 1 percent decrement in percent arterial oxygen saturation [696]. It has also been shown that these athletes experience the greatest decrement in aerobic capacity when they perform in hypoxic environments. Even relatively small changes in altitude (about 1000 m), which does not effect arterial oxygen saturation or maximal aerobic capacity appreciably in untrained individuals, produces substantial hypoxemia at the high work rates achieved by elite athletes. This results in significant decrements in both aerobic power and endurance performance [08324, 08325].

As a result of years of training elite athletes often experience intra-and extrathoracic respiratory problems and may also experience expiratory flow limitation. The most difficult respiratory problem to treat in this population may be the sudden paradoxical narrowing of the glottis, usually a manifestation of vocal cord dysfunction. Inspiratory stridor is an important differentiating symptom. The reported prevalence among athletes competing outdoors is 8.3 percent. Vocal cord dysfunction usually occurs during very heavy exercise, when the inspiratory flow rates are extreme. This condition immediately results in dyspnea, hypoxemia, retention of carbon dioxide and compromised performance. Treatment is not easy because it often involves a variety of therapies and modification of activity. Approaches that may be considered include the management of any associated conditions (e.g. gastroesophageal reflux disease) as well as speech and relaxation therapy. Other treatments that have been used include Botox injections, inhalation of heliox (21 % oxygen in helium) and training of the respiratory muscles and breathing mechanics with a resistive device [08326].

Respiratory symptoms cannot be relied on to make a diagnosis of asthma and airways hyperresponsiveness (AHR) in elite athletes. For this reason, the diagnosis should be confirmed with bronchial provocation tests. Asthma management in elite athletes should follow established treatment guidelines (e.g. “Global Initiative for Asthma”) and should include education, an individually tailored treatment plan, minimization of aggravating environmental factors, and appropriate drug therapy that must meet the requirements of the World Anti-Doping Agency. Asthma control can usually be achieved with inhaled corticosteroids and inhaled beta2-agonists to minimize exercise-induced bronchoconstriction and to treat intermittent symptoms. The rapid development of tachyphylaxis to beta2-agonists after regular daily use poses a dilemma for athletes. Long-term intense endurance training, particularly in unfavorable environmental conditions, appears to be associated with an increased risk of developing asthma and airways hyperresponsiveness in elite athletes. Globally, the prevalence of asthma, exercise-induced bronchoconstriction, and AHR in Olympic athletes reflects the known prevalence of asthma symptoms in each country. The policy of requiring Olympic athletes to demonstrate the presence of asthma, exercise-induced bronchoconstriction, or AHR to be approved to inhale beta2-agonists will continue [08327].
In general, the airways are capable of meeting the respiratory demands of heavy work within the limits of the normal maximal flow volume loop. However, in some athletes, the increase in minute ventilation may cause a portion of the tidal breathing loop to intersect with the maximal flow volume loop. This expiratory flow limitation and may be present because of the substantial demand on the pulmonary system with intense exercise. Trained female athletes may be particularly susceptible to expiratory flow limitation because their airways are smaller in diameter, they have lower peak flow rates and their lung volumes are smaller than those of their male counterparts [08328]. Expiratory flow limitation may influence performance by contributing to exercise-induced arterial hypoxemia and by increasing the work of breathing at the expense of meeting the metabolic needs of working skeletal muscles [08309].

Asthma and sympathomimetica

The prevalence of asthma and bronchial hyper-responsiveness is greater in elite athletes than in the general population, and its association with mild airway inflammation has recently been reported. To study the relationship between the type of sport practised at the highest levels of competition (on land or in water) and sputum induction cell counts in a group of healthy people and people with asthma 50 athletes were enrolled. Medical history, results of methacholine challenge tests and sputum induced by hypertonic saline were analysed. Full results were available for 43 athletes, who were classified by asthma diagnosis and type of sport (land or water sports). Nineteen were healthy (10 land and 9 water athletes) and 24 had asthma (13 land and 11 water athletes). Although the eosinophil counts of healthy people and people with asthma were significantly different (mean difference 3.1%, 95% confidence interval 0.4 to 6.2), analysis of variance showed no effect on eosinophil count for either diagnosis of asthma or type of sport. However, an effect was found for neutrophil counts. There was also a significant correlation between neutrophil counts and both duration of training and bronchial hyper-responsiveness among athletes exposed to water. It was concluded that elite athletes who practice water sports have mild neutrophilic inflammation, whether or not asthma is present, related to the degree of bronchial hyper-reactivity and the duration of training in pool water [07187].

In asthmatic subjects, either bronchodilatation or bronchoconstriction may develop during exercise. It was studied two groups of asthmatic subjects with baseline mild-to-moderate airflow obstruction with the aims to quantify the bronchodilator effect of incremental maximum exercise hyperpnea in comparison with inhaled albuterol, to assess the impact of this effect on airway response to prolonged constant-load exercise, and to evaluate if the bronchodilator effects of exercise and albuterol are additive. Changes in airway caliber were measured by changes in partial forced expiratory flow. Incremental-load exercise was associated with a bronchodilatation that was similar to that obtainable with 400 microg of albuterol but about 60 percent of the maximal bronchodilatation obtainable with 1,500 microg albuterol. Constant-load exercise was associated with an initial moderate bronchodilatation, which was followed by airway re-narrowing. With both exercise protocols, premedication with inhaled albuterol (400 microg) promoted sustained bronchodilatation during exercise, which was additive to that caused by exercise hyperpnea. In conclusion, the data show that exercise hyperpnea has a potent bronchodilator effect, but less that inhaled albuterol. This effect seems to contribute to delay the development of exercise-induced bronchoconstriction and is additive with that of albuterol [09235].

The aim of one study was to identify the prevalence of allergic disease in young soccer players compared to age-matched students and to evaluate if this prevalence changes as the
intensity of training increases. A modified ECRHS questionnaire was administered to 194 soccer players divided by age as "beginners" (8-11 years), "juniors" (12-16 years) and "under 21" (17-20 years) to evaluate the prevalence of allergic diseases and symptoms as well as drug consumption. Subjects with a positive personal history of allergic diseases underwent skin prick and/or patch tests. Age-matched students (n=136) were used as a control group. The prevalence of allergic diseases was 35 percent in soccer players and 32 percent in control subjects. Skin sensitization to inhalant allergens was detected in 14 percent of symptomatic soccer players and in 19 percent of control students. Patch tests were positive in 36 percent of soccer players and 23 percent of controls with allergic dermatitis. The prevalence of allergic diseases did not significantly change in relation to the intensity of training. Although the relative prevalence of sensitization to perennial allergens and asthma was less frequent in soccer players than in controls, and the occurrence of exercise-induced bronchoconstriction was similar in the two groups, soccer players used twice as many anti-allergic and anti-asthmatic drugs as control students. The authors concluded that increasingly intensive training programme is not associated with greater risk of allergic disease in soccer players. Therapy regimens of allergic athletes and exercisers should be monitored more closely to guarantee adequate treatment yet avoid inappropriate drug use and doping practices [09236].

Approximately 10 to 50 percent of competitive athletes experience asthma symptoms with exercise, due to either chronic asthma or exercise-induced bronchospasm. Early recognition and management of asthma symptoms may improve athletic performance and quality of life for athletes with asthma or exercise-induced bronchospasm. Athletic trainers may have frequent opportunities to identify asthma symptoms and assist athletes with management. To survey athletic trainers about their experience and comfort with evaluation and management of asthma symptoms in athletes and identify athletic trainer characteristics associated with higher comfort levels a questionnaire was sent to athletic trainers web-based. Response rate was 14 percent (304 of 2,175). At least 23 percent of respondents evaluated asthma symptoms five or more times the previous year. Respondents working exclusively with junior high and/or high school athletes evaluated asthma symptoms more frequently than those working exclusively with college and/or professional athletes. Fifty-eight percent of respondents were unsatisfied with their asthma education. Only 25 percent were "very" comfortable managing asthma. Respondents with higher comfort levels evaluated asthma symptoms more frequently and were more likely to be satisfied with their asthma education. Over 95 percent of respondents endorsed more asthma education in athletic training curricula. Results of this pilot study indicate that athletic trainers have opportunities to help athletes manage asthma symptoms that can compromise athletic performance or limit sports participation. However, few athletic trainers are very comfortable managing asthma, and most are unsatisfied with their asthma education [09237].

The aim of one study was to investigate the prevalence of asthma with or without exercise induced symptoms among elite and elite aspiring swimmers and to compare sport specific exercise provocation with mannitol provocation. 101 adolescent swimmers were investigated with mannitol provocation and sport specific exercise challenge test. Mannitol positivity was defined as either direct FEV₁ PD15 (ordinary criteria) or as beta₂-reversibility ≥15 percent after challenge (extended criteria). A direct positive exercise test was defined as a drop in FEV₁ of 10 percent (ordinary criteria) or a difference in FEV of ≥15 percent either spontaneous, variability, or with beta₂-agonist, reversibility (extended criteria). It was found a high prevalence of mannitol and/or exercise positivity. Twenty-six swimmers were mannitol direct positive and 14 were direct exercise positive using ordinary criteria. Using extended criteria 43 were mannitol positive and 24 were exercise positive. When including reversibility and variability to define a positive test the sensitivity for current asthma with or without exercise induced symptoms increased while the specificity remained roughly unchanged.
Direct positivity for mannitol and exercise poorly overlapped using ordinary criteria but improved using extended criteria. Thus, the use of variability and reversibility (liability) as additional criteria to define a positive test provided to our mind relevant information and should be considered [11479].

Athletes active in endurance sports are at an increased risk of acquiring asthma through their sports activities, especially so for cross-country skiers, biathlon skiers, swimmers and athletes of other endurance sports. Asthma may be present from early childhood or develop while in active sports. This article focuses on the physical activity and sports activities in children and adolescents. Exercise-induced asthma (EIA) is found in 8-10 percent of a normal child population of school age and in about 35 percent of children with current asthma. EIA is caused by the markedly increased ventilation during exercise, with increased heat and water loss through respiration, leading to bronchial constriction. The risk of developing asthma in the young athlete is related to the repeated daily training activity with increased epithelial damage of the airways, delayed repair due to the daily repetition of the training and increased airway mucosal inflammation. The increased environmental exposure through the sports activity to environmental agents, such as cold, dry air in skiers and chlorine compounds in swimmers, increases symptoms and signs of asthma and bronchial hyper-responsiveness, either worsening an existing asthma or leading to a novel disease in a previously healthy athlete. Several specific aspects of daily training life, environmental exposure, diagnostic procedures and aspects of treatment related to the regulations of medication use in sports need particular attention when addressing the adolescent athlete with respiratory symptoms [11480].

It was postulated that high level swimming can promote airway inflammation and thus asthma by enhancing local vascular permeability. It was aimed to test this hypothesis by a cross-sectional study comparing swimmers (n=13, 17 ± 3 years, competing 7 ± 4 years, training 18 ± 3 h per week), asthmatic-swimmers (n=6, 17 ± 2 years, competing 8 ± 3 years, training 16 ± 4 h per week), and asthmatics (n=19, 14 ± 3 years). Subjects performed induced sputum and had exhaled nitric oxide, lung volumes, and airway responsiveness determined. Airway vascular permeability index was defined as the ratio of albumin in sputum and serum. Results from the multiple linear regression showed each unit change in airway vascular permeability index was associated with an increase of 0.97 percent in sputum eosinophilis, and of 2.64 percent in sputum neutrophils after adjustment for confounders. In a general linear model no significant differences between airway vascular permeability between index study groups existed, after controlling for sputum eosinophilis and neutrophils. In conclusion, competitive swimmers training in chlorine-rich pools have similar levels of airway vascular permeability than asthmatics. Although competitive swimming has been associated with asthma, airway inflammation and airway hyperresponsiveness do not seem to be dependent on increased airway vascular permeability [11481].

One article reviewed the diagnostic challenge methods-both exercise and surrogate for diagnosis of exercise-induced bronchoconstriction (EIB) and EIB with known asthma. Indirect challenges that release the entire repertoire of mediators representative of EIB and asthma are more specific for diagnosis and are recommended over direct challenges such as methacholine challenge, which are sensitive but nonspecific. Self-reported history and empiric therapeutic trials are not adequate for diagnosis of EIB with or without known asthma. Objective pulmonary function documentation with bronchodilator reversibility or exercise or surrogate challenge are optimal for diagnosis of EIB or EIB with known asthma. Such objective pulmonary function documentation is optimal for the proper management and healthy lifestyle of the exercising athlete or individual [11482].
Elite athletes, particularly those engaged in endurance sports and those exposed chronically to airborne pollutants/irritants or allergens, are at increased risk for upper and lower airway dysfunction. Airway epithelial injury may be caused by dehydration and physical stress applied to the airways during severe exercise hyperpnoea and/or by inhalation of noxious agents. This is thought to initiate an inflammatory cascade/repair process that, ultimately, could lead to airway hyperresponsiveness (AHR) and asthma in susceptible athletes. The authors review the evidence relating to prevention or reduction of the risk of AHR/asthma development. Appropriate measures should be implemented when athletes exercise strenuously in an attempt to attenuate the dehydration stress and reduce the exposure to noxious airborne agents. Environmental interventions are the most important. Non-pharmacological strategies can assist, but currently, pharmacological measures have not been demonstrated to be effective. Whether early prevention of airway injury in elite athletes can prevent or reduce progression to AHR/asthma remains to be established [12304].

**Definition of asthma in sports**

To investigate how changes to the World Anti-Doping Agency (WADA) guidelines on asthma medication requests have impacted the management of asthmatic athletes in Portugal. It was made a retrospective analysis of asthma medication requests submitted in 2008 to 2010 of athletes requesting the use of inhaled corticosteroids and/or beta2-agonists. It was analyzed 326 requests: 173 abbreviated Therapeutic Use Exemptions in 2008 (objective tests not required), 9 Declaration of Use (DoU) and 76 Therapeutic Use Exemptions (TUEs) in 2009, and 39 DoU and 29 TUEs in 2010. Spirometry was performed in 87 and 37 percent of athletes in 2009 and 2010, respectively; the corresponding figures for bronchoprovocation were 59 percent and 16 percent, almost all positive in both years. It was concluded that applications for inhaler use have decreased by approximately half since objective asthma testing became mandatory. The findings show that WADA guidelines have an impact on asthmatic athletes care: In 2009 a more rigorous screening was possible, leading to withdrawal of unnecessary medication. Constant changes, however, jeopardize this achievement and nowadays introduce safety issues stemming from the unsupervised use of inhaled beta2-agonists [12303].

**Extended diagnostic criteria**

The aim of one study was to investigate the prevalence of asthma with or without exercise induced symptoms among elite and elite aspiring swimmers and to compare sport specific exercise provocation with mannitol provocation. 101 adolescent swimmers were investigated with mannitol provocation and sport specific exercise challenge test. Mannitol positivity was defined as either direct FEV$_1$ PD15 (ordinary criteria) or as beta$_2$-reversibility ≥15 percent after challenge (extended criteria). A direct positive exercise test was defined as a drop in FEV$_1$ of 10 percent (ordinary criteria) or a difference in FEV of ≥15 percent either spontaneous, variability, or with beta$_2$-agonist, reversibility (extended criteria). It was found a high prevalence of mannitol and/or exercise positivity. Twenty-six swimmers were mannitol direct positive and 14 were direct exercise positive using ordinary criteria. Using extended criteria 43 were mannitol positive and 24 were exercise positive. When including reversibility and variability to define a positive test the sensitivity for current asthma with or without exercise induced symptoms increased while the specificity remained roughly unchanged. Direct positivity for mannitol and exercise poorly overlapped using ordinary criteria but improved using extended criteria. It was found a high prevalence of asthma among elite swimmers. The use of variability and reversibility (liability) as additional criteria to define a positive test provided to our mind relevant information and should be considered [12305].
Diagnosis of asthma

To review the methacholine tests performed in a laboratory up until 2008, to compare them with previously reported data in 2006, and to examine if the anti-doping rules are meeting the needs of asthmatic athletes who really need bronchodilator treatment a study was performed between 2004 and 2008 of 89 high-level athletes who were examined in the laboratory in order to obtain an abbreviated therapeutic use exemption for beta-2 agonists. Of these, 50 men (23 years) and 23 women (21 years) performed a methacholine inhalation test with increasing concentrations of methacholine (0.025, 0.25, 2.5, 5, 10 and 25 mg/mL) until a fall of 20 percent in forced expiratory volume in 1 s (FEV\textsubscript{1}) was achieved. Thirty-one candidates (43 %) had a provocative concentration causing a 20 percent fall in FEV\textsubscript{1}, PC\textsubscript{20} <2 mg/ml; 12 (16 %) were between 2 and 4 mg/ml; 8 (11 %) between 4.1 and 8 mg/ml and 22 candidates (30 %) had a PC\textsubscript{20} >8 mg/ml. Seven of the 73 candidates had an obstructive pattern in the spirometry at rest, demonstrated by a FEV\textsubscript{1}% <70 percent but with a FEV\textsubscript{1}>70 percent of the reference value. It was concluded that the anti-doping regulations with respect to beta-2 agonists need to be reviewed, and measures should be adopted to include a fall of 70 percent in FEV\textsubscript{1}% as an obstruction criterion to indicate a bronchodilation test and to extend the criterion for a positive methacholine test to a PC\textsubscript{20} of 8 mg/ml [10172].

How should bronchial hyperreactivity be defined?

The regulations for doping control prohibit the use of beta\textsubscript{2}-agonist bronchodilators (salbutamol, salmeterol, formoterol, and terbutaline) unless the subject follows the procedure known as abbreviated therapeutic use exemption (ATUE). To highlight how the interest in discovering possible cheats may result in damage to athletes who really need bronchodilator treatment 31 high level athletes (18 men and 13 women) with a previous diagnosis of asthma were examined in our laboratory in order to obtain an ATUE for beta\textsubscript{2}-agonist. All the subjects underwent spirometry at rest. If the results were normal, the subjects underwent an effort test and, if negative, a methacholine test inhaling progressive doses of methacholine until a fall of 20 percent in forced expiratory volume in one second (FEV1) was achieved. The international anti-doping regulations require that the fall in FEV1 occurs with a concentration of methacholine (PC20) lower than 2 mg/mL (4 mg/mL for Torino 2006). In clinical practice, a test is positive if the response occurs with a PC20 lower than 8 mg/mL. Only one subject met the criterion for the bronchodilation test at rest. The remaining 30 athletes underwent an effort test, which was positive in nine of them. In 21 cases (13 men and 8 women) the effort test was negative so a methacholine test was carried out. Seven (33 %) were negative for ATUE with a PC20 higher than 8 mg/ml, seven (33 %) were positive for ATUE with a PC20 less than 2 mg/mL, in four (19 %) the PC20 was 2-4 mg/mL, and in three (14 %) it was 4-8 mg/mL. Thus, strict vigilance of fair play should be pursued, but excessive control can lead to situations of inequality for asthmatic athletes such that a third of athletes cannot be treated with beta\textsubscript{2}-agonist. Therefore under current regulations, asthmatic athletes are often denied the most effective therapeutic option [06201].

Testing of asthma in athletes

Beta-2 Agonists bronchodilators (salbutamol, salmeterol, formoterol and terbutaline), as well as inhaled corticoids, are prohibited in sports unless the participant follows the procedure known as Therapeutic Use Exemption (TUE). An abbreviated form (ATUE) was accepted until 2008. In a revised version from 2009, the concept of an ATUE has been abolished. With the abbreviated form, the athlete could start (or continue) the treatment while the formal
process was in progress (taking into account that this process used to be very long), while with the standard form, treatment can only start after receiving the authorisation notice. It is the International Olympic Committee Medical Commission who established the criteria for accepting the use of inhaled beta-2 agonists late in 2001 for the Salt Lake City Winter Olympic Games. Due to the success of its application, these criteria were renewed in 2004 for the Athens Summer Olympic Games and assumed by WADA. These criteria require an athlete to prove the existence of bronchial hyper-responsiveness and the measures of forced expiratory volume in 1 s (FEV₁) at rest, as well as changes in FEV₁ in response to either an inhaled bronchodilator or to a bronchial provocation test. These are the essential criteria that must be completed on the TUE form for beta-2 agonists. Between 2004 and 2008, 89 high-level athletes were examined in order to obtain an abbreviated therapeutic use exemption for beta-2 agonists. Of these, 50 men and 23 women performed a methacholine inhalation test with increasing concentrations of methacholine (0.025, 0.25, 2.5, 5, 10 and 25 mg/ml) until a fall of 20 percent in forced expiratory volume in 1 s (FEV₁) was achieved. Thirty candidates (43 %) had a provocative concentration causing a 20 percent fall in FEV₁ (PC₂₀) <2 mg/mL; 12 (16 %) were between 2 and 4 mg/mL; 8 (11 %) between 4.1 and 8 mg/mL, and 22 candidates (30 %) had a PC₂₀ >8 mg/mL. Seven of the 73 candidates had an obstructive pattern in the spirometry at rest, demonstrated by a FEV₁% <70 percent but with a FEV₁ >70 percent of the reference value. The anti-doping regulations with respect to beta-2 agonists need to be reviewed, and measures should be adopted to include a fall of 70 percent in FEV₁% as an obstruction criterion to indicate a bronchodilation test and to extend the criterion for a positive methacholine test to a PC₂₀ of 8 mg/mL [11187].

**Predictive values of tests**

To study the predictive value of allergy and pulmonary function tests for the diagnosis of asthma in athletes 98 national preOlympic athletes underwent an accurate medical examination including a validated questionnaire for asthma and rhinitis, spirometric recordings and skin prick testing with a panel of the most frequent inhalant allergens. Bronchodilator and/or exercise challenge were also performed in asthmatic subjects. Clinical asthma was present in 20 percent of athletes, rhinitis in 35 percent (in 21 % of cases alone and in 14 % associated with asthma). Positive prick tests were recorded in 44 percent of athletes (in 61 % of asthmatics, in 95 % of rhinitics and in 21 % of nonasthmatic-nonrhinitic subjects). Mean spirometric values and distribution of abnormal values were not different among asthmatics, rhinitics and nonasthmatics-nonrhinitic patients. Skin-tests positivity was not related to the abnormal spirometric data found in individual cases. Provocation tests with bronchodilators or exercise did not appear sensitive enough to diagnose mild forms of asthma in subjects with normal basal spirometric values. It was concluded that allergy testing and spirometry should be performed routinely in athletes because of the high prevalence of allergy, rhinitis and asthma in this population. However, the predictive value of these tests and of the bronchial provocation tests performed in this study seems too low to document mild or subclinical asthma in athletes [07192].

**Asthma in sports**

Athletes attempt to improve performance with drugs that act on the beta-adrenergic system directly or indirectly. Of three beta-adrenoceptor subtypes, the beta₂-adrenoceptor is the main target in sport; they have bronchodilator and anabolic actions and enhance anti-inflammatory actions of corticosteroids. Although demonstrable in animal experiments and humans, there is little evidence that these properties can significantly improve performance in trained athletes. Their actions may also be compromised by receptor desensitization and
by common, naturally occurring receptor mutations (polymorphisms) that can influence receptor signalling and desensitization properties in individuals. Indirectly acting agents affect release and reuptake of noradrenaline and adrenaline, thereby influencing all adrenoceptor subtypes including the three beta-adrenoceptors. These agents can have potent psychostimulant effects that provide an illusion of better performance that does not usually translate into improvement in practice. Amphetamines and cocaine also have considerable potential for cardiac damage. beta-adrenoceptor antagonists (beta-blockers) are used in sports that require steadiness and accuracy, such as archery and shooting, where their ability to reduce heart rate and muscle tremor may improve performance. They have a deleterious effect in endurance sports because they reduce physical performance and maximum exercise load. Recent studies have identified that many beta-adrenoceptor antagonists not only block the actions of agonists but also activate other (mitogen-activated PK) signalling pathways influencing cell growth and fate. The concept that many compounds previously regarded as "blockers" may express their own spectrum of pharmacological properties has potentially far-reaching consequences for the use of drugs both therapeutically and illicitly [08329].

Asthma, a chronic inflammatory disorder of the airways is associated with variable obstruction to the airways and is provoked by many triggers including exercise. The management of asthma is primarily pharmacological, but exercise, despite causing bronchoconstriction in almost all asthmatics, is an important adjunct to treatment. With adequate control of the hyperresponsive airways obtained with inhaled corticosteroids (ICS) and inhaled beta 2 agonists (IBA), used as both a pre-exercise preventive agent and a reliever if necessary, all asthmatics should benefit from an exercise program. Some have realised this benefit with such success as to become Olympic and world champions in many sports. Exercise programs should be individually tailored, follow established guidelines and result in similar benefits to those obtained by non-asthmatics. However asthmatics must try to avoid or minimise triggers whenever possible. A specific benefit of a physical training program is that it allows asthmatics to exercise with less bronchoconstriction at the same exercise stress, although it does not abolish or reduce airway hyperresponsiveness (AHR) [11181].

In a meta-analysis, studies on swimming and asthma were divided into four groups: Group I compared frequency of asthma among elite swimmers to that of other athletes; Group II examined the association between asthma and swimming during childhood; Group III evaluated effects of swimming programs on asthma severity and pulmonary function; and Group IV compared immediate respiratory effects of swimming to those of other types of exercise. The summary results were expressed as meta-odds ratios (ORs) for binary endpoints such as presence of asthma, and meta-differences for continuous endpoints such as changes in post-exercise pulmonary function tests (PFTs). All summary measures of effect were calculated using random effects models accompanied by a corresponding 95 percent confidence interval (CI) and a test for heterogeneity. In the analysis comparing frequency of asthma among elite swimmers to that among other athletes (Group I), meta-ORs ranged from 2.3 to 2.6 with all 95 percent confidence interval excluding 1.0. The corresponding meta-ORs reflecting the association between asthma and swimming pool use during childhood (Group II) were in the 0.63-0.82 range and were not statistically significant. In comparison to swimming, running and/or cycling was associated with a statistically significant four-to six-fold increase in exercise induced bronchospasm. Although asthma is more commonly found among elite swimmers than among other high-level athletes, it is premature to draw conclusions about the causal link between swimming and asthma because most studies available to date used cross-sectional design, because the association is not confirmed among non-competitive swimmers, and because asthmatics may be more likely to select swimming as the activity of choice because of their condition [08330].
Common conditions affecting the lower airway, is for example asthma. Asthma is highly prevalent in the general population, and even more prevalent among athletes [08331, 08332]. Airway hyperresponsiveness has been reported to occur in 25-79 percent of athletes in endurance sports, and in about 20 percent of athletes in power and speed sports [08333, 08334]. The prevalence of asthma and airway hyperresponsiveness, therefore, seems to be influenced by the type of sport or the environmental conditions during training, or both.

Asthma is a chronic inflammatory disorder of the airways associated with airway hyperresponsiveness and variable airway obstruction and is considered responsible for recurrent episodes of breathlessness, wheezing, chest tightness, phlegm production and coughing. Asthma can be triggered by various stimuli, including allergens in sensitized individuals, respiratory irritants (e.g. air pollutants), cold air and exercise. Exercise-induced asthma is considered to be due to the cooling, but mostly the drying, of the airways following exercise-induced hyperventilation. The result is the development of a hyperosmolar airway fluid. Rewarming of the airways due to a post-exercise increase in airway blood flow and transient plasma transudation may also contribute to the induced bronchoconstriction [08335, 08336].

Physical activity is often recommended to patients with asthma, and regular exercise can improve asthma control. However, there is mounting evidence that frequent, intense exercise by highly trained athletes contributes to the development of asthma. Indeed, long-term endurance training may influence airway structure and function and lead to airway hyperresponsiveness. Various factors could contribute to the development of asthma in athletes, including environmental exposures, mechanical stress to the airways, increased prevalence of respiratory infections and dysautonomia [08337]. The mechanisms by which these factors could influence asthma development may be related to their ability to induce airway inflammation and structural changes (remodelling). These processes are considered to be responsible for the development of airway hyperresponsiveness and variable or persistent airway obstruction [08338, 08339].

Airway inflammation and remodelling have been observed in athletes, even those without asthma [08340, 08341]. In general, bronchial inflammation is of a mixed type, with increased neutrophil and eosinophil counts. In swimmers, airway inflammation and potentiation of the effects of allergens on airways from chlorine derivatives result in epithelial damage, which has been proposed as a mechanism that leads to airway hyperresponsiveness, respiratory symptoms and asthma [08341]. Furthermore, mechanical stress caused by intense breathing efforts may also damage the airway epithelium and promote airway remodeling [08308].

Current recommendations indicate that asthma in highly trained athletes should be managed according to existing general national and international asthma management guidelines 08[327, 08342]. Special consideration, however, should be given to the diagnosis of asthma in athletes and assessment of asthma control; preventive measures; the management of exercise-induced asthma; and medication use, which should comply with the criteria of regulatory agencies. However, pharmacotherapy for asthma in athletes should be individualized. It should be based on reduction of inflammation, mainly with the use of inhaled corticosteroid therapy (the best drug therapy for asthma control), and optimization of airway control with other add-on therapies as needed. Rapid-acting beta₂-agonists are the most frequently used medications to relieve acute intermittent symptoms and to prevent exercise-induced bronchoconstriction. Protection against exercise-induced bronchoconstriction diminishes, however, when these agents are used regularly. The minimum dose and frequency required to minimize this loss of effect are recommended. Such tachyphylaxis to their bronchoprotective effects occurs after only a few days of use and
is not antagonized by inhaled corticosteroid therapy, which can reduce exercise-induced bronchoconstriction in most people with asthma after a few weeks of regular use [08343-08346].

**Hard training as a cause of bronchial hyperreactivity**

The different approaches that the International Olympic Committee (IOC) had adopted to beta2-agonists and the implications for athletes are reviewed by a former Olympic team physician who later became a member of the Medical Commission of the IOC (IOC-MC). Steadily increasing knowledge of the effects of inhaled beta2-agonists on health, is concerned with the fact that oral beta2-agonists may be anabolic, and rapid increased use of inhaled beta2-agonists by elite athletes has contributed to the changes to the IOC rules. Since 2001, the necessity for athletes to meet IOC criteria (i.e., that they have asthma and/or exercise-induced asthma, EIA) has resulted in improved management of athletes. The prevalence of beta2-agonist use by athletes mirrors the known prevalence of asthma symptoms in each country, although athletes in endurance events have the highest prevalence. The age-of-onset of asthma/EIA in elite winter athletes may be atypical. Of the 193 athletes at the 2006 Winter Olympics who met th IOC's criteria, only 32 percent had childhood asthma and 49 percent of athletes reported onset at age 20 years or older. These findings lead to speculation that years of intense endurance training may be a causative factor in bronchial hyperreactivity. The distinction between oral (prohibited in sports) and inhaled salbutamol is possible, but athletes must be warned that excessive use of inhaled salbutamol can lead to urinary concentrations similar to those observed after oral administration. One article provided justification that athletes should provide evidence of asthma or EIA before being permitted to use inhaled beta2-agonists [06202].

**Prevalence of asthma in sports**

One review article concerned physical activity and sports in asthmatic adolescents. Exercise induced asthma (EIA) is found in 8-10 percent of a normal child population and in approximately 35 percent of children with current asthma as reported from a population based birth cohort study. The mechanisms of EIA are related to markedly increased ventilation during exercise, causing increased heat and water loss through respiration, leading to bronchial constriction. In athletes and especially in endurance athletes, the repeated daily physical activity during training will over time cause epithelial damage and increase inflammation in the respiratory mucosa. With increased exposure to environmental agents as cold air in skiers and chlorine compounds in swimmers, the athlete may contract symptoms and signs of asthma and bronchial hyperresponsiveness, either worsening an existing asthma or causing symptoms in a previous healthy adolescent athlete. There are several causes of breathlessness in adolescents including EIA, vocal cord dysfunction, poor physical fitness and others, important to consider in the diagnostic procedure. The asthmatic athlete should follow the same guidelines for treating his/her asthma as the ordinary asthmatic patient with concern made to the special diagnostic rules given for the use of asthma drugs in sports, especially for inhaled beta2-agonists [11182].

Asthma is the most common chronic medical condition that school-teachers are likely to encounter among their pupils. This study aimed to identify the needs of physical education teachers in dealing with adolescents with exercise-induced asthma, study their self-reported knowledge of asthma and identify future topics for education about exercise-induced asthma. A questionnaire was drawn up on the basis of the requirements that had emerged in the course of interviews with 18 physical education teachers. One hundred and six physical education teachers at secondary schools in the city of Trondheim and colleges in Sør-
Trøndelag County in Norway answered the questionnaire (65 % response rate). Eighty-two physical education teachers (78 %) had pupils with asthma in their sports classes, and 89 percent answered positively regarding their need for advice on teaching pupils with asthma. Twenty-seven (26 %) reported that they had sufficient knowledge to teach adolescents with asthma. Topics about asthma, its management and activities suitable for asthmatics were given high priority by the teachers [11183].

The objective of one study was to determine the prevalence of asthma and use of asthma medications in elite athletes compared with an age-matched non-athlete population. Data were collected from the respiratory component of annual medical screening of 424 elite athletes. Measures included the prevalence of current asthma and ever doctor-diagnosed asthma, and the prevalence of use of treatment for asthma including beta-agonists and inhaled corticosteroid medication. The prevalence of current asthma in athletes aged 18-29 years was 14 percent (95 % confidence interval 9 to 19 %), which did not differ significantly from the prevalence in the non-athlete control population (11 %; 95 % confidence interval 9 to 12 %). Of athletes with current asthma, 27 percent were not taking any medications for asthma, and 25 percent were treated with short-acting beta-agonist medications alone and were not taking inhaled corticosteroids. These data indicate that the overall cumulative and period prevalence of asthma in athletes is similar to that in the general age-matched population. Athletes use beta-agonists with a frequency similar to the general population [07188].

**Asthma in elite athletes**

Asthma is frequently found among elite athletes performing endurance sports such as swimming, rowing and cross-country skiing. Although these athletes often report symptoms while exercising, they seldom have symptoms at rest. Moreover, compared with nonathletic asthmatic individuals, elite athletes have been shown to have a different distribution of airway inflammation and unequal response to bronchial provocative test. Elite athletes display signs of exercise-induced symptoms, for example, nonasthmatic inspiratory wheeze, vocal cord dysfunction and cardiac arrhythmias, which could limit their physical capacity. Elite athletes should undergo comprehensive assessment to confirm an asthma diagnosis and determine its degree of severity. Treatment should be as for any other asthmatic individual, including the use of beta2-agonist, inhaled steroid as well as leukotriene-antagonist. It should, however, be noted that daily use of beta-agonists could expose elite athletes to the risk of developing tolerance towards these drugs. Use of beta2-agonist should be replaced with daily inhaled corticosteroid treatment, the most important treatment of exercise-induced asthma. All physicians treating asthma should be aware of the doping aspects. Systemic beta2-agonist intake is strictly prohibited, whereas inhaled treatment is allowed in therapeutic doses when asthma is documented and dispensation has been granted when needed [11184].

**In elite swimmers**

An increased risk of developing asthma has been reported among swimmers exposed to chloramine in pool arenas. The aim of one study was to compare the prevalence of asthma and respiratory symptoms among elite aspiring swimmers compared with age-matched controls with different degrees of physical activity. It was also aimed to relate these findings to mental and psychosocial factors. One hundred and one elite swimmers and 1628 age-matched controls answered a questionnaire containing questions about respiratory symptoms, lifestyle factors, mental and physical well-being. The controls were divided into three different groups according to the degree of physical activity, no physical activity,
recreational training and elite training. Swimmers reported significantly more asthma symptoms, with 37 percent having physician-diagnosed asthma, compared with 16 percent among the controls. Use of regular medication was more common (15 % vs 8 %) and more swimmers reported an exacerbation of their asthma during the previous 12 months (17 %) versus (6 %) for the controls. Despite an increased prevalence of asthma symptoms, the swimmers reported best physical performance and best mental and physical well-being. They also had a healthier lifestyle without smoking and low alcohol consumption [12306].

In canoe- and kayak athletes

Asthma is common in elite athletes, but the knowledge of asthma in elite canoe and kayak athletes is limited. The aim of one prospective cross-sectional study was therefore to investigate the prevalence of asthma, including asthma-like symptoms, exhaled nitric oxide, and airway reactivity to mannitol in Danish elite canoe and kayak athletes. The study group consisted of 29 (of 33 eligible) elite athletes aged 17-43 years, and the examination programme consisted of questionnaires, including the Asthma Control Questionnaire, fraction of exhaled nitric oxide (FENO), spirometry and airway reactivity to mannitol. Asthma was defined as a history of doctor-diagnosed asthma and/or elevated FENO and airway reactivity. Seven of the elite athletes (24 %) were found to have asthma, including four subjects with previously doctor-diagnosed asthma. Of the four athletes (all treated with inhaled corticosteroids) with doctor-diagnosed asthma, all reported asthma-symptoms and two had elevated FENO, but none had airway hyperresponsiveness (AHR) to mannitol. All three athletes with previously undiagnosed asthma had elevated FENO and AHR to mannitol, but reported no asthma-like symptoms. Asthma is common in elite canoe and kayak athletes, and classical signs of asthmatic airway inflammation are also found in asymptomatic athletes [12307].

Misdiagnosis of exercise-induced bronchoconstriction in professional soccer players

Physicians typically rely heavily on self-reported symptoms to make a diagnosis of exercise-induced bronchoconstriction (EIB). However, in elite sport, respiratory symptoms have poor diagnostic value. In 2009, following a change in international sports regulations, all elite athletes suspected of asthma and/or EIB were required to undergo pulmonary function testing (PFT) to permit the use of inhaled beta2-agonists. The aim of one study was to examine the diagnostic accuracy of physician diagnosis of asthma/EIB in English professional soccer players. Sixty-five players with a physician diagnosis of asthma/EIB were referred for pulmonary function assessment. Medication usage and respiratory symptoms were recorded by questionnaire. A bronchial provocation test with dry air was conducted in 42 players and a mannitol challenge in 18 players. Five players with abnormal resting spirometry performed a bronchodilator test. Of the 65 players assessed, 57 (88 %) indicated regular use of asthma medication. Respiratory symptoms during exercise were reported by 57 (88 %) players. Only 33 (51 %) of the players tested had a positive bronchodilator or bronchial provocation test. Neither symptoms nor the use of inhaled corticosteroids were predictive of pulmonary function tests’ outcome. It was concluded that a high proportion of English professional soccer players medicated for asthma/EIB (a third with reliever therapy only) do not present reversible airway obstruction or airway hyperresponsiveness to indirect stimuli. This underlines the importance of objective PFT to support a symptoms-based diagnosis of asthma/EIB in athletes [12308].

Use of antiasthmatic medicine in athletes
Use of asthma medication is common among athletes. In 2009, the World Anti-Doping Committee (WADA) and the International Olympic Committee removed the need to document asthma by lung function tests before the use of inhaled beta2-agonists. It was assessed the changes in asthma medication use in Finnish Olympic athletes 8 years apart in 2002 (n=446) and 2009 (n=372). The athletes filled out a questionnaire on asthma symptoms, diagnosis, and medication. The use of asthma medication increased from 9.4 percent in 2002 to 12.6 percent in 2009 (adjusted odds ratio (OR) = 1.71, 95 % confidence interval 1.08 to 2.69). Fixed combinations of inhaled long-acting beta2-agonists (LABAs) and inhaled corticosteroids (ICSs) were used three times more in 2009 versus 2002 (OR = 3.38, 95 % confidence interval 1.26 to 9.12). At the same time, no significant changes were observed in the occurrences of physician-diagnosed asthma (13.9 % vs 15.9 %) or wheezing (10.3 % vs 10.2 %). In 2002, all athletes on asthma medication also had a physician-diagnosed disease, but in 2009, 11.8 percent of the athletes on medication were lacking it. It was concluded that especially, the use of combination therapy of LABAs and ICSs is increasing among Finnish Olympic athletes. This trend is worrying as it is not based on increasing occurrence of symptoms, asthma diagnoses, or objective lung function measurements [12309].

Allergic rhinitis in athletes

The aim of one review was to highlight the prevalence of allergic rhinitis in athletes and the impact this condition may have on their athletic performance. Furthermore, the optimal management of medical conditions in the elite athlete forms an important part of protecting the health of the athlete. The use of pharmacological intervention in the treatment of allergic rhinitis in elite athletes requires careful planning. A variety of factors must be considered prior to prescription such as drug efficacy and safety both at rest and in conjunction with strenuous exercise, associated side effects on athletic performance and well being and whether the chosen drug is on the World Anti-Doping Agency (WADA) banned list. Allergic rhinitis is, however, common in elite athletes and may impair athletic performance and recovery. We advise that all elite and professional athletes should be screened for allergic rhinitis using validated questionnaire such as the Allergy Questionnaire for Athletes (AQUA) alongside skin prick testing or specific IgE blood tests for inhalant allergens. Intranasal corticosteroids are highly recommended as the management drug of choice for athletes in conjunction with second-generation antihistamines (severity dependant) and when practicable, allergen avoidance [11185].

During Olympic games

The asthmatic athlete has a long history in competitive sport in terms of success in performance and issues related to doping. Well documented are detailed objective tests used to evaluate the athlete with symptoms of asthma or airway hyperresponsiveness and the medical management. Initiated at the 2002 Salt Lake City Games, the International Olympic Committee's Independent Asthma Panel required testing to justify the use of inhaled beta-2 agonists in Olympic athletes and has provided valuable guidelines to the practicing physician. This program was educational and documented the variability in prevalence of asthma and/or airway hyperresponsiveness and of inhaled beta-2 agonists use between different sports and different countries. It provided a standard of care for the athlete with respiratory symptoms and led to the discovery that asthmatic Olympic athletes outperformed their peers at both Summer and Winter Olympic Games from 2002 to 2010. Changes to the World Anti-Doping Agency's Prohibited List in 2010 permitted the use of 2 of inhaled beta-2 agonists produced by the same pharmaceutical company. All others remain prohibited. However, there is no pharmacological difference between the permitted and prohibited of
inhaled beta-2 agonists. As a result of these changes, asthmatic athletes are being managed differently based on a World Anti-Doping Agency directive that has no foundation in pharmacological science or in clinical practice [11186].

Prevalence of use beta-2-agonists

The prevalence of asthma and the use of anti-asthmatic medication is high among elite athletes. Elite athletes require a TUE certificate (Therapeutic Use Exemption) if they require anti-asthmatic medication which is on the prohibited list. The aim of the study was to determine the distribution of Danish TUE certificates and to examine the use of anti-asthmatic medication among Danish elite athletes. A cross-sectional study of all applications for TUE certificates in 2005 was carried out. It was focused on applications including anti-asthmatic medication. All applications resulted in certificates being issued. A total of 694 TUE certificates were issued. Of these, 445 (64 %) concerned anti-asthmatic medication. Short-acting beta-2-agonists (SABA) were the most frequent medication (79 %). Only 2 percent received long-acting beta-2-agonists (LABA) as single therapy. Inhaled steroids were used by 69 percent. Swimmers received significantly higher doses of inhaled steroids compared to all others athletes (1031 microg/day). The applications for TUE certificates were generally handled by general practitioners (78 %). It was concluded that most TUE certificates issued in 2005 concerned anti-asthmatic medication. Only a few athletes were treated with non-recommended anti-asthmatic medication like LABA as single therapy. Swimmers received higher doses of inhaled steroids compared to all others athletes. Most of the applications for TUE certificates were handled by general practitioners [07193].

Exercise-induced bronchoconstriction (EIB)

Exercise-related respiratory symptoms in the diagnosis of exercise-induced bronchoconstriction (EIB) have poor predictive value. The aim of one study was to evaluate how athletes presenting with these symptoms are diagnosed and managed in primary care. An electronic survey was distributed to a random selection of family practitioners in England. The survey was designed to assess the frequency with which family practitioners encounter adults with exercise-related respiratory symptoms and how they would approach diagnostic work-up and management. The survey also evaluated awareness of and access to diagnostic tests in this setting and general knowledge of prescribing asthma treatments to competitive athletes. 257 family practitioners completed the online survey. One-third of respondents indicated they encountered individuals with this problem at a frequency of more than one case per month. Over two-thirds of family practitioners chose investigation as an initial management strategy, while one-quarter would initiate treatment based on clinical information alone. PEFR pre- and post-exercise was the most commonly selected test for investigation (44 %), followed by resting spirometry pre- and post-bronchodilator (35 %). Short-acting beta2-agonists were the most frequently selected choice of treatment indicated by respondents (90 %). Family practitioners encounter individuals with exercise-related respiratory symptoms commonly and although objective testing is often employed in diagnostic work-up, the tests most frequently utilised are not the most accurate for diagnosis of EIB. This diagnostic approach may be dictated by the reported lack of access to more precise testing methods, or may reflect a lack of dissemination or awareness of current evidence. Overall the findings have implications both for the management and hence welfare of athletes presenting with this problem to family practitioners and also for the competitive athletes requiring therapeutic use exemption [09238].

To investigate the incidence of asthma symptoms in 171 young amateur swimmers (6-14
years of age), and to describe the clinical treatment of the children with asthma in a private
sports club in the city of São Paulo, Brazil all of the participants or their legal guardians were
asked to complete the International Study of Asthma and Allergies in Childhood (ISAAC)
questionnaire, and 119 were submitted to pulmonary function testing at rest. The overall
incidence of asthma symptoms (ISAAC score > 6) among the swimmers was 17 percent. Of
the 119 swimmers submitted to spirometry, 39 (33 %) presented spirometric alterations
(FEV1/FVC < 0.75). Among those with an ISAAC score > 6, there were 10 (31 %) who stated
that they were receiving no asthma treatment. Of those who reported receiving
pharmacological treatment, 24 percent made use of bronchodilators but not of
corticosteroids. The incidence of asthma symptoms and pulmonary function alterations
among amateur swimmers within the 6-14 age bracket was high. In addition, a relevant
proportion of these athletes were receiving no treatment [09239].

Exercise induced bronchoconstriction (EIB) describes the acute transient airway narrowing
that occurs during and most often after exercise, and is prevalent in elite athletes. Prolonged
hyperventilation of dry or cold air and increased inhalation of pollutants or allergens could
account for the bronchoconstrictive reaction. The subsequent airway inflammation seems to
differ from typical asthma. Objective measures of lung function and provocation tests should
be used for an accurate and reliable diagnosis. EIB is currently treated with inhalation of
beta2-agonists or, as second choice, sodium cromoglycate approximately 15 min before
exercise. If this proves to be insufficient then inhaled steroids should be added. Leukotriene
receptor antagonists can be used in patients whose symptoms do not respond to inhaled
steroids. The screening of high risk populations such as swimmers, cyclists, rowers and
winter athletes is recommended by some authors [08348].

The International Olympic Committee-Medical Commission (IOC-MC) accepts a number of
bronchial provocation tests for the diagnosis of exercise-induced bronchoconstriction (EIB) in
elite athletes, none of which have been studied in elite swimmers. With the suggestion of a
different pathogenesis involved in the development of EIB in swimmers, there is a possibility
that the recommended test for EIB in elite athletes, the eucapnic voluntary hyperpnoea
(EVH) challenge, may be missing the diagnosis in elite swimmers. The aim of one study was
to assess the effectiveness of the EVH challenge, the field swim challenge and the laboratory
cycle challenge in the diagnosis of EIB in elite swimmers. Thirty-three elite swimmers were
evaluated on separate days for the presence of EIB using 3 different bronchial provocation
challenge tests: an 8 minute field swim challenge, a 6 minute laboratory EVH challenge, and
an 8 minute laboratory cycle challenge. Only 1 of the 33 subjects (3 %) had a positive field
swim challenge with a fall in FEV1 of 16 percent from baseline. Eighteen of the 33 subjects
(55 %) had a positive EVH challenge, with a mean fall in FEV1 of 20 percent from baseline.
Four of the subjects (12 %) had a positive laboratory cycle challenge, with a mean fall in
FEV1 of 15 percent from baseline. Only 1 of the 33 subjects was positive to all 3 challenges.
These results suggest that the EVH challenge is a highly sensitive challenge for identifying
EIB in elite swimmers, in contrast to the laboratory and field-based exercise challenge tests,
which significantly underdiagnose the condition. The EVH challenge, a well-established and
standardised test for EIB in elite winter and summer land-based athletes, should thus be
used for the diagnosis of EIB in elite swimmers, as recommended by the IOC-MC [10173].

The role of mast cells in the airway response to exercise and the benefit of sodium
cromoglycate (SCG) in athletes are unclear. The purpose of one study was to clarify the role
of mast cell mediators in the airway response to exercise in athletes and to investigate the
effect of SCG. Eleven athletes with exercise-induced bronchoconstriction (EIB+) and 11
without (EIB-) performed a eucapnic voluntary hyperpnea (EVH) test (a surrogate for
exercise) 10 min after inhalation of a placebo or 40 mg of the mast cell stabilizing agent
sodium cromoglycate. The urinary concentrations of 9a,11β-PGF2 (a metabolite of PGD2

1335
and a marker of mast cell activation) and leukotriene E4 (LTE4) were measured by enzyme immunoassay 60 min before and for 90 min after the challenge. The results support mast cell activation with release of bronchoconstrictive mediators after hyperpnea in athletes with and without EIB and inhibition by SCG. The degree of airway responsiveness to the specific mediator released is likely to determine whether or not bronchoconstriction will occur after EVH [10486].

Prevalence of exercise-induced bronchoconstriction

To assess the progression of bronchial reactivity (BR) and incidence of bronchial hyperreactivity (BH), exercise-induced bronchoconstriction (EIB) and asthma in triathletes over 2 years seven athletes from the Swiss national triathlon team (mean age 24 years), who initially were not asthmatic, not treated with antiasthmatic medication, and who had performed at international level for more than 3 consecutive years (2001-2003). To assess BR, BH and EIB, subjects ran on a 400 m track for 8 min at intensities equal to the anaerobic threshold. Tests were conducted in ambient temperatures of 4 degrees C, -9 degrees C and 4 degrees C, and humidity of 52, 83, and 93 percent. Forced expiratory volume in 1 s (FEV1) was measured before and at 2, 5, 10 and 15 min after EIB, and 5 min after inhalation of a beta2-agonist. Two methods were used to calculate the incidence: the standard assessment and extrapolation of the decrease in FEV1 to the BH limit. BR increased significantly in the seven athletes. Within 2 years, BR had increased significantly and even reached BH in some athletes. Three athletes exhibited BH. After extrapolation of the decrease in FEV1 in all seven athletes, the limit of 10 percent by definition for BH was determined to occur within 2-5 years, resulting in 21-57 percent of athletes with newly developed BH per year. It was concluded that athletes develop EIB quickly, a rate of increase 195-286 times that of the normal rate for development of asthma [07189].

Exercise-induced bronchospasm (EIB) occurs more commonly in elite athletes than in the general population. There have been relatively few prevalence studies examining EIB in college athletes despite studies which have shown significant morbidity from asthma attacks related to exercise occurring in athletes in this age group. None of the previous studies utilized euopnic voluntary hyperpnea (EVH) testing, which is the currently recommended test to document EIB in Olympians. One hundred seven athletes from 22 sports participated. Forty-two of 107 athletes (39 %) were EIB positive according to EVH results. Thirty-six of 42 EIB-positive athletes (86 %) had no prior history of EIB or asthma. There were no significant differences in the prevalence of EIB according to sex of the athlete or ventilation demands of the sport. Symptoms were not predictive of EIB. The prevalence of EIB was 36 percent in athletes with negative symptoms and 35 percent for those with positive symptoms. Athletes in high-ventilation sports were significantly more symptomatic (48 %) than athletes in low-ventilation sports (25 %); however, there was no difference in the prevalence of EIB between the two groups. It was concluded that varsity athletes show a high incidence of EIB when objectively diagnosed by a variety of pulmonary function criteria. Sex of the athlete or ventilation demands of the sport does not affect the prevalence of EIB. The use of symptoms to diagnose EIB is not predictive of whether athletes have objectively documented EIB. Empiric diagnosis and treatment of EIB on the basis of subjective symptoms alone may lead to an increased number of inaccurate diagnoses and increased morbidity [07190].

The prevalence of exercise-induced bronchospasm (EIB) is significantly higher in athletes than that in the general population and can result in significant morbidity in young, competitive athletes. Guidelines emphasize that education and written treatment protocols improve clinical outcomes for asthmatics. Evidence also supports objective testing when EIB is suspected, when there is immediate availability of rescue inhalers, and when there is
involvement of asthma specialists in the care of asthmatic athletes. It was sought to determine how EIB is managed at the National Collegiate Athletic Association (NCAA) sports medicine programs. A survey consisting of multiple-choice questions related to EIB in athletes was sent electronically to 3200 athletic trainers affiliated with NCAA sports medicine programs. Five hundred and forty-one athletic trainers responded. A minority of athletic trainers surveyed (21%) indicated that an asthma management protocol exists at their institution. Twenty-two percent indicated that pulmonologists are on staff or consultants to the sports medicine department. Many indicated that a short-acting beta-agonist is not required to be available at all practices (39%) and games (41%), and few athletic trainers indicated that their programs use objective testing to diagnose EIB (17%). Regression modeling demonstrated education about EIB, and involvement of pulmonologists significantly improved adherence to current consensus guidelines. On the basis of these data, many NCAA sports medicine programs do not manage athletes with EIB according to current consensus guidelines. This may result in inaccurate diagnoses and may be detrimental to clinical outcomes and overall health of student athletes. Providing education about EIB and involvement of pulmonologists significantly increase adherence to guidelines that likely improves clinical care of athletes and potentially athletic performance [09240].

**Eucapnic voluntary hyperpnea**

Exercise challenge testing is the typical method for diagnosing exercise induced bronchoconstriction; however, alternate tests have been developed. The purpose of this paper was to summarize the current literature comparing eucapnic voluntary hyperpnea and mannitol with standard exercise challenge testing to determine whether either test is a suitable alternative to standard exercise testing for the diagnosis of exercise-induced bronchoconstriction. Using valid systematic review methods, a comprehensive search strategy to avoid publication bias, it was identified 10 studies that compared exercise challenge testing with either eucapnic voluntary hyperpnea or mannitol. For the 7 diagnostic cross-sectional studies that examined eucapnic voluntary hyperpnea, the sensitivity and specificity values were heterogeneous, ranging from 25 to 90% for sensitivity and 0 to 71% for specificity. In the 3 diagnostic cross-sectional studies that evaluated mannitol, the sensitivity and specificity ranged from 58 to 96 percent and 65 to 78 percent, respectively. For most studies, a representative spectrum of participants being tested was not used. Given the heterogeneity in sensitivity and specificity of eucapnic voluntary hyperpnea studies and the relatively small number of studies that have examined mannitol, insufficient evidence is available to conclude that either of these tests are suitable alternatives to exercise challenge testing to detect exercise-induced bronchoconstriction [11364].

**In children**

Exercise-induced bronchoconstriction (EIB) is defined as acute, reversible bronchoconstriction induced by physical exercise. It is widely believed that EIB occurs after exercise. However, in children with asthma the time to maximal bronchoconstriction after exercise is short, suggesting that the onset of EIB in such children occurs during exercise. In one study the authors investigated pulmonary function during exercise in cold air in children with asthma. Thirty-three children with asthma with a mean age of 12 years and a clinical history of exercise induced symptoms, underwent a prolonged, submaximal, exercise test of 12 min duration at approximately 80 percent of the predicted maximum heart rate. Pulmonary function was measured before and each minute during exercise. If EIB occurred (fall in forced expiratory volume in 1 s >15% from baseline), exercise was terminated and salbutamol was administered. Nineteen children showed EIB. In 12 of these children bronchoconstriction occurred during exercise (breakthrough EIB), while seven children
showed bronchoconstriction immediately after exercise (non-breakthrough EIB). Breakthrough EIB occurred between 6 and 10 min of exercise (mean 8 min). It was concluded that in the majority of children with EIB in this study (i.e. 12 out of 19), bronchoconstriction started during, and not after, a submaximal exercise test [11365].

A lot of emphasis has been placed in screening individuals with exercise-induced bronchospasm in order to avoid persistence bronchial hyperactivity and consequent chronic silent inflammation of the respiratory tract. The purpose of one study was to evaluate the effect of interval training on the respiratory function and endurance in children with exercise-induced asthma (EIA) participating in the sport of soccer. Twenty-nine boys ages 10-14, who developed EIA after a 6-minute free running test (decline in forced expiratory volume in 1 second: \(FEV_1\) 10 %), participated in the study. They were divided into 2 groups (experimental: \(n=18\), and control: \(n=11\)), fulfilling the same criteria (i.e. age, body height and weight, and severity of asthma). The experimental group exercised with the interval training method for a period of 8 weeks, (3 sessions per week), whereas the control group exercised with the usual football program. Measurements were made for \(FEV_1\) and endurance in both groups, before and after the application of training (8 weeks). Following the implementation of the training program, a significant improvement in \(FEV_1\) and endurance was documented in the experimental group, as well as significant differences between the 2 groups. In conclusion, duration and aerobic training via the interval method seems to be beneficial to soccer players with EIA [07191].

**Comparison of blood and urin levels between routes of administration**

It was aimed to assess the plasma and urine concentrations of beta\(_2\)-agonists and evaluate the difference between three routes of administration in trained adults in order to distinguish doping from prevention of exercise-induced asthma. Ten young healthy Caucasian male subjects received during a four treatment period study: 1) inhaled salbutamol (S(I)) 2 x 100 microg t.i.d. for 3 days, 2) inhaled formoterol (F(I)) 2 x 12 microg b.i.d. for 3 days, 3) a single subcutaneous injection of salbutamol (S(S)) 0.5 mg, and 4) salbutamol 2 x 2 mg t.i.d. orally for 3 days (S(O)). Blood samples were taken during the first and the third day of experimentation at baseline, 30 min, 1 h, 2 h, 4 h and 6 h after administration; additional blood samples were drawn at 15 min for S(I), S(S) and F(I) and at 12 h for F(I). Urinary samples were collected at baseline, 2 h, 4 h, 6 h and 12 h after administration. Urinary concentrations were 20 to almost 50 times higher after S(O) than after S(I). Mean urinary concentration after S(O) increased to above 800 ng/mL within the two hours and above 1000 ng/mL at 6 to 12 hours post-drug administration. Urinary concentrations after S(S) were maximal during the first 2 hours (mean: 340 ± 172 ng/mL). Plasma concentrations were very low, whatever the routes of administration. Results showed that we could eliminate the use of S(I) (authorized) and S(S) administration when individual urinary concentrations are higher than 230 ng/mL and 615 ng/mL, respectively. Therefore, at rest, the cut-off value used to discriminate therapeutic from doping salbutamol intake could be fixed at 250 ng/mL instead of the 1000 ng/mL still authorized by international committees [06203].

**Ergogenic effects**

*In chronic pulmonary disease*

Chronic obstructive pulmonary disease is currently considered a systemic disease, presenting structural and metabolic alterations that can lead to skeletal muscle dysfunction.
This negatively affects the performance of respiratory and peripheral muscles, functional capacity, health-related quality of life and even survival. The decision to prescribe ergogenic aids for patients with chronic obstructive pulmonary disease is based on the fact that these drugs can avert or minimize catabolism and stimulate protein synthesis, thereby reducing the loss of muscle mass and increasing exercise tolerance. One review summarized the available data regarding the use of anabolic steroids, creatine, L-carnitine, branched-chain amino acids and growth hormones in patients with chronic obstructive pulmonary disease. The advantage of using these ergogenic aids appears to lie in increasing lean muscle mass and inducing bioenergetic modifications. Within this context, most of the data collected deals with anabolic steroids. However, to date, the clinical benefits in terms of increased exercise tolerance and muscle strength, as well as in terms of the effect on morbidity and mortality, have not been consistently demonstrated. Dietary supplementation with substances of ergogenic potential might prove to be a valid adjuvant therapy for treating patients with advanced chronic obstructive pulmonary disease, especially those presenting loss of muscle mass or peripheral muscle weakness [06204].

In non-asthmatics

To provide an overview of the current literature on the use of inhaled beta2-agonists in non-asthmatic competitive athletes, and to assess the performance enhancing effect of inhaled beta2-agonists. Twenty randomised, placebo controlled studies (19 double blind, one single blind) were located. Only three studies reported a performance enhancing effect of inhaled beta2 agonists. However, methodological shortcomings were most likely responsible for these findings (for example, non-elite athletes, inconsistent results in different tests, subgroups with above-average responsiveness). The review reveals that there is no ergogenic potential of inhaled beta2-agonists in non-asthmatic athletes. In view of the epidemiology of asthma in athletes and the considerable workload involved in provision of therapeutic use exemptions the inclusion of inhaled beta2-agonists on the list of prohibited substances should be reconsidered [06205].

Treatment

The aims of one report was to review the current recommended treatment of exercise-induced asthma (EIA), respiratory and allergic disorders in sports, and to review the evidence on possible improvement of performance in sports by asthma drugs and to make recommendations for their treatment. To assess the evidence of the literature regarding use of beta2-agonists related to athletic performance, the Task Force searched Medline for relevant papers up to November 2006 using the present search words: asthma, bronchial responsiveness, exercise-induced bronchoconstriction, athletes, sports, performance and beta2-agonists. Treatment recommendations for EIA and bronchial hyper-responsiveness in athletes are set forth with special reference to controller and reliever medications. Evidence for lack of improvement of exercise performance by inhaled beta2-agonists in healthy athletes serves as a basis for permitting their use. There is a lack of evidence of treatment effects of asthma drugs on EIA and bronchial hyper-responsiveness in athletes whereas extensive documentation exists in treatment of EIA in patients with asthma. The documentation on lack of improvement on performance by common asthma drugs as inhaled beta2-agonists with relationship to sports in healthy individuals is of high evidence, level (1+). It was concluded that exercise induced asthma should be treated in athletes along same principles as in ordinary asthma patients with relevance to controller and reliever treatment after careful diagnosis. There is very high level of evidence for the lack of improvement in athletic performance by inhaled beta2-agonists [08347].
Meta-analysis of beta₂-agonists effects

Inhaled beta₂-agonists are commonly used as bronchodilators in the treatment of asthma. Their use in athletes, however, is restricted by anti-doping regulations. Controversies remain as to whether healthy elite athletes who use bronchodilators may gain a competitive advantage. The aim of one systematic review and meta-analysis was to assess the effects of inhaled and systemic beta₂-agonists on physical performance in healthy, non-asthmatic subjects. To this end, MEDLINE, EMBASE, and the Cochrane Central Register of Controlled Trials (CENTRAL) were searched up to August 2009. Reference lists were searched for additional relevant studies. The search criteria were for randomized controlled trials examining the effect of inhaled or systemic beta₂-agonists on physical performance in healthy, non-asthmatic subjects. Two authors independently performed the selection of studies, data extraction and risk of bias assessment. Parallel-group and crossover trials were analysed separately. Mean difference (MD) and 95 percent confidence intervals were calculated for continuous data and, where possible, data were pooled using a fixed effects model. Twenty-six studies involving 403 participants (age range 7-30 years) compared inhaled beta₂-agonists with placebo. No significant effect could be detected for inhaled beta₂-agonists on maximal oxygen consumption (VO₂max) (mean difference -0.14 mL/kg/min; 95 confidence interval -1.07 to 0.78; 16 studies), endurance time to exhaustion at 105-110 percent VO₂max (mean difference -1.5 s; 95 % confidence interval -15.6, 12.6; four studies), 20-km time trial duration (mean difference -4.4 s; 95 % confidence interval -23.5 to 14.7; two studies), peak power (mean difference -0.14 W/kg; 95 % confidence interval -0.54 to 0.27; four studies) and total work during a 30-second Wingate test (mean difference 0.80 J/kg; 95 % confidence interval -2.44 to 4.05; five studies). Thirteen studies involving 172 participants (age range 7-22 years) compared systemic beta₂-agonists with placebo, with 12 studies involving oral and one study involving intravenous salbutamol. A significant effect was detected for systemic beta₂-agonists on endurance time to exhaustion at 80-85% VO₂max (mean difference 402 s; 95 % confidence interval 34 to 770; two studies), but not for VO₂max (placebo 42.5 ± 1.7 mL/kg/min, salbutamol 42.1 ± 2.9 mL/kg/min, one study), endurance time to exhaustion at 70 percent VO₂max (mean difference 400 s; 95 % confidence interval -408 to 1208; one study) or power output at 90 % VO₂max (placebo 234.9 ± 16 W, salbutamol 235.5 ± 18.1 W, one study). A significant effect was shown for systemic beta₂-agonists on peak power (mean difference 0.91 W/kg; 95 % confidence interval 0.25 to 1.57; four studies), but not on total work (mean difference 7.8 J/kg; 95 percent confidence interval -3.3 to 18.9; four studies) during a 30-second Wingate test. There were no randomized controlled trials assessing the effects of systemic formoterol, salmeterol or terbutaline on physical performance. In conclusion, no significant effects were detected for inhaled beta₂-agonists on endurance, strength or sprint performance in healthy athletes. There is some evidence indicating that systemic beta₂-agonists may have a positive effect on physical performance in healthy subjects, but the evidence base is weak [11189].

Designer beta2-agonists

Beta2-adrenergic agonists, or beta2-agonists, are considered essential bronchodilator drugs in the treatment of bronchial asthma, both as symptom-relievers and, in combination with inhaled corticosteroids, as disease-controllers. The use of beta2-agonists is prohibited in sports by the World Anti-Doping Agency (WADA) due to claimed anabolic effects, and also, is prohibited as growth promoters in cattle fattening in the European Union. One paper reviewed the last seven-year (2006-2012) literature concerning the development of novel
beta2-agonists molecules either by modifying the molecule of known beta2-agonists or by introducing moieties producing indole-, adamantyl- or phenyl urea derivatives. New emerging beta2-agonists molecules for future therapeutic use are also presented, intending to emphasize their potential use for doping purposes or as growth promoters in the near future [13407].

Salbutamol

The World Anti-doping Agency stipulates that athletes who declare salbutamol use should not exceed 1600 microg over a 24 h period. No studies have investigated the physiological effect of 1600 microg of inhaled salbutamol on intermittent sports. This study investigated the physiological effect of inhaling 800 microg and 1600 microg of salbutamol prior to a football specific run at high ambient temperatures. Five male non-asthmatic football players (mean ± SD; age 24 ± 4 years; weight 71 ± 4 kg; height 175 ± 5 cm) volunteered. Participants attended the lab on three occasions to inhale either a placebo (PLA), 800 microg of salbutamol (800 SAL) or 1600 microg of salbutamol (1600 SAL) 15 min prior to performing a football-specific run for 45 min at 30°C. The football specific run consisted of seven stages which included two high intensity stages and five low intensity stages. During each stage VO\textsubscript{2}, RER, HR and blood lactate was measured. Repeated measures ANOVA were performed to investigate the changes in VO\textsubscript{2}, RER, HR and blood lactate during each stage. During stage one and two HR was significantly higher in 800 SAL (143 ± 10 b/min; 148 ±12 b/min) and 1600 SAL (142 ± 3 b/min; 147 ± 4.0 b/min) when compared to PLA (119 ± 12 b/min; 129 ± 10 b/min). Following stage two blood lactate was significantly higher in 800 SAL (4.2 ± 1.8 mmol/L) and 1600 SAL (4.5 ± 1.6 mmol/L) when compared with PLA (2.4 ± 1.2 mmol/L). Following stage five blood lactate was significantly higher in 800 SAL (4.2 ± 1.6 mmol/L) and 1600 SAL (5.0 ± 1.4 mmol/L) when compared with PLA (2.8 ± 1.0 mmol/L). The increased HR (stages one and two) and increased blood lactate concentration (stages two and five) observed following salbutamol inhalation, suggests supratherapeutic doses of salbutamol may increase the physiological cost during a football match [11483].

The World Anti-doping Agency stipulates that athletes who declare the use of salbutamol should not exceed 1600 microg over a 24 h period. Most studies investigating the effect of inhaled salbutamol on maximal flow volume values, such as FEV\textsubscript{1}, have investigated doses of up to 800 microg of salbutamol. The purpose of this study was to investigate the effect of inhaling 800 microg or 1600 microg on the FEV\textsubscript{1} in non-asthmatic football players. Five male non-asthmatic football players (mean ± SD; age 24 + 4 year; weight 71 ± 4 kg; height 175 ± 5 cm) volunteered. Participants attended the laboratory on six occasions to inhale either a placebo, 800 microg of salbutamol or 1600 microg salbutamol and complete a football-specific run. Maximal Flow Volume Loops were measured at baseline, 10 min following inhalation of salbutamol or placebo and 5 min following the football specific run. Repeated measures ANOVA were performed to investigate the changes in FEV\textsubscript{1} 10 min post salbutamol and post football specific treadmill run. There was a significant difference between FEV\textsubscript{1} following the inhalation of either 800 microg (4.4 ± 0.5 L) or 1600 microg (4.4 ± 0.4 L) salbutamol when compared to placebo (4.3 ± 0.5 L) prior to the football-specific run. This significant difference was maintained following the completion of the football specific run following the inhalation of either 800 microg or 800 μg (4.5 ± 0.5 L) or 1600 microg (4.5 ± 0.5 L) salbutamol when compared placebo (4.3 ± 0.5 L). The improvements in FEV\textsubscript{1} following the inhalation of 800 microg or 1600 microg salbutamol prior to the football-specific treadmill run appears to suggest there is a potential for significant bronchodilation in the airways of non-asthmatic football players. The difference in FEV\textsubscript{1} between placebo and salbutamol appears to be maintained following the completion of a football-specific treadmill run [11484].
One study examined the effects of an oral acute administration of the beta2-agonist salbutamol (Sal) (6 mg) versus placebo on muscle strength and fatigability in 12 non-asthmatic recreational male athletes in a randomized double-blind protocol. Contractile properties of the right quadriceps muscle were measured during electrical stimulations, i.e. twitch, 1-s pulse trains at 20 (P(20)) and 80 Hz (P(80)) and during maximal voluntary isometric contraction (MVIC) before (PRE) and after (POST) a fatigue-producing protocol set by an electromyostimulation (30 contractions, frequency: 75 Hz, on-off ratio: 6.25-20s). In addition, the level of muscle voluntary activation was measured. In PRE and POST conditions, the peak torque (PT) of twitch, P(80) and MVIC were not modified by the treatment. The PT in POST P(20) was slightly, although not significantly, less affected by fatigue in Sal compared with placebo condition. Moreover, twitch half-relaxation time at PRE was smaller under Sal than under placebo. No significant changes in the degree of voluntary activation were observed with Sal treatment in PRE or POST condition. It was concluded that although these findings did not exclude completely an effect of Sal on peripheral factors of human skeletal muscle, oral acute administration of the beta2-agonist salbutamol seems to be without any relevant ergogenic effect on muscle contractility and fatigability in non-asthmatic recreational male athletes [11485].

Salbutamol is sometimes misused or abused, which can result in various cardiovascular adverse effects. We report one case of fatal salbutamol misuse or abuse in a 36-year-old poorly controlled female asthmatic patient with a past medical history of alcoholism and a recent smoking cessation. She died shortly after hospital admission following acute dyspnea and sudden collapse at home. Toxicological analyses evidenced salbutamol overdose, and necropsy showed acute lung edema and marked dysplasia of the right ventricle and revealed the patient was pregnant. The involvement of an initial disorder of the ventricular rhythm leading to cardiac failure is suggested by the presence of several combined pro-arrhythmogenic factors, such as arrhythmogenic right ventricle dysplasia, hypoxemia related to bronchospasm and salbutamol overdose [11486].

One study was designed to examine the dose-response relationship of inhaled salbutamol and its concentration in the urine while resting at various times after inhalation, and to compare these values against the current World Anti-Doping Code limits. Eight healthy, nonasthmatic males participated in the study. Administration of three different doses of inhaled salbutamol (800, 400, and 200 microg) in a randomized fashion separated by at least 72 hours gave highly variable urine concentrations between subjects and increased as dose increased, with a significant difference noted between 800 and 200 microg at 30, 60, and 120 minutes after inhalation. Urine concentrations of salbutamol peaked at 60 minutes for all doses. No samples exceeded the doping criterion of 1000 ng/mL, and the maximum value observed was 904 ng/mL. These results indicate that after inhalation of doses up to 800 microg, urinary concentrations of salbutamol are well below the limits used in doping control [08349].

A fast and reliable quantitative method for salbutamol using direct analysis of the urine sample by ultraperformance liquid chromatography tandem mass spectrometry (UPLC/MS/MS) has been developed. Urine samples were spiked with salbutamol-d6 (internal standard), and, then, they were diluted with ultrapure water (1:1, v/v). Aliquots of 1 microl of the mixture were directly analyzed by UPLC/MS/MS. The chromatographic separation was performed in a UPLC BEH C18 (100 mm x 2.1 mm, 1.7 microm) column with a mobile phase contained 0.01 percent formic acid in ultrapure water (v/v) and 0.01 percent formic acid in acetonitrile (v/v), using gradient elution at 0.6 ml/min. The temperature of the column was set to 45 degrees C. The total run time was 3.2 min. Electrospray ionization in positive ion mode was used under multiple reaction monitoring (MRM) at different collision
energies. Nitrogen and argon were used as desolvation and collision gas, respectively. The method was shown to be linear from 200 to 5000 ng/ml. The limit of quantitation was estimated in 200 ng/ml. Intra-assay precision and accuracies, evaluated by using quality control samples containing 550 and 1100 ng/ml salbutamol, were always better than 8.4 percent. The intermediate precision was estimated to be in the range of 5.6-8.9 percent. The method was shown to be reliable when applying to routine samples, and the short analysis time resulting from a simple sample preparation and a fast instrumental analysis makes it of great interest for antidoping control purposes [09241].

Data on blood and urinary concentrations of salbutamol after inhalation and oral administration in healthy subjects are scarce. Accordingly, it was examined the pharmacokinetics of inhaled and oral salbutamol in asthmatic subjects. It was enrolled 10 men aged 18-45 years in an open-label study in which 0.8 mg of inhaled or 8 mg of systemic salbutamol was administered in a crossover design. All subjects had doctor-diagnosed asthma, used beta2-agonist when needed, and abstained from any medicine, beta2-agonist inclusive, for 14 d before visit. Urine was collected from all subjects (0-4, 4-8, and 8-12 h), and blood samples were taken at 0, 0.5, 1, 2, 3, 4, and 6 h after salbutamol administration. Maximum urine concentration was reached during the first 4 h after administration of both inhaled and oral salbutamol. It was found significant differences in median urinary concentrations (C_{max}) of 261 and 2422 ng/mL, respectively. Urinary concentrations show high individual variability irrespective of the route of administration. Blood analyses showed a systemic exposure of salbutamol after both inhaled and oral salbutamol with peak concentration after inhalation before the oral intake. A significant difference in median C_{max} after inhalation and oral treatment was found: 1.75 and 18.77 ng/mL, respectively. It was concluded that median urinary concentrations after oral administration of 8 mg of salbutamol were significantly higher than those after inhalation of 0.8 mg of salbutamol [10169].

It was examined blood and urine concentrations of repetitive doses of inhaled salbutamol in relation to the existing cut-off value used in routine doping control. It was compared the concentrations in asthmatics with regular use of beta2-agonists prior to study and healthy controls with no previous use of beta2-agonists. It was enrolled 10 asthmatics and 10 controls in an open-label study in which subjects inhaled repetitive doses of 400 microgram salbutamol every second hour (total 1600 microgram), which is the permitted daily dose by the World Anti-Doping Agency (WADA). Blood samples were collected at baseline, 30 min, 1, 2, 3, 4, and 6 h after the first inhalations. Urine samples were collected at baseline, 0-4 h, 4-8 h, and 8-12 h after the first inhalations. Median urine concentrations peaked in the period 4-8 h after the first inhalations in the asthmatics and between 8-12 h in controls and the median ranged from 268 to 611 ng/mL. No samples exceeded the WADA threshold value of 1000 ng/mL when corrected for the urine specific gravity. When not corrected one sample exceeded the cut-off value with urine concentration of 1082 ng/mL. In conclusion it was found no differences in blood and urine concentrations between asthmatic and healthy subjects. It was found high variability in urine concentrations between subjects in both groups. The variability between subjects was still present after the samples were corrected for urine specific gravity [11188].

The prevalence of asthma is higher in elite athletes than in the general population. The risk of developing asthmatic symptoms is the highest in endurance athletes and swimmers. Asthma seems particularly widespread in winter-sport athletes such as cross-country skiers. Asthmatic athletes commonly use inhaled beta2-agonists to prevent and treat asthmatic symptoms. However, beta2-agonists are prohibited according to the Prohibited List of the World Anti-Doping Agency. An exception can be made only for the substances formoterol, salbutamol, salmeterol and terbutaline by inhalation, as long as a therapeutic use exemption has been applied for and granted. In this context, the question arises of whether beta2-
agonists have ergogenic benefits justifying the prohibition of these substances. In 17 of 19 randomised placebo-controlled trials in non-asthmatic competitive athletes, performance-enhancing effects of the inhaled beta$_2$-agonists formoterol, salbutamol, salmeterol and terbutaline could not be proved. This is particularly true for endurance performance, anaerobic power and strength performance. In three of four studies, even supratherapeutic doses of salbutamol (800-1200 microg) had no ergogenic effect. In contrast to inhaled beta$_2$-agonists, oral administration of salbutamol seems to be able to improve the muscle strength and the endurance performance. There appears to be no justification to prohibit inhaled beta$_2$-agonists from the point of view of the ergogenic effects [07194].

Data on pharmacokinetics of inhaled and oral salbutamol in elite athletes with asthma are needed to differentiate between therapeutic use and doping in doping control. Eight elite athletes with asthma and 10 nonasthmatic subjects aged 18 to 33 years were given 0.8 mg of inhaled salbutamol and 8 mg of oral salbutamol separated by 14 days and it was measured urine concentration of free salbutamol. Maximum urine concentrations peaked in the period of 0 to 4 hours after the administration of inhaled and oral salbutamol in both groups. Median concentrations after inhaled salbutamol and oral salbutamol were 402 and 2108 ng/mL in healthy subjects and 335 and 2975 ng/mL in elite athletes with asthma. There were no significant statistical differences between the groups. One sample exceeded the World Anti-Doping Agency threshold value of 1000 ng/mL with a urinary salbutamol concentration of 1057 ng/mL 4 hours after inhalation, when no correction for urine specific gravity was done. When this sample was corrected for urine specific gravity, the result was 661 ng/mL. It was thus concluded that there was no significant difference in pharmacokinetic profile of inhaled and oral salbutamol between elite athletes with asthma and nonasthmatic subjects. The results indicate that urine salbutamol concentrations should be corrected for urine specific gravity when evaluating doping cases [12310].

The prevalence of asthma is higher among elite athletes than in the general population. This has resulted in the frequent use of anti-asthmatic medication such as beta2-agonists among asthmatic athletes. Beta2-agonists are on the prohibited list of WADA. The use of the beta2-agonist salbutamol is only permitted in therapeutic inhaled doses. Most studies have reported the lack of ergogenic effects of therapeutic doses of inhaled beta2-agonists measured in maximal oxygen uptake. No previous studies have examined any possible effects of high-dose inhaled salbutamol on oxygen uptake kinetics. It was enrolled nine healthy well-trained men in a randomized, blinded, placebo-controlled crossover study. Subjects were randomized to inhalation of 40 puffs of 0.2 mg salbutamol or two placebo tablets and performed an incremental test to exhaustion and three submaximal tests at 75% of peak power to determine oxygen uptake kinetics. During the incremental test, there were no effects of inhaled salbutamol on VO$_2$$_{max}$ in absolute or relative terms, and no effect on peak power and lactate threshold. During the submaximal test, we found no effects on the time constant, time delay, the mean response time or O$_2$ deficit related to oxygen uptake kinetics. In conclusion, no ergogenic effect of a high dose of salbutamol on aerobic capacity was found [12311].

The renal elimination of salbutamol in asthmatic and non-asthmatic subjects was investigated, who received either 0.8 mg of salbutamol via inhalation or 8 mg in tablet formulation orally. The inhaled salbutamol did not result in urinary concentrations exceeding the threshold of 1000 ng/mL when correction for specific gravity was applied. In contrast, the oral application of 8 mg yielded peak values of free urinary salbutamol of more than 6000 ng/mL. The comparison of pharmacokinetic profiles of elite athletes and non-asthmatic individuals did not reveal a statistically significant difference. In order to provide a means to differentiate a potential misuse of beta$_2$-agonists from therapeutic usage, two studies focusing on either inhaled formoterol (18 mg) or inhaled salmeterol (100 mg) were presented.
Demonstrating limits of quantification (LOQs) at sub-ng/mL concentrations in urine, both analytes were sensitively determined in administration study urine samples and authentic doping control specimens. In case of formoterol peak values of 11.4 ng/mL were observed while salmeterol did not exceed 1.3 ng/mL in elimination studies; doping control specimens concentrations below 30 ng/mL and 2 ng/mL prevailed for formoterol and salmeterol, respectively [12017].

Prevalence of exercise-induced bronchoconstriction (EIB) is high in elite athletes, especially after many years training in cold and dry air conditions. The primary treatment of EIB is inhaling a short-acting beta-2-agonist such as salbutamol. However, professional speed skaters also inhale nebulized isotonic saline or tap water before and after a race or intense training. The use of nebulized isotonic saline or tap water to prevent EIB has not been studied before, raising questions about safety and efficacy. The aim of one study was to analyze the acute effect of nebulized isotonic saline or salbutamol on EIB in elite speed skaters following a 1,500-meter race. The randomized controlled trial compares single dose treatment of 1 mg nebulized salbutamol in 4 mL of isotonic saline, or with 5 mL of isotonic saline. A minimum of 13 participants will be allocated in each treatment group. Participants should be between 18 and 35 years of age and able to skate 1,500 m in less than 2 min 10 s (women) or 2 min 05 s (men). Repeated measurements of spirometry, forced oscillation technique, andelectromyography will be performed before and after an official 1,500-m race. Primary outcome of the study is the difference in fall in FEV1 after exercise in the different treatment groups. The trial is currently enrolling participants. Elite athletes run the risk of pulmonary inflammation and remodeling as a consequence of their frequent exercise, and thus increased ventilation in cold and dry environments. Although inhalation of nebulized isotonic saline is commonplace, no study has ever investigated the safety or efficacy of this treatment [13408].

According to WADA, all beta$_2$-agonists are per se categorized as prohibited with the exemptions of inhaled salbutamol (maximum allowed dosage 1600 microg/day), inhaled formoterol (maximum allowed dosage 54 microg/day) and inhaled salmeterol. Further to the permitted routes and daily dosages of salbutamol and formoterol, urinary threshold levels have been enforced [13009].

**Effect on performance**

Salbutamol may affect lung function and exercise performance differently in individuals with and without asthma. To compare the effects of inhaled salbutamol on lung function, exercise performance and respiratory parameters during cycling exercise in athletes with a positive response to a eucapnic voluntary hyperpnoea (EVH+) and negative (EVH-) challenge, indicative of exercise-induced bronchoconstriction was investigated. In a randomised controlled trial with a crossover design, a total of 49 well-trained male athletes (14 EVH+ and 35 EVH-) performed two simulated 10 km time-trials on a cycle ergometer 60 min after the inhalation of either 400 microg of salbutamol or a placebo. Lung function, assessed by forced expiratory volume in 1 s, was measured immediately before and 30 min after inhalation. Performance was measured by mean power output. Despite a significant increase in lung function after the inhalation of salbutamol compared to the placebo, salbutamol did not affect athletes' perceptions of dyspnoea or leg exertion during exercise. Salbutamol did not affect mean power output: EVH+ and EVH- athletes averaged 4.0 (0.5) and 4.1 (0.5) W/kg after salbutamol and 4.0 (0.5) W/kg and 4.0 (0.4) W/kg after placebo, respectively. It was concluded that the inhalation of salbutamol induced a significant increase in resting lung function in EVH+ and EVH- athletes but this improvement in lung function did not translate to improved exercise performance. Salbutamol had no discernible effect on key ventilatory and exercise parameters regardless of EVH challenge outcome [13409].
Neuromuscular function

The potential ergogenic effects of therapeutic inhaled salbutamol doses in endurance athletes have been controversially discussed for decades. It was hypothesized that salbutamol inhalation may increase peripheral muscle contractility, reduce fatigability, and improve force recovery after a localized exercise in endurance athletes. Eleven healthy, nonasthmatic male athletes with high aerobic capacities were recruited to be compared in a double-blinded, randomized crossover study of two dose levels of salbutamol (200 and 800 microg) and a placebo administered by inhalation before a quadriceps fatigue test. Subjects performed an incremental exercise protocol consisting in sets of 10 intermittent isometric contractions starting at 20 percent of maximum voluntary contraction (MVC) with 10 percent MVC increment until exhaustion. Femoral nerve magnetic stimulation was used during and after MVC to evaluate neuromuscular fatigue after each set, at task failure, and after 10 and 30 min of recovery. Initial MVC and evoked muscular responses were not modified with salbutamol. The total number of submaximal contractions until task failure significantly differed between treatments. MVC and evoked muscular responses were similarly reduced with all treatments during the fatiguing task. Voluntary activation was unaffected by the fatiguing task and treatments. It was concluded that supratherapeutic inhaled doses of beta2-agonists increased quadriceps endurance during an incremental and localized fatiguing task in healthy endurance-trained athletes without significant effect on neuromuscular fatigue. Further studies are needed to clarify the underlying mechanisms [13410].

After intense exercise in endurance athletes

The objective of one study was to investigate urine concentrations of 8 mg oral salbutamol in samples collected after intense exercise in endurance athletes. Nine male endurance athletes with a VO2max of 70 mL/min/kg (mean) took part in the study. Two hours after administration of 8 mg oral salbutamol, subjects performed submaximal exercise for 15 min followed by two, 2-min exercise bouts at an intensity corresponding to 110 percent of VO2max and a bout to exhaustion at same intensity. Urine samples were collected 4, 8, and 12 h following administration of salbutamol. Samples were analyzed by the Norwegian World Anti-doping Agency (WADA) laboratory. Adjustment of urine concentrations of salbutamol to a urine specific gravity (USG) of 1.020 g/mL was compared with no adjustment according to WADA's technical documents. It was observed greater urine concentrations of salbutamol 4 h after administration when samples were adjusted to a USG of 1.020 g/mL compared with no adjustment (3089 ± 911 vs 1918 ± 1081 ng/mL). With the current urine decision limit of 1200 ng/mL for salbutamol on WADA's 2013 list of prohibited substances, fewer false negative urine samples were observed when adjusted to a USG of 1.020 g/mL compared with no adjustment. In conclusion, adjustment of urine samples to a USG of 1.020 g/mL decreases risk of false negative doping tests after administration of oral salbutamol [043]. Adjusting urine samples for USG might be useful when evaluating urine concentrations of salbutamol in doping cases [13411].

Renal elimination

The renal elimination of salbutamol in asthmatic and non-asthmatic subjects was investigated, who received either 0.8 mg of salbutamol via inhalation or 8 mg in tablet formulation orally. The inhaled salbutamol did not result in urinary concentrations exceeding the threshold of 1000 ng/ml when correction for specific gravity was applied. In contrast, the oral application of 8 mg yielded peak values of free urinary salbutamol of more than
6000 ng/ml. The comparison of pharmacokinetic profiles of elite athletes and non-asthmatic individuals did not reveal a statistically significant difference [13012].

**Acute effects on muscles**

The potential ergogenic effects of therapeutic inhaled salbutamol doses in endurance athletes have been controversially discussed for decades. It was hypothesized that salbutamol inhalation may increase peripheral muscle contractility, reduce fatigability, and improve force recovery after a localized exercise in endurance athletes. Eleven healthy, nonasthmatic male athletes with high aerobic capacities were recruited to be compared in a double-blinded, randomized crossover study of two dose levels of salbutamol (200 and 800 microg) and a placebo administered by inhalation before a quadriceps fatigue test. Subjects performed an incremental exercise protocol consisting in sets of 10 intermittent isometric contractions starting at 20 percent of maximum voluntary contraction (MVC) with 10 percent MVC increment until exhaustion. Femoral nerve magnetic stimulation was used during and after MVC to evaluate neuromuscular fatigue after each set, at task failure, and after 10 and 30 min of recovery. Initial MVC and evoked muscular responses were not modified with salbutamol. The total number of submaximal contractions until task failure significantly differed between treatments. MVC and evoked muscular responses were similarly reduced with all treatments during the fatiguing task. Voluntary activation was unaffected by the fatiguing task and treatments. Supratherapeutic inhaled doses of the beta2-agonists increased quadriceps endurance during an incremental and localized fatiguing task in healthy endurance-trained athletes without significant effect on neuromuscular fatigue. Further studies are needed to clarify the underlying mechanisms [13412].

**Side effects**

**Effects on bone remodeling**

Animal studies suggest that bone remodeling is under beta-adrenergic control via the sympathetic nervous system. The impact of beta-agonist substances, at doping doses, has not been studied in adult rats. The purpose of one study was to examine the effects of salbutamol injections with or without treadmill exercise on trabecular and cortical bone in adult rats. Adult (36 week of age) female Wistar rats (n=56) were treated with salbutamol (3 mg/kg/day sc, 5 days/week) or vehicle (sham) with or without subsequent treadmill exercise (13 m/min, 60 min/day, 5 days/week) for 10 week. Tibial and femoral bone mineral density was analyzed by dual-energy X-ray absorptiometry. Metaphysic trabecular bone structure was analyzed by micro-CT at the time of the animals' death. Bone cell activities were assessed histomorphometrically. After 10 wk, the increase in bone mineral density was less in salbutamol-treated than in sham rats (+3.3 % vs +12.4 %), and trabecular parameters were altered and bone resorption was increased in salbutamol-treated rats compared with controls. The negative effect on bone architecture in salbutamol-treated rats persisted, even with treadmill exercise. These results confirm the deleterious effect of beta2-agonists on bone mass during chronic treatment and describe its effects on bone mechanical properties in adult rats. Bone loss occurred independently of a salbutamol-induced anabolic effect on muscle mass and was equally severe in sedentary and exercising rats, despite a beneficial effect of exercise on the extrinsic and intrinsic energy to ultimate strain. These bone effects may have important consequences in athletes who use salbutamol as a doping substance [06206].

**Experimental**

A key question regarding the biochemical basis of potential salbutamol-mediated anabolic
effects concerns whether salbutamol activates such effects through beta-adrenoreceptor stimulation or by other mechanisms. Beta-2 agonist-mediated anabolic effects on muscle have been reported to be dependent and independent of actions on beta-adrenoreceptors. Salbutamol has been shown to mediate anabolic effects after intravenous administration. However, the mechanism responsible for the anabolic actions of salbutamol remains unknown. The potential androgenic activity of salbutamol was investigated in vitro by the A-Screen assay that measures androgen-dependent inhibition of proliferation of the androgen receptor (AR)-positive human mammary carcinoma cell line, MCF7-AR1. The results indicate that salbutamol exerts anabolic effects through androgen receptor agonistic activity in vitro [07185].

**Laboratory techniques**

Salbutamol is commonly used in asthma treatment, being considered a short-effect bronchodilator. This drug poses special interest in certain fields of chemical analysis, such as food, clinical and doping analyses, in which it needs to be analyzed with quantitative precision and accuracy. Salbutamol, however, is known to degrade under certain conditions and this is critical if quantitative results must be generated. One study aimed to investigate salbutamol extraction from urine samples, to determine whether salbutamol is unstable in other solvents as well as in urine samples, to elucidate the structures of the possible degradation products and to validate an analytical method using the extraction procedure evaluated. Stability investigations were performed in urine at different pH values, in methanol and acetone at different temperatures. Semi-preparative liquid chromatography was performed for the isolation of degradation products, and gas chromatography coupled to mass spectrometry as well as nuclear magnetic resonance were used for identification. Three unreported methylation products were detected in methanolic solutions and had their structures elucidated. Urine samples showed a reduction in salbutamol concentration of up to 26 percent after 5 weeks. These results show that special care must be taken regarding salbutamol quantitative analyses, since degradation either in standard solutions or in urine could lead to incorrect values [13413].

Matrix effects in determination of three beta-receptor agonists including salbutamol (SAL), clenbuterol, and terbutaline in animal-derived foodstuffs were studied by ultra-performance LC-MS/MS with cleanup of immunoaffinity SPE column (IAC). Some animal tissue samples including pig liver, swine muscle, and fish muscle were hydrolyzed by the mixed enzyme solution or HCl solution, and the cleanup efficiencies with SAL IAC, MCX SPE column, and C(18)-SCX tandem columns were examined and compared by using spiked experiments. The results showed that the matrix effects in the determination of SAL and terbutaline can be eliminated with SAL IAC cleanup, and the average recoveries of SAL were 77-82, 79-83, and 85-87 percent in pig liver, swine muscle, and fish muscle, respectively. The decision limit (ccalpha) and detection capability (ccbeta) for SAL in pig liver were 0.02 and 0.05 microg/kg, respectively [12312].

**Terbutaline**

Terbutaline is a fast-acting beta2-adrenergic agonist used in the treatment of obstructive pulmonary diseases. Doping control for beta2-agonists, which are forbidden in sports by the World Anti-doping Agency (WADA), is performed in screening by liquid chromatography/mass spectrometry after hydrolysis of phase-II metabolites. In one study, the mono-sulfoconjugated phase-II metabolite of terbutaline was synthesized and the chemical structure was characterized by 1H-nuclear magnetic resonance spectrometry and
high resolution/high accuracy Orbitrap mass spectrometry. The metabolite was designated as the phenolic esterified compound, which has been mentioned in most literature reports but has not been verified so far. The benzylic esterified compound was also synthesized and characterized by high-resolution/high accuracy Orbitrap mass spectrometry but was not detectable in urine samples from an excretion study performed after a single application of one terbutaline capsule (7.5 mg terbutaline sulfate salt). The phenolic sulfate of terbutaline was detected for two to four days after administration, whereas the unchanged terbutaline was detected for four to five days. A glucuronidated, disulfated or trisulfated phase-II metabolite of terbutaline was not found. The measurement of phase-II metabolites is planned to be incorporated into existing screening procedures to allow a faster sample preparation.

It was examined urine and serum concentrations after therapeutic use of single and repetitive doses of inhaled and supratherapeutic oral use of terbutaline. It was compared the concentrations in 10 asthmatics and 10 healthy subjects in an open-label, cross-over study with 2 mg inhaled and 10 mg oral terbutaline on 2 study days. Further, 10 healthy subjects were administrated 1 mg inhaled terbutaline in 4 repetitive doses with total 4 mg. Blood samples were collected at baseline and during 6 h after the first inhalations. Urine samples were collected at baseline and during 12 h after the first inhalations. Median (IQR) urine concentrations peaked in the period 0-4 h after inhalation with Cmax 472 (324) ng/mL in asthmatics and 661 (517) ng/mL in healthy subjects, and 4-8 h after oral use with Cmax 666 (877) ng/mL in asthmatic and 402 (663) ng/mL in healthy subjects. In conclusion it was found no significant differences in urine and serum concentrations between asthmatic and healthy subjects. It was compared urine and serum concentrations after therapeutic inhaled doses and supratherapeutic oral doses and observed significant statistical differences in both groups but found it impossible to distinguish between therapeutic and prohibited use based on doping tests with urine and blood samples.

One study aimed to investigate the effects on a possible improvement in aerobic and anaerobic performance of oral terbutaline (TER) at a supra-therapeutic dose in 7 healthy competitive male athletes. On day 1, ventilatory threshold, maximum oxygen uptake and corresponding power output were measured and used to determine the exercise load on days 2 and 3. On days 2 and 3, 8 mg of TER or placebo were orally administered in a double-blind process to athletes who rested for 3 h, and then performed a battery of tests including a force-velocity exercise test, running sprint and a maximal endurance cycling test at delta 50 percent. Lactatemia, anaerobic parameters and endurance performance were raised during the corresponding tests. It was found that TER administration did not improve any of the parameters of aerobic performance. In addition, no change in kinetic parameters was found with TER compared to placebo. Moreover, no enhancement of the force-velocity relationship was observed during sprint exercises after TER intake and, on the contrary, maximal strength decreased significantly after TER intake but maximal power remained unchanged. In conclusion, oral acute administration of TER at a supra-therapeutic dose seems to be without any relevant ergogenic effect on anaerobic and aerobic performances in healthy athletes. However, all participants experienced adverse side effects such as tremors.

Repeated injury of the airway epithelium caused by hyperpnoea of poorly conditioned air has been proposed as a key factor in the pathogenesis of exercise-induced bronchoconstriction (EIB) in athletes. In animals, the short-acting beta2-agonist terbutaline has been shown to reduce dry airflow-induced bronchoconstriction and the associated shedding of airway epithelial cells. Our aim was to test the efficacy of inhaled terbutaline in attenuating hyperpnoea-induced bronchoconstriction and airway epithelial injury in athletes. Twenty-seven athletes with EIB participated in a randomized, double-blind, placebo-controlled,
crossover study. Athletes completed an 8-min eucapnic voluntary hyperpnoea (EVH) test with dry air on two separate days 15 min after inhaling 0.5 mg terbutaline or a matching placebo. Forced expiratory volume in 1 s (FEV1) and urinary concentration of the club cell (Clara cell) protein 16 (CC16, a marker of airway epithelial perturbation) were measured before and up to 60 min after EVH. The maximum fall in FEV1 of 17 ± 8 percent on placebo was reduced to 8 ± 5 percent following terbutaline. Terbutaline gave bronchoprotection (i.e. post-EVH FEV1 fall <10%) to 22 (81 %) athletes. EVH caused an increase in urinary excretion of CC16 in both conditions, and terbutaline significantly reduced this rise (pre-to postchallenge CC16 increase 416 ± 495 pg/micromol creatinine after placebo versus 315 ± 523 pg/micromol creatinine after terbutaline). These results suggest that the inhalation of a single therapeutic dose of terbutaline offers significant protection against hyperpnoea-induced bronchoconstriction and attenuates acute airway epithelial perturbation in athletes [13415].

Using an analytical set-up with modified internal standard, a study allowing to assess the possible differentiation of inhaled versus orally administered terbutaline was conducted with healthy (10 male volunteers) as well as asthmatic (10 male volunteers) individuals. While the expected differences in urinary concentrations were observed in both groups following inhalation and oral application of 2-4 mg and 10 mg, respectively, no significant difference was found between the healthy and asthmatic persons. Moreover it remained impossible to adequately distinguish between therapeutic and non-therapeutic use of the beta2-agonist [13009].

**Urine and serum concentrations of inhaled and oral terbutaline**

It was examined urine and serum concentrations after therapeutic use of single and repetitive doses of inhaled and supratherapeutic oral use of terbutaline. It was compared the concentrations in 10 asthmatics and 10 healthy subjects in an open-label, cross-over study with 2 mg inhaled and 10 mg oral terbutaline on 2 study days. Further, 10 healthy subjects were administrated 1 mg inhaled terbutaline in 4 repetitive doses with total 4 mg. Blood samples were collected at baseline and during 6 h after the first inhalations. Urine samples were collected at baseline and during 12 h after the first inhalations. Median (IQR) urine concentrations peaked in the period 0-4 h after inhalation with Cmax 472 (324) ng/mL in asthmatics and 661 (517) ng/mL in healthy subjects, and 4-8 h after oral use with Cmax 666 (877) ng/mL in asthmatic and 402 (663) ng/mL in healthy subjects. In conclusion we found no significant differences in urine and serum concentrations between asthmatic and healthy subjects. It was compared urine and serum concentrations after therapeutic inhaled doses and supratherapeutic oral doses and observed significant statistical differences in both groups but found it impossible to distinguish between therapeutic and prohibited use based on doping tests with urine and blood samples [12314].

**Formoterol**

It was examined urinary and serum concentrations of formoterol in asthmatic and healthy individuals after a single dose of 18 µg inhaled formoterol and after repeated inhaled doses in healthy individuals. Results were evaluated with the WADA 2012 threshold for formoterol. On the day of this open-label, crossover study, 10 asthmatic subjects who regularly used beta2-agonists and 10 healthy participants with no previous use of beta2-agonists received a single dose of 18 µg formoterol. Further, 10 non-asthmatic participants inhaled 18 µg formoterol every second hour until obtaining a total of 72 µg, which is twice the maximum daily dose (36 microg formoterol) permitted by the World Anti-Doping Agency (WADA). Blood
samples were collected at baseline, 30 min, 1, 2, 3, 4, and 6 hours after the first inhalation. Urine samples were collected at baseline, 0-4, 4-8, and 8-12 hours after the first inhalation. Median urine concentration, corrected for specific gravity, after the single-dose administration peaked during 0-4 hours after inhalation at a maximum of 7.4 ng/mL in asthmatic subjects and 7.9 ng/mL in healthy subjects. Median urine concentration after repeated doses peaked during 4-8 hours after inhalation of a total of 72 microg formoterol at a maximum of 16.8 ng/mL in healthy participants. The maximal individual concentration of 25.6 ng/mL was found after inhalation of a total of 72 microg formoterol. It was thus not found any significant differences in urinary and serum concentrations of formoterol between asthmatic and healthy subjects. It was found high inter-individual variability in the concentrations in all groups. The data support the WADA 2012 urinary threshold of 30 ng/mL formoterol as being an adverse analytical finding [12511].

Formoterol is a frequently prescribed beta2-agonist used for the treatment of asthma. Due to performance-enhancing effects of some beta2-agonists, formoterol appears on the prohibited list, published by the World Anti-doping Agency (WADA). Its therapeutic use is allowed but restricted to inhalation. Since the data on urinary concentrations originating from therapeutic use is limited, no discrimination can be made between use and misuse when a routine sample is found to contain formoterol. Therefore the urinary excretion of six volunteers after inhalation of 18 microg of formoterol was investigated. A liquid chromatography-tandem mass spectrometry (LC-MS/MS) method was developed and validated for the quantification of formoterol in urine samples. Sample preparation consists of an enzymatic hydrolysis of the urine samples, followed by a liquid-liquid extraction at pH 9.5 with diethyl ether/isopropanol (5/1, v/v). Analysis was performed using selected reaction monitoring after electrospray ionization. The method was linear in the range of 0.5-50 ng/mL. The limit of quantification (LOQ) was 0.5 ng/ml. The bias ranged between -1.0 and -6.8 percent. Results for the urinary excretion show that formoterol could be detected for 72 h. The maximum urinary concentration detected was 8.5 ng/ml without and 11.4 ng/ml after enzymatic hydrolysis. Cumulative data showed that maximum 12 and 23 percent of the administered dose is excreted as parent drug within the first 12 h, respectively, non-conjugated and conjugated. Analysis of 82 routine doping samples, declared positive for formoterol during routine analysis, did not exhibit concentrations which could be attributed to misuse [12315].

Formoterol is a long-acting beta2-adrenoceptor agonist used for the treatment of bronchial asthma, prevention of exercise-induced bronchospasm, and for chronic obstructive pulmonary disease (COPD). It is formulated as a fumarate salt, and consists of a racemic mixture of two enantiomers. It is normally administered by inhalation either alone or in combination with a glucocorticosteroid. Formoterol has an extended duration of action (up to 12 h) compared to short-acting beta2 agonists such as salbutamol. In addition to the desired pharmacological action, there is some evidence indicating that systemic beta2-agonists may have a positive effect on physical performance in healthy subjects and, for this reason, its use in sports is restricted by the World Anti-Doping Agency (WADA). All beta2-agonists are prohibited with the exception of salbutamol, formoterol, and salmeterol when taken by inhalation in accordance to the manufacturer's recommended therapeutic regime. Recently, a threshold concentration of 30 ng/mL was defined by the World Anti-Doping Agency (WADA) to distinguish between therapeutic and forbidden use of formoterol. The objective of one work was to evaluate that threshold concentration. Concentrations of formoterol were measured in urine samples collected after administration of 18 microg of inhaled formoterol to five healthy volunteers, and in samples collected in routine doping tests belonging to athletes having declared inhaled formoterol use. Formoterol was detected up to 8 h after administration in all volunteers with concentrations up to 19.6 ng/mL. From 28 routine samples, 27 had less than 10 ng/mL of formoterol and only in one of the samples the concentration was 25 ng/mL. Therefore, administration of formoterol by inhalation at the
maximum dose allowed by WADA will not produce false positive results using a threshold concentration of 30 ng/mL, and the experience up to now in routine doping tests indicates that the probability of obtaining urines with concentrations greater than 30 ng/mL is close to nil. For this reason, sports authorities should re-evaluate the need of a threshold concentration for formoterol and its practical usefulness [13416].

In order to provide a means to differentiate a potential misuse of beta2-agonists from therapeutic usage, two studies focusing on either inhaled formoterol (18 microg) or inhaled salmeterol (100 microg) were presented. Demonstrating limits of quantification (LOQs) at sub-ng/mL concentrations in urine, both analytes were sensitively determined in administration study urine samples and authentic doping control specimens. In case of formoterol peak values of 11.4 ng/mL were observed while salmeterol did not exceed 1.3 ng/mL in elimination studies; doping control specimens concentrations below 30 ng/mL and 2 ng/mL prevailed for formoterol and salmeterol, respectively [13012].

Since 1992, formoterol is included in the prohibited list of doping substances and methods, presently reviewed and updated by the World Anti-Doping Agency. Recently a threshold value of 40 ng/mL has been established to differentiate between the prohibited (oral) and the permitted (inhalatory) administration of formoterol to athletes. This paper considers the urinary excretion profile of formoterol and its main metabolites after inhalation of different doses of two of the most used medicaments, available in Italy, containing formoterol fumarate bihydrate (12 and 36 microg twice a day of Foradil® or 9 and 27 microg twice a day of Symbicort®), focusing also on the effects, on the measured levels of formoterol, of potential alteration processes (thermal and/or microbiological) that may take place after the collection of the urine samples. Urine sample preparation included an enzymatic hydrolysis and a dilution step. Detection of analytes was performed by a newly developed and validated direct LC-ESI-MS/MS procedure, using a triple quadrupole mass spectrometer under positive ion electro-spray ionization conditions and selected reaction monitoring acquisition mode. The results showed the capability and suitability of the direct LC-ESI-MS/MS analysis for the quantitative confirmation analysis of formoterol in urine samples. The data from the analysis of the urine samples obtained in the excretion studies showed that formoterol is excreted mainly as unmodified drug and to a lesser degree as O-demethylated metabolite. The urinary levels of formoterol (40-60 %) and its metabolites (O-demethylated metabolite 5-25 %; glucuronide metabolites 25-40%) vary significantly depending both on the administered drug formulation and the subject tested. The maximum urinary concentration reached in this study was 15 ng/mL (free+glucuronide), that is significantly lower than the threshold value fixed to report an adverse analytical finding. Finally, the results also showed that formoterol is stable for at least 4 weeks in urine samples correctly collected and stored [13417].

The use of formoterol in sports is allowed by inhalation at the maximum recommended therapeutic dose. Recently, a threshold concentration of 30 ng/mL was defined by the World Anti-Doping Agency (WADA) to distinguish between therapeutic and forbidden use of formoterol. The objective of this work was to evaluate that threshold concentration. Concentrations of formoterol were measured in urine samples collected after administration of 18 microg of inhaled formoterol to five healthy volunteers, and in samples collected in routine doping tests belonging to athletes having declared inhaled formoterol use. Formoterol was detected up to 8 h after administration in all volunteers with concentrations up to 19.6 ng/mL. From 28 routine samples, 27 had less than 10 ng/mL of formoterol and only in one of the samples the concentration was 25 ng/mL. Therefore, administration of formoterol by inhalation at the maximum dose allowed by WADA will not produce false positive results using a threshold concentration of 30 ng/mL, and the experience up to now in routine doping tests indicates that the probability of obtaining urines with concentrations greater than 30
ng/mL is close to nil. For this reason, sports authorities should re-evaluate the need of a threshold concentration for formoterol and its practical usefulness [13418].

It was examined urinary and serum concentrations of formoterol in asthmatic and healthy individuals after a single dose of 18 microg inhaled formoterol and after repeated inhaled doses in healthy individuals. Results were evaluated using the World Anti-Doping Agency (WADA) 2012 threshold for formoterol. On the day of an open-label, crossover study, 10 asthmatic subjects who regularly used beta2-agonists and 10 healthy participants with no previous use of beta2-agonists received a single dose of 18 microg formoterol. Further, 10 nonasthmatic participants inhaled 18 microg formoterol every second hour until obtaining a total of 72 microg, which is twice the maximum daily dose (36 microg formoterol) permitted by the WADA. Blood samples were collected at baseline, 30 min, 1, 2, 3, 4, and 6 h after the first inhalation. Urine samples were collected at baseline, 0-4, 4-8, and 8-12 h after the first inhalation. Median urine concentration, corrected for specific gravity, after the single-dose administration peaked during 0-4 h after inhalation at a maximum of 7.4 ng/mL in asthmatic subjects and 7.9 ng/mL in healthy subjects. Median urine concentration after repeated doses peaked during 4-8 h after inhalation of a total of 72 microg formoterol at a maximum of 16.8 ng/mL in healthy participants. The maximum individual concentration of 25.6 ng/mL was found after inhalation of a total of 72 microg formoterol. It was found no significant differences in urinary and serum concentrations of formoterol between asthmatic and healthy subjects. It was found high interindividual variability in the concentrations in all groups. The data support the WADA 2012 urinary threshold of 30 ng/mL formoterol as being an adverse analytical finding [13419].

Formoterol is a new threshold substance in the prohibited list 2012 according to World Anti-Doping Agency. Extracted by ethyl acetate using formoterol-D6 as internal standard, formoterol underwent a constant flow rate gradient elution separation in reversed-phase liquid chromatography. Subsequently, mass spectrometry analysis was conducted by tandem mass spectrometry in the multiple reaction monitoring mode. According to the proposed method, a calibration curve was constructed in the range of 0.2-500 ng/mL with a limit of quantification 0.2 ng/mL. The mean extracted recovery assessed at three different concentrations (1, 30 and 100 ng/mL) was more than 80 percent. The method was validated by the analysis of three quality control samples from World Association of Anti-Doping Scientists. In conclusion, the developed and validated method was sensitive, accurate and precise for the quantification of formoterol in human urine for doping control purposes [13420].

Since 1992, formoterol is included in the prohibited list of doping substances and methods, presently reviewed and updated by the World Anti-Doping Agency. Recently a threshold value of 40 ng/mL has been established to differentiate between the prohibited (oral) and the permitted (inhalatory) administration of formoterol to athletes. One paper considers the urinary excretion profile of formoterol and its main metabolites after inhalation of different doses of two of the most used medicaments, available in Italy, containing formoterol fumarate bihydrate (12 and 36 microg twice a day of Foradil® or 9 and 27 microg twice a day of Symbicort®), focusing also on the effects, on the measured levels of formoterol, of potential alteration processes (thermal and/or microbiological) that may take place after the collection of the urine samples. Urine sample preparation included an enzymatic hydrolysis and a dilution step. Detection of analytes was performed by a newly developed and validated direct LC-ESI-MS/MS procedure, using a triple quadrupole mass spectrometer under positive ion electro-spray ionization conditions and selected reaction monitoring acquisition mode. The results showed the capability and suitability of the direct LC-ESI-MS/MS analysis for the quantitative confirmation analysis of formoterol in urine samples. The data from the analysis of the urine samples obtained in the excretion studies showed that formoterol is excreted
mainly as unmodified drug and to a lesser degree as O-demethylated metabolite. The urinary levels of formoterol (40-60 %) and its metabolites (O-demethylated metabolite 5-25 %; glucuronide metabolites 25-40 %) vary significantly depending both on the administered drug formulation and the subject tested. The maximum urinary concentration reached in this study was 15ng/mL (free + glucuronide), that is significantly lower than the threshold value fixed to report an adverse analytical finding. Finally, the results also showed that formoterol is stable for at least 4 weeks in urine samples correctly collected and stored [13421].

To the permitted routes and daily dosages of salbutamol and formoterol, urinary threshold levels have been enforced. For formoterol, this threshold was increased from 30 ng/mL to 40 ng/mL as of January 2013, and various studies were conducted to demonstrate the capability of doping control analytical assays to quantify the target analyte in sports drug testing samples as well as to probe for the rationale of the 2012 and 2013 thresholds for urinary formoterol [13009].

**Procaterol**

While the use of oral beta₂-agonists by athletes is prohibited because of their anabolic effects, some inhaled beta₂-agonists can be used in accordance with the World Anti-Doping Agency regulations. It was examined the dose disparity between the bronchodilating effect and anabolic effect of inhaled procaterol, a beta₂-agonists, to determine if the drug might be effective for athletes with asthma. Intact rats were given nebulized procaterol at 0.001, 0.01, 0.1 and 1 mg/mL by inhalation, and its inhibitory effect on carbachol-induced bronchoconstriction was evaluated. Castrated rats were given nebulized procaterol at 0.03, 0.1, 0.3 and 1 mg/mL by inhalation 3 times a day for 14 days, and anabolic markers (body weight gain, weight of the levator ani muscle and gastrocnemius muscle) were measured. At 0.01 mg/mL and higher, procaterol dose-dependently inhibited carbachol-induced bronchoconstriction with a significant effect. At doses of up to 0.3 mg/mL, there were no signs indicating an anabolic effect of procaterol. At 1 mg/mL, however, a slight but statistically significant increase in the weight of the levator ani muscle was observed with no significant changes in other anabolic markers. It was suggested that inhaled procaterol might be useful for athletes with asthma because of the big dose disparity between its bronchodilating effect and anabolic effect in rats [08350].

**Clenbuterol**

Rapid screening of clenbuterol in urine was performed by combining desorption electrospray ionization (DESI) and tandem mass spectrometry (MS/MS). Optimization experiments were carried out including the selection of substrates, spray solutions, nebulizing gas pressures, high-voltage power supplies and flow rates of spray solution. The limit of detection (LOD), defined as the lowest quantity that can be detected, was 5.0 pg for the pure compound. Using DESI coupled with solid-phase extraction (SPE), the linear response range was from 10 to 400 ng/mL and the concentration LOD for urine sample was 2.0 ng/mL. The analysis for one spiked urine sample was achieved within 4 min. In addition to the fast analysis speed, MS/MS provided structural information for the confirmation of clenbuterol. Urine samples from different people were investigated and the recoveries were within 100 ± 20 percent [08351].

Beta-agonists such as ractopamine (RAC) and clenbuterol (CLEN), have similar effects as anabolic steroids i.e. they promote growth of muscular tissue and reduce body fat. They have
been used successfully with animals and humans but have also been banned in many countries principally, because of their serious side effects. However, their illegal use persists. Thus, their interaction with biomolecules such as bovine serum albumin (BSA) is of significance, especially the co-operative reaction of mixed ligands with the protein. Fluorescence and UV-vis spectra of complex mixtures of individual ligands, binary and ternary complexes with BSA resulted in significantly overlapping spectral profiles. Qualitative and quantitative information about the various complex ligand-protein species formed, was obtained with the resolution of the excitation-emission fluorescence three-way data matrices by chemometrics methods-MCR-ALS and PARAFAC. Individual spectra of the ligands, their binary complexes with BSA and their ternary complexes were extracted, and quantitative concentration profiles for each species in a particular interaction were constructed. Such analyses made it possible to interpret the role and behaviour of each reaction component. It was found that both ligands, RAC and CLEN, bound co-operatively in site I of the BSA. This was confirmed with the use of site markers such as warfarin (site I) and ibuprofen (site II). However, CLEN formed a 1:1 CLEN-BSA complex, while RAC formed a 2:1 RAC(2)-BSA binary species. Interestingly, when CLEN or RAC was added to RAC(2)-BSA or CLEN-BSA, respectively, ternary complexes were produced such as RAC(2)-BSA-CLEN. Significantly, the presence of the second ligand in such an interaction in excess, appeared to increase the affinity of the added ligand for BSA. This may have consequences on the amount of steroid required to achieve a desired tissue growth effect [10375].

The beta-adrenergic signaling pathway represents a novel therapeutic target for skeletal muscle wasting and weakness due to its role in the mechanisms controlling protein synthesis and degradation and in modulating fiber type. Stimulation of the pathway with beta-adrenoceptor agonists (beta-agonists) has therapeutic potential for muscle wasting disorders including: sarcopenia, cancer cachexia, disuse and inactivity, unloading or microgravity, sepsis and other metabolic disorders, denervation, burns, HIV-AIDS, chronic kidney or heart failure, and neuromuscular diseases. However, there are also pitfalls associated with beta-agonist administration and clinical applications have so far been limited, largely because of cardiovascular side effects. In rats and mice, newer generation beta-agonists (such as formoterol) can elicit an anabolic response in skeletal muscle even at very low doses, with reduced effects on the heart and cardiovascular system compared with older generation beta-agonists (such as fenoterol and clenbuterol). However, the potentially deleterious cardiovascular side effects of beta-agonists have not been obviated completely and so it is important to refine their development and therapeutic approach in order to overcome these obstacles. A review describes the therapeutic potential of stimulating the beta-adrenergic signaling pathway with beta-agonists, highlighting the beneficial effects on skeletal muscle structure and function and identifying some of the pitfalls associated with short- and long-term beta-agonist administration [08352].

The beta2-agonist clenbuterol [4-amino-alpha(t-buty-l-amino)methyl-3,5-dichlorobenzyl alcohol] is used as a non-steroidal anabolic drug for sports doping. The effects of clenbuterol on the transcriptional process and mRNA stability of beta-adrenoceptor in skeletal and cardiac muscles are still unknown. Therefore, it was investigated the effects of clenbuterol on beta1- and beta2-adrenoreceptor mRNA expressions of fast-twitch fiber-rich extensor digitorum longus, slow-twitch fiber-rich soleus, and left ventricle muscles by real-time RT-PCR. Adult male Sprague Dawley rats were divided into the clenbuterol-administered group and control group. The administration (1.0 mg/kg body weight/day, subcutaneously) of clenbuterol was maintained for 10 days. The administration of clenbuterol significantly increased the weight, RNA concentration, and total RNA content of extensor digitorum longus muscle. No effects of clenbuterol on those of soleus and left ventricle muscles, however, were observed. The administration of clenbuterol significantly decreased beta1-AR mRNA expression of left ventricle muscle. Furthermore, the administration of clenbuterol
significantly decreased beta2-AR mRNA expression of extensor digitorum longus and left ventricle muscles. No effect of clenbuterol on beta2-AR mRNA expression of soleus muscle, however, was observed. These results suggest that the effects of clenbuterol on beta1- and beta2-AR mRNA expressions and muscle hypertrophy depend on muscle fiber types [08353].

The aim of one study was to evaluate the effect of joint immobilization on morphometric parameters and glycogen content of soleus muscle treated with clenbuterol in male Wistar (3-4 months old) rats. The clenbuterol group showed an increase in glycogen without alteration in weight, cross-sectional area or connective tissue compared with the control group. The immobilized group showed a reduction in muscle weight, glycogen content, and cross-sectional area, and an increase in connective tissue. However, the immobilized + clenbuterol group showed an increase in weight, glycogen, and cross-sectional area, and a reduction in connective tissue. This study emphasizes the importance of anabolic pharmacological protection during immobilization to minimize skeletal muscle alterations resulting from disuse [09246].

Enantiomers of clenbuterol were separated by a new HPLC method on a chiral column. Enantiomeric resolution was achieved on a vancomycyin macrocyclic antibiotic chiral stationary phase known as chirobiotic V with UV detection at 247 nm. The polar ionic mobile phase consisting of methanol-triethylamine-glacial acetic acid was used at a flow rate of 1.0 mL/min. The method was validated for linearity, accuracy, precision, and robustness. Standard linear calibration curves were established for the R-(-) and S-(+) enantiomers over the range of 0.2-20 microg/mL, and an average recovery of 98 percent and a mean relative standard deviation of 1.5 percent were obtained at 5.0 microg/mL. The lower limit of detection was 0.05 microg/mL for each enantiomer. The mean recovery for R-(-) and S-(+) clenbuterol enantiomers from plasma was 91.0-97.0% at 0.20-20 microg/mL. The method was successfully used to identify and quantify the clenbuterol enantiomers in human plasma [09247].

The aim of one study was to determine the level of clenbuterol residues in muscle tissue of pigs after repeat administration in a growth-promoting dose. An anabolic dose of clenbuterol (20 mug/kg body mass per day) was administered orally to experimental group (n=12) for 28 days, whereas control animals (n=3) were left untreated. Clenbuterol treated pigs were randomly sacrificed (n=3) on days 0, 3, 7 and 14 of treatment discontinuation and clenbuterol residues determined in muscle tissue. Determination of residual clenbuterol was by enzyme-linked immunosorbent assay (ELISA) as a screening method and liquid chromatography tandem mass spectrometry (LC-MS/MS) as a confirmation method. The highest clenbuterol content in the muscle of treated animals was recorded on day 0 of treatment cessation and significantly exceeded the maximum residue limit (MRL) of 0.1 ng/g. On day 3 of withdrawal, it was 0.49 ng/g and on day 7 0.1 (at MRL); on day 14 of treatment discontinuation, clenbuterol content was below the limit of detection (<0.1ng/g) in all samples. Administration of clenbuterol as a growth promoter in pig production could lead to residues in meat for human consumption up to 7 days after treatment discontinuation [10170].

In one report, it was presented a novel approach to detect clenbuterol based on competitive surface-enhanced Raman scattering (SERS) immunoassay. Herein, a SERS nanoprobe that relies on gold nanoparticle (GNP) is labeled by 4,4'-dipyridyl (DP) and clenbuterol antibody, respectively. The detection of clenbuterol is carried out by competitive binding between free clenbuterol and clenbuterol-BSA fastened on the substrate with their antibody labeled on SERS nanoprobe. The present method allows us to detect clenbuterol over a much wider concentration range (0.1-100 pg/mL) with a lower limit of detection (about 0.1 pg/mL) than the conventional methods. Furthermore, by the use of this new competitive SERS immunoassay, the clenbuterol-BSA (antigen) is chosen to fasten on the substrate instead of
the clenbuterol antibody, which could reduce the cost of the assay. Results demonstrate that the proposed method has the wide potential applications in food safety and agonist control.

beta-Adrenoceptor agonists are reported to induce skeletal muscle hypertrophy and hence serve as valuable adjunct to the treatment of wasting disorders. In the present study, we attempted to find out whether metabolic and physiologic characteristics of fibres are important in determining skeletal muscle response to clenbuterol (an adrenergic receptor agonist) therapy, as proposed in the treatment of wasting disorders. The treatment of mice with clenbuterol (2 mg/kg body wt for 30 days) resulted in skeletal muscle hypertrophy, more common amongst fast-twitch glycolytic fibres/muscle, with increase in body mass and a parallel rise in muscle mass to body mass ratio. Measurement of fibre diameters in soleus (rich in slow-twitch oxidative fibres), ALD or anterior latissimus dorsi (with a predominance of fast-twitch glycolytic fibres) and gastrocnemius (a mixed-type of muscle) from clenbuterol-treated mice for 30 days revealed noticeable increase in the per cent population of narrow slow-twitch fibre and a corresponding decline in white-type or fast-twitch glycolytic fibres in gastrocnemius and ALD. As revealed by counting of muscle cells in soleus, narrow red fibres declined with corresponding increase in white-type glycolytic fibres population. A significant decline in the succinic dehydrogenase activity was observed, thereby suggesting abnormality in oxidative activity of skeletal muscles in response to clenbuterol therapy.

**Induction of IGF and myostatin**

Clenbuterol, a beta₂-adrenergic agonist, increases the hypertrophy of skeletal muscle. Insulin-like growth factor (IGF) is reported to work as a potent positive regulator in the clenbuterol-induced hypertrophy of skeletal muscles. However, the precise regulatory mechanism for the hypertrophy of skeletal muscle induced by clenbuterol is unknown. Myostatin, a member of the TGFβ super family, is a negative regulator of muscle growth. The aim of the present study is to elucidate the function of myostatin and IGF in the hypertrophy of rat masseter muscle induced by clenbuterol. To investigate the function of myostatin and IGF in regulatory mechanism for the clenbuterol-induced hypertrophy of skeletal muscles, we analysed the expression of myostatin and phosphorylation levels of myostatin and IGF signaling components in the masseter muscle of rat to which clenbuterol was orally administered for 21 days. Hypertrophy of the rat masseter muscle was induced between 3 and 14 days of oral administration of clenbuterol and was terminated at 21 days. The expression of myostatin and the phosphorylation of smad2/3 were elevated at 21 days. The phosphorylation of IGF receptor 1 (IGFR1) and akt1 was elevated at 3 and 7 days. These results suggest that myostatin functions as a negative regulator in the later stages in the hypertrophy of rat masseter muscle induced by clenbuterol, whereas IGF works as a positive regulator in the earlier stages.

**Clenbuterol in food**

The therapeutic agent clenbuterol [(RS)-1-(4-Amino-3,5-dichlorphenyl)-2-(tert-butylamino)ethanol] is an approved bronchodilator and tocolytic agent, which has been further investigated as a potential means in therapy concerning various different conditions including, for example, amyotrophic lateral sclerosis, muscle atrophy, Pompe disease, and heart failure. However, the particular growth-promoting properties of clenbuterol, whose mechanism(s) of action have recently been further clarified, have also been a temptation to abuse as proven, for example, in stock farming/meat production and elite sport, which resulted in the prohibition of the drug in animal husbandry and sport. The issue of illicit administration of clenbuterol to animals destined for food production has evidently resulted in
several cases and epidemics of poisoning, stressing particularly the corresponding health problems. In addition, the contamination of dietary products with clenbuterol can affect an athlete’s integrity and career when the drug is inadvertently ingested, resulting in an adverse analytical finding during doping controls. Despite the continuously improving analytical options and methods in sports drug testing programmes especially by means of liquid chromatography/(tandem) mass spectrometry [LC-MS/(MS)], the differentiation of therapeutic/deliberately administered clenbuterol from ingested unintentionally residues remains a complex challenge. Consequently, any adverse analytical finding (AAF) necessitates careful investigation and evaluation of circumstantial evidence that might prove the athlete’s innocence. In the present communication, the inquest into a food contamination issue concerning elite soccer players who competed in Mexico in 2011 is presented. Induced by five AAFs of the Mexican seniors’ national soccer team with clenbuterol in May of 2011, the Fédération Internationale de Football Association (FIFA) recognized the need for a thorough investigation of the circumstances of these and potential future anti-doping rule violations, particularly in the light of the FIFA U-17 World Cup 2011 to be held between 18 June and 10 July 2011 in Mexico. Hence, during the period of this U-17 competition, samples from meals containing meat were collected at team-hosting hotels concomitantly to doping control specimens routinely sampled at competition sites from randomly selected players. While urine samples were subjected to regular doping controls, meat specimens underwent dedicated clenbuterol analyses [13424].

The illicit use of growth promoters in animal husbandry has frequently been reported in the past. Among the drugs misused to illegally increase the benefit of stock farming, clenbuterol has held a unique position due to the substance’s composition, mechanism of action, metabolism, and disposition. Particularly clenbuterol’s disposition in animals’ edible tissues destined for food production can cause considerable issues on consumption by elite athletes registered in national and international doping control systems as demonstrated in this case-related study. Triggered by five adverse analytical findings with clenbuterol among the Mexican national soccer team in out-of-competition controls in May 2011, the Fédération Internationale de Football Association (FIFA) initiated an inquest into a potential food contamination (and thus sports drug testing) problem in Mexico, the host country of the FIFA U-17 World Cup 2011. Besides 208 regular doping control samples, which were subjected to highly sensitive mass spectrometric test methods for anabolic agents, 47 meat samples were collected in team hotels during the period of the tournament and forwarded to Institute of Food Safety. In 14 out of 47 meat samples (30 %), clenbuterol was detected at concentrations between 0.06 and 11 microg/kg. A total of 109 urine samples out of 208 doping control specimens (52 %) yielded clenbuterol findings at concentrations ranging from 1–1556 pg/ml, and only 5 out of 24 teams provided urine samples that did not contain clenbuterol. At least one of these teams was on a strict “no-meat” diet reportedly due to the known issue of clenbuterol contamination in Mexico. Eventually, owing to the extensive evidence indicating meat contamination as the most plausible reason for the extraordinary high prevalence of clenbuterol findings, none of the soccer players were sanctioned. However, elite athletes have to face severe consequences when testing positive for a prohibited anabolic agent and sufficient supporting information corroborating the scenario of inadvertent ingestion are required to be acquitted from anti-doping rule violations. Hence, governmental contribution is urgently needed to combat the illegal use of clenbuterol in stock breeding [13424].

_Clenbuterol in hair_

The illegal use of clenbuterol has been an increasingly serious issue in today's livestock products industry. It becomes an important project to develop a reliable approach to detect its content in food animals. A simple and sensitive LC-MS/MS method was developed to
detect clenbuterol residue in hair, with the low limit of quantitation (LLOQ) about 0.5 ng/g. Hogs fed with 340 microg/day of clenbuterol for 2 weeks were found a high clenbuterol residue in their hair approximately at 1-2 months after withdrawal. There remained 3.31 ng/g clenbuterol in hog hair approximately 5 months after the last administration, focused on the tip of the hair (mainly in hogs with dark hair). An extensive contamination was observed in twenty investigated market hogs whose dark hair obviously had a higher clenbuterol residue than the light ones. Volunteers (60%) from Xuhui district (Shanghai) were found to have a detectable amount of clenbuterol in their hair (>0.5 ng/g). In conclusion, hair residue detection is a reliable method to evaluate the clenbuterol contamination in animals and humans. Meat supply in the Xuhui district might have serious potential safety risks which should be further investigated and discussed to determine the safety range of clenbuterol residue [13425].

Clenbuterol and heart problems

Clenbuterol is an orally administered long-acting beta-2 adrenergic agonist closely related to albuterol that, in recent years, has become a substance of abuse in the bodybuilding and athletic community. It was repored two cases of acute myocardial ischemia associated with clenbuterol abuse in two healthy young male body builders. Two male bodybuilders, ages 18 and 22 years, presented to the Emergency Department with palpitations, nausea, vomiting, chest pain, diaphoresis, and tachycardia shortly after ingesting clenbuterol. Both patients experienced prolonged sinus tachycardia that, in one patient, was relatively resistant to both beta- and calcium channel blockade. Both patients were found to have elevated troponin levels, the first patient as high as 4.71 ng/mL (normal <0.04 ng/mL). Further investigation revealed normal coronary arteries at catheterization and normal cardiac magnetic resonance imaging in the first patient, and normal echocardiograms for both patients. The tachycardia gradually resolved and both patients recovered uneventfully. The etiology of cardiac ischemia in these patients is uncertain. Thus, emergency physicians should be aware of the clinical presentation of clenbuterol abuse and overdose, and the possibility of related cardiac ischemia and rhythm disturbances. Suggested treatment includes intravenous fluids, oxygen, aspirin, beta-blockers, and benzodiazepines, although efficacy remains unproven [13426].

A novel, sensitive, and reliable LC-MS/MS method for multiresidue analysis of nine beta-agonists (salbutamol, terbutaline, cimaterol, fenoterol, clorprenaline, ractopamine, tulobuterol, clenbuterol, and penbuterol) in four farm animal muscles was developed. Muscle matrix was extracted with acetonitrile-10 percent sodium carbonate solution, and then was subjected to cleanup using a SPE cartridge packed with new polymer synthesized in acetone. Chromatographic separation of the components was performed on a Luna C18 column using 0.1 percent of formic acid in water and acetonitrile. The mass spectrometer was operated in the positive electrospray mode. Good precision and accuracy were obtained for all analytes (except for fenoterol) at the spiked three levels of 1.0, 10, and 50 microg/kg. The decision limit and detection capability of nine beta-agonists ranged from 0.04 to 0.18 and 0.15 to 0.69 microg/kg, respectively. The method developed was successfully applied to the monitoring of nine beta-agonists in pork, beef, mutton, and chicken from Chinese markets [13427].

Clenbuterol is a beta2-agonist approved in the United States for veterinary use in nonfood animals. Clenbuterol use is emerging among bodybuilders and fitness enthusiasts attracted to the hypertrophic and lipolytic effects. It was presented a retrospective chart review of clenbuterol exposures reported to 2 poison control centers. Misuse of clenbuterol for weight loss and bodybuilding was reported in 11 of 13 clenbuterol users. Reported clinical effects included tachycardia, widened pulse pressure, tachypnea, hypokalemia, hyperglycemia, ST changes on electrocardiogram (ECG), elevated troponin, elevated creatine phosphokinase
(CPK), palpitations, chest pain, and tremor. Measured serum clenbuterol concentration was 2983 pg/mL post 4.5 mg ingestion. Co-ingestants included T3 and anabolic steroids. Treatments included activated charcoal, benzodiazepines, beta-blockers, potassium replacement, and intravenous (IV) fluid. There is an increasing use of the Internet for illicit drug use for bodybuilding and weight loss purposes. These patients may not present as the stereotype of illicit drug abusers, but as healthy athletic low-risk patients. Clinical effects persisted greater than 24 hours with evidence of myocardial injury in 2 patients. Clenbuterol is increasingly being abused within the bodybuilding subculture. These cases illustrate the hidden dangers of clenbuterol abuse among bodybuilders and fitness enthusiasts [13428].

**Supression of bacterial phagocytosis**

Splenic marginal zone macrophages expressing macrophage receptor with collagenous structure (MARCO) contribute to the clearance of blood-borne pathogens. It was determined a splenic adherent cell fraction abundantly containing cells expressing a higher level of MARCO by flow cytometry, and examined the effects of daily administration of an anabolic dose of beta2-agonist clenbuterol on the phagocytic capacity of the cells in mice. After 6 weeks of clenbuterol (1.0 mg/kg body weight/d) or vehicle administration to the mice, splenic adherent cells were isolated. These cells were separated into three cell-size subpopulations. Among them, the small-cell subpopulation contained abundantly the cells with markedly higher levels of MARCO and exhibited more intense phagocytic capacity against Escherichia coli, as compared with the other subpopulations. The phagocytic capacity of the small cells was significantly reduced after clenbuterol administration. These results suggest that the utilization of clenbuterol as doping drug impairs bacterial clearance in the spleen [13434].

**Salbutamol and clenbuterol**

The aim of the study was to evaluate the adequacy of enzyme-linked immunosorbent assay (ELISA) in the post-exposure determination of the beta-agonists clenbuterol and salbutamol in animal plasma and serum. Experimental guinea pigs (n=20) were treated with two doses (0.25 and 2.5 mg/kg) of clenbuterol (n=10) and salbutamol (n = 10) for seven days, whereas the control animal group (n=10) was left untreated. Validation of the applied method yielded acceptable recovery (mean > 70 %) and repeatability rates, showing ELISA to be applicable for the semi-quantitative determination of both analytes in both matrices, preferably in plasma. In both matrices, clenbuterol concentrations were proven to be significantly (14-fold) higher than those of salbutamol. Concentrations of both analytes were higher in plasma than in serum. The application of a 10-fold higher clenbuterol and salbutamol dose (2.5 mg/kg) resulted in concentrations 3- to 4-fold higher for clenbuterol and 2- to 3-fold higher for salbutamol, indicating a different release rate of these two beta-agonists [13433].

**Laboratory technique**

An ultrasensitive electrochemiluminescence (ECL) immunosensor based on CdSe quantum dots (QDs) has been designed for the detection of clenbuterol. The immunosensor was fabricated by layer by layer and characterized with atomic force microscopic images (AFM) and electrochemical impedance spectra (EIS). In oxygen-saturated pH=9.0 Tris-HCl buffer, a strong ECL emission of QDs could be observed during the cathodic process due to the H2O2 product from electrochemical reduction of dissolved oxygen. Upon the formation of immunocomplex, the second antibody labeled with horseradish peroxidase was simply immobilized on the electrode surface. The ECL emission decreased since steric hindrance of the immunocomplex slowed down the electron-transfer speed of dissolved oxygen, and also could be greatly amplified by an enzymatic cycle to consume the self-produced coreactant.
Using clenbuterol as model analyte, the ECL intensity was determined by the concentration of competitive immunoassay of clenbuterol with a wide calibration in the range of 0.05 ng/mL to 1000 ng/mL, and a low detection limit was 0.02 ng/mL. The immunosensor shows good stability and fabrication reproducibility. It was applied to detecting practical samples with the satisfactory results. This immunosensing strategy opens a new avenue for detection of residue and application of QDs in ECL biosensing [13422].

Clenbuterol is a beta-2 agonist agent with anabolic properties given by the increase in the muscular mass in parallel to the decrease of the body fat. For this reason, the use of clenbuterol is forbidden by the World Anti-Doping Agency (WADA) in the practice of sport. This compound is of particular interest for anti-doping authorities and WADA-accredited laboratories due to the recent reporting of risk of unintentional doping following the eating of meat contaminated with traces of clenbuterol in some countries. In this work, the development and the validation of an ultra-high pressure liquid chromatography coupled to electrospray ionization tandem mass spectrometry (UHPLC-ESI-MS/MS) method for the quantification of clenbuterol in human urine is described. The analyte was extracted from urine samples by liquid-liquid extraction (LLE) in basic conditions using tert butyl-methyl ether (TBME) and analyzed by UHPLC-MS/MS with a linear gradient of acetonitrile in 9 min only. The simple and rapid method presented here was validated in compliance with authority guidelines and showed a limit of quantification at 5 pg/mL and a linearity range from 5 pg/mL to 300 pg/mL. Good trueness (86-105 %), repeatability (5.7-10.6 % RSD) and intermediate precision (5.9-14.9 % RSD) results were obtained. The method was then applied to real samples from eighteen volunteers collecting urines after single oral doses administration (1, 5 and 10 μg) of clenbuterol-enriched yogurts [13423].

Detecting the misuse of clenbuterol in sports drug testing has been a challenge to anti-doping laboratories ever since the drug was banned in the early 1990s. Initially, meeting the minimum required performance levels (MRPLs) and detection limits required for efficient clenbuterol testing was a complex task due to the comparably poor GC-MS properties of the analyte. However, various strategies including derivatization, high resolution and/or tandem mass spectrometry allowed for the analysis at sub-ng/mL levels. Urine samples were enzymatically hydrolyzed, liquid-liquid extracted, and the residue was trimethylsilylated with in situ generated trimethylidodosilane to yield clenbuterol-bis-TMS. By means of chiral liquid chromatography and high resolution/high accuracy tandem mass spectrometry, doping control as well as elimination study urine samples containing clenbuterol were analyzed, demonstrating that such enantiomeric analyses can support the interpretation of clenbuterol findings; however, inconclusive results were also obtained, demonstrating the need for further research [13009].

Clenbuterol is a beta2 agonist agent with anabolic properties given by the increase in the muscular mass in parallel to the decrease of the body fat. For this reason, the use of clenbuterol is forbidden by the World Anti-Doping Agency (WADA) in the practice of sport. This compound is of particular interest for anti-doping authorities and WADA-accredited laboratories due to the recent reporting of risk of unintentional doping following the eating of meat contaminated with traces of clenbuterol in some countries. In one work, the development and the validation of an ultra-high pressure liquid chromatography coupled to electrospray ionization tandem mass spectrometry (UHPLC-ESI-MS/MS) method for the quantification of clenbuterol in human urine is described. The analyte was extracted from urine samples by liquid-liquid extraction (LLE) in basic conditions using tert butyl-methyl ether (TBME) and analyzed by UHPLC-MS/MS with a linear gradient of acetonitrile in 9 min only. The simple and rapid method presented here was validated in compliance with authority guidelines and showed a limit of quantification at 5 pg/mL and a linearity range from 5 pg/mL to 300 pg/mL. Good trueness (85.8-105 %), repeatability (5.7-10.6 % RSD) and
One study demonstrates the development of a gas chromatography-triple quadrupole tandem mass spectrometry (GC-MS-MS) assay to detect clenbuterol in human urine and the comparison of this method with GC-MS techniques and gas chromatography-high resolution mass spectrometry (GC-HRMS) techniques. Urine samples were hydrolyzed with β-glucuronidase, extracted with methyl tert-butyl ether and dried under nitrogen. The derivative reagent was N-methyl-N-(trimethylsilyl)-trifluoroacetamide with NH₄I and was analyzed by GC-MS, GC-MS-MS and GC-HRMS. A validation study was conducted by GC-MS-MS. The analyses of clenbuterol using different mass spectrometric techniques were compared. The limit of detection (LOD) for clenbuterol in human urine was 2 ng/mL by GC-MS (selected ion monitoring mode: SIM mode), 0.06 ng/mL by GC-HRMS and 0.03 ng/mL by GC-MS-MS, respectively, while the LOD by GC-HRMS was 0.06. With GC-MS-MS, the intra-assay and inter-assay precisions were less than 15%, the recoveries were 86 to 112% and the linear range was 0.06 to 8.0 ng/mL. The GC-MS under SIM mode can be used as a screening tool to detect clenbuterol at trace levels in human urine. The GC-MS-MS and GC-HRMS methods can confirm clenbuterol when its concentration is below 2 ng/mL. The results demonstrate that the GC-MS-MS method is quite sensitive, specific and reliable for the detection of clenbuterol in doping analysis [12318].

A simple and inexpensive pretreatment procedure was developed for 10 β-agonists (clenbuterol, ractopamine, salbutamol, bmbuterol, penbuterol, tulobuterol, clorprenaline, mabuterol, cimaterol and terbutaline) in swine urine using dispersive solid phase extraction (dSPE) with multi-walled carbon nanotubes (MWCNTs). The sample was analysed after purification by ultra high performance liquid chromatography-positive electrospray ionisation tandem mass spectrometry (UHPLC-ESI-MS/MS). The pH value of the swine urine, extraction time, type and amount of MWCNTs and type of eluent were optimised to increase the sample throughput and sensitivity. The samples were quantified using clenbuterol-D9, ractopamine-D6 and salbutamol-D3 as internal standards. The recoveries of the target compounds from swine urine samples at pH 10.0 were most efficient when using 20 mg of MWCNTs with a 30-50 nm outer diameter and a length of 10-30 μm, while a mixture of water/methanol (90:10, v/v) with 0.5 beta formic acid was shown to be the most suitable solvent for desorbing the compounds from the MWCNTs. The proposed method was validated according to the European Commission Decision 2002/657/EC, which determines linearity, specificity, decision limit (CCα), detection capability (CCβ), recovery, precision and stability [12319].

One study demonstrates the development of a gas chromatography-triple quadrupole tandem mass spectrometry (GC-MS-MS) assay to detect clenbuterol in human urine and the comparison of this method with GC-MS techniques and gas chromatography-high resolution mass spectrometry (GC-HRMS) techniques. Urine samples were hydrolyzed with β-glucuronidase, extracted with methyl tert-butyl ether and dried under nitrogen. The derivative reagent was N-methyl-N-(trimethylsilyl)-trifluoroacetamide with NH₄I and was analyzed by GC-MS, GC-MS-MS and GC-HRMS. A validation study was conducted by GC-MS-MS. The analyses of clenbuterol using different mass spectrometric techniques were compared. The limit of detection (LOD) for clenbuterol in human urine was 2 ng/mL by GC-MS (selected ion monitoring mode: SIM mode), 0.06 ng/mL by GC-HRMS and 0.03 ng/mL by GC-MS-MS, respectively, while the LOD by GC-HRMS was 0.06. With GC-MS-MS, the intra-assay and inter-assay precisions were less than 15%, the recoveries were 86 to 112% and the linear range was 0.06 to 8.0 ng/mL. The GC-MS under SIM mode can be used as a screening tool to detect clenbuterol at trace levels in human urine. The GC-MS-MS and GC-HRMS methods
can confirm clenbuterol when its concentration is below 2 ng/mL. The results demonstrate that the GC-MS-MS method is quite sensitive, specific and reliable for the detection of clenbuterol in doping analysis [13429].

Clenbuterol, terbutaline and salbutamol are beta2-agonists drugs included in the list of banned substances of the World Anti Doping Agency (WADA) prohibited in and out of competition. In this article, the excretion of urinary metabolites of clenbuterol, terbutaline and salbutamol have been studied using liquid chromatography electrospray time-of-flight mass spectrometry (LC-TOFMS), after a single therapeutic dose administration in rats. Urine collected was processed with solid-phase extraction prior to LC-TOFMS analyses using electrospray in the positive ion mode and pseudo MS/MS experiments from in-source collision induced dissociation (CID) fragmentation (without precursor ion isolation). The strategy applied for the identification of metabolites was based on the search of typical biotransformations with their corresponding accurate mass shift and the use of common diagnostic fragment ions from the parent drugs. The approach was satisfactory applied, achieving the identification of 11 metabolites (5 from clenbuterol, 4 from salbutamol and 3 from terbutaline), 4 of them not previously reported in urine. Novel metabolites identified in rat urine included N-oxide-salbutamol, hydroxy-salbutamol, methoxy-salbutamol glucuronide and terbutaline N-oxide, which are all reported here for the first time [13430].

The development of new approaches to study the affinity between ligands and G-protein-coupled receptors proves to be of growing interest for pharmacologists, chemists, and biologists. The aim of one work was to determine the binding of seven drugs to beta2-adrenoceptors by frontal analysis using immobilized receptor stationary phase. The dissociation constants (Kd ) were determined to be (3.16 ± 0.09) × 10⁻⁴ M for salbutamol, (4.29 ± 0.12) × 10⁻⁴ M for terbutaline, (6.19 ± 0.16) × 10⁻⁴ M for methoxyphenamine, (2.11 ± 0.07) × 10⁻⁴ M for tulobuterol, (1.82 ± 0.11) × 10⁻⁴ M for fenoterol, (9.75 ± 0.24) × 10⁻⁶ M formoterol, and (9.84 ± 0.26) × 10⁻⁵ M for clenbuterol. These results showed a good correlation with the data determined by radioligand binding assay. Further investigations revealed that the dissociation constant mainly attributed to the number of hydrogen bonds in the structures of ligands. The study indicates that affinity chromatography using immobilized receptor stationary phase can be used for the direct determination of drug-receptor binding interactions and has the potential to become a reliable alternative for quantitative studies of ligand-receptor interactions [13431].

Clenbuterol (4-amino-alpha-[(tert-butylamino)methyl]-3,5-dichlorobenzyl alcohol) is approved for human and veterinary use primarily for the treatment of pulmonary afflictions. Despite the authorized administration in cases of medical indications, the misuse of clenbuterol in animal husbandry as well as elite and amateur sport has frequently been reported, arguably due to growth-promoting properties. Due to various recent incidences of doping control specimens containing clenbuterol, strategies towards the discrimination of a surreptitious application from unintended intake via animal-derived edibles or dietary supplements were required. The enantiomeric compositions of clenbuterol in human urine samples derived from administration studies with therapeutic amounts of the beta2-agonist and authentic doping control specimens were determined. Due to the facts that therapeutic clenbuterol consists of a racemic mixture of (+)- and (-)-stereoisomers and that the first mentioned (dextrorotatory) stereoisomer is retained to a greater extent in edible animal tissue, the differentiation of a recent administration of (+)-clenbuterol from food contamination (stereoisomerically depleted clenbuterol) was considered. Employing deuterated clenbuterol as internal standard, the target analytes were extracted from human urine by means of concerted liquid-liquid and solid-phase extractions and subjected to chiral liquid chromatography hyphenated to high resolution/high accuracy mass spectrometry with electrospray ionization. Both enantiomers of clenbuterol were baseline separated and
relative abundances of corresponding labeled and unlabeled stereoisomers were determined, demonstrating that the therapeutic use of clenbuterol results in racemic mixtures in urine for at least 24 h while adverse analytical findings presumably originating from food contaminations can yield (−)-clenbuterol-depleted pairs of analytes. Thus, the determination of relative abundances of clenbuterol enantiomers can indicate the ingestion of clenbuterol via contaminated food; however, depletion of (−)-clenbuterol in edible animal tissue is time-dependent and thus results can still be inconclusive as to the inadvertent ingestion of clenbuterol when clenbuterol administration to animals was conducted until slaughter [13432].

Experimental

Spinal cord injury (SCI) is generally associated with a rapid and significant decrease in muscle mass and corresponding changes in skeletal muscle properties. Although beta2-adrenergic and androgen receptor agonists are anabolic substances clearly shown to prevent or reverse muscle wasting in some pathological conditions, their effects in SCI patients remain largely unknown. Here it was studied the effects of clenbuterol and testosterone propionate administered separately or in combination on skeletal muscle properties and adipose tissue in adult CD1 mice spinal-cord-transected (Tx) at the low-thoracic level (i.e. induced complete paraplegia). Administered shortly post-Tx, these substances were found to differentially reduce loss in body weight, muscle mass, and muscle fiber cross-sectional area (CSA) values. Although all three treatments induced significant effects, testosterone-treated animals were generally less protected against Tx-related changes. However, none of the treatments prevented fat tissue loss or muscle fiber type conversion and functional loss generally found in Tx animals. These results provide evidence suggesting that clenbuterol alone or combined with testosterone may constitute better clinically-relevant treatments than testosterone alone to decrease muscle atrophy (mass and fiber CSA) in SCI subjects [10171].

Clenbuterol, a beta2-adrenergic receptor (beta2-AR) selective agonist, has been shown to decrease body fat in animals and can induce apoptosis in adipose tissue in mice. We hypothesized that direct actions of a beta-adrenergic receptor agonist on adipocytes could trigger the observed apoptotic effect. The hypothesis was inspected by investigating the direct effect of clenbuterol on apoptosis, adipogenesis, and lipolysis in vitro using the 3T3-L1 cell line and rat primary adipocytes. Cells were treated with 10^−9 to 10^−5 M clenbuterol depending on the experiments. There was no apoptotic effect of clenbuterol both in 3T3-L1 cells and rat primary adipocytes. Adipogenesis monitored by Oil Red O staining and AdipoRed assay was modestly decreased by clenbuterol treatment. In fully differentiated primary adipocytes, clenbuterol significantly increased basal lipolysis compared with the control. In summary, direct stimulation of beta2-adrenergic receptor by clenbuterol does not cause apoptosis in adipocytes, despite a direct lipolytic stimulation and attenuation of adipogenesis [10376].

Illegal in cattle

Recent discovery of clenbuterol contamination in Portuguese food led to the specific inspection of 16 cattle farms for beta-agonists, involving the analysis of a total of 486 samples (78 feed, 106 drinking water, 168 urine and 134 hair). The samples were screened for the beta-agonists: bromobuterol, cimaterol, clenbuterol, clenpenterol, clenproperol, hydroxymethylclenbuterol, mapenterol, salbutamol and terbutaline. Only clenbuterol was found in all analyzed matrices and the most likely method of illegal administration to animals was through drinking water. Of all samples analysed, 14 percent of drinking water were
found positive in the range 0.03-3.80 mg/L clenbuterol. Inclusion of hair samples in the Portuguese plan for clenbuterol residue control in live animals is discussed [09248].

**In horses**

Clenbuterol is a beta₂-agonist and potent selective bronchodilator that is used to treat bronchospasm in the horse. The drug is normally administered to horses orally as a syrup formulation. Once absorbed into the systemic circulation, clenbuterol has the potential to cause many side effects, including a repartitioning effect and major alterations in cardiac and skeletal muscle function. Recent studies have also reported that clenbuterol can affect bone and the immune, endocrine and reproductive systems. A great deal of information has been published on the beneficial effects of short term therapeutic doses of clenbuterol on the equine respiratory system, although there is limited information about chronic administration, particularly since this has been associated with adverse physiological effects on other systems [08354].

**Methoxyphenamine**

Methoxyphenamine (o-methoxy-N,alpha-dimethylphenethylamine) used in earlier times as a bronchodilator is prohibited in sports according to the regulations of the World Anti-Doping Agency. The drug and several of its metabolites are commonly analysed in doping control screening assays using gas chromatography-mass spectrometry requiring extraction from urine specimens. A complementary method employing liquid chromatography-atmospheric pressure chemical ionisation-tandem mass spectrometry and direct injection of urine aliquots was developed, which provided a fast and sensitive alternative to confirm the presence of the prohibited compound and degradation products in sports drug testing samples. In particular, the chromatographic separation of the active drug from isomeric compounds such as the designer drug p-methoxymetamphetamine was of particular interest to unambiguously identify the applied substance and was accomplished using a C6-phenyl reverse-phase column with isocratic elution. The established procedure was validated for methoxyphenamine with regard to specificity, limit of detection (0.7 ng/mL), intraday- and interday precision (2.5-5.8 % and 10.8-16.2 %, respectively) and its applicability was demonstrated with an authentic doping control sample which tested positive for the prohibited compound early in 2008 [08355].

**Laboratory techniques**

A sensitive and specific liquid chromatography-electrospray ionization-mass spectrometry (LC-ESI-MS) is described for quantitation of salbutamol in human urine using nadolol as the internal standard (IS). Urine samples were hydrolyzed with beta-glucuronidase followed by a solid-phase extraction procedure using Bond Elut-Certify cartridges. The HPLC column was an Agilent Zorbax SB-C(18) column. A mixture of 0.01 M ammonium formate buffer (pH 3.5)-acetonitrile (85:15, v/v) was used as the mobile phase. Analytes were quantitated using positive electrospray ionization in a quadrupole spectrometer. Selected ion monitoring (SIM) mode was used to monitor m/z 166 for salbutamol and m/z 310 for I.S. Good linearity was obtained in the range of 10.0-2000.0 ng/mL. The limit of quantification was 10.0 ng/mL. The intra- and inter-run precision, calculated from quality control (QC) samples was less than 7.3 percent. The accuracy as determined from QC samples was within ± 2.6 percent. The method was applied for determining excretion curves of salbutamol [06208].
In official doping controls, about 300 drugs and metabolites have to be screened for each sample. Moreover, the number of determinations to be routinely processed increases continuously as the number of both samples and potential illicit drugs keeps growing. As a consequence, increasingly specific, sensitive, and, above all, fast methods for doping controls are needed. One study presented an efficient fast-GC/MS approach to the routine screening of two different classes of doping agents, namely beta-adrenoceptor ligands and diuretics (belonging to the S3, P2, and S5 groups of the WADA list of prohibited substances). Narrow bore columns (100 mm id) of different lengths and coated with apolar stationary phases were successfully used to separate the derivatized analytes; preliminary experiments (results not shown) showed better performances with OV-1701 for the separation of beta-adrenoceptor ligands. On the same stationary phase some diuretics required too high a temperature or a long isothermal time for elution, in which case a DB1-MS column was preferred. Two methods of sample preparation, derivatization, and analysis were used on aqueous standard mixtures of, respectively, (i) eight beta-adrenoceptor ligands, including five beta-antagonists (acebutolol, alprenolol, atenolol, metoprolol, pindolol) and three beta2-agonists (salbutamol, clenbuterol, terbutaline) and (ii) seventeen diuretic drugs (acetazolamide, althiazide, bendroflumethiazide, bumethanide, canrenone, chlorothiazide, chlorotalidone, clopamide, ethacrinic acid, furosemide, hydrochlorothiazide, hydroflumethiazide, indapamide, indomethacine, spironolactone, triamterene, trichloromethiazide) and one masking agent (probenecid). The mixture of beta-adrenoceptor ligand derivatives was efficiently separated in about 5.6 min, while the one of 18 diuretics and masking agents required less than 5 min for analysis. Limits of detection were from 1 microg/L for pindolol, ethacrinic acid, furosemide, indomethacine, and trichloromethiazide, to 20 microg/L for terbutaline, salbutamol, and metoprolol, and 50 microg/L for clopamide; the instrumental repeatability proved to be excellent (area RSD% <2 for almost all analytes). For this work a quadrupole MS with inert ion source has been used, demonstrating that the quadrupole technology is perfectly adequate to provide precise integration of 400 ms-wide GC peaks [06209].

A method using hollow fibre-protected liquid-phase microextraction (HF-LPME) with in situ derivatization followed by gas chromatography/mass spectrometry (GC/MS) was established for the analysis of beta-agonists and beta-blockers in urine. Because it can simultaneously extract and derivatize compounds of interest by methylbenzol and N-methyl-N-(trimethylsilyl)trifluoroacetamide (MSTFA) in HF-LPME, the approach overcomes the drawbacks of considerable time-consuming and tedious operation, meanwhile improves enrichment multiple. The optimized conditions were extraction for 20 min at 35 degrees C with 5.0 microL of mixed extraction solvent (methylbenzol/MSTFA=1:1, v/v) with stirring speed of 925 rpm in 5.0 mL sample under pH 12.0 and 14% (w/v) NaCl. The method provided very wide linear ranges (0.25-400 ng/mL) and low detection limits in the range of 0.08-0.10 ng/mL for clenbuterol, metoprolol and propranolol while enrichment factors reached up to 256. The analytes could be determined in spiked urine by the method with high extraction efficacy (93.79-109.04% recoveries) and precision (<9.70 % RSD). It has a satisfactory result for metoprolol in practical human urine samples for a single-dose administration of 50 mg after 36 h. The proposed method only needs few microliters of organic solvent and derivatizing agent; the operation is simple, convenient and rapid for the trace analysis of beta-agonists and beta-blockers in biological fluids; it can be readily generalized for high sample throughput [09243].

One paper presents a capillary electrophoresis method, developed for the detection, in human urine, of beta-adrenergic agents and phenolalkylamines. The electrophoretic separation is achieved in less than 10 min and is based on the use of CEfix kit, for the dynamic capillary coating. The effects of accelerator buffer pH and separation voltage were investigated. The optimum buffer pH was found to be 2.5 for beta2-agonists and 6.2 for beta-
blockers and phenoalkylamines with a separation voltage of 15 kV. Urine samples spiked with the compounds here studied were treated according to the standard procedure (SPE and evaporation to dryness) and analyzed by CE interfaced with an UV diode-array, set at 195 and 210 nm. The quantitative validation results, obtained analyzing samples at three different concentrations, show a good precision of peak areas that do not exceed 5 percent for intra-day assays and 10 percent for inter-day assays. Good linearity was obtained within the 50-500 ng/mL concentration range. The analytes were clearly distinguishable in urine, with LOD and LOQ in the range of 10-80 and 40-100 ng/mL, respectively [09244].

A general screening method based on solid phase extraction (SPE) and liquid chromatography/time-of-flight mass spectrometry (LC/TOFMS) was developed and investigated with 124 different doping agents, including stimulants, beta-blockers, narcotics, beta2-adrenergic agonists, agents with anti-estrogenic activity, diuretics and cannabinoids. Mixed mode cation exchange/C8 cartridges were applied to SPE, and chromatography was based on gradient elution on a C18 column. Ionization of the analytes was achieved with electrospray ionization in the positive mode. Identification by LC/TOFMS was based on retention time, accurate mass and isotopic pattern. Validation of the method consisted of analysis of specificity, analytical recovery, limit of detection and repeatability. The minimum required performance limit (MRPL), established by World Anti-Doping Agency (WADA), was attained to 97 doping agents. The extraction recoveries varied between 33 and 98 percent and the median was 58 percent. Mass accuracy was always better than 5 ppm, corresponding to a maximum mass error of 0.7 mDa. The repeatability of the method for spiked urine samples, expressed as median of relative standard deviations (RSD%) at concentrations of MRPL and 10 times MRPL, were 14 and 9 percent, respectively. The suitability of the LC/TOFMS method for doping control was demonstrated with authentic urine samples [07195].

Experimental

Systemic administration of beta-adrenoceptor (beta-AR) agonists has been found to induce skeletal muscle hypertrophy and significant metabolic changes. In the context of energy homeostasis, the importance of beta-AR signaling has been highlighted by the inability of beta(1-3)-AR-deficient mice to regulate energy expenditure and susceptibility to diet induced obesity. However, the molecular pathways and gene expression changes that initiate and maintain these phenotypic modulations are poorly understood. Therefore, the aim of one study was to identify differential changes in gene expression in murine skeletal muscle associated with systemic (acute and chronic) administration of the beta2-AR agonist formoterol. Skeletal muscle gene expression (from murine tibialis anterior) was profiled at both 1 and 4 hours following systemic administration of the beta2-AR agonist formoterol. Illumina expression profiling revealed significant expression changes in genes associated with skeletal muscle hypertrophy, myoblast differentiation, metabolism, circadian rhythm, transcription, histones, and oxidative stress. Differentially expressed genes relevant to the regulation of muscle mass and metabolism (in the context of the hypertrophic phenotype) were further validated by quantitative RT-PCR to examine gene expression in response to both acute (1-24 h) and chronic administration (1-28 days) of formoterol at multiple timepoints. In terms of skeletal muscle hypertrophy, attenuation of myostatin signaling (including differential expression of myostatin, activin receptor IIB, phospho-Smad3 etc) was observed following acute and chronic administration of formoterol. Acute (but not chronic) administration of formoterol also significantly induced the expression of genes involved in oxidative metabolism, including hexokinase 2, sorbin and SH3 domain containing 1, and uncoupling protein 3. Interestingly, formoterol administration also appeared to influence some genes associated with the peripheral regulation of circadian rhythm (including nuclear
factor interleukin 3 regulated, D site albumin promoter binding protein, and cryptochrome 2). It was concluded in this study to utilize gene expression profiling to examine global gene expression in response to acute beta_2-AR agonist treatment of skeletal muscle systemic administration of a beta_2-AR agonist had a profound effect on global gene expression in skeletal muscle. In terms of hypertrophy, beta_2-AR agonist treatment altered the expression of several genes associated with myostatin signaling, a previously unreported effect of beta-AR signaling in skeletal muscle. The study also demonstrates a beta_2-AR agonist regulation of circadian rhythm genes, indicating crosstalk between beta-AR signaling and circadian cycling in skeletal muscle. Gene expression alterations discovered in this study provides insight into many of the underlying changes in gene expression that mediate beta-AR induced skeletal muscle hypertrophy and altered metabolism [09245].
A second-order multivariate calibration method based on a combination of unfolded partial least-squares (U-PLS) with residual bilinearization (RBL) has been applied to second-order data obtained from excitation-emission fluorescence matrices for determining atenolol in human urine, even in the presence of background interactions and fluorescence inner filter effects, which are both sample dependent. Atenolol is a cardioselective beta-blocker, which is considered a doping agent in shoot practice, so that its determination in urine can be required for monitoring the drug. Loss of trilinearity due to analyte-background interactions which may vary between samples, as well as inner filter effects, precludes the use of methods like parallel factor analysis (PARAFAC) that cannot handle trilinearity deviations, and justifies the employment of U-PLS. Successful analysis required to include the background in the calibration set. Unexpected components appear in new urine samples, different from those used in calibration set, requiring the second-order advantage which is obtained from a separate procedure known as residual bilinearization. Satisfactory results were obtained for artificially spiked urines, and also for real urine samples. They were statistically compared with those obtained applying a reference method based on high-performance liquid chromatography (HPLC) [11191].
ANGIOTENSIN CONVERTING ENZYME (ACE) INHIBITORS AND ANGIOTENSIN II TYPE RECEPTOR ANTAGONISTS

In the decade since the angiotensin-converting enzyme (ACE) gene was first proposed to be a “human gene for physical performance”, there have been numerous studies examining the effects of ACE genotype on physical performance phenotypes such as aerobic capacity, muscle function, trainability, and athletic status. While the results are variable and sometimes inconsistent, and corroborating phenotypic data limited, carriers of the ACE insertion allele (the presence of an alu repeat element in intron 16 of the gene) have been reported to have higher maximum oxygen uptake (VO$_{2\text{max}}$), greater response to training, and increased muscle efficiency when compared with individuals carrying the ‘deletion’ allele (absence of the alu repeat). Furthermore, the insertion allele has been reported to be over-represented in elite athletes from a variety of populations representing a number of endurance sports. The mechanism by which the ACE insertion genotype could potentiate physical performance is unknown. The presence of the ACE insertion allele has been associated with lower ACE activity (ACE$_{\text{plasma}}$) in number of studies, suggesting that individuals with an innate tendency to have lower ACE levels respond better to training and are at an advantage in endurance sporting events. This could be due to lower levels of angiotensin II (the vasoconstrictor converted to active form by ACE), higher levels of bradykinin (a vasodilator degraded by ACE) or some combination of the two phenotypes. Observations that individuals carrying the ACE insertion allele (and presumably lower ACE$_{\text{plasma}}$) have an enhanced response to training or are over-represented amongst elite athletes raises the intriguing question: would individuals with artificially lowered ACE$_{\text{plasma}}$ have similar training or performance potential? As there are a number of drugs (i.e. ACE inhibitors and angiotensin II type 1 receptor antagonists; angiotensin receptor blockers, ARBs) that have the ability to either reduce ACE$_{\text{plasma}}$ activity or block the action of angiotensin II, the question is relevant to the study of ergogenic agents and to the efforts to rid sports of doping. The article discussed the possibility that ACE inhibitors and ARBs, by virtue of their effects on ACE or angiotensin II function, respectively, have performance-enhancing capabilities; it also reviews the data on the effects of these medications on VO$_{2\text{max}}$, muscle composition and endurance capacity in patient and non-patient populations. It was concluded that, while the direct evidence supporting the hypothesis that ACE-related medications are potential doping agents is not compelling, there are insufficient data on young, athletic populations to exclude the possibility, and there is ample, albeit indirect, support from genetic studies to suggest that they should be. Unfortunately, given the history of drug experimentation in athletes and the rapid appropriation of therapeutic agents into the doping arsenal, this indirect evidence, coupled with the availability of ACE-inhibiting and ACE-receptor blocking medications may be sufficiently tempting to unscrupulous competitors looking for a shortcut to the finish line [10163].

Recent research has analyzed the genetic factors that influence world-class athletic status. Much of what we know comes from association studies, with the ACE I/D and ACTN3 R577X polymorphisms having been extensively studied. The association between the ACTN3 R577X variation and elite athlete status in power sports is strongly documented, yet whether the current body of knowledge on other variants can be extrapolated to athletic champion status remains to be determined. Athletic champion status is a complex polygenic trait in which numerous candidate genes, complex gene-gene interactions, and environment-gene interactions are involved. Besides the need for more studies and new approaches taking into account the complexity of the problem, we believe that factors beyond genetic endowment are likely to have a stronger influence in the attainment of athletic champion status [10164].
Hypertension is a prevalent disease worldwide. Its inadequate treatment leads to major cardiovascular complications, such as myocardial infarction, stroke, and heart failure. These conditions decrease life expectancy and are a substantial cost burden to health care systems. Physically active individuals and professional athletes are not risk free for developing this condition. Although the percentage of persons affected is substantially lower than the general population, these individuals still need to be thoroughly evaluated and blood pressure targets monitored to allow safe competitive sports participation. Regarding treatment, lifestyle modification measures should be routinely emphasized to athletes and active individuals with the same importance as for the general population. Medication treatment can be complicated because of restrictions by athletic organizations and possible limitations on maximal exercise performance. In addition, the choice of an antihypertensive drug should be made with consideration for salt and water losses that routinely occur in athletes, as well as preservation of exercise performance and endothelial function. First-line therapies for athletes and physically active individuals may be different from the general population. Some authorities believe that blocking the renin-angiotensin system with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) is more beneficial compared with diuretics because of ACE inhibitors and ARBs being able to avoid salt and water losses. Dihydropyridine calcium channel blockers (CCBs) are another reasonable choice. Despite effects on heart rate, nondihydropyridine CCBs do not appear to impair exercise performance. beta-Blockers are not used as a first-line therapy in athletes because of effects on exercise and prohibition by the National Collegiate Athletic Association and World Anti-Doping Agency in certain sports [10165].

In the decade since the angiotensin-converting enzyme (ACE) gene was first proposed to be a “human gene for physical performance”, there have been numerous studies examining the effects of ACE genotype on physical performance phenotypes such as aerobic capacity, muscle function, trainability, and athletic status. While the results are variable and sometimes inconsistent, and corroborating phenotypic data limited, carriers of the ACE insertion allele (the presence of an ALU repeat element in intron 16 of the gene) have been reported to have higher maximum oxygen uptake (VO$_{2\text{max}}$), greater response to training, and increased muscle efficiency when compared with individuals carrying the deletion allele (absence of the ALU repeat). Furthermore, the insertion allele has been reported to be over-represented in elite athletes from a variety of populations representing a number of endurance sports. The mechanism by which the ACE insertion genotype could potentiate physical performance is unknown. The presence of the ACE insertion allele has been associated with lower ACE activity (ACE$_{\text{plasma}}$) in number of studies, suggesting that individuals with an innate tendency to have lower ACE levels respond better to training and are at an advantage in endurance sporting events. This could be due to lower levels of angiotensin II (the vasoconstrictor converted to active form by ACE), higher levels of bradykinin (a vasodilator degraded by ACE) or some combination of the two phenotypes. Observations that individuals carrying the ACE insertion allele (and presumably lower ACE$_{\text{plasma}}$) have an enhanced response to training or are over-represented amongst elite athletes raises the intriguing question: would individuals with artificially lowered ACE$_{\text{plasma}}$ have similar training or performance potential? As there are a number of drugs (i.e. ACE inhibitors and angiotensin II type 1 receptor antagonists; angiotensin receptor blockers - ARBs) that have the ability to either reduce ACE$_{\text{plasma}}$ activity or block the action of angiotensin II, the question is relevant to the study of ergogenic agents and to the efforts to rid sports of doping. It was concluded that, while the direct evidence supporting the hypothesis that ACE-related medications are potential doping agents is not compelling, there are insufficient data on young, athletic populations to exclude the possibility, and there is ample, albeit indirect, support from genetic studies to suggest that they should be. Unfortunately, given the history of drug experimentation in athletes and the rapid appropriation of therapeutic agents into the doping arsenal, this indirect evidence, coupled with the availability of ACE-inhibiting and ACE-receptor blocking medications may
be sufficiently tempting to unscrupulous competitors looking for a shortcut to the finish line [08362].

In the decade since the angiotensin-converting enzyme (ACE) gene was first proposed to be a 'human gene for physical performance', there have been numerous studies examining the effects of ACE genotype on physical performance phenotypes such as aerobic capacity, muscle function, trainability, and athletic status. While the results are variable and sometimes inconsistent, and corroborating phenotypic data limited, carriers of the ACE "insertion" allele (the presence of an ALU repeat element in intron 16 of the gene) have been reported to have higher maximum oxygen uptake (VO_2max), greater response to training, and increased muscle efficiency when compared with individuals carrying the "deletion" allele (absence of the ALU repeat). Furthermore, the insertion allele has been reported to be over-represented in elite athletes from a variety of populations representing a number of endurance sports. The mechanism by which the ACE insertion genotype could potentiate physical performance is unknown. The presence of the ACE insertion allele has been associated with lower ACE activity (ACE plasma) in number of studies, suggesting that individuals with an innate tendency to have lower ACE levels respond better to training and are at an advantage in endurance sporting events. This could be due to lower levels of angiotensin II (the vasoconstrictor converted to active form by ACE), higher levels of bradykinin (a vasodilator degraded by ACE) or some combination of the two phenotypes. Observations that individuals carrying the ACE insertion allele (and presumably lower ACE plasma) have an enhanced response to training or are over-represented amongst elite athletes raises the intriguing question: would individuals with artificially lowered ACE plasma have similar training or performance potential? As there are a number of drugs (i.e. ACE inhibitors and angiotensin II type 1 receptor antagonists) that have the ability to either reduce ACE plasma activity or block the action of angiotensin II, the question is relevant to the study of ergogenic agents and to the efforts to rid sports of "doping". It may be discussed the possibility that ACE inhibitors and angiotensin receptor blockers, by virtue of their effects on ACE or angiotensin II function, respectively, have performance-enhancing capabilities. It may be concluded that, while the direct evidence supporting the hypothesis that ACE-related medications are potential doping agents is not compelling, there are insufficient data on young, athletic populations to exclude the possibility, and there is ample, albeit indirect, support from genetic studies to suggest that they should be. Unfortunately, given the history of drug experimentation in athletes and the rapid appropriation of therapeutic agents into the doping arsenal, this indirect evidence, coupled with the availability of ACE-inhibiting and ACE-receptor blocking medications may be sufficiently tempting to unscrupulous competitors looking for a shortcut to the finish line [09282].

It was assessed the possible association between variants of the genes encoding for the angiotensin-converting enzyme (ACE) and alpha-actinin-3 ACTN3 (both individually and combined) and several endurance phenotypic traits, e.g., peak power output (PPO), ventilatory (VT) and respiratory compensation threshold (RCT), among others, in professional road cyclists and sedentary controls (n=46 each). It was only found a significant genotype effect with no concomitant covariate effect for ACTN3, with cyclists who were not alpha-actinin-3 deficient (RR + RX genotypes) having higher PPO and VT values than their XX counterparts. Cyclists with an "extreme" ACTN3 and ACE genotype combination, i.e. most strength/power oriented (DD + RR/RX), had higher RCT values than those with the "intermediate" combinations but similar to those with the most endurance oriented genotype (II + XX). No significant differences were found in controls. In summary, in world-class cyclists, it was only found an association between ACTN3 genotypes and VT and PPO, and between ACTN3/ACE genotype combinations and RCT [09283].

Previous studies have linked an insertion/deletion polymorphism in the angiotensin-
converting enzyme (ACE) gene with variability in muscle strength responses to strength training, though conclusions have been inconsistent across investigations. Moreover, most previous studies have not investigated the influence of sex on the association of ACE I/D genotype with muscle phenotypes. The purpose of one study was to investigate the association of ACE genotype with muscle phenotypes before and after ST in older men and women. Eighty-six inactive men and 139 inactive women, ages 50-85 years, were studied before and after 10 weeks of unilateral knee extensor strength training. The one-repetition maximum (1RM) test was used to assess knee extensor muscle strength, and computed tomography was used to measure quadriceps muscle volume (MV). Across the entire cohort at baseline, ACE genotype was significantly associated with total lean mass and body weight, with significantly higher values in DD genotype carriers. At baseline, DD genotype carriers exhibited significantly greater MV compared with II genotype carriers for both the trained leg and untrained leg with no significant genotype x sex interaction. No ACE genotype associations were observed for the 1RM or MV adaptations to strength training in either men or women. This means that ACE genotype was associated with baseline differences in muscle volume, but it was not associated with the muscle hypertrophic response to strength training [09284].

An ALU insertion (I)/deletion (D) polymorphism in the angiotensin I converting enzyme (ACE) gene has been associated with ACE activity. Opposing effects on elite athletic performance have been proposed for the I and D alleles; while the D allele favours improved endurance ability, the I allele promotes more power-oriented events. It was tested this hypothesis by determining the frequency of ACE ID alleles amongst 121 Israeli top-level athletes classified by their sporting discipline (marathon runners or sprinters). Genotyping for ACE ID was performed using polymerase chain reaction on DNA from leucocytes. The ACE genotype and allele frequencies were compared with those of 247 healthy individuals. Allele and genotype frequencies differed significantly between the groups. The frequency of the D allele was 0.77 in the marathon runners, 0.66 in the control subjects and 0.57 in the sprinters. The ACE DD genotype was significantly more prevalent among the endurance athletes than among the control subjects and the power athletes. In the group of elite athletes, the odds ratio of ACE DD genotype being an endurance athlete was 3.26 (95 % confidence interval 1.49 to 7.11), and of ACE II genotype was 0.41 (95 % confidence interval 0.14 to 1.19). It was conclude that in Israeli elite marathon runners the frequency of the ACE D allele and ACE DD genotype seems to be higher than in sprinters, suggesting a positive association between the D allele and the likelihood of being an elite endurance athlete in some ethnic groups [09285].

East African runners are continually successful in international distance running. The extent to which genetic factors influence this phenomenon is unknown. The insertion (I) rather than deletion (D) of a 287 bp fragment in the human angiotensin converting enzyme (ACE) gene is associated with lower circulating and tissue ACE activity and with endurance performance amongst Caucasians. To assess the association between ACE gene variation and elite endurance athlete status in an African population successful in distance running, DNA samples were obtained from 221 national Kenyan athletes (N), 70 international Kenyan athletes (I), and 85 members of the general Kenyan population (C). Blood samples were obtained from C and assayed for circulating ACE activity. It was concluded that ACE I/D and A22982G polymorphisms are not strongly associated with elite endurance athlete status amongst Kenyans [09286].

Angiotensin converting enzyme gene (ACE) is the most frequent investigated gene in the context of genetic conditioning of sports-predispositions. Product of this gene is a key-element in the renin-angiotensin system responsible for the regulation of blood pressure. In one study DNA polymorphism in the ACE gene was studied in Polish rowers in order to examine the hypothesis that ACE genotype is associated with athletes performance. Fifty-
five male Polish rowers including Olympic and World champions were recruited for this study. Control samples were prepared from 115 unrelated volunteers. PCR amplification of the insertion (I) or deletion (D) fragment of ACE gene was performed. Genotype distribution and allele frequencies were determined by genotype and gene counting. ACE genotype distributions amongst subjects and controls were in Hardy-Weinberg equilibrium. Compared with controls, the frequency of I allele differ significantly from that found in rower's group. The data confirm a positive association of the insertion allele of ACE gene with endurance performance [09287].

The most widely-studied candidate gene for endurance performance is the Angiotensin Converting Enzyme (ACE) gene. The best endurance runners in the world hail from Kenya and Ethiopia, so the lack of association between the ACE gene and elite endurance athlete status we previously reported in Kenyans requires replication in Ethiopians. DNA was extracted from buccal swabs collected from subjects filling four groups: elite endurance runners from the Ethiopian national athletics team specializing in 5 km to marathon distances (n=76), controls demographically matched to the elite endurance athletes (n=410) controls representing the general Ethiopian population (n=317), and sprint and power event athletes from the Ethiopian national athletics team (n=38). ACE I/D and A22982G (rs4363) genotype frequencies were determined for each of these groups. There were no significant deviations from Hardy-Weinberg equilibrium in endurance athletes or either control group. Endurance athletes did not differ significantly in ACE I/D genotype frequency when compared to the endurance athlete-matched control group, general controls, or sprint and power athletes. Similarly, no significant differences were found in ACE A22982G genotype between groups. Thus, as previously shown in elite Kenyan athletes, ACE I/D and A22982G polymorphisms are not associated with elite endurance athlete status in Ethiopians [10384].

In one study, genotype frequencies of several polymorphisms that are candidates to influence sports performance (ie, ACTN3 R577X, ACE ID, PPARGC1A Gly482Ser, AMPD1 C34T, CKMM 985bp/1170bp and GDF8 (myostatin) K153R) were compared in 123 nonathletic controls, 50 professional cyclists, 52 Olympic-class runners and 39 world-class rowers (medallists in world championships, lightweight category). Significant differences in genotype distributions among the groups were not found except for the ACE gene, that is, lower proportion of II in rowers (10 %) than in the total subject population (22 %). In summary, sports performance is likely polygenic with the combined effect of hundreds of genetic variants, one possibly being the ACE ID polymorphism (at least in the sports studied here), but many others remain to be identified [10387].

It was investigated the association between the angiotensin I-converting enzyme (ACE) gene insertion (I)/deletion (D) polymorphism and endurance running performance in Japanese elite runners, including several Olympic athletes. The frequency of the I/I genotype was not significantly higher and the frequency of the D/D genotype was not significantly lower in elite runners compared with non-athletes. However, the frequency of the I/D genotype tended to be lower in elite runners than in non-athletes. The best performance was significantly higher for runners with the D/D genotype than for those with the I/I genotype, and the average running speed was significantly higher for those with the combined D/D + I/D genotypes than for those with the I/I genotype. There were no I/I genotypes among the five fastest marathon runners. These results suggest that the D allele of the ACE gene I/D polymorphism is associated with a high level of human endurance [10386].

Angiotensin-converting enzyme (ACE) is associated with the development of cardiac hypertrophy and improved physical fitness. The objective of one study was to investigate the relationship between the ACE gene insertion/deletion (I/D) polymorphism and adaptation to sports training. The study included 299 elite Spanish athletes (193 men and 106 women)
from 32 different sports disciplines, which were grouped according to their static and dynamic components. All participants underwent body composition analysis, Doppler echocardiography at rest, and ergospirometry. Their ACE genotype was determined using the polymerase chain reaction. The most common genotype in both males and females was the deletion-insertion (DI) heterozygote (58 % and 55 %, respectively), followed by the DD homozygote (31 % and 35 %), and the II homozygote (12 % and 10 %). Differences in morphometric and functional cardiac adaptation were observed between the different sports disciplines, but there was no statistically significant relationship with the ACE I/D polymorphism. Moreover, when athletes with different genotypes were compared, the only differences observed were between the DD and DI groups in female athletes, who differed in body mass index and longitudinal right atrial dimension. The ACE I/D polymorphism did not appear to influence cardiovascular adaptation in response to training. However, the DI genotype was the most common, probably because the sample was biased by being made up of elite athletes [10385].

Regular physical activity and training are associated with reductions in blood pressure (BP), yet elevated BP is one of the most common abnormalities found during the pre-participation physical evaluation of athletes. Hypertension remains the most common cardiovascular condition encountered in athletic populations, therefore all athletes require screening for hypertension. Because athletes often have white coat hypertension, BP recordings outside the office are also necessary. The 36th Bethesda Conference classified sports according to their varying physiologic demands and provided specific recommendations for the evaluation, treatment, and sport participation of athletes with HTN. In general, angiotensin-converting enzyme inhibitors and other vasodilators are the medications of choice for active and athletic patients because of their limited interference with cardiovascular conditioning. Other agents can be used but some sports governing bodies proscribe the use of certain antihypertensive medications such as beta-blockers for elite athletes [09288].

It was examined the association between the angiotensin I-converting enzyme (ACE) gene (insertion (I) and deletion (D)) polymorphism in Japanese university track athletes and race distance, as well as to evaluate the gender effects on this association. The ACE I/D allele frequency was determined in 277 athletes (176 men, 101 women), who were then grouped on the basis of their major competitive race distances (short distance (SD), \( < 200 \) m; middle distance (MD), 400-800 m, and long distance (LD), \( \geq 1500 \) m). The ACE I allele frequency increased significantly with the distance (44 %, 48 %, and 66 % for the SD (n=107), MD (n=62), and LD (n=108) groups). On multinomial logistic regression analysis, significant associations between ACE genotype and race distance were observed only in male athletes. There was no significant association between ACE genotype and race distance in female athletes. It was concluded that the ACE I allele is overrepresented in endurance athletes, and that its frequency varies depending on gender [09289].

The most widely studied candidate gene for endurance performance is the angiotensin-converting enzyme (ACE) gene. The best endurance runners in the world hail from Kenya and Ethiopia, so the lack of association between the ACE gene and elite endurance athlete status we previously reported in Kenyans requires replication in Ethiopians. DNA was extracted from buccal swabs collected from subjects filling four groups: elite endurance runners from the Ethiopian national athletics team specializing in 5 km to marathon distances (n=76), controls demographically matched to the elite endurance athletes (n=410), controls representing the general Ethiopian population (n=317), and sprint and power event athletes from the Ethiopian national athletics team (n=38). ACE I/D and A22982G (rs4363) genotype frequencies were determined for each of these groups. There were no significant deviations from Hardy-Weinberg equilibrium in endurance athletes or either control group. Endurance athletes did not differ significantly in ACE I/D genotype frequency when compared with the
An Alu insertion (I)/deletion (D) polymorphism in the angiotensin I converting enzyme (ACE) gene has been associated with ACE activity. Opposing effects on elite athletic performance have been proposed for the I and D alleles; while the D allele favours improved endurance ability, the I allele promotes more power-orientated events. It was tested this hypothesis by determining the frequency of ACE ID alleles amongst 121 top-level athletes classified by their sporting discipline (marathon runners or sprinters). Genotyping for ACE ID was performed using polymerase chain reaction on DNA from leucocytes. The ACE genotype and allele frequencies were compared with those of 247 healthy individuals. Allele and genotype frequencies differed significantly between the groups. The frequency of the D allele was 0.77 in the marathon runners, 0.66 in the control subjects and 0.57 in the sprinters. The ACE DD genotype was significantly more prevalent among the endurance athletes (0.62) than among the control subjects (0.43) and the power athletes (0.34). In the group of elite athletes, the odds ratio of ACE DD genotype being an endurance athlete was 3.26 (95% confidence interval 1.49 to 7.11), and of ACE II genotype was 0.41 (95% confidence interval 0.14 to 1.19). It was concluded that in Israeli elite marathon runners the frequency of the ACE D allele and ACE DD genotype seems to be higher than in sprinters, suggesting a positive association between the D allele and the likelihood of being an elite endurance athlete in some ethnic groups [07196].

The aim of one study was to examine the distribution of insertion/deletion (I/D) polymorphism in the ACE gene among Korean male elite athletes. Participants of the study were 139 Korean male elite athletes (15 basketball, 41 soccer, 31 baseball, 12 gymnastics, 7 volleyball, 8 long-distance running, 8 judo, and 17 ice hockey players). The control group consisted of 163 non-athletes. Polymerase chain reaction method was used to investigate I/D polymorphism of the ACE gene. The distribution of genotype and allele frequencies did not indicate the differences between the athletes and controls. However, an excess of II genotype and I allele was shown in long distance runners, although it was not statistically significant. It may be necessary to perform further studies using a homogeneous cohort of subjects from single sporting discipline, because the probable role of I allele in athletic performance has been hard to be detected by heterogeneous groups of diverse sporting disciplines [07197].

To investigate the relationship between genetic variation in the renin-angiotensin system and the effect of 12-week endurance training in Korean women 17 women who participated in an endurance training program for 12 weeks were genotyped for the angiotensinogen M235T polymorphism, angiotensin II type 1 receptor A1166C polymorphism, angiotensin-converting enzyme (ACE) T-3892C polymorphism, and angiotensin II type 2 receptor C3123A polymorphism. The following clinical parameters were measured before and after the endurance training program: blood pressure, body composition, ventilatory response, total cholesterol, triglyceride, and glucose. Of the genetic markers investigated, the frequency of the T allele for the ACE T-3892C polymorphism was significantly associated with the change in body mass index and VO2max after 12 weeks of endurance training. None of the other polymorphisms were significantly associated with the effect of training. The significant association between ACE T-3892C and the change in body mass index and VO2max in Korean women are attributed to training, suggesting that this genetic variation is a useful genetic marker for clarifying the interindividual response to endurance training [07198].
To determine the role of the angiotensin converting enzyme, ACE, (I/D) gene polymorphism on erythropoietic response in endurance athletes after natural exposure to moderate altitude erythropoietic activity was measured in 63 male endurance athletes following natural exposure to moderate altitude (2200 m) during 48 h. Erythropoietin (EPO) levels and hemoglobin (Hb) concentrations were measured at baseline and 12, 24, and 48 h after reaching the set altitude. Reticulocyte counts were determined at baseline and 48 h thereafter. Subjects were grouped into two groups (responders and nonresponders) based on significant increase in EPO levels (median: > 16.5 ng/m) after 24 h at altitude. ACE gene polymorphism was ascertained by polymerase chain reaction (DD, 31 (49 %); ID, 24 (38 %); II, 8 (13 %)). Overall, EPO levels significantly increased at 12 (70 %) and 24 h (72 %) above baseline concentration following exposure to 2200 m. Thereafter, EPO concentration decreased at 48 h, but a significant increase in Hb levels and reticulocyte count was observed at the end of the experiment, suggesting negative feedback. There were no significant differences in EPO and Hb concentration profiles between subjects with DD genotype and those with other genotypes (ID/II). Moreover, responders (n=42; DD, 50 %; ID/II, 50 %) and nonresponders (n= 21; DD, 48 %; ID/II, 52 %) showed a similar erythropoietic profile during the experiment and the ACE gene polymorphism did not influence the time course of the erythropoietic response. It was concluded that the ACE gene polymorphism does not influence erythropoietic activity in endurance athletes after short-term exposure to moderate altitude [06218].

Myocardial tolerance to ischaemia/reperfusion (I/R) injury is improved by exercise training, but this cardioprotection is impaired by the chronic use of anabolic androgenic steroids (AAS). The present study evaluated whether blockade of angiotensin II receptor (AT\textsubscript{1}-R) with losartan and aldosterone receptor (mineralocorticoid receptor, MR) with spironolactone could prevent the deleterious effect of AAS on the exercise-induced cardioprotection. Male Wistar rats were exercised and treated with either vehicle, nandrolone decanoate (10 mg/kg/week i.m.) or the same dose of nandrolone plus losartan or spironolactone (20 mg/kg/day orally) for 8 weeks. Langendorff-perfused hearts were subjected to I/R and evaluated for the postischaemic recovery of left ventricle (LV) function and infarct size. mRNA and protein expression of angiotensin II type 1 receptor (AT\textsubscript{1}-R), mineralocorticoid receptor (MR), and K\textsubscript{ATP} channels were determined by reverse-transcriptase polymerase chain reaction and Western blotting. Postischaemic recovery of LV function was better and infarct size was smaller in the exercised rat hearts than in the sedentary rat hearts. Nandrolone impaired the exercise-induced cardioprotection, but this effect was prevented by losartan (AT\textsubscript{1}-R antagonist) and spironolactone (MR antagonist) treatments. Myocardial AT\textsubscript{1}-R and MR expression levels were increased, and the expression of the K\textsubscript{ATP} channel subunits SUR2a and Kir6.1 was decreased and Kir6.2 increased in the nandrolone-treated rat hearts. The nandrolone-induced changes of AT\textsubscript{1}-R, MR, and K\textsubscript{ATP} subunits expression was normalized by the losartan and spironolactone treatments. The chronic nandrolone treatment impairs the exercise-induced cardioprotection against ischaemia/reperfusion injury by activating the cardiac renin-angiotensin-aldosterone system and downregulating K\textsubscript{ATP} channel expression [13561].

**Telmisartan**

Due to its PPAR-affecting properties, telmisartan (an angiotensin II receptor blocker, ARB) was suggested to be implemented into the class of hormone and metabolic modulators in accordance, for example, to GW1516. By its modus operandi, it would fit into the category of metabolic modulators; however, its structure is not related to any of the listed and thus
prohibited substances. Consequently, if evidence (rather than hypotheses) for performance-enhancing properties in healthy athletic individuals is given, an inclusion of the substance might follow [13012].

It has recently been shown that the angiotensin II receptor blocker telmisartan might induce similar biochemical, biological, and metabolic changes (e.g., mitochondrial biogenesis and changes in skeletal muscle fiber type) as those reported for the former call of substances. It was suspect that metabolic modulators abuse such as telmisartan might become a tangible threat in sports and should be thereby targeted as an important antidoping issue. The 2012 WADA prohibited list does not provide telmisartan for a potential doping drug, but arguments supporting the consideration to include them among "metabolic modulators" are at hand [12333].

Due to its PPAR-affecting properties, telmisartan (an angiotensin II receptor blocker, ARB) was suggested to be implemented into the class of hormone and metabolic modulators. By its modus operandi, it would fit into the category of metabolic modulators; however, its structure is not related to any of the listed and thus prohibited substances. Consequently, if evidence (rather than hypotheses) for performance-enhancing properties in healthy athletic individuals is given, an inclusion of the substance might follow [12017].

Experimental

It was evaluated the effects of swimming and anabolic steroids on ventricular function, collagen synthesis, and the local renin-angiotensin system in rats. Male Wistar rats were randomized into control (C), steroid (S; nandrolone decanoate; 5 mg/kg sc, 2x/wk), steroid + losartan (SL; 20 mg/kg/day), trained (T), trained + steroid (T+S), and trained + steroid + losartan (T+SL; n=14/group) groups. Swimming was performed 5 times/wk for 10 weeks. Serum testosterone increased in S and T+S. Resting heart rate was lower in T and T+S. Percent change in left ventricular (LV) weight-to-body weight ratio increased in S, T, and T+S. LV systolic pressure declined in S and T+S. LV contractility increased in T. LV relaxation increased in T. It was significantly lower in T+S compared with C. Collagen volumetric fraction (CVF) and hydroxyproline were higher in S and T+S than in C and T, and the CVF and LV hypertrophy were prevented by losartan treatment. LV-ANG I-converting enzyme activity increased (28 %) in the S group (33 %), and type III collagen synthesis increased (56 %) in T+S but not in T group. A positive correlation existed between LV-ANG I-converting enzyme activity and collagen type III expression. The ANG II and angiotensin type 1a receptor expression increased in the S and T+S groups but not in T group. Supraphysiological doses of AS exacerbated the cardiac hypertrophy in exercise-trained rats. Exercise training associated with AS induces maladaptive remodeling and further deterioration in cardiac performance. Exercise training associated with AS causes loss of the beneficial effects in LV function induced by exercising. These results suggest that aerobic exercise plus AS increases cardiac collagen content associated with activation of the local renin-angiotensin system [09290].
In sports, diuretics are used for two main reasons: to flush previously taken prohibited substances with forced diuresis and in sports where weight classes are involved to achieve acute weight loss. A common property observed for thiazides is hydrolysis in aqueous media resulting in the formation of the degradation product aminobenzenedisulphonamide. This degradation product can be observed for several thiazides. Because there is limited information regarding the effect of pH, temperature and light on the stability of thiazides, these parameters were investigated for chlorothiaizide, hydrochlorothiazide and altizide. For all three compounds the degradation product could be detected after incubation at pH 9.5 for 48h at 60 degrees C. At lower pH and temperature the degradation product could not be detected for all compounds. When samples were exposed to UV-light altizide and hydrochlorothiazide were photodegraded to chlorothiazide. When the degradation rate between the different compounds was compared for a given temperature and pH, altizide is the most unstable compound. This study confirms that thiazide degradation products can be formed in urine during transport [08356].

Diuretics are drugs that increase the rate of urine flow and sodium excretion to adjust the volume and composition of body fluids. There are several major categories of this drug class and the compounds vary greatly in structure, physicochemical properties, effects on urinary composition and renal haemodynamics, and site and mechanism of action. Diuretics are often abused by athletes to excrete water for rapid weight loss and to mask the presence of other banned substances. Because of their abuse by athletes, diuretics have been included on The World Anti-Doping Agency's (WADA) list of prohibited substances; the use of diuretics is banned both in competition and out of competition and diuretics are routinely screened for by anti-doping laboratories. One review provided an overview of the pharmacology and toxicology of diuretics and discusses their application in sports. The most common analytical strategies currently followed by the anti-doping laboratories accredited by the WADA are discussed along with the challenges laboratories face for the analysis of this diverse class of drugs [10383].

The variety of chemical structures of diuretic compounds has encouraged the development of new methods and techniques of analysis, especially as regards to acidic compounds. LC/MS has so grown to be the reference technique for this kind of analysis in forensic and anti-doping confirmation purposes. Multiple stage MS permits identification of single drugs with high selectivity, but some unexpected pathways could weaken the entire process. In one work it was explained some unusual fragmentation steps using high-resolution MSn. For example, in the case of amiloride an intense product ion in MS3 analysis generates an apparent loss of 10Da. Water adduct formation and successive carbon monoxide elimination can explain this uncommon behavior, which was studied using different ion traps. Bendroflumethiazide MSn spectra show instead three successive HF losses, in spite of the presence of a radical site in the parent structure. Homolytic cleavages with radical ion production occur also in the case of protonated positive ion of ethacrynic acid (loss of chlorine radical) showing that such fragmentation behavior is not so rare as generally reported. Different ionization modes were studied and a tentative correlation with acidic-base properties was done. Multiple stage high-resolution mass spectra of positive and negative ions may be discussed [08357].

In one paper, a sensitive, rapid and convenient analytical method for the determination of acidic (furosemide and bumetanide) and basic (triamterene) diuretics in human urine was developed by hollow fiber-based liquid-liquid-liquid microextraction (LLLME) coupled with
HPLC-UV. The LLLME conditions, such as the organic extraction solvent, the acidity and basicity of the donor- and acceptor-phases, stirring speed, extraction time and ionic strength, were studied in detail. Under the optimum conditions, the linear ranges of furosemide, bumetanide and triamterene were 1.2-250, 1.2-250 and 5.0-500 ng/mL, respectively. The detection limits were 0.5 ng/mL for furosemide, 1.2 ng/mL for bumetanide and 2.0 ng/mL for triamterene. The LLLME obtained a great improvement of the detection limits for all the analytes considered here, to the ng/mL level, which almost reaches the level of the LC-MS method. This new LLLME method provided very high enrichments: 117-fold for furosemide, 175-fold for bumetanide and 68-fold for triamterene. Since the hollow fiber membrane was sealed, it could be used for extracting the diuretics directly from "dirty" human urine samples without any clean-up procedures. The method was successfully applied to analyse the amounts of the three diuretics in real urine samples of volunteers after oral drug-taking [08358].

The reliability of ultra-performance liquid chromatography coupled to tandem mass spectrometry (UPLC-MS/MS) for high throughput screening in anti-doping control has been tested. A method to screen for the presence of diuretics and other doping agents in urine has been optimised and validated. The extraction procedure consisted of an alkaline extraction (pH 9.5) with ethyl acetate and salting-out effect (sodium chloride). The extracts were analysed by UPLC-MS/MS. Analysis of 34 forbidden drugs and metabolites was achieved in a total run time of 5 min, using a C18 column and a mobile phase containing deionised water and acetonitrile with formic acid, with gradient elution at a flow-rate of 0.6 mL/min. Identification of the compounds was performed by multiple reaction monitoring, using electrospray ionisation in positive- or negative-ion mode. Precursor and product ions were studied for each compound and cone voltage and collision energy were optimised. Due to the different chemical structure of the compounds under study, extraction recoveries varied from less than 10 to 100 percent depending on the analyte. The limits of detection ranged from 50 ng/mL to 200 ng/mL, and all the compounds comply with the requirements of quality established by the World Anti-doping Agency. Intra-assay precision was evaluated at two concentrations for each compound and, in most cases, a relative standard deviation of the signal ratio lower than 20 percent was obtained [08359].

Trace amounts of diuretics were determined in human urine by hollow fiber liquid-phase microextraction (LPME) combined with liquid chromatography-electrospray ionization-tandem mass spectrometry (LC-ESI-MS/MS) in this study. Chromatography was performed on a C8 reversed-phase column. A 25 microL n-octanol was used to extract analytes in urine. Extraction was optimized using a pH 2 solution spiked with 0.15 g/mL NaCl for 40 min at 40 degrees C with 1010 rpm stirring. The limits of detection of diuretics in urine were 0.3-6.8 ng/mL, and linearity range was 1-1000 ng/mL. Recoveries of spiked 50 ng/mL diuretics were 98-103 percent. The diuretics concentration profiles in patient urine were also determined. The results of this study reveal the adequacy of LPME-LC-MS/MS method for analyzing diuretics in urine and quantification limits exceed WADA requirements [08360].

Trace amounts of diuretics were determined in human urine by hollow fiber liquid-phase microextraction (LPME) combined with liquid chromatography-electrospray ionization-tandem mass spectrometry (LC-ESI-MS/MS) in this study. Chromatography was performed on a C8 reversed-phase column. A 25 microL n-octanol was used to extract analytes in urine. The intra-day precision and inter-day precision were 3-18 percent and 4-21 percent, respectively. The diuretics concentration profiles in patient urine were also determined. The results of this study reveal the adequacy of LPME-LC-MS/MS method for
analyzing diuretics in urine and quantification limits exceed World Anti-Doping Agency requirements [07199].

In sports, athletes abuse diuretics to reduce body weight so as to qualify themselves for a lower weight-class (such as boxing, weightlifting, and wrestling). Interestingly, diuretics are abused along with androgenic-anabolic steroids by bodybuilders to accentuate muscle definition and body tone as reported in this case. Practically, the most effective use of diuretics in sport doping is likely before an anti-doping test, as these agents reduce the urinary concentration of other prohibited substances and to avoid a positive doping result. Hence, use of all class of diuretics in sports is banned. Diuretics are also abused by models, ballet-dancers, or stewardesses for weight control purposes. Some of the challenges to diagnose diuretic abuse in the emergency department (ED) are related to an individual's behavior such as denial, intermittent use, or co-consumption with native plant materials and pharmacokinetics of these agents. It is important to note that the diuretics most abused by athletes have a short half-life and are therefore untraceable in urine if samples are not collected within 12 to 24 hours after the last administration. Furthermore, sustained exercise will decrease the renal and hepatic blood flow. Therefore, these substances are not always detected in urine samples collected post-competition or at the end of an intense training session. Despite diuretic misuse among sports persons, it is rarely mentioned in clinical teaching. A clinical picture of hypokalemic metabolic alkalosis is most often due to surreptitious vomiting, diuretic abuse, or Bartter's syndrome. These conditions can be differentiated by measuring urine chloride concentration. Low urinary chloride (<15 mEq/L) is seen in vomiting, whereas high urinary chloride is observed in the rest. For example urinary chloride level may vary between 20 and 70 mEq/L considerably in those persons using loop diuretics. Indeed, highly variable urinary chloride levels are not seen in any other conditions causing hypokalemic metabolic alkalosis. This has not received much attention in literature, although it provides an insight to diuretic abuse. As diuretic abuse often creates confusing clinical situations, more emphasis may be given to this easily obtained laboratory measurement as an indicator of diuretic abuse. A diurnal pattern of urinary chloride excretion may also be an adjunct to clinical diagnosis. Moreover laboratory aspects of diuretic misuse are not considered in busy ED, unless the emergency physicians are tuned their mind towards this entity [13801].

**Thiazides**

In sports, athletes abuse diuretics to reduce body weight so as to qualify themselves for a lower weight-class (such as boxing, weightlifting, and wrestling). Interestingly, diuretics are also abused along with androgenic-anabolic steroids by bodybuilders to accentuate muscle definition and body tone as reported in this case. In sports, thiazide diuretics are used to flush out previously taken prohibited substances with forced diuresis and in sports where weight classes are involved to achieve acute weight loss. Thiazide diuretics include compounds which are very unstable and hydrolyse in aqueous media. Because information regarding the urinary detection of the hydrolysis products is limited, urinary excretion profiles for the hydrolysis product 4-amino-6-chloro-1,3-benzenedisulphonamide were established in 6 healthy volunteers after oral administration of altizide (15 mg per tablet) and hydrochlorothiazide (25mg per tablet). Additionally, the excretion profile of chlorothiazide, a metabolite of altizide and hydrochlorothiazide, was also determined. A quantitative liquid-chromatographic tandem mass spectrometric method to detect the 4 substances was developed and validated. The result of this work shows that altizide is eliminated within 48 h in urine whereas hydrochlorothiazide was detectable after 120 h. Chlorothiazide was determined to be a minor metabolite of altizide and hydrochlorothiazide and could be detected up to 120 h. The hydrolysis product, 4-amino-6-chloro-1,3-benzenedisulphonamide, was detectable 120 h after administration, with concentrations at least 10 times higher than the parent drug. Concentrations ranged between 41-239 and 60-287 ng/mL after altizide and hydrochlorothiazide administration, respectively. The study shows that 4-amino-6-chloro-1,3-benzenedisulphonamide is an important target compound for the long time detection of thiazide diuretics in urine [09281].

Hydrochlorothiazide (HCTZ) has become by far the most commonly prescribed antihypertensive drug in the US. In 2008, 47.8 million prescriptions were written for HCTZ alone and 87.1 million prescriptions for HCTZ combinations. However, there is no evidence that HCTZ in its usual dose of 12.5-25 mg daily reduces myocardial infarction, stroke, or death. In a meta-analysis of 19 randomized trials with over 1400 patients, the 24-hour decrease in blood pressure with HCTZ was inferior to angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, beta-blockers, and calcium channel blockers. Even in combination with an angiotensin-converting enzyme inhibitor, HCTZ was found to reduce morbidity and mortality less well than a calcium channel blocker. As measured by the adherence rate, thiazides are less well tolerated than any other drug class. Because outcome data at the usual daily dose of 12.5-25 mg are lacking, antihypertensive efficacy is paltry, and adherence is poor, HCTZ is an inappropriate first-line drug in hypertension. If a "thiazide-type" diuretic is indicated, either chlorthalidone or indapamide should be selected [11512].

Rapid weight loss

One article briefly reviewed the weight loss processes in combat sports. It was aimed to discuss the most relevant aspects of rapid weight loss (RWL) in combat sports The review
was performed in the databases MedLine, Lilacs, PubMed and SciELO, and organized into sub-topics: prevalence, magnitude and procedures, psychological, physiological and performance effects, possible strategies to avoid decreased performance organizational strategies to avoid such practices. There was a high prevalence (50 %) of RWL, regardless the specific combat discipline. Methods used are harmful to performance and health, such as laxatives, diuretics, use of plastic or rubber suits, and sauna. RWL affects physical and cognitive capacities, and may increase the risk of death. Recommendations during different training phases, educational and organizational approaches were presented to deal with or to avoid RWL [12335].

**Mannitol**

The osmoïduretic mannitol can be potentially misused in sports, owing to its urine diluting effect and the possibility to decrease bodyweight. To reveal a doping offence, resulting urinary mannitol concentrations after a prohibited intravenous application and a permitted oral intake have to be differentiated. Therefore, a reliable gas chromatography-mass spectrometry (GC-MS) method was established based on peracetyl derivatives of the analytes. All possible hexitols (allitol, galactitol, iditol, altritols, sorbitol and mannitol) that can occur in human urine were separated and identified on a phenyl-methylpolysiloxane column (HP-5MS) within 10.75 min, and the method demonstrated its capability for quantification purposes. The lower limit of detection and lower limit of quantification were estimated at 0.9 microg/mL and 2.4 microg/mL, respectively, and the assay was validated for mannitol and sorbitol regarding the parameters specificity, linearity, intra- (<10 %) and inter-day precision (<15 %) and accuracy (92-102 %). To investigate urinary mannitol concentrations after oral intake the method was applied to an excretion study, providing a mean urinary excretion of mannitol of 20 percent. Comparison of theoretically expected urinary levels after a common therapeutic dose of mannitol and preliminary results on physiological urinary mannitol levels were promising, regarding a threshold level for mannitol that can be utilised for doping control purposes [08361].

**Laboratory techniques**

An analytical procedure was developed for the fast screening of 16 diuretics (acetazolamide, althiazide, amiloride, bendroflumethiazide, bumetanide, canrenonic acid, chlorthalidone, chlorthiazide, clopamide, ethacrynic acid, furosemide, hydrochlorothiazide, hydroflumethiazide, indapamide, triamterene, trichlormethiazide) and a masking agent (probenecid) in human urine. The whole method involves three analytical steps, including liquid/liquid extraction of the analytes from the matrix, their reaction with methyl iodide at 70 degrees C for 2 h to form methyl derivatives, and analysis of the resulting mixture by fast gas chromatography/electron impact mass spectrometry (fast GC/EI-MS). The analytical method was validated by determining selectivity, linearity, accuracy, intra and inter assay precision, extraction efficiencies and signal to noise ratio (S/N) at the lowest calibration level (LCL) for all candidate analytes. The analytical performances of three extraction procedures and five combination of derivatization parameters were compared in order to probe the conditions for speeding up the sample preparation step. Limits of detection (LOD) were evaluated in both EI-MS and ECNI-MS (electron capture negative ionization mass spectrometry) modes, indicating better sensitivity for most of the analytes using the latter ionization technique. The use of short columns and high carrier gas velocity in fast GC/MS produced efficient separation of the analytes in less than 4 min, resulting in a drastic reduction of the analysis time, while a resolution comparable to that obtained from classic GC conditions is
maintained. Fast quadrupole MS electronics allows high scan rates and effective data acquisition both in scan and selected ion monitoring modes [06216].
OTHER MASKING AGENTS

Masking agents that are forbidden in both in- and out-of-competition doping tests consist of a series of compounds that are misused in sports to mask the administration of other doping agents, and includes: diuretics, used to reduce the concentration in urine of other doping agents either by increasing the urinary volume or by reducing the excretion of basic doping agents by increasing the urinary pH; probenecid, used to reduce the concentration in urine of acidic compounds, such as glucuronoconjugates of some doping agents; 5alpha-reductase inhibitors, used to reduce the formation of 5alpha-reduced metabolites of anabolic androgenic steroids; plasma expanders, used to maintain the plasma volume after misuse of erythropoietin or red blood cells concentrates; and epitestosterone, used to mask the detection of the administration of testosterone. Diuretics may be also misused to achieve acute weight loss before competition in sports with weight categories [10199].

Epitestosterone

Epitestosterone (ET) has been used as a masking agent and prohibited by the World Anti-Doping Agency (WADA) because its administration will decrease the urinary testosterone/epitestosterone ratio, a marker of testosterone administration. In one study, an off-line immunoaffinity extraction coupled with high performance liquid chromatography (HPLC) was developed to quantify the endogenous steroid ET in human urine. The immunoaffinity column (IAC) was prepared by immobilizing the anti-ET monoclonal antibodies on CNBr-activated Sepharose 4B, which can remove the contaminations and non-target compounds from matrix to enrich the target analyte ET. The mobile phase was ammonium acetate at an isocratic flow of 1.0 mL/min and the UV absorbance detection wavelength was 244 nm for the detection of ET. The IAC showed good reliability and durability since it had been used for more than 100 runs in a year. The limit of quantification (LOQ) was 1 ng/mL. Satisfied repeatability and precision of the day-to-day and within-day were obtained with the RSD values less than 10 percent. Results of the recovery of the urine samples were ranged from 98 to 102 percent with repeatability less than 9 percent, indicating that the method developed can be used for the real urine sample analysis [10200].

Epitestosterone has been used as a masking agent and prohibited by the World Anti-Doping Agency (WADA) because its administration will decrease the urinary testosterone/epitestosterone ratio, a marker of testosterone administration. In one study, an off-line immunoaffinity extraction coupled with high performance liquid chromatography (HPLC) was developed to quantify the endogenous steroid epitestosterone in human urine. The immunoaffinity column (IAC) was prepared by immobilizing the anti-epitestosterone monoclonal antibodies on CNBr-activated Sepharose 4B, which can remove the contaminations and non-target compounds from matrix to enrich the target analyte epitestosterone. The mobile phase was ammonium acetate (10 mM, pH 4.0)/acetonitrile (45/55, v/v) at an isocratic flow of 1.0 mL/min and the UV absorbance detection wavelength was 244 nm for the detection of ET. The IAC showed good reliability and durability since it had been used for more than 100 runs in a year. The limit of quantification (LOQ) was 1 ng/mL. Results of the recovery of the urine samples were ranged from 98 to 102 percent with repeatability less than 9 percent, indicating that the method developed can be used for the real urine sample analysis [10201].

Proteases
Manipulation of urinary samples in sports drug testing with proteases is being used by athletes as masking agents to complicate or inhibit the detection of peptide hormones and proteins such as erythropoietin, human growth hormones or insulin. A great number of strategies have been suggested to prevent the use of proteases. The main problem in the use of proteases is that athletes have usually introduced proteases into the urethra before delivering a doping control urine sample. It was propose a viable, relatively simple, and inexpensive solution to prevent the use of proteases in sports [10202].

Desmopressin

Blood doping improves physical performance in sport. This is the reason why the antidoping authorities subject athletes to blood tests. Plasma volume expanders are prohibited agents used to reduce an artificial increase in hematological values using different illegal practices. The aim of our study was to test whether desmopressin (DDAVP)-induced hemodilution would alter the concentration of hematological parameters used to detect blood doping in sports. This was an intra-subject crossover study. Venous blood samples were obtained from eight physically active males on two occasions. On the first occasion the subjects ingested 1.5 L of mineral water and 4.3 microg/kg of DDAVP. On the second occasion the subjects ingested 1.5 L of mineral water. The samples were analyzed for hematocrit, hemoglobin, reticulocytes, OFF Hr-Score, glucose, albumin, creatinine and total proteins. After treatment with DDAVP it was found a significant decrease in the hematocrit, hemoglobin and in the OFF Hr-Score values. It was also found a significant decrease in glucose, albumin, creatinine and total proteins concentration; however, in this case, all the values were significantly below the physiological levels. Treatment with DDAVP has a very effective hemodilution effect [10204].

Desmopressin is a peptidic drug with antidiuretic properties, which can be administered either orally, intranasally, or intravenously. In 2011, a method allowing for the determination of 20 pg/mL of desmopressin in urine was presented, employing weak cation exchange SPE followed by liquid chromatography- ESI-QTOF-MS/MS. Applied to authentic elimination study urine samples, the drug was detected up to 22 h following intranasal or oral administration. A similar methodology for plasma was evaluated in 2012, where protein precipitation followed by weak cation exchange and subsequent LC-QqQ-MS/MS was used allowing for LODs of 50 pg/mL. Due to the comparably low concentration of desmopressin in plasma after therapeutic dosing, only intravenous applications resulted in detectable amounts of the banned substance in three different administration studies [12017].

The World Anti-Doping Agency (WADA) has recently added desmopressin, a synthetic analogue of the endogenous peptide hormone arginine vasopressin, to the Prohibited List, owing to the potential masking effects of this drug on hematic parameters useful to detect blood doping. A qualitative method for detection of desmopressin in human urine by high-performance liquid chromatography-electrospray tandem mass spectrometry (LC-ESI-MS/MS) has been developed and validated. Desmopressin purification from urine was achieved by means of delipidation with a 60:40 di-isopropyl ether/n-butanol and solid-phase extraction with WCX cartridges. The lower limit of detection was 25 pg/mL. Extraction recovery was determined as 59 percent, and signal reduction owing to ion suppression was estimated to be 43 percent. The applicability of the method was proven by the analysis of real urine samples obtained after intravenous, oral and intranasal administration of desmopressin, achieving unambiguous detection of the peptide in all the cases [12339].
One work described a liquid chromatography-electrospray tandem mass spectrometry method for detection of desmopressin in human plasma in the low femtomolar range. Desmopressin is a synthetic analogue of the antidiuretic hormone arginine vasopressin and it might be used by athletes as a masking agent in the framework of blood passport controls. Therefore, it was recently added by the World Anti-Doping Agency to the list of prohibited substances in sport as a masking agent. Mass spectrometry characterization of desmopressin was performed with a high-resolution Orbitrap-based mass spectrometer. Detection of the peptide in the biological matrix was achieved using a triple-quadrupole instrument with an electrospray ionization interface after protein precipitation, weak cation solid-phase extraction and high performance liquid chromatography separation with an octadecyl reverse-phase column. Identification of desmopressin was performed using three product ions, m/z 328.0, m/z 120.0, and m/z 214.0, from the parent ion, m/z 535.5. The extraction efficiency of the method at the limit of detection was estimated as 40 percent (n=10), the ion suppression as 5 percent (n=10), and the limit of detection was 50 pg/mL (signal-to-noise ratio greater than 3). The selectivity of the method was verified against several endogenous and synthetic desmopressin-related peptides. The performance and the applicability of the method were tested by analysis of clinical samples after administration of desmopressin via intravenous, oral, and intranasal routes. Only after intravenous administration could desmopressin be successfully detected [12340].

The World Anti-Doping Agency (WADA) has recently added desmopressin, a synthetic analogue of the endogenous peptide hormone arginine vasopressin, to the Prohibited List, owing to the potential masking effects of this drug on hematic parameters useful to detect blood doping. A qualitative method for detection of desmopressin in human urine by high-performance liquid chromatography-electrospray tandem mass spectrometry (LC-ESI-MS/MS) has been developed and validated. Desmopressin purification from urine was achieved by means of delipidation with a 60:40 di-isopropyl ether/n-butanol and solid-phase extraction with WCX cartridges. The lower limit of detection was 25 pg/mL. Extraction recovery was determined as 59 percent, and signal reduction owing to ion suppression was estimated to be 43 percent. The applicability of the method was proven by the analysis of real urine samples obtained after intravenous, oral and intranasal administration of desmopressin, achieving unambiguous detection of the peptide in all the cases [13562].

While diuretics are commonly included in multi-analyte screening procedures, two compounds (desmopressin and glycerol) potentially masking other doping measures necessitate more dedicated approaches. Desmopressin is a peptidic drug with antidiuretic properties, which can be administered either orally, intranasally, or intravenously. In 2011, a method allowing for the determination of 20 pg/ml of desmopressin in urine was presented, employing weak cation exchange SPE followed by liquid chromatography-ESI-QTOF-MS/MS. Applied to authentic elimination study urine samples, the drug was detected up to 22 h following intranasal or oral administration. A similar methodology for plasma was evaluated in 2012, where protein precipitation followed by weak cation exchange and subsequent LC-QqQ-MS/MS was used allowing for LODs of 50 pg/mL. Due to the comparably low concentration of desmopressin in plasma after therapeutic dosing, only intravenous applications resulted in detectable amounts of the banned substance in three different administration studies [13012].

Despite the facts that diuretics are readily detected with established analytical approaches in doping controls and severe side effects of diuretics abuse (such as temporary paralysis due to diuresis-induced hypokalemia) are sporadically reported, hundreds of AAFs were reported again in 2012. A more challenging situation is presented by masking agents such as the anti-diuretic drug desmopressin, a peptide hormone-based therapeutic that either necessitates a dedicated sample preparation and analysis or an implementation in a multi-analyte peptide
screening procedure. It was suggested an LLE-based delipidation of urine followed by weak cation exchange SPE to isolate desmopressin and its internal standard (deamino-Cys¹,Val⁴,D-Arg⁸-vasopressin) from 3 mL of urine. The analysis of the extract is subsequently conducted on a C-18 column (1 x 50 mm, particle size 3.5 microm) interfaced via ESI to a QqQ analyzer, allowing for detection limits for desmopressin of 25 pg/mL. The accomplished sensitivity is sufficient to determine the analyte in post-administration urine samples collected after intranasal, oral, and intravenous application of therapeutic doses [13009].

Other chemical and physical manipulation of doping tests

In 2009/2010, identical steroid profiles of supposedly eight different athletes (from different teams and collection sites) were found and DNA analyses requested, demonstrating that all eight urine specimens were provided from a single donor. This donor was eventually identified as the doping control officer and none of the athletes was actively involved in the sample manipulation. In another case of urine substitution, no natural endogenous steroid was observed in steroid profile analyses, triggering further investigations into the composition of the specimen. Based on findings of hordenine, trace amounts of alcohol, various saccharides and intact proteins including Serpin-Z4, the liquid was identified as non-alcoholic beer. This manipulation however entailed the suspension of the athlete [13012].
GLUCOCORTICOSTEROIDS

Overview

In addition to their therapeutic applications, glucocorticosteroids have been widely used and abused in the belief that these substances may enhance athletic performance. Analysis of athlete urine samples by antidoping laboratories around the world support this conclusion. It is commonly accepted in medical practice to use local glucocorticosteroid injections in the treatment of non-infectious local musculotendinous inflammatory conditions conveying symptom relief and often a speedier return to sporting activity. This practice is not to be considered illicit, but sports physicians must accept that such an intervention is not in itself an immediate cure and that an athlete will still require a period of recuperation before continuing sporting activity. How long such a period of recuperation should last is a matter of conjecture and there is little concrete data to support what is, or what is not, an acceptable period of inactivity. In the interest of athlete safety, we would propose to maintain systemic glucocorticosteroids on the World Anti-Doping Agency (WADA) list of prohibited substances, both in and out-of-competition as well as a mandatory period of 48 hours of rest from play after receiving a local glucocorticosteroid injection [12320].

Glucocorticoids are listed on the World Anti-Doping Agency (WADA) Prohibited List of substances. The detection of the administration of hydrocortisone and cortisone is complicated by the fact that the human body also produces these steroids naturally. Gas chromatography-combustion-isotope ratio mass spectrometry can be utilized to determine the use of endogenous glucocorticoids by measuring the carbon isotope ratio (CIR) of their resulting metabolites in human urine samples. A comprehensive sample preparation protocol for the analysis of endogenous glucocorticoid urinary metabolites was developed and validated, incorporating the use of high performance liquid chromatography (HPLC) for purification and chemical oxidation for derivatisation. Target compounds were tetrahydrocortisol and tetrahydrocortisone, and 11beta-hydroxyetiocholanolone, 11-oxoetiocholanolone and 11beta-hydroxyandrostosterone, while pregnanediol functioned as the endogenous reference compound. Urine samples from a population of 50 volunteers were analyzed to determine CIR reference limits. Excretion studies of the endogenous glucocorticoid preparation cortisone acetate (25 mg oral) and the dietary supplement adrenosterone (75 mg oral) were conducted with six male individuals. Variable changes in steroid metabolite isotopic composition were found across subjects after administration. The study also revealed that CIR analysis of the major glucocorticoid metabolites tetrahydrocortisol and tetrahydrocortisone is necessary to unambiguously distinguish administration of cortisone and adrenosterone, the former officially restricted to out-of-competition use by athletes, the latter not being restricted at the current time. Moreover, this study reaffirms that CIR methods for the doping control of endogenous steroids should not rely upon a single ERC, as the administration of an appropriate precursor to that ERC could cause complications during analysis [12321].

Systemic administration of glucocorticoids (GCs) is banned by the World Anti-Doping Agency (WADA) during competition. Few studies have examined the effects of GCs on exercise performance, but increasing evidence has shown that short-term GC intake enhances performance in animals and humans. However, there are many health risks associated with GC use. Based on the available evidence, as presented in one article, it was concluded that GCs are doping agents and should remain on the WADA's list of banned products. Because of the complexity of GCs, however, determining the boundaries between their medical use and abuse (eg, in sports) is a constant challenge for the WADA [10487].
Hair has long been used in toxicology, forensic science, doping control and other fields as a biological specimen for the detection of environmental agents, drugs, or toxins. Most recent evidence suggests that also hormones are incorporated and trapped inside the growing hair. This has led to the hypothesis that cortisol measurement of distinct hair segments could provide a retrospective calendar of cortisol production for the individual. In this first proof-of-concept study in humans, it was analyzed cortisol in hair donated by mothers with a neonate child (n-Mothers=103), mothers with toddlers 3-9 months of age (t-Mothers=19), and control women (n=20). It was cut hair strands from each women into at least three 3-cm segments, which, based on an average hair growth rate of 1 cm per month, would represent hair grown over the past three, six, and nine months, respectively. Since in the third trimester of pregnancy there is a well-documented increased production of cortisol, it was expected to see elevated levels of cortisol in the most proximal hair segment of women who had just given birth to a child (n-Mothers) compared with the control women. Likewise, it was expected to see elevated levels in the second, third, or fourth segment of mothers of 3-month olds, 6-months olds, and 9-months olds, respectively. These hair segments, cut at 4-12cm from the scalp, would represent hair grown throughout the third trimester of pregnancy. Results showed that there was a strong monotonic decline in cortisol concentration from the segment closest to the scalp to the most distal hair segment. Cortisol levels decreased by 30-40 percent from one segment to the next for the most recent four hair segments. Segments from hair older than one year had similarly, low levels of cortisol. Comparisons of cortisol levels in hair between n-Mothers and control women yielded the expected results: cortisol levels in the first 3-cm hair segment (i.e. closest to the scalp) of n-Mothers were two-fold higher than in controls, probably reflecting increased cortisol levels throughout the third trimester of pregnancy. No differences in cortisol content were apparent for the second or third 3-cm segments in n-Mothers. When hair from mothers with 6-9 months old toddlers was analyzed, the hair segment representing the third trimester period contained the same amount of cortisol as the hair grown more recently in mothers with 3-4 months old toddlers only. Age of the women, hair curvature, hair color, and frequency of hair washes per week were unrelated to cortisol levels. It was conclude that cortisol measured in human hair can be a valid reflection of increased cortisol production for a period of up to six months. Due to a rapid decline of cortisol levels in human adult hair, a retrospective calendar of cortisol exposure may be limited to the past six months [08363].

One paper described a liquid chromatographic/tandem mass spectrometric (LC/MS-MS) method specifically designed for the screening of synthetic glucocorticosteroids in human urine. The method is designed to recognize a common mass spectral fragment formed from the particular portion of the molecular structure that is common to all synthetic glucocorticosteroids and that is fundamental to their pharmacological activity. As such, the method is also suitable for detecting unknown substances, provided they contain the portion of the molecular structure selected as the analytical target. The effectiveness of this approach was evaluated on seventeen synthetic glucocorticosteroids. Urine samples, including blank urines spiked with one or more synthetic glucocorticosteroids, were treated according to a standard procedure (enzymatic hydrolysis, liquid/liquid extraction and evaporation to dryness) and analyzed using LC/MS-MS with electrospray ionization (ESI). MS-MS acquisition was carried out in a precursor ion scan, and the results were compared with those obtained by a previously developed reference technique based on acquisition in the multiple reaction monitoring (MRM) mode. All of the glucocorticosteroids considered in this study are clearly detectable in urine, with a limit of detection in the concentration range 5-20 ng/mL, depending on the glucocorticosteroid structure. The proposed method is therefore suitable for the detection of glucocorticosteroids in urine samples taken for "in competition" sport anti-doping control tests, matching the requirements of the World Anti-Doping Agency (WADA) for accredited anti-doping laboratories [08364].
Glucocorticoid hormones are important regulators of several physiological processes. Despite having been initially named based on their role in glucose metabolism, glucocorticoids are also fundamental in the regulation of developmental, metabolic, and neurobiological processes, as well as several other biological functions. Due to their involvement in a diverse array of biological pathways, its wide spectrum of action, it is predicted that a wide range of genes may have their expression regulated by the activated glucocorticoid receptor (GR). In fact, it has been demonstrated that in addition to the regulation of several effectors genes, the expression of the gene encoding for GR itself is regulated by physiological stimuli and fine-tuning mechanisms. Importantly, such generalized effector responses and fine-tuning responses seem to be largely mediated by mechanisms of gene regulation. Therefore, one review aimed to describe the mechanisms of gene regulation by glucocorticoid hormones, which are capable of regulating differential gene transcription, within a physiological context. From this discussion, it was hoped to shed light on how a single molecule that is capable of exerting such divergent effects is also capable of promoting such distinct responses in different target tissues [10377].

To examine variations in neuromuscular and hormonal status and their relationship to performance throughout a season of elite Australian Rules Football 15 elite players performed a single jump and 5 repeated countermovement jumps, and provided saliva samples for the analysis of cortisol and testosterone before the season commenced and during the 22-match season. It was concluded that the response of single jump flight time/contraction time suggests periods of neuromuscular fatigue. Change in testosterone to cortisol indicates subjects were unlikely to have been in a catabolic state during the season. Increase in cortison during the season compared with before had a small negative correlation with performance [09228].

Edge plane pyrolytic graphite electrode (EPPGE) modified with single-wall carbon nanotubes (SWNTs) has been used as a sensor to determine triamcinolone, abused by athletes for doping. A comparison of the voltammetric behavior between SWNTs modified EPPGE and fullerene - C(60)-modified EPPGE indicated that SWNTs modified EPPGE is more sensitive. The electrode exhibited an effective catalytic response with good reproducibility and stability. The effect of several parameters such as pH, square wave frequency and steroid concentration were studied. The square wave voltammetric response of the electrode to triamcinolone is linear in the range 0.1-25 nM with a detection limit and sensitivity of 8.9 x 10^7 to 2.06 microA per nM, respectively. The method was applied for the determination of triamcinolone in several commercially available pharmaceuticals and real urine samples obtained from patients undergoing pharmacological treatment with triamcinolone. A comparison of the observed results with HPLC analysis indicated a good agreement. The product obtained after reduction of triamcinolone was also characterized using 1H NMR and GC-MS and the site of reduction is found to be carbonyl group at position 20. The method described is rapid, simple and accurate and can be easily applied for detecting cases of doping [09229].

One study investigated whether short-term oral administration of glucocorticoid would modify performance and selected hormonal and metabolic parameters during submaximal exercise in healthy women. Nine recreational female athletes completed cycling trials at 70-75 percent VO2max until exhaustion after either placebo (Pla, gelatin) or oral prednisone (Cor, Cortancyl, 50 mg per day for 1 week) treatment, according to a double-blind and randomized protocol. Blood samples were collected at rest; after 10, 20, and 30 min of exercise; at exhaustion; and after 10 and 20 min of passive recovery for adrenocorticotropic hormone (ACTH), dehydroepiandrosterone (DHEA), prolactin (PRL), growth hormone (GH), insulin (Ins), blood glucose (Glu), and lactate (Lac) determination. Cycling time was significantly increased with
short-term prednisone intake. ACTH and DHEA remained completely blunted throughout the experiment with prednisone versus placebo whereas GH and PRL were significantly decreased with prednisone after, respectively, 20 and 30 min of exercise. No significant difference in insulin or blood glucose values was found between the two treatments but lactate concentrations were significantly increased with prednisone versus placebo between 10 and 30 min of exercise. These data indicate that short-term glucocorticoid intake improved endurance performance in women, but further investigation is needed to determine whether these results are applicable to elite female athletes and, if so, current WADA legislation needs to be changed [09230].

Certain international sports federations are requesting that glucocorticoids (GCs) be removed from the World Antidoping Agency's list of banned products. Their arguments are based on the fact that GCs are in widespread use in sports medicine and have no demonstrated ergogenic activity. However, there is scientific evidence that GCs mediate ergogenic effects in animals and humans. Moreover, the health risks of using GCs are well characterized. GCs are doping agents and should remain on the World Antidoping Agency's list of banned products [10161].

Doping control samples are normally collected under non-sterile conditions and sometimes, storage and transportation are influenced by parameters such as the temperature. Therefore, microbial contamination and subsequent alteration of a sample’s composition are possible. Studies regarding sample collection in cattle breeding have already shown enzymatic transformation of endogenous testosterone to boldenone causing false-positive findings. The aim of one study was to investigate whether positive doping cases with the synthetic corticosteroids prednisolone and prednisone may result from microbial transformation of the endogenous corticosteroids cortisol and cortisone, respectively. A method comprising parameters such as pH values and screening results for synthetic glucocorticosteroids as well as incubation experiments followed by liquid chromatographic and mass spectrometric analysis was employed to test for contaminating germs with delta-1-dehydrogenase activity. Over 700 urine samples comprising inpatient and doping control specimens were investigated. In none of them, 1,2-dehydrogenating activity was confirmed. These findings are in accordance with other studies. However, the problem of microbial alteration of doping control specimens with special respect to 1,2-dehydrogenation must not be underestimated [10162].

Glucocorticoid (GC) is an adrenal steroid hormone that controls a variety of physiological processes such as metabolism, immune response, cardiovascular activity, and brain function. In addition to GC induction in response to stress, even in relatively undisturbed states its circulating level is subjected to a robust daily variation with a peak around the onset of the active period of the day. It has long been believed that the synthesis and secretion of GC are primarily regulated by the hypothalamus-pituitary-adrenal (HPA) neuroendocrine axis. However, recent chronobiological research strongly supports the idea that multiple regulatory mechanisms along with the classical HPA neuroendocrine axis underlie the diurnal rhythm of circulating GC. Most notably, recent studies demonstrate that the molecular circadian clockwork is heavily involved in the daily GC rhythm at multiple levels. The daily GC rhythm is implicated in various human diseases accompanied by abnormal GC levels. Patients with such diseases frequently show a blunted GC rhythmicity and, more importantly, circadian rhythm-related symptoms. In one review, it was focused on recent advances in the understanding of the circadian regulation of adrenal GC and its implications in human health and disease [11175].

Corticosteroid-binding globulin (CBG) binds cortisol with high affinity and facilitates its transport in the blood. A recent discovery suggests that CBG may have a role beyond that of
a simple transport carrier protein. CBG functions as a protein thermocouple that is exquisitely sensitive to temperature change, releasing cortisol in response to increasing temperatures within the human physiological range. It is also expressed in the human hypothalamus and cerebrospinal fluid, while in the rodent it is also found in other intracellular neuronal locations, suggesting a role in regulating access of glucocorticoids to their receptors in the CNS. Genetic variants of CBG have been detected in man and have been associated with fatigue-pain syndromes and hypotension, again suggesting a potential effect of CBG on the access of cortisol to brain glucocorticoid receptors. These new findings provide the basis for a novel concept of the mechanisms through which the body regulates access of glucocorticoids to the brain and other tissues of the body [11176].

Changes in glucocorticoid (GC) receptor sensitivity can be categorized in three different types. First, generalized GC resistance syndrome is a hereditary disease. Patients present with signs and symptoms of increased androgen and/or mineralocorticoid action, combined with biochemical hypercortisolism, but lack of cushingoid features. Second, at a tissue level, transient changes in GC sensitivity are present during disease. Transient changes in GC sensitivity of leukocytes during infectious diseases like sepsis have been found, but also acquired forms or GC resistance occur, in particular in some types of neoplasms, major depression, AIDS, and several autoimmune diseases. Third, at the level of the general population, the diversity in GC sensitivity has a wide interindividual variation which in part can be explained by genetic variation of the GC receptor gene. Several single nucleotide polymorphisms of the gene have been associated with changes in GC sensitivity and its clinical phenotype. Four genetic variants are described of which two (rs6198 and rs6189/6190) are associated with a relative GC resistance and two (rs1695 and rs41423247) are associated with a relative GC hypersensitivity [11177].

One review considers the problem of the serious concomitant side effects of powerful anti-inflammatory drugs modelled upon the principal human glucocorticoid hormone, cortisol. The very nature of the original bio-assays to validate their cortisol-like hormonal and anti-inflammatory activities ensured that pleiotropic toxins were selected for clinical studies. Other complicating factors have been (1) considerable reliance on bio-assays conducted in laboratory animals that primarily secrete corticosterone, not cortisol, as their principal anti-inflammatory adrenal hormone; (2) some differences in the binding of xenobiotic cortisol analogues (vis à vis cortisol) to transport proteins, detoxifying enzymes and even some intracellular receptors; (3) the "rogue" properties of these hormonal xenobiotics, acting independently of—but still able to suppress—hormonal mechanisms regulating endogenous cortisol; and (4) problems of intrinsic/acquired "steroid resistance", diminishing their clinical efficacy, but not necessarily all their toxicities. The rather gloomy conclusion is that devising new drugs to reproduce the effect of multi-potent hormones may be a recipe for disaster, in contexts other than simply remedying an endocrine deficiency. Promising new developments include "designed" combination therapies that allow some reduction in total steroid doses (and hopefully their side effects); sharpening strategies to limit the actual duration of steroid administration; and resurgent interest in searching for more selective analogues (both steroidal and non-steroid) with less harmful side effects. Some oversights and neglected areas of research are also considered. Overall, it now seems timely to engage in some drastic rethinking about (retaining?) these "licensed toxins" as fundamental therapies for chronic inflammation [11178].

Similar to discussions as to whether cannabinoids should be banned in elite sport, glucocorticosteroids have also caused numerous controversies. In a recent editorial, the importance of controlling the use and misuse of glucocorticosteroids was presented from a sports medicine viewpoint and issues associated particularly with long-term/high-dose abuse were broached. Concerning analytical challenges, the possibility of microbial transformation
of cortisol to prednisolone was investigated. A series of micro-organisms possess delta-
steroid dehydrogenase activity and, thus, could potentially convert endogenous (urinary) cortisol into the prohibited substance prednisolone. Using in vitro methodologies, the conversion of deuterated cortisol to deuterated prednisolone was unambiguously demonstrated; however, so far no urine sample was found to contain the currently known germs allowing for the transformation of cortisol to prednisolone [13012].

The risk of infection is increased in patients treated with glucocorticoids, especially in those taking long-term and high dosage treatment. However, there is little valid practice for the prevention of infections in this patient population. The risk of reactivation or worsening of a latent infection (e.g. hepatitis B, tuberculosis, strongyloidiasis) is proved and individual reflection should be conducted in at-risk patients. Preventions of Pneumocystis jiroveci or upper urinary tract infections are considered differently according to practitioners’ habits and their specialties. Adequate prevention should be prescribed in glucocorticoid-treated patients who have been in contact with varicella zoster or measles virus. Many vaccines could be prescribed in those people but live vaccines should be avoided. A consultation of travel medicine should be systematically proposed before a travel in intertropical zone. Anti-inflammatory and stimulant properties of glucocorticoids are frequently misused in order to improve sport performances. All glucocorticoids are considered as performance-enhancing drugs. Their prescription should therefore be adapted to the laws in force in the sport. By reducing vomiting and pain, glucocorticoids may be beneficial in patients undergoing surgery. However, in people prescribed long-term glucocorticoid therapy, the risk of postoperative adrenal insufficiency has to be considered, even though very few data are available on this topic. Oral contraceptives or intra-uterine devices are effective contraceptives methods in patients treated with systemic glucocorticoids [13550].

The use of glucocorticosteroids is manifold in different fields of medicine, and their therapeutic potential has been utilized as well as abused also in elite sport. In order to prevent inadvertent doping and to ensure best practice in asthma care and other health conditions to athletes, guidelines concerning the use and declaration of glucocorticosteroids have been established by WADA. These have been shown to substantially influence, for example, asthma management in sport. For doping control laboratories, the main challenge concerning this class of compounds resides in the differentiation of natural/endogenous corticosteroids and their synthetic preparations, especially regarding cortisol and, as recently corroborated, the natural or artifact-derived occurrence of prednisolone in human urine [13009].

An additional issue with glucocorticosteroid analysis in doping controls is the fact that systemic administrations are prohibited while topical applications are not, and viable analytical means to differentiate these routes of administration are desirable. In this context, it was therefore conducted elimination studies with methylprednisolone and studied the relative and absolute amount of the intact drug as well as its main urinary metabolites. Comparing the metabolic profiles, two analyte candidates were suggested to support distinguishing systemic (oral) and topical use of the drug, namely 16beta,17alpha,21-trishydroxy-6alpha-methylpregna-1,4-diene-3,11,20-trione and 17alpha,20alpha,21-trishydroxy-6alpha-methylpregna-1,4-diene-3,11-dione. These metabolites were predominantly observed after oral application and only at trace amount level following topical administration [13009].

Stimulation of myocytes
Muscle wasting is associated with poor prognosis in chronic obstructive pulmonary disease (COPD). Exercise stimulates muscle recovery but its efficacy is variable depending on the clinical condition and medical treatment. Systemic glucocorticoids, commonly administered in high-doses during acute disease exacerbations or as maintenance treatment in end-stage disease are known to contribute to muscle wasting. As muscle mass recovery involves IGF-I signaling, which can be stimulated by anabolic steroids, the impact of glucocorticoids and the effect of simultaneous IGF-I stimulation by anabolic steroids on muscle recovery and growth were investigated. The effects of and interactions between glucocorticoid and IGF-I signaling on skeletal muscle growth were assessed in differentiating C2C12 myocytes. As proof-of-principle, it was performed a post-hoc analysis stratifying patients by glucocorticoid use, of a clinical trial investigating the efficacy of anabolic steroid supplementation on muscle recovery in muscle wasted patients with COPD. Glucocorticoids strongly impaired protein synthesis signaling, myotube formation and muscle-specific protein expression. In contrast, in presence of glucocorticoids, IGF-I synergistically stimulated myotube fusion and myofibrillar protein expression, which corresponded with restored protein synthesis signaling by IGF-I and increased transcriptional activation of muscle-specific genes by glucocorticoids. In COPD patients on maintenance glucocorticoid treatment, the clinical trial also revealed an enhanced effect of anabolic steroids on muscle mass and respiratory muscle strength. In conclusion, synergistic effects of anabolic steroids and glucocorticoids on muscle recovery may be caused by relief of the glucocorticoid-imposed blockade on protein synthesis allowing effective translation of glucocorticoid-induced accumulation of muscle-specific gene transcripts [12322].

Effects on exercise performance

To study the effects of a therapeutical dose of corticosteroid alone or associated with beta-2 agonist on performance and substrate response during intense submaximal exercise, seven healthy moderately trained male volunteers participated in the double-blind randomized cross-over study. An intense endurance exercise test to exhaustion was performed after ingestion of placebo (Pla), 20 mg prednisolone (Pred), and 20 mg prednisolone plus 4 mg salbutamol (Pred-Sal). Blood samples were collected at rest, after 5, 10 min of exercise, at exhaustion, and after 5 (r5), 10 (r10), and 20 (r20) min of passive recovery for ACTH, growth hormone, insulin, blood glucose, and lactate measurements. There were no significant differences in exercise time to exhaustion between the three treatments. ACTH was significantly lowered after Pred and Pred-Sal vs. Pla from the start of exercise to the end of the experiment. Pred and Pred-Sal increased resting and recovery (r10 and r20) significantly but not exercise blood glucose values. There were no significant differences in growth hormone concentrations between the three treatments whereas insulin was significantly higher at rest, during exercise, and at r20 after Pred-Sal administration versus Pred and Pla. Pred and Pred-Sal showed no significant effect on blood lactate compared with Pla treatment. These preliminary results do not support the hypothesis that acute oral therapeutic corticosteroid intake alone or associated with beta-2 mimetic improves performance during intense submaximal exercise, but further studies are necessary with tests of longer duration [06210].

To examine whether acute glucocorticoid (GC) intake alters performance and selected hormonal and metabolic variables during submaximal exercise in total, 14 recreational male athletes completed two cycling trials at 70-75 percent maximum O$_2$ uptake starting 3 h after an ingestion of either a lactose placebo or oral GC (20 mg of prednisolone) and continuing until exhaustion, according to a double-blind randomised protocol. Blood samples were collected at rest, after 10, 20, 30 minutes, and at exhaustion and recovery for measurement
of growth hormone (GH), adrenocorticotropic hormone (ACTH), dehydroepiandrosterone (DHEA), prolactin, insulin, blood glucose, lactate and interleukin (IL) -6 determination. Cycling duration was not significantly changed after GC or placebo administration. A significant decrease in ACTH and DHEA was observed with GC during all of the experiments and in IL-6 after exhaustion. No change in basal, exercise or recovery GH, prolactin, insulin or lactate was found between the two treatments but blood glucose was significantly higher with GC at any time point. From these data, acute systemic GC administration does seem to alter some metabolic markers but did not influence performance during submaximal exercise [07181].

To examine the prednisolone's ergogenic and metabolic effects during submaximal exercise ten recreational male athletes completed two cycling trials at 70-75 percent peak O2 consumption until exhaustion after either placebo (Pla, lactose) or oral prednisolone (Pred, 60 mg/day for 1 week) treatment, according to a double-blind and randomized protocol. Blood samples were collected at rest and during exercise and recovery to determine ACTH, growth hormone (GH), prolactin (PRL), DHEA, insulin, blood glucose, and blood lactate values. Time of cycling was significantly increased after chronic Pred treatment (Pred: 75; Pla: 46). Pred intake significantly lowered basal, exercise, and recovery ACTH, DHEA, and PRL concentrations, whereas GH concentrations were significantly lowered by Pred after 30 min of exercise. Blood glucose and insulin were significantly increased by Pred during the whole experiment and until 30 min of exercise. Blood lactate concentrations were higher after Pred versus Pla at 10 min of exercise until 10 min of recovery. From these data, short-term Pred intake did seem to significantly improve performance during submaximal exercise, with concomitant alterations in hormonal and metabolic responses. Further studies will be necessary to elucidate the mechanisms of these hormonal and metabolic changes, and to determine whether the changes may be associated with the marked performance improvement obtained [07182].

**Adrenal insufficiency after use of corticosteroids**

The frequent use of glucocorticoids by athletes necessitates testing for adrenal insufficiency because of the risk of death in cases of associated severe stress (trauma, infection). During the 2001 and 2002 sporting seasons, we assessed the value of measuring baseline serum cortisol concentrations and the frequency of corticosteroid use during compulsory medical tests carried out by the French Cycling Federation on 659 elite cyclists (585 men and 74 women); the risk of adrenal insufficiency is negatively correlated with the basal serum cortisol level. Adrenal insufficiency was suspected in 34 cyclists (5%; 22 in 2001 and 12 in 2002) on the basis of below normal cortisol concentrations and in three cyclists (in 2001) because they had received corticosteroid treatment. In 2001, 10 of the 25 cyclists convoked underwent baseline follow-up serum cortisol determinations and 15 underwent dynamic exploration of adrenal function with the short ACTH test. Adrenal function was found to be deficient in four of these cyclists, at the limits of the normal range in four and normal in seven. Based on these results, the FFC sent a questionnaire in 2002 to all the cyclists to assess the use of corticosteroid in this population. This survey revealed that 85 of 538 cyclists (16%) had received corticosteroid treatment in the previous 3 months. Moreover, 11 of the 12 cyclists (92%) with low basal serum cortisol concentrations had received corticosteroid therapy. These results show that basal serum cortisol is relevant to detect adrenal insufficiency in sportsmen, in particular in cases of values below the normal range. The high frequency of corticosteroid use among elite cyclists, and in particular road cyclists who are at risk of trauma and infection, justifies screening tests to detect adrenal insufficiency [06211].

*Corticosteroid-induced adrenal insufficiency in elite cyclists*
The frequent use of glucocorticoids by athletes necessitates testing for adrenal insufficiency because of the risk of death in cases of associated severe stress (trauma, infection). During the 2001 and 2002 sporting seasons, we assessed the value of measuring baseline serum cortisol concentrations and the frequency of corticosteroid use during compulsory medical tests carried out by the French Cycling Federation on 659 elite cyclists (585 men and 74 women); the risk of adrenal insufficiency is negatively correlated with the basal serum cortisol level. Adrenal insufficiency was suspected in 34 cyclists (5 %; 22 in 2001 and 12 in 2002) on the basis of below normal cortisol concentrations and in three cyclists (in 2001) because they had received corticosteroid treatment. In 2001, 10 of the 25 cyclists convoked underwent baseline follow-up serum cortisol determinations and 15 underwent dynamic exploration of adrenal function with the short ACTH test. Adrenal function was found to be deficient in four of these cyclists, at the limits of the normal range in four and normal in seven. Based on these results, the FFC sent a questionnaire in 2002 to all the cyclists to assess the use of corticosteroid in this population. This survey revealed that 85 of 538 cyclists (16 %) had received corticosteroid treatment in the previous 3 months. Moreover, 11 of the 12 cyclists (92 %) with low basal serum cortisol concentrations had received corticosteroid therapy. These results show that basal serum cortisol is relevant to detect adrenal insufficiency in sportsmen, in particular in cases of values below the normal range. The high frequency of corticosteroid use among elite cyclists, and in particular road cyclists who are at risk of trauma and infection, justifies screening tests to detect adrenal insufficiency [07183].

ACTH

To investigate the effects of short-term prednisolone ingestion combined with intense training on exercise performance, hormonal (adrenocorticotropic hormone (ACTH), prolactin, luteinising hormone (LH), growth hormone (GH), thyroid-stimulating hormone (TSH), dehydroepiandrosterone (DHEA), testosterone, insulin) and metabolic parameters (blood glucose, lactate, bicarbonate, pH). Eight male recreational athletes completed four cycling trials at 70-75 percent peak O\textsubscript{2} consumption until exhaustion just before and after either oral placebo or prednisolone (60 mg/day for 1 week) treatment coupled with standardised physical training (2 hours/day), according to a double-blind and randomised protocol. Blood samples were collected at rest, during exercise and passive recovery for the hormonal and metabolic determinations. Time of cycling was not significantly changed after placebo but significantly increased after prednisolone administration (50 min for placebo 1, 64 min for placebo 2, 56 min for prednisolone 1 and 107 min for prednisolone 2). There was no significant difference in any measured parameters after the week of training with placebo but a decrease in ACTH, DHEA, PRL, GH, TSH and testosterone was seen with prednisolone treatment during the experiment. No significant change in basal, exercise or recovery LH, insulin, lactate, pH or bicarbonate was found between the two treatment, but blood glucose was significantly higher under prednisolone at all time points. It was concluded that short-term glucocorticoid administration induced a marked improvement in endurance performance [07184].

Synacthen®

Despite the controversy regarding the performance enhancing properties of corticotrophins, informed “street talk” has frequently indicated that substances such as Synacthen have been misused in sports. As shown also in earlier studies, Synacthen proved extremely unstable in plasma if the specimen is not stored frozen immediately after sampling [12016].
Synacthen is a synthetic analogue to human adrenocorticotropic hormone, which plays an important physiological role by stimulating production of cortisol. In sports, corticosteroids as well as releasing factors (corticotropins) are prohibited according to the regulations of the World Anti-Doping Agency, and the misuse of Synacthen has been reported several times. Hence, an assay enabling the detection of Synacthen in doping control samples has been developed using immunoaffinity chromatographic isolation of Synacthen from human plasma combined with a concentration of collected fractions using solid-phase extraction. Unambiguous determination of the target analyte was accomplished using microbore liquid chromatography/electrospray ionization tandem mass spectrometry. Diagnostic product ions such as m/z 223 were characterized using high-resolution/high-accuracy Orbitrap mass spectrometry and employed for triple quadrupole MS/MS analysis. The established assay requiring 2 mL of plasma allowed a lower limit of detection (LLD) at 100 fmol/mL, a recovery of 97 percent and a precision at the LLD < 20 percent. Authentic plasma samples obtained from a patient undergoing a standard short Synacthen test were used to prove the applicability of the developed procedure [06213].

A peptide hormone termed synacthen, which belongs to the class of corticotrophins, has also been determined in human plasma using immunoaffinity purification and LC-MS/MS analysis. The peptide consists of 24 amino acids and mimics the adrenocorticotropic hormone ACTH, which triggers the secretion of endogenously produced cortisone. Due to its relatively small size, no further enzymatic hydrolysis was required and unambiguous information on its presence was obtained by multiple reaction monitoring experiments, including those monitoring the quadruply charged precursor ion and the diagnostic product ion a2 at m/z 223. Using administration study specimens as well as spiked blank plasma samples, detection limits of 0.3 ng/mL have been obtained, while sampling and storage have been identified as key factors regarding the stability of the target analyte. Only specimens stored at −20 °C were stable for up to three months, which demonstrates that blood sampling requires different conditions than the collection of urine specimens in doping controls [07050].

Tetracosactide (Synacthen®), a synthetic analogue of adrenocorticotropic hormone (ACTH), can be used as a doping agent to increase the secretion of glucocorticoids by adrenal glands. The only published method for anti-doping control of this drug in plasma relies on purification by immunoaffinity chromatography and LC/MS/MS analysis. Its limit of detection is 300 pg/mL, which corresponds to the peak value observed 12 h after 1 mg Synacthen IM administration. It was reported here a more sensitive method based on preparation of plasma by cation exchange chromatography and solid-phase extraction and analysis by LC/MS/MS with positive-mode electrospray ionization using 7-38 ACTH as internal standard. Identification of Synacthen was performed using two product ions. The recovery was estimated at 70 percent. A linear calibration curve was obtained from 25 to 600 pg/mL (R² = 0.99). The lower limit of detection was 8 pg/mL (S/N > 3). The lower limit of quantification was 15 pg/mL (S/N > 10; CV % < 20 %). The performance of the method was illustrated by an 8-h kinetic analysis of plasma samples from nine subjects submitted to IM injections of either Synacthen® (five subjects) or Synacthen® Depot, the slow-release form of the drug (four subjects). Concentrations of Synacthen between 16 and 310 pg/mL were observed. A sensitive method for quantitation of Synacthen in plasma is proposed for anti-doping control analyses [11179].

Doping control analysis of performance-enhancing peptides in urine represents a challenging requirement in modern sports drug testing. Low dosing, effective metabolism and short half-life lead to target concentrations in the low fmol/mL range in urine. Synthetic adrenocorticotropic hormone (1-24, Syn-ACTH-en) shares all these characteristics and improved analytical performance is required for its sufficient determination by means of liquid
chromatography/tandem mass spectrometry (LC/MS/MS). The desired effects for cheating sportsmen are mainly due to enhanced release of corticosteroids as well as androgenic steroids into the circulation after systemic administration of the drug. Immunoaffinity purification with coated magnetic beads and subsequent liquid chromatography with nano-ultra-performance liquid chromatography (UPLC) coupled to tandem mass spectrometry (high resolution/high mass accuracy) of Synacthen from urinary specimens is described in the present study. The general proof of principle was obtained by analysis of excretion study urine samples and validation was performed with focus on the limit of detection (3 pg/mL), linearity, precision (<20 %), recovery (approximately 30 %), robustness, specificity and stability. For all experiments, the ACTH fragment 1-17 was used as the internal standard [09231].

Budesonide

Budesonide, a corticosteroid frequently used in the treatment of asthma, is most often administered via inhalation. Its use in sports is allowed when medically necessary. A fast, sensitive and accurate LC-MS method was developed and validated for the quantification of budesonide and its major metabolite 16alpha-hydroxyprednisolone in urine samples after inhalation of a metered dose (Pulmicort-Turbohaler 200). Sample preparation consists of an alkaline liquid-liquid extraction with ethyl acetate. Analysis was performed using liquid chromatography-tandem mass spectrometry with electrospray ionization (ESI). The method was linear in the range of 5-100 and 0.5-10ng/mL for 16alpha-hydroxyprednisolone and budesonide, respectively. The limits of quantification were 5ng/ml for 16alpha-hydroxyprednisolone and 0.5ng/mL for budesonide. The accuracy ranged from 2.2 to 3.5% for 16alpha-hydroxyprednisolone and from 0.8 to 16.4 percent for budesonide. After administration of 200microg of budesonide to five healthy volunteers budesonide could not be detected in any urine sample whereas 16alpha-hydroxyprednisolone was detectable up to 12 h post-administration [06212].

Budesonide (BUD) is a glucocorticoid widely used for the treatment of asthma, rhinitis, and inflammatory bowel disease. Its use in sport competitions is prohibited when administered by oral, intravenous, intramuscular, or rectal routes. However, topical preparations are not prohibited. Strategies to discriminate between legal and forbidden administrations have to be developed by doping control laboratories. For this reason, metabolism of BUD has been re-evaluated using liquid chromatography-tandem mass spectrometry (LC-MS/MS) with different scan methods. Urine samples obtained after oral administration of 3 mg of BUD to two healthy volunteers have been analyzed for metabolite detection in free and glucuronide metabolic fractions. Structures of the metabolites have been studied by LC-MS/MS using collision induced dissociation and gas chromatography-mass spectrometry (GC/MS) in full scan mode with electron ionization. Combination of all structural information allowed the proposition of the most comprehensive picture for BUD metabolism in humans to this date. Overall, 16 metabolites including ten previously unreported compounds have been detected. The main metabolite is 16alpha-hydroxy-prednisolone resulting from the cleavage of the acetal group. Other metabolites without the acetal group have been identified such as those resulting from reduction of C20 carbonyl group, oxidation of the C11 hydroxyl group and reduction of the A ring. Metabolites maintaining the acetal group have also been identified, resulting from 6-hydroxylation (6alpha and 6beta-hydroxy-budesonide), 23-hydroxylation, reduction of C6-C7, oxidation of the C11 hydroxyl group, and reduction of the C20 carbonyl group. Metabolites were mainly excreted in the free fraction. All of them were excreted in urine during the first 24 h after administration, and seven of them were still detected up to 48 h after administration for both volunteers [12323].
**Methylprednisolone**

Methylprednisolone (MP) is prohibited in sports competitions when administered by systemic routes; however its use by topical administration is allowed. Therefore, analytical approaches to distinguish between these different administration pathways are required. A reporting level of 30 ng/mL was established for this purpose. However, the suitability of that reporting level for MP is not known. In the present work, excretion profiles of MP and different metabolites after oral and topical administrations have been compared. A method for the quantification of MP and the qualitative detection of fifteen previously reported metabolites has been validated. The method involved an enzymatic hydrolysis, liquid-liquid extraction and analysis by liquid chromatography coupled to tandem mass spectrometry. The method was found to be linear, selective, precise and accurate. The high sensitivity (limit of detection 0.1 ng/mL) and linear range (0.1-250 ng/mL) achieved allowed for the quantification of MP at both the low concentrations present after topical administration and the high concentrations detected after oral intake. The method was applied to samples collected after oral (4 or 40 mg) and topical administration (10 mg of MP aceponate/day for 5 consecutive days) to healthy volunteers. After oral administration, MP and all metabolites were detected in urines collected up to at least 36 h. Only MP and five metabolites were detected in samples obtained after topical administration. As expected, concentrations of MP after topical administration were well below current reporting level (30 ng/mL), however 3 out of 4 samples in range 8-24 h after the low oral dose (4 mg) were also below that concentration. Taking into account metabolites detected after both administration routes, metabolites 16beta,17alpha,21-trihydroxy-6alpha-methylpregna-1,4-diene-3,11,20-trione (M8) and 17alpha,20alpha,21-trihydroxy-6alpha-methylpregna-1,4-diene-3,11-dione (M11) are best markers to differentiate between topical and oral administrations. Their signals after topical administration were lower than those obtained in the first 48 h after all oral doses [13551].

**Dexamethasone**

The illegal administration of hormones, steroids, beta-agonists and other anabolic agents to productive livestock in the European Union continues, despite the long-term ban on their use and despite the measures provided under the directives to monitor certain substances and residues thereof in the interest of protecting consumer health and animal wellbeing. Often administered in low doses in the form of a drug cocktail, these compounds escape detection by common analytical techniques. The aim of one study was to determine whether low-dose dexamethasone administration (0.4 mg orally per day, for 20 days) in white-meat calves produced variations in blood coagulation, as measured by thromboelastometry. A second aim was to determine whether such variations could be valid in detecting illicit low-dose dexamethasone treatment. The study population was 42 Friesian calves kept under controlled conditions until 6 months of age. The calves were subdivided into 2 groups: a control group (group A, n=28) and a group treated with dexamethasone (group B, n=14) for 20 days beginning at 5 months of age. When compared against the age-matched control group, the dexamethasone-treated calves showed a significant increase in alpha angle, maximum clot firmness and a significant decrease in clot formation time on all thromboelastometric profiles. The clotting time was significantly decreased on the in-TEM® profile but increased on the ex-TEM® and fib-TEM® profiles. The Receiver Operating Characteristic curves, plotted for the Maximum Clot Elasticity (MCE), had a cut-off value ≥ 488.23 mm for in-TEM® and a cut-off value ≥ 63.94 mm for fib-TEM®. In order to increase the sensitivity of the test two parameters (in-TEM® and fib-TEM® MCE) were used as two
parallel tests; subsequently, the sensitivity rose to a point value of 99 percent. It was concluded that thromboelastometry identified a state of hypercoagulability in the dexamethasone-treated subjects. Furthermore, the results of this preliminary study suggest that TEM may be useful in the detection of illicit low-dose dexamethasone treatment [13552].

**Cortisol value during an exercise season**

The purpose of this study was to track creatine kinase (CK) and serum cortisol over an American college football season starting with the preseason practice. A secondary purpose was to observe changes in basic clinical chemistries. Twenty-two National Collegiate Athletic Association Division I football players (age: 20 years) volunteered to participate in the study. Each of the players had participated in the summer strength and conditioning supervised program. Resting blood samples were obtained just before the start of preseason practice (T-1), 2 weeks later (T-2), and the day after game 2 (T-3), game 4 (T-4), game 6 (T-5), and game 9 (T-6) of a 12-game season. Creatine kinase, a panel of clinical chemistries, cortisol, and testosterone were assayed at each time point. No significant changes in CK concentrations were observed over the season with peak values of each range ≤1,070.0 IU/L, but the largest range was observed at T-6 after game 9 (119–2,834 IU/L). The analysis of covariance analysis demonstrated that the number of plays in the ninth game (T-6) explained the magnitude of the changes in CK. No changes in serum cortisol concentrations were observed yet, again large variations existed with peak values of each range ≤465.0 nmol/L. Clinical chemistries showed various significant changes from T-1, but none were considered clinically relevant changes for any player over the time course of the study. In conclusion, the strength and conditioning program before preseason camp or the structure of summer camp practices and the in-season strength and conditioning appeared to mute muscle damage and the stress response of cortisol. Such data demonstrate that changes in muscle damage and adrenal cortical stress over the season are minimal, yet large individual variations can be observed. Management of these variables appears to be related to optimal strength and conditioning and sports medicine programs. Thus, the greater concerns for student-athlete safety in the sport of American football are related to preventing sudden death, traumatic injury, and managing concussion syndromes [13553].

**Prednisolone in human urine**

The possibility of an endogenous presence of the glucocorticoid prednisolone has already been demonstrated in bovine and horse urine, with the aim of clarifying its origin in this matrix, which is used by official agencies for the control of illicit treatments. From this point of view, the endogenous nature of prednisolone could be a major topic in doping control of both amateur and professional human athletes. A study was therefore made on 34 human volunteers (13 males and 21 females; aged 22–62) to detect the presence of prednisolone in their urine by HPLC-MS(3). One of the volunteers underwent vernal allergy treatment with betamethasone for two subsequent years. An investigation was carried out with the aim of verifying if the suppression, and the circadian rhythm, of cortisol urinary levels could also apply to prednisolone. The results of the study show that prednisolone was present in the urine of all 34 volunteers, with a concentration very close to 100-times lower that of cortisol, with no dependence on gender. The same ratio (1/100) was observed in the prednisolone and cortisol levels detected during the 24h together with the suppression of prednisolone by betamethasone treatment. These data demonstrate the endogenous nature of low concentrations of prednisolone in human urine, and motivate further studies about the
biosynthetic pathways of this corticosteroid and its relationship with stress in humans, as already described in cows [13554].

**Topical administration of prednisolone**

Methylprednisolone (MP) is prohibited in sports competitions when administered by systemic routes; however its use by topical administration is allowed. Therefore, analytical approaches to distinguish between these different administration pathways are required. A reporting level of 30 ng/mL was established for this purpose. However, the suitability of that reporting level for MP is not known. In one work, excretion profiles of MP and different metabolites after oral and topical administrations have been compared. A method for the quantification of MP and the qualitative detection of fifteen previously reported metabolites has been validated. The method involved an enzymatic hydrolysis, liquid-liquid extraction and analysis by liquid chromatography coupled to tandem mass spectrometry. The method was found to be linear, selective, precise and accurate. The high sensitivity (limit of detection 0.1ng/mL) and linear range (0.1-250 ng/mL) achieved allowed for the quantification of MP at both the low concentrations present after topical administration and the high concentrations detected after oral intake. The method was applied to samples collected after oral (4 or 40mg) and topical administration (10 mg of MP acepionate/day for 5 consecutive days) to healthy volunteers. After oral administration, MP and all metabolites were detected in urines collected up to at least 36 h. Only MP and five metabolites were detected in samples obtained after topical treatment. As expected, concentrations of MP after topical administration were well below current reporting level (30ng/mL), however 3 out of 4 samples in range 8-24 h after the low oral dose (4 mg) were also below that concentration. Taking into account metabolites detected after both administration routes, metabolites 16beta,17alpha,21-trihydroxy-6alpha-methylpregna-1,4-diene-3,11,20-trione (M8) and 17alpha,20alpha,21-trihydroxy-6alpha-methylpregna-1,4-diene-3,11-dione (M11) are best markers to differentiate between topical and oral administrations. Their signals after topical administration were lower than those obtained in the first 48 h after all oral doses [13555].

**Effect on muscles**

Muscle wasting is associated with poor prognosis in chronic obstructive pulmonary disease (COPD). Exercise stimulates muscle recovery, but its efficacy is variable, depending on the clinical condition and medical treatment. Systemic glucocorticoids, commonly administered in high doses during acute disease exacerbations or as maintenance treatment in end-stage disease, are known to contribute to muscle wasting. As muscle mass recovery involves insulin-like growth factor (IGF)-I signaling, which can be stimulated by anabolic steroids, the impact of glucocorticoids and the effect of simultaneous IGF-I stimulation by anabolic steroids on muscle recovery and growth were investigated. The effects of, and interactions between, glucocorticoid and IGF-I signaling on skeletal muscle growth were assessed in differentiating C2C12 myocytes. As proof of principle, we performed a post hoc analysis stratifying patients by glucocorticoid use of a clinical trial investigating the efficacy of anabolic steroid supplementation on muscle recovery in muscle-wasted patients with COPD. Glucocorticoids strongly impaired protein synthesis signaling, myotube formation, and muscle-specific protein expression. In contrast, in the presence of glucocorticoids, IGF-I synergistically stimulated myotube fusion and myofibrillar protein expression, which corresponded with restored protein synthesis signaling by IGF-I and increased transcriptional activation of muscle-specific genes by glucocorticoids. In COPD patients on maintenance glucocorticoid treatment, the clinical trial also revealed an enhanced effect of anabolic
steroids on muscle mass and respiratory muscle strength. In conclusion, synergistic effects of anabolic steroids and glucocorticoids on muscle recovery may be caused by relief of the glucocorticoid-imposed blockade on protein synthesis signaling, allowing effective translation of glucocorticoid-induced accumulation of muscle-specific gene transcripts [13556].

Glucocorticoid-induced skeletal muscle atrophy

Many pathological states characterized by muscle atrophy (e.g. sepsis, cachexia, starvation, metabolic acidosis and severe insulinopenia) are associated with an increase in circulating glucocorticoids (GC) levels, suggesting that GC could trigger the muscle atrophy observed in these conditions. GC-induced muscle atrophy is characterized by fast-twitch, glycolytic muscles atrophy illustrated by decreased fiber cross-sectional area and reduced myofibrillar protein content. GC-induced muscle atrophy results from increased protein breakdown and decreased protein synthesis. Increased muscle proteolysis, in particular through the activation of the ubiquitin proteasome and the lysosomal systems, is considered to play a major role in the catabolic action of GC. The stimulation by GC of these two proteolytic systems is mediated through the increased expression of several Atrogenes (“genes involved in atrophy”), such as FOXO, Atrogin-1, and MuRF-1. The inhibitory effect of GC on muscle protein synthesis is thought to result mainly from the inhibition of the mTOR/S6 kinase 1 pathway. These changes in muscle protein turnover could be explained by changes in the muscle production of two growth factors, namely Insulin-like Growth Factor (IGF)-I, a muscle anabolic growth factor and Myostatin, a muscle catabolic growth factor. This review will discuss the recent progress made in the understanding of the mechanisms involved in GC-induced muscle atrophy and consider the implications of these advancements in the development of new therapeutic approaches for treating GC-induced myopathy [13557].

Transfer factor

Inhaled glucocorticoids are the most effective and potent drugs used to control the inflammatory bronchial reaction in patients with asthma. There are several research projects evaluating the use of immune modulators in the treatment of the asthma related inflammatory process. To evaluate the effect of transfer factor in the treatment of pediatric patients with moderate persistent allergic asthma in terms of inhaled glucocorticoid dosing and time of using a randomized, double blind, placebo controlled pilot clinical trial in a cohort of pediatric patients (6-17 years old) with moderate persistent allergic asthma was performed. Two groups were formed. Group one received transfer factor and group two was given placebo. Both groups received conventional therapy with inhaled budesonide and formoterol. Daily respiratory symptoms (cough during day, or at night, and wheezing episodes) were recorded in a personal diary. Spirometric evaluations were performed before enrolling patients, and at 1, 3 and 6 months after. Eleven patients were enrolled in each group. Patients in the transfer factor group showed a statistical significant reduction in the inhaled glucocorticoid doping since month 3, and this difference was maintained until the end of study. Patients on transfer factor group showed also a non statistical significant improvement in spirometrical findings and also showed a better asthma control. Transfer factor helps to reduce inhaled glucocorticoids dose in patients with allergic rhinitis; however, studies with a larger number of patients should be done in order to obtain better results [09232].

Use in football
Glucocorticosteroids are widely used in medicine and have shown unchallenged therapeutic potential in several chronic inflammatory and other diseases. They are also widely used in sports medicine for the treatment of conditions such as asthma and acute injuries. In fact, as banned substances, most requests for therapeutic use exemption concern glucocorticosteroids. Nevertheless, their beneficial effect in certain conditions in sports, where inflammation is only a secondary reaction, remains to be validated. One paper aimed to provide a comprehensive review of the literature covering the therapeutic use of glucocorticosteroids since 1977 in conditions ranging from chronic rheumatic illness to peritendinous or intra-articular injection in acute injuries. Search of the medical literature published between 1977 and 2006 using PubMed. Articles relevant to the question "When and if at all is the use of glucocorticosteroids justified in football?" were selected and analysed. The findings clearly point out that, despite the common use of glucocorticosteroids in acute injuries in sports, there is actually limited evidence of the true benefits of such a practice. Physicians must take the possible adverse effects into consideration. In an athlete with clinically verified asthma, inhalational glucocorticosteroids remain first line therapy. Finally, for the purposes of education and prevention of misuse, it should be stressed that a measurable performance enhancing effect of glucocorticoids could not be proved on the basis of the results of the scientific studies to date [06214].

Endogenous prednisolone

The possibility of an endogenous presence of the glucocorticoid prednisolone has already been demonstrated in bovine and horse urine, with the aim of clarifying its origin in this matrix, which is used by official agencies for the control of illicit treatments. From this point of view, the endogenous nature of prednisolone could be a major topic in doping control of both amateur and professional human athletes. A study was therefore made on 34 human volunteers (13 males and 21 females; aged 22-62) to detect the presence of prednisolone in their urine by HPLC-MS(3). One of the volunteers underwent vernal allergy treatment with betamethasone for two subsequent years. An investigation was carried out with the aim of verifying if the suppression, and the circadian rhythm, of cortisol urinary levels could also apply to prednisolone. The results of the study show that prednisolone was present in the urine of all 34 volunteers, with a concentration very close to 100-times lower that of cortisol, with no dependence on gender. The same ratio (1/100) was observed in the prednisolone and cortisol levels detected during the 24h together with the suppression of prednisolone by betamethasone treatment. These data demonstrate the endogenous nature of low concentrations of prednisolone in human urine, and motivate further studies about the biosynthetic pathways of this corticosteroid and its relationship with stress in humans, as already described in cows [12324].

Microbial transformation of cortisol to prednisolone

Doping control samples are normally collected under non-sterile conditions and sometimes, storage and transportation are influenced by parameters such as the temperature. Therefore, microbial contamination and subsequent alteration of a sample's composition are possible. Studies regarding sample collection in cattle breeding have already shown enzymatic transformation of endogenous testosterone to boldenone causing false-positive findings. The aim of the present study was to investigate whether positive doping cases with the synthetic corticosteroids prednisolone and prednisone may result from microbial transformation of the endogenous corticosteroids cortisol and cortisone, respectively. A method comprising parameters such as pH values and screening results for synthetic glucocorticosteroids as
well as incubation experiments followed by liquid chromatographic and mass spectrometric analysis was employed to test for contaminating germs with \( \Delta_1 \)-dehydrogenase activity. Over 700 urine samples comprising inpatient and doping control specimens were investigated. In none of them, 1,2-dehydrogenating activity was confirmed. These findings are in accordance with other studies. However, the problem of microbial alteration of doping control specimens with special respect to 1,2-dehydrogenation must not be underestimated [12325].

**Ophtalmological aspects**

Prescribing for athletes requires an up-to-date knowledge of the World Anti-Doping Agency's list of prohibited substances. As the London 2012 Olympic Games attract athletes from around the world, we review the current guidelines with respect to all medications licensed for ophthalmic use in the United Kingdom. It was described the process that an ophthalmologist can use to check for permissible medications and also highlight treatments that are contraindicated. It was systematically reviewed all 77 drugs listed in Section 11 of the British National Formulary (Issue 63) for use in the treatment of ophthalmic conditions, and referenced these against the 2012 Prohibited List published by the World Anti-Doping Agency. The majority of ophthalmic preparations are suitable for use in- and out-of-competition. Some preparations, such as glucocorticoids, are prohibited when administered systemically but permitted for topical administration. Beta-blockers are prohibited in-competition and oral carbonic anhydrase inhibitors are prohibited in- and out-of competition. Thus, the 2012 Prohibited List has important implications for the pharmacological treatment of ophthalmic conditions in athletes. Clinicians prescribing for athletes have a duty to familiarize themselves with the list in order to avoid causing significant damage to their patient's career and reputation [12326].

**Side effects**

**Heart**

Glucocorticoids are classified as doping substances and so their use in any form for therapeutic reasons must be declared. An indirect side effect that concerns the cardiovascular system is the disturbance of lipid metabolism, leading to an increase in total cholesterol, triglycerides, and LDL cholesterol. The main direct complication is arterial hypertension, which is attributable to fluid retention, an increase in peripheral vascular resistances, and an increase in myocardial contractility [12126].

**Laboratory technique**

A liquid chromatography/time-of-flight mass spectrometry (LC/TOFMS) method was developed using the latest high-resolution LC column technology, the ultra performance liquid chromatography (UPLC), and electrospray ionization (ESI) in the positive ion mode. Gradient UPLC separation conditions were optimized for a group of 22 analytes comprising 17 glucocorticosteroids, specific designer steroids such as tetrahydrogestrinone (THG) and specific beta2-agonists such as formoterol. The UPLC/TOFMS separation obtained required 5.5 min only for all the substances tested. Even the critical pair of dexamethasone and betamethasone isomers was almost completely resolved. Thanks to the over 10,000 full-width at half maximum (FWHM) mass resolution and high mass accuracy features of TOFMS.
50 mDa window accurate mass chromatograms could be reconstructed for the individual analytes. Sensitive screening in human and calf urine samples fortified at the glucocorticosteroids minimum required performance limit (MRPL) of 30 microg/L (human urine, sports doping) and 2 microg/L (calf urine, veterinary control) could be obtained. The potential of UPLC/TOFMS for confirmatory analysis was shown by determining the accurate mass of all compounds and fragment ions upon in-source collision-induced dissociation (CID) at different energies. The exact mass measurement errors for all glucocorticosteroids were found to be within 6 ppm. Considering veterinary control, limits of detection (LOD) and limits of quantification (LOQ) were determined for most of the analytes in calf urine and found to range from 0.1 to 3.3 and from 0.4 to 4.4 microg/L, respectively. The method can be easily extended with other banned substances of interest, as demonstrated by the addition of 21 beta2-agonists to the original analyte mixture in urine, without causing any interferences [06215].

One study presents a fast multi-analyte screening method specifically developed for the detection of xenobiotics in urine. The proposed method allows the screening of several classes of substance in a single chromatographic method with a run-time of 11 min, inclusive of post-run and reconditioning times. Chromatographic separation is achieved in 7.2 min using a reversed-phase 2.7 µm fused-core particle column, generating a back-pressure not exceeding 400 bar and therefore enabling the use of traditional high performance liquid chromatography (HPLC) instruments. The effectiveness of this approach was evaluated, by liquid-chromatography tandem mass spectrometry (LC-MS/MS) in positive electrospray ionization, using 20 blank urine samples spiked with 45 compounds prohibited in sport: 11 diuretics, 16 glucocorticoids, 9 stimulants, 5 anti-oestrogens, as well as formoterol, carboxyfinasteride (previously prohibited by the World Anti-Doping Agency (WADA) in 2008), gestrinone and tetrahydrogestrinone. Qualitative validation shows the proposed method to be specific with no significant interference. All of the analytes considered in this study were clearly distinguishable in urine, with limits of detection ranging from 5 ng/mL to 350 ng/mL, significantly below the Minimum Required Performance Levels (MRPL) set by WADA for the accredited sports anti-doping laboratories. All compounds of interest were separated, including synthetic and endogenous glucocorticoids with similar retention times and fragmentation patterns [10378].

The detection of corticosteroids and sex steroids in samples with no content indication, which are confiscated for forensic investigation, is a challenge in doping analysis. A screening method based on the identification of androgens, estrogens, gestagens, and their esters by means of a mass spectral library, along with a fast ultra-performance liquid chromatography-mass spectrometry (UPLC-MS) method, was recently developed in a laboratory for the analysis of dietary supplements. However, for forensic investigations, it is important to extend the scope of the method to corticosteroids in various matrices. Therefore, 36 corticosteroids were added to the mass spectral library, and the sample preparation step was modified so that androgens, gestagens, corticosteroids, and their esters could be analyzed with only one injection with the UPLC-MS method. A complementary tool to the existing library identification was found in the extraction of common fragment ions out of the full scan data obtained for the library search. The fragment ion with m/z 147 was found to be a good marker for the detection of steroids. Extra confirmation was obtained from the fragment ions with m/z 135 (for all steroids) and 237 (specific for corticosteroids) or from the fragment ions with m/z 77, 91, and 105. The effectiveness of this approach was evaluated on some samples previously screened for forensic investigation with thin-layer chromatography and confirmed with a targeted gas chromatography-mass spectrometry method. The study shows that the combination of the library identification and the common fragment ions approach can be a valuable tool in the detection of steroids without defining any target at the start of the analysis [11366].
Glucocorticoids are listed on the World Anti-Doping Agency (WADA) Prohibited List of substances. The detection of the administration of hydrocortisone and cortisone is complicated by the fact that the human body also produces these steroids naturally. Gas chromatography-combustion-isotope ratio mass spectrometry can be utilized to determine the use of endogenous glucocorticoids by measuring the carbon isotope ratio (CIR) of their resulting metabolites in human urine samples. A comprehensive sample preparation protocol for the analysis of endogenous glucocorticoid urinary metabolites was developed and validated, incorporating the use of high performance liquid chromatography (HPLC) for purification and chemical oxidation for derivatisation. Target compounds were tetrahydrocortisol and tetrahydrocortisone, and 11beta-hydroxyetiocholanolone, 11-oxoetiocholanolone and 11beta-hydroxyandrosterone, while pregnanediol functioned as the endogenous reference compound. Urine samples from a population of 50 volunteers were analyzed to determine CIR reference limits. Excretion studies of the endogenous glucocorticoid preparation cortisone acetate (25 mg oral) and the dietary supplement adrenosterone (75 mg oral) were conducted with six male individuals. Variable changes in steroid metabolite isotopic composition were found across subjects after administration. The study also revealed that CIR analysis of the major glucocorticoid metabolites tetrahydrocortisol and tetrahydrocortisone is necessary to unambiguously distinguish administration of cortisone and adrenosterone, the former officially restricted to out-of-competition use by athletes, the latter not being restricted at the current time. Moreover, this study reaffirms that CIR methods for the doping control of endogenous steroids should not rely upon a single ERC, as the administration of an appropriate precursor to that ERC could cause complications during analysis [12327].

The use of prednisolone and prednisone is prohibited by the World Anti-Doping Agency (WADA) due to their performance-enhancing effect. The purpose of one work was to explore the possibility of identification and detection of various metabolites of prednisolone by liquid chromatography-tandem mass spectrometry (LC-MS/MS) in excretion study samples. Ten metabolites of prednisolone could be identified namely prednisone (11-oxo metabolite) [M-1], 6-beta-OH-prednisolone [M-2], 20-beta-OH-prednisolone [M-3], 20-alpha-OH-prednisolone [M-4], 20-alpha-OH-prednisone [M-5], 20-beta-OH-prednisolone [M-6], 2 tetrahydro epimers of 20-beta-OH-prednisolone [M-7], 2 tetrahydro epimers of 20-alpha-OH-prednisolone [M-8], 2 tetrahydro epimers of 20-beta-OH-prednisone [M-9], and 2 tetrahydro epimers of 20-alpha-OH-prednisone [M-10]. Prednisolone was administered in 10, 20, and 40 mg dosage to healthy volunteers to study detection of various metabolites. The parent, M-1, M-2, and M-3 could be detected up to 72 h while rest of the metabolites were detectable up to 24 h after drug administration. The detection of newer metabolites of the drug can further be used for confirmatory purposes [12328].

**Measurement in hair**

Endogenous corticosteroids and endocannabinoids are both known to be involved in stress adaption and anti-inflammatory and immuneregulatory effects. The application of hair as retrospective specimen for long-term recording of corticosteroids and its association with stress-induced biochemical alterations was intensively examined. To evaluate the stability and correlation of various parameters of the endocannabinoid and corticosteroid systems, a prospective study was carried out. Hair samples were collected monthly over a pregnancy cycle (sixth week of pregnancy to 9 weeks postpartum). By comparison of hair concentrations in particular segments (ie, grown in the same time span but collected at different times), an examination of analyte stability in hair was achieved. Additionally, the comparison of proximal segments provided on biochemical information that is independent of
alteration due to physical instability. The detection limits of a validated procedure using solid-phase extraction cleanup and liquid chromatography-mass spectrometry proved to be suitable to identify the endogenous levels of cortisol (limits of detection = 1.6 pg/mg), cortisone (2.1 pg/mg), anandamide (AEA, 0.3 pg/mg), and 2-arachidonoylglycerol (15 pg/mg). Corticosteroid concentrations in corresponding hair segments were found to be reduced with increasing hair age; an average decline of cortisol and cortisone by 50% in 4 months was estimated. Independently, an increase of cortisol and cortisone in proximal segments collected during pregnancy was confirmed, which is assumed to be stress related. Endocannabinoids proved to be by far more stable, as demonstrated by subsequent monthly collection of corresponding segments and there was hardly any washout of AEA detectable. Elevated hair concentrations of AEA and 2-arachidonoylglycerol were detected in the first-second trimester of pregnancy, which corresponds to negative correlations between AEA, cortisol, and cortisone [13558].

**Experimental**

Although exercise is a common and potent activator of the hypothalamic-pituitary adrenal (HPA) axis, the effects of exercise on the acute stress response are not well understood. Here, we investigated the effects of short- (2 wk) and long-term (8 wk) voluntary wheel running on adrenal sensitivity to ACTH stimulation and the acute stress response to restraint in male rats. Diurnal glucocorticoid patterns were measured on days 7 (all groups) and 35 (8-wk groups). Rats were subjected to 20 min of restraint stress on either week 1 or on week 7 of treatment to assess HPA activation. One week later, exogenous ACTH (75 ng/kg) was administered to assess adrenal sensitivity to ACTH. Following this, adrenals were collected and analyzed for key proteins involved in corticosterone synthesis. The results show that volitional wheel running initially causes hyperactivation of the HPA axis, due to enhanced adrenal sensitivity to ACTH, but that these alterations in HPA activity are completely restored by 8 wk of training [09233].

Overload tendon injuries are frequent in recreational and elite sports. The optimal treatment strategy remains unknown, but local administration of corticosteroids is one common treatment option. The direct effects of the corticosteroid administration on the tissue are not fully understood. One study examined the biomechanical effects of intratendinous corticosteroid injections on healthy rat-tail tendon collagen fascicles. A total of 24 Wistar male rats were divided into (A) a corticosteroid group where the animals were injected in the tail tendon with methylprednisolone acetate, 1.0 mL of 40 mg/mL mixed with 1.0 mL 9 percent saline (n=12), and (B) a control group that was injected with 9 percent saline (n=12). Three days after the injections, the animals were sacrificed and single individual collagen fascicles were collected and underwent displacement to failure. Corticosteroid administration significantly reduced tensile fascicle yield strength, while the strain properties were unaffected. Peak stress was similar between the two groups. There was no difference in fascicle diameter between the two groups [09234].
MELATONIN

Melatonin (N-acetyl-5-methoxytryptamine) is a pineal gland hormone with effects upon circadian rhythms, sleep onset and reproductive systems. Blood levels of melatonin are generally undetectable during daytime, but rise sharply during darkness. Light–dark sensations at the retina are relayed to the suprachiasmatic nucleus of the hypothalamus. Fibres from the hypothalamus descend to the spinal cord and ultimately project to the superior cervical ganglia, from which sympathetic postganglionic neurons ascend back to the pineal gland. Melatonin peak amplitudes decrease with age, which may explain the flattening of the circadian rhythm also associated with ageing. Melatonin is well known as an antioxidant, immunomodulator and anticancer agent. Melatonin is of interest to sports performance due to its direct actions on body temperature and improved management of jet lag. It may potentially be of interest in cases of amenorrhoea. A meta-analysis of seven studies has shown little evidence of adverse effects. Mild heat loss initiation by peripheral vasodilation, modulated by melatonin secretion, may be the mechanism that initiates sleep. Supplemental melatonin could allow planned induction of this heat loss and potentially be advantageous to exercise performance. Studies have investigated supplementation of melatonin prior to exercise in the heat without finding reductions in core body temperature or improved performance: however, these have limited general applicability given only low-intensity exercise in clothing that did not allow environmental heat loss. A further study looked at aspects of both physical and mental performance following daytime supplementation with melatonin and found decreased intra-aural temperature but without any change to short-duration athletic performance. Notably, decrements in mental performance were identified. With increasing levels of international travel, optimising recovery from jet lag may offer a significant performance advantage. Jet lag has been defined as occurring in response to a minimum of a three-zone change at a rate faster than one zone per day and has been suggested to cause decreased performance and increased injury risk though direct evidence is limited. Supplemental melatonin appears to reduce both subjective and objective symptoms of jet lag. It is unclear at this point whether the main action is hypnotic, that is, inducing sleepiness, or chronobiotic, helping to “reset” the body clock to the new time zone. There does not appear to be a performance hangover from supplementation taken the night before exercise. Melatonin inhibits the secretion of luteinizing hormone and follicle-stimulating hormone from the anterior pituitary. As an apparent result of the loss of this inhibition, female long-term nightworkers have a higher risk of breast cancer risk than women who do not work at night. Disturbances in melatonin production through continuous changes in time zone may also be linked to the frequency of amenorrhoea found in flight attendants. There also appears to be a relationship between melatonin levels, exercise and amenorrhoea in female athletes that requires further investigation [11359].

Low overnight urinary melatonin metabolite concentrations have been associated with increased risk for breast cancer among postmenopausal women. The Postmenopausal Women's Alcohol Study was a controlled feeding study to test the effects of low to moderate alcohol intake on potential risk factors for breast cancer including serum and urinary levels of hormones and other biomarkers. Previously, it was observed significant increases in concentrations of serum estrone sulfate and dehydroepiandrosterone sulfate in participants after consumption of 15 or 30 g (one or two drinks) of alcohol per day. In one analysis, it was evaluated the relationship of alcohol consumption with 24-h urinary 6-sulfatoxymelatonin (6-SMT) concentration (micrograms per 24 h). Healthy postmenopausal women (n=51) consumed a controlled diet plus each of three treatments (a nonalcoholic placebo beverage or 15 or 30 g alcohol/d) during three 8-weeks periods in random order under conditions of weight maintenance. 6-SMT was measured in 24-h urine samples that were collected at entry into the study (baseline) and at the midpoint (4 wk) and end (8 wk) of each of the three
diet periods. Concentration of 6-SMT was not significantly modified by the alcohol treatment after adjustment for body mass index, hours of sleep, daylight hours, and baseline level of 6-SMT. These results suggest that low to moderate daily alcohol consumption does not significantly affect 24-h urinary levels of melatonin among healthy postmenopausal women [11511].

As marker for training

The objectives of the study were to evaluate the influence of a whole training season on 6-sulfatoxymelatonin (alphaMT6s) and citrate excretion in 12 elite swimmers. Urine samples were obtained (before bedtime and after waking up) at the beginning of the season, basic training, macrocycle I, tapering and macrocycle II stages. For alphaMT6s, at basic training, mainly with aerobic training, the evening concentrations were significantly lower than at the beginning, tapering and macrocycle II stages. At macrocycle II stage, with the maximal training workload, the total sum (evening plus morning) was significantly higher than at the beginning, basic training and macrocycle I stages. The ratio (morning/evening) that represents the capacity to produce melatonin at night depending on the evening values at the basic training stage and the nocturnal increment at the macrocycle II stage were significantly higher than at all other stages. Citrate morning values at basic training and tapering stages were significantly lower than in the evening indicating that a metabolic recuperation took place. The total sum significantly decreased as the aerobic training progressed from the beginning to macrocycle I. The basic training ratio (morning/evening) was significantly lower compared to the beginning and macrocycle II stages, and the nocturnal increment was significantly higher compared to the beginning. Melatonin and citrate represent complementary markers that could be used to evaluate the assimilation of the training workload by noninvasive methods [10529].

Effect of performance

One study investigated the effects of a heavy resistance exercise session (RES) with the oral daytime ingestion of melatonin on the physiological responses and acute performance. In a randomized and double-blind controlled study 10 healthy male subjects undertook an 80 min intensive hypertrophic RES for major muscles of the lower and upper extremities. The subjects were studied on two occasions receiving either melatonin (6 mg) or placebo (6 mg) in random order 60 min before each RES. Blood samples were taken from an antecubital vein both in fasting conditions in the morning and before RES (pre 60 min, pre 0 min), during RES (middle) and after RES (post 0 min, post 15 min, post 30 min, post 60 min). Maximal jumping ability and maximal strength in bench press and squat were measured before and immediately after RES in which there were no differences between the melatonin and placebo groups. The serum melatonin concentration increased significantly in the melatonin group following oral ingestion of melatonin and was elevated at every time point after that. The concentration reached a peak value of 1171 ± 235 pg/mL in 60 min at pre 0. Serum melatonin increased slightly but significantly also in the placebo group just before RES, in the middle of RES and after RES (post 0, post 15). There were large differences in the serum melatonin concentration between the groups at all time points. There were no differences in the growth hormone (GH), testosterone and cortisol peak concentrations at any time points between the groups but the area under the curve of GH during RES and during the 60 min after RES was lower in the melatonin condition. In conclusion, the present findings give evidence that oral ingestion of melatonin (6 mg) during daytime with heavy resistance exercise may slightly decrease GH concentrations. On the other hand, it seems that
Effects on strenuous exercise

Strenuous exercise induces inflammatory reactions together with high production of free radicals and subsequent muscle damage. One study was designed to investigate for the first time and simultaneously whether over-expression of inflammatory mediators, oxidative stress, and alterations in biochemical parameters induced by acute exercise could be prevented by melatonin. This indoleamine is a potent, endogenously produced free radical scavenger and a broad-spectrum antioxidant; consequently, it might have positive effects on the recovery following an exercise session. The participants were classified into two groups: melatonin-treated men (MG) and placebo-treated individuals (controls group, CG). The physical test consisted in a constant run that combined several degrees of high effort (mountain run and ultra-endurance). The total distance of the run was 50 km with almost 2800 m of ramp in permanent climbing and very changeable climatic conditions. Exercise was associated with a significant increase in TNF-alpha, IL-6, IL-1ra (in blood), and also an increase in 8-hydroxy-2'-deoxyguanosine (8-OHdG) and isoprostane levels (in urine), and indicated the degree of oxidative stress and inflammation induced. Oral supplementation of melatonin during high-intensity exercise proved efficient in reducing the degree of oxidative stress (lower levels of lipid peroxidation, with a significant increase in antioxidative enzyme activities); this would lead to the maintenance of the cellular integrity and reduce secondary tissue damage. Data obtained also indicate that melatonin has potent protective effects, by preventing over-expression of pro-inflammatory mediators and inhibiting the effects of several pro-inflammatory cytokines. In summary, melatonin supplementation before strenuous exercise reduced muscle damage through modulation of oxidative stress and inflammation signaling associated with this physical challenge [11228].

Experimental

One study aimed to determine the changes in plasma melatonin levels of rats performing acute swimming exercise, immediately following the exercise and after 24 and 48 hours. The study included 40 Spraque Dawley species adult male rats divided in to 4 groups as follows: group 1: general control group, group 2: swimming group A, the animals were decapitated after performing 30-minute acute swimming exercise, group 3: Swimming group B, the animals were decapitated 24 hours after performing 30-minute acute swimming exercise and group 4: swimming group C, the animals were decapitated 48 hours after performing 30-minute acute swimming exercise. Blood samples were collected from all experimental animals by decapitation method and plasma melatonin levels were determined according to RIA method. The comparison of plasma melatonin levels among groups revealed that group 3 had the highest plasma melatonin levels. The levels in group 1 (control) and group 4 were not different. The lowest plasma melatonin levels were found in group 2. The results of our study demonstrate that plasma melatonin levels that decrease immediately after acute swimming exercise increase significantly after 24 hours and restore to resting levels after 48 hours [12331].

Acute sport exercise leads to a strong stimulation of muscle tissue and a change in the organism energy demands. This study was designed to investigate the effect of oral melatonin supplementation on human physiological functions associated with acute exercise. Immune, endocrine and metabolic parameters were measured in 16 young male football players, who were divided into two groups, an experimental group (supplementation with 6
mg of melatonin administered 30 min prior to exercise) and a control group (placebo without melatonin). They performed a continuous exercise of high intensity (135 beats/min). Samples were collected 30 min before the exercise and 3, 15 and 60 min during the exercise. The results indicated that the acute sport training presented increased lipid peroxidation products (MDA) in both groups, control and experimental, with levels significantly decreased in the group treated with melatonin after 15 and 60 min of high-intensity exercise, and the total antioxidant activity (TAS) was lower in the control group than in the experimental, the latter showing significant differences at 60 min of high-intensity exercise. Moreover, the lipid profile of subjects in the experimental group showed lower triglyceride levels than the control group after 15 and 60 min of high-intensity exercise, and immunological studies only showed, in the experimental group, an increase in IgA levels at 60 min after the exercise, and finally there were no significant differences between the groups for any of the other variables. In conclusion these results indicated that treatment with melatonin in acute sports exercise reversed oxidative stress, improved defenses and lipid metabolism, which would result in an improvement in fitness [12332].

Jet lag

Jet lag has potentially serious deleterious effects on performance in athletes following transmeridian travel, where time zones are crossed eastwards or westwards; as such, travel causes specific effects related to desynchronization of the athlete's internal body clock or circadian clock. Athletes are particularly sensitive to the effects of jet lag, as many intrinsic aspects of sporting performance show a circadian rhythm, and optimum competitive results require all aspects of the athlete's mind and body to be working in tandem at their peak efficiency. International competition often requires transmeridian travel, and competition timings cannot be adjusted to suit individual athletes. It is therefore in the interest of the individual athlete and team to understand the effects of jet lag and the potential adaptation strategies that can be adopted. In this review, we describe the underlying genetic and physiological mechanisms controlling the circadian clock and its inherent ability to adapt to external conditions on a daily basis. It was then examine the fundamentals of the various adaptation stimuli, such as light, chronobiotics (e.g. melatonin), exercise, and diet and meal timing, with particular emphasis on their suitability as strategies for competing athletes on the international circuit. These stimuli can be artificially manipulated to produce phase shifts in the circadian rhythm to promote adaptation in the optimum direction, but care must be taken to apply them at the correct time and dose, as the effects produced on the circadian rhythm follow a phase-response curve, with pronounced shifts in direction at different times. Light is the strongest realigning stimulus and careful timing of light exposure and avoidance can promote adjustment. Chronobiotics such as melatonin can also be used to realign the circadian clock but, as well as timing and dosage issues, there are also concerns as to its legal status in different countries and with the World Anti-Doping Agency. Experimental data concerning the effects of food intake and exercise timing on jet lag is limited to date in humans, and more research is required before firm guidelines can be stated. All these stimuli can also be used in pre-flight adaptation strategies to promote adjustment in the required direction, and implementation of these is described. In addition, the effects of individual variability at the behavioural and genetic levels are also discussed, along with the current limitations in assessment of these factors, and we then put forward three case studies, as examples of practical applications of these strategies, focusing on adaptations to travel involving competition in the 2016 Summer Olympics in Rio de Janeiro, Brazil [12330].

To perform at the highest level of international competition, athletes need to maximize rest during long travel, and expeditiously overcome the detrimental effects of "jet lag" (JL). The
negative effects of JL may be alleviated by adopting a multimodality approach, including the judicious use of melatonin and other pharmacologic agents to aid re-entrainment and improve sleep characteristics. Strict compliance with anti-doping policy is pivotal before and during competition. There have been several recent updates regarding the use of selected medications, which mandate constant vigilance by sports medicine personnel to both evaluate drug efficacy and judiciously prescribe approved medications. It is critical that medical staff maintain familiarity and awareness on a continual basis to effectively educate athletes and support staff [11227].

Salivary

Salivary melatonin concentration is an established marker of human circadian rhythmicity. It is thought that melatonin is relatively robust to the masking effects of exercise. Nevertheless, the extent and even the direction of exercise-related change is unclear, possibly due to between-study differences in the time of day exercise is completed. Therefore, it was aimed to compare melatonin responses between morning and afternoon exercise, and explore the relationships between exercise-related changes in melatonin and heart rate. At 08:00 and 17:00 hours, seven male subjects (27 ± 5 years) completed 30 min of cycling at 70 percent peak oxygen uptake followed by 30 min of rest. Light intensity was maintained at about 150 lux. Salivary melatonin (ELISA) and heart rate were measured at baseline, 15 min during exercise, immediately post-exercise and following 30 min recovery. Melatonin was significantly higher in the morning trials compared with the afternoon. The exercise-related increase in melatonin was more pronounced in the morning than in the afternoon. The slope of the heart rate-melatonin relationship was significantly steeper in the morning than in the afternoon. In conclusion, it was reported for the first time that the masking effect of moderate-intensity exercise on melatonin is approximately twice as high in the morning than the afternoon. The much steeper relationship between heart rate and melatonin changes in the morning raises the possibility that time of day alters the relationships between exercise-mediated sympathetic nervous activity and melatonin secretion [11229].

Experimental

Influence on plasma glucose

The aim of one study was to examine how melatonin supplementation affects plasma glucose and liver glycogen levels in rats subjected to acute swimming exercise. Sprague-Dawley species thirty adult male rats were allocated to 3 groups with equal number of animals: general control group which was not subjected to any procedure (Group 1), the group subjected to a 30-minute acute swimming exercise (Group 2), and the group subjected to a 30-minute acute swimming exercise after intraperitoneal (i.p.) melatonin supplementation (3 mg/kg/day) for 4 weeks (Group 3). Blood samples collected from the experimental animals by decapitation method were analyzed in terms of plasma glucose, and glycogen levels were determined in liver tissue samples by histological method. The highest plasma glucose levels were obtained in group 2. Plasma glucose levels in groups 1 and 3 were not different. Mean liver glycogen level in group 3 was significantly higher than those in the other groups, while there was no significant difference between group 1 and group 2 in terms of this parameter. Results of the study demonstrate that melatonin supplementation can have a protective effect on liver glycogen reserves in rats subjected to acute swimming exercise [10417].
**Combination with imipramine**

Although there are tools to treat depressive patients, a considerable amount of the cases remains to be untreated. These drug-resistant patients need new drugs or drug combinations to overcome this problem. Thus, the potential synergistic effect of melatonin on a classical drug, imipramine was evaluated in the present study. To test this hypothesis, porsolt swim test, a test predictive of antidepressant-like action, was conducted in mice. Imipramine at doses of 20 and 40 mg/kg caused no alteration and statistically significant reduction in the duration of immobility in forced swim test, respectively. While 5 mg/kg melatonin had no effect, 10 mg/kg melatonin slightly reduced the duration of immobility. When sub-effective doses of imipramine and melatonin (20 and 5 mg/kg, respectively) were co-administered, there was no alteration in responses compared with those of each drug alone. Likewise, the effective dose of melatonin (10 mg/kg) did not cause any increase in responses to 20 mg/kg imipramine. Although combination of imipramine (40 mg/kg) and melatonin (5 mg/kg) did not exert an antidepressant effect above that of imipramine alone, co-administration of the effective doses (10 and 40 mg/kg for melatonin and imipramine, respectively) displayed an additive effect. There were no significant differences between groups in relation with locomotor activity test. The results show that co-administration of imipramine and melatonin exhibits an additive effect and that there seems to be no interaction between the drugs [08407].
SILDENAFIL (VIAGRA®)

Viagra (sildenafil citrate) has surfaced as the latest everyday-product-turned-performance-booster. Athletes are said to be popping the anti-impotence pill because it increases blood flow to the lungs, thereby boosting cardiovascular capacity. One study found that in some cases the pill improved cyclists' times on a 6-kilometre course by up to 15 percent [08322].

The discovery of the vasodilator role of nitric oxide (NO) has led to a revolution in pharmacology over the past two decades which has brought considerable innovations in NO-related therapy. Apart from helping to elucidate the mode of action of well established treatments such as nitroglycerine, the contribution of advances in NO research have mainly exerted an effect in the clinic through advances in the understanding and application of nitrite, a precursor to NO. Just over a decade ago, the efficiency of NO production by the metallo-enzyme xanthine oxidoreductase was demonstrated. In vitro and under hypoxia, this enzyme is considerably more effective than nitric oxide synthase at generating NO. More recently, this phenomenon was observed for deoxyhaemoglobin, leading to the recent demonstration that nitrite has considerable protective effects in a range of cardiovascular conditions, including myocardial infarctions. It is not surprising that many athletes have looked at vasodilators to embellish their performances on the playing field. Reports of reliance on vasodilator drugs used for sexual dysfunction are common, even at the national team level. One report identifies the distributions of Viagra® to a national soccer team playing at high altitude, supposedly without the players' knowledge. This use has also been recognised by sport governing bodies as the World Anti Doping Agency (WADA) currently sponsor a study of the performance enhancing effects of sildenafil (Viagra®) at mild altitude. Reports suggesting the use of prescription vasodilators to enhance athletic performance by professional athletes, may lead to an increased interest in prescription vasodilators in the sub-elite level of athletes leading to wider public health concerns. Furthermore, use of prescription vasodilators, whether obtained by prescription or not, may lead to the adoption of non-prescription nitrite supplements. For these reasons, it is timely to study the observed interest in these distinct classes of vasodilators in order to compare and contrast trends in interest by athletes. One study aimed to explore potential misuse of vasodilators by the athletes, and to highlight the growing concern over these agents. Retrospective analyses of anonymous inquiries recorded in the Drug Information Database (DID) between January 2006 and June 2008 (inclusive). In this 30-month period, the DID recorded 198,023 inquiries, of which 118,724 were UK Licensed Pharmaceutical products with a further 79,299 inquiries made for substance not found in the database. Phosphodiesterase type 5 (PDE-5) inhibitors, dominated by Viagra®, ranked 16th among the substance groups. The proportion of the inquiries made regarding PDE-5 inhibitors, especially in comparison to antibiotics, painkillers or alcohol, appears to be above the level that would normally be expected from medical need. No significant change in the months leading up to the Beijing Olympics was observed. On the contrary, the Nitric/Nitrate group showed a notable increase between 2006-2007 and 2008, suggesting a potential increase in interest in using nitric oxide among athletes. It was concluded that with patents recently filed for the use of agents containing sodium nitrite/nitrate to enhance blood flow for performance enhancement in sport, coupled with anecdotal evidence from internet athlete forums and media, there is a concern that athletes may endanger their health by using vasodilators to enhance athletic performance. PDE-5 inhibitors or chemicals in the nitrate/nitrate group are currently not prohibited or tested for by the doping control agencies but some are highly dangerous to health and can lead to cardiovascular collapse, coma and death. Its promotion among athletes as a performance enhancing supplement is ethically and medically questionable. This report demonstrates that, in contrast to interest in prescription vasodilators, athletes exhibited an increasing interest in
"nitric-oxide precursor" vasodilators as observed in the DID records. There was a marked increase in inquiries made about these supplements leading up to the Beijing Olympics. Without medical supervision, use of vasodilators, especially (sodium) nitrite is potentially very serious and the adverse effects should be publicised [10214].

The market success of the three approved synthetic phosphodiesterase type-5 (PDE-5) inhibitors for the treatment of erectile dysfunction has led to an explosion in counterfeit versions of these drugs. In parallel a large market has developed for herbal products claimed to be natural alternatives to these synthetic drugs. The herbal products are heavily advertised on the internet and are freely available to purchase without prescription. Furthermore, adulteration of these supposed natural medicines is a very common and serious phenomenon. Recent reports have shown that the adulteration has extended to the analogues of the three approved synthetic PDE-5 inhibitors. An Atmospheric Solids Analysis Probe (ASAP) was used for the direct analysis of the counterfeit pharmaceuticals and herbal products. Using the ASAP combined with time-of-flight mass spectrometry (TOF MS) it was possible to detect fraudulent counterfeit tablets. The physical appearance of the pills resembled the pills from the original manufacturer but contained the wrong active pharmaceutical ingredient (API). Detecting adulteration for five herbal supplements marketed as natural alternatives to PDE-5 inhibitors was also possible using the ASAP. Three types of adulteration were found in the five samples: adulteration with tadalafil or sildenafil, mixed adulteration (tadalafil and sildenafil), and adulteration with analogues of these drugs [10215].

The presence of a sildenafil derivative, the thiosildenafil, in an herbal product has been evidenced first by HPTLC and later determined by isolation and analysis of spectroscopic data. The analyzed product is nowadays marketed as dietary supplement containing herbal extracts and claimed for male and female sexual improvement. One report is noteworthy since it is clear that adulterated materials can cause serious health problems if they are consumed as herbal "natural" products, generally considered deprived of toxicity by the consumers. The use of a simple and reliable method, based on HPTLC, to determine synthetic adulterations is reported in the paper [11368].

Particularly in healthy males, 20 mg of tadalafil administered 8 h before exercise increased salivary cortisol response to acute aerobic exercise and blood lactate concentrations after anaerobic power exercise, with respect to placebo. In addition, it was found that a two-day administration of tadalafil reduced the hypothalamus–pituitary–adrenal axis responses to exercise test until exhaustion in vivo, and that in skeletal muscle cells tadalafil influences aerobic and anaerobic energy metabolisms depending on its doses and duration of exposure [12094].

Moderate exercise training improves energetic metabolism, tissue perfusion and induces cardiac and skeletal muscle remodeling. Sildenafil, a potent phosphodiesterase-5 inhibitor used to treat erectile dysfunction, reduces infarct size and increases tissue oxygenation in experimental models of cardiovascular disease. We have evaluated the effects of prolonged moderate exercise training and a repeat administration of sildenafil on the rat gastrocnemius and cardiac muscles. Animals were divided into two groups: sedentary and trained. Each group was subdivided into animals treated with vehicle or with two doses of sildenafil (10 or 15 mg/kg/day) during the last week of training. Physical exercise did not induce cardiac hypertrophy, whereas it increased mRNA levels of the PGC-1alpha, HIF-1alpha and VEGF genes, which are involved in mitochondrial biogenesis and angiogenesis, and reduced mRNA levels of FoxO3a, MuRF-1 and Atrogin-1. Sildenafil dose-dependently promoted both angiogenesis, as shown by increased capillary density, and muscle atrophy, as shown by muscle fibre size. These effects were more pronounced in trained animals. The data confirm
the beneficial effects of a moderate and prolonged training on cardiovascular and skeletal systems and document the positive and negative effects of sildenafil on these tissues at doses higher than those used in clinical practice. This report may impact on the use of sildenafil as a substance able to influence sports performance [13565].

Idiopathic pulmonary fibrosis (IPF) is a progressive lung disease with pulmonary vasculopathy. The purpose of one study was to determine whether sildenafil improves 6-min walk distance (6MWD) in subjects with IPF and right ventricular dysfunction. The IPFnet, a network of IPF research centers in the United States, conducted a randomized trial examining the effect of sildenafil on 6MWD in patients with advanced IPF, defined by carbon monoxide diffusing capacity; 35 percent predicted. A substudy examined 119 of 180 randomized subjects where echocardiograms were available for independent review by two cardiologists. Right ventricular (RV) hypertrophy (RVH), right ventricular systolic dysfunction (RVSD), and right ventricular systolic pressure (RVSP) were assessed. Multivariable linear regression models estimated the relationship between RV abnormality, sildenafil treatment, and changes in 6MWD, St. George's Respiratory Questionnaire (SGRQ), the EuroQol instrument, and SF-36 Health Survey (SF-36) from enrollment to 12 weeks. The prevalence of RVH and RVSD were 13 percent and 19 percent, respectively. RVSP was measurable in 71 of 119 (60 %) subjects; mean RVSP was 42.5 mm Hg. In the subgroup of subjects with RVSD, subjects treated with sildenafil experienced less decrement in 6MWD and greater improvement in SGRQ and EuroQol visual analog scores than subjects receiving placebo. In the subgroup with RVH, sildenafil was not associated with change in 6MWD, but was associated with greater relative improvement in SGRQ versus subjects receiving placebo. Sildenafil treatment in those with RVSD and RVH was not associated with change in SF-36. It was concluded that sildenafil treatment in IPF with RVSD results in better preservation of exercise capacity as compared with placebo. Sildenafil also improves quality of life in subjects with RVH and RVSD [13566].
A selective and sensitive screening method for the detection of prohibited narcotic and stimulating agents in doping control is described and validated. This method is suitable for the detection of all narcotic agents mentioned on the World Anti-Doping Agency (WADA) doping list in addition to numerous stimulants. The analytes are extracted from urine by a combined extraction procedure using CH$_2$Cl$_2$/MeOH (9/1, v/v) and t-butylmethyl ether as extraction solvents at pH 9.5 and 14, respectively. Prior to GC-MS analysis the obtained residues are combined and derivatised with MSTFA. The mass spectrometer is operated in the full scan mode in the range between m/z 40 and 550. The obtained limits of detection (LOD) for all components included in this extensive screening method are in the range 20-500 ng/ml, which is in compliance with the requirements set by WADA. Besides narcotic and stimulating agents, this method is also capable of detecting several agents with anti-estrogenic activity and some beta-agonists. As an example, a positive identification of hydroxyl-methoxy-tamoxifen is shown [07201].

A hydrophilic interaction liquid chromatography-time-of-flight mass spectrometry (HILIC-TOFMS) method for the quantification and confirmation of morphine (M), codeine (C), morphine-3-glucuronide (M3G), morphine-6-glucuronide (M6G) and codeine-6-glucuronide (C6G) is presented. The method was validated in terms of specificity, selectivity, extraction recovery, accuracy, repeatability, linearity and matrix effect. After a straightforward sample preparation by solid phase extraction (SPE) the compounds were analyzed directly without the need for hydrolysis, solvent transfer, evaporation or reconstitution. The HILIC technique provided good chromatographic separation which was critical for isomers M3G and M6G. The analytes were detected after electrospray ionization (ESI) in positive mode with mass accuracies below 2 mDa using a 5-mDa window. A measurement range of 50-5000 ng/mL was applied for calibration using deuterated analogs as internal standards. The precision of the method was 5.7% and 10.2 percent (RSD) within and between days, respectively. The applicability of the method was demonstrated with authentic urine samples known to contain codeine and/or morphine and their intact glucuronide conjugates. Identification of the analytes was based on in-source collision induced dissociation (ISCID), applying three diagnostic ions with accurate mass [10379].

A rapid method has been developed to analyse morphine, codeine, morphine-3-glucuronide, 6-monoacetylmorphine, cocaine, benzylegonine, buprenorphine, dihydrocodeine, cocaethylene, 3,4-methylenedioxymethamphetamine, ketamine, 3,4-methylenedioxymethamphetamine, pseudoephedrine, lignocaine, benzylpiperazine, methamphetamine, amphetamine, 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine and methadone in human urine. Urine samples were diluted with methanol:water (1:1, v/v) and sample aliquots were analysed by hybrid linear ion trap-triple quadrupole mass spectrometry with a runtime of 12.5 min. Multiple reaction monitoring (MRM) as survey scan and an enhanced product ion (EPI) scan as dependent scan were performed in an information-dependent acquisition (IDA) experiment. Finally, drug identification and confirmation was carried out by library search with a developed in-house MS/MS library based on EPI spectra at a collision energy spread of 35 ± 15 in positive mode and MRM ratios. The method was validated in urine, according to the criteria defined in Commission Decision 2002/657/EC. At least two MRM transitions for each substance were monitored in addition to EPI spectra and deuterated analytes were used as internal standards for quantitation. The reporting level was 0.05 µg/mL for the range of analytes tested. The regression coefficients in the study were ≥0.98. The method proved to be simple and time efficient and was implemented as an analytical strategy for the illicit drug monitoring of opioids, cocaines and amphetamines in criminal samples from crime offenders, abusers or victims in the Republic of Ireland. To the best of our knowledge there are no
hybrid LC-MS applications using MRM mode and product ion spectra in the linear ion trap mode for opioids, cocaines or amphetamines with validation data in urine [10493].

A rapid method has been developed to analyse morphine, codeine, 6-monoacetylmorphine, cocaine, benzoylcgonine, dihydrocodeine, cocaethylene, 3,4-methylenedioxyamphetamine, ketamine, 3,4-methylenedioxymethamphetamine, pseudoephedrine, lignocaine, benzylpiperazine, methamphetamine, methadone, phenylethylamine and levamisole in human blood. Blood samples were cleaned up using mixed mode solid phase extraction using Evolute™ CX solid phase extraction cartridges and the sample aliquots were analysed by hybrid triple quadrupole linear ion trap (QTRAP) mass spectrometry with a runtime of 12.5 min. Multiple reaction monitoring (MRM) as survey scan and an enhanced product ion (EPI) scan as dependent scan were performed in an information-dependent acquisition (IDA) experiment. Finally, drug identification and confirmation was carried out by library search with a developed in-house MS/MS library based on EPI spectra at a collision energy spread of 35 ± 15 in positive mode and MRM ratios. The method was validated in blood, according to the criteria defined in Commission Decision 2002/657/EC. At least two MRM transitions for each substance were monitored in addition to EPI spectra. Deuterated analogues of analytes were used as internal standards for quantitation where possible. The method proved to be simple and time efficient and was implemented as an analytical strategy for the illicit drug monitoring of opioids, cocaines, amphetamines and adulterants in forensic cases of crime offenders, abusers or victims in the Republic of Ireland [11222].

**Decreased sensitivity after exercise**

Numerous studies have shown a decreased analgesic potency of morphine in exercise trained animals. Since G-protein subunits have a critical role in opioid effects at the cellular level and the exact mechanism(s) of exercise-induced morphine insensitivity has not been fully clarified, the present study was designed to determine the changes in the levels of Ga\(_i\) and G\(\beta\) proteins gene expression involved in this phenomenon. All experiments were carried out on male Wistar rats. Nociceptive thermal threshold was determined by the tail-flick method. Physical training was performed using treadmill apparatus. Semiquantitative RT-PCR and Western blot techniques were used to estimate Galphai and Gbeta mRNA and protein levels, respectively and normalized to an internal standard (beta-actin). The antinociceptive effect of intrathecal morphine (5, 10 and 15 microg) was significantly suppressed in trained rats. Following physical training, a significant decrease in the mRNA and protein levels of Galphai and Gbeta were observed in the dorsal portion of the lumbar spinal cord. In conclusion, the results reveal that the expression patterns of the opioid receptor signaling elements change in exercise training animals. This may be, at least partly, responsible for exercise-induced morphine insensitivity [13518].

Electromembrane extraction (EME) coupled with electrochemical detection on screen-printed carbon electrode has been developed for the quantification of morphine in urine samples. Charged morphine molecules were extracted from an aqueous sample by applying an electrical potential through a thin supported liquid membrane (SLM) into an acidic aqueous acceptor solution (20 microL) placed inside the lumen of a hollow fiber. Then, the acceptor solution was mixed with 20 microL of NaOH solution (0.1M) and analyzed using screen printed electrochemical strip. Differential pulse voltammetry (DPV) peak current at 0.18V was selected as the signal and the influences of experimental parameters were investigated and optimized using Box-behnken design and also one-variable-at-a-time methodology as follows: adsorptive accumulation time, 40s; SLM, 2-nitrophenyl octyl ether+10 percent tris-(2-ethylhexyl) phosphate+10% di-(2-ethylhexyl) phosphate; pH of the sample solution, 6.0; pH
of the acceptor solution, 1.0; EME time, 24 min; EME potential, 90 V and stirring rate, 1000rpm. The calibration curve which was plotted by the variation of DPV currents as a function of morphine concentration was linear within the range of 0.005-2.0 microg/mL. The limit of detection and the limit of quantification were 0.0015 (S/N=3) and 0.005 microg/mL, respectively. Finally, the proposed method was able to determine morphine simply and effectively at concentration levels encountered in toxicology and doping [13519].

**Dermorphine**

Dermorphine and HYP₆-dermorphin are hepta-peptides and natural opioids originally isolated from the skin of South American frogs. They are more potent than morphine but less likely to produce drug tolerance and addiction. These properties make them ideal candidates for the doping of racehorses to enhance performance during competition. Dermorphin was recently classified as a Class I drug by Racing Commissioners International, indicating that it is a banned substance in equine athletes. To enforce this ban, a fast and sensitive method was developed for dermorphin and HYP₆-dermorphin analysis in equine plasma. Equine plasma (2 ml) was extracted on a mixed mode cation exchange solid-phase column. After extraction, dermorphin and HYP₆-dermorphin were separated and detected using a liquid chromatography (LC) triple quadrupole linear ion trap mass spectrometry in positive multiple-reaction-monitoring (MRM) mode. Each analysis was 3.5 min. Four MRM transitions were used for identification of each compound. The extraction procedure was efficient and the limits of detection (LOD) were 2 pg/ml and 10 pg/ml for dermorphin and HYP₆-dermorphin, respectively. The method has good selectivity and precision. Results of stability studies showed that both analytes were stable at low temperature. This is the first report of dermorphin and HYP₆-dermorphin analysis in equine plasma, which could be adopted as a regular screening or confirmation method for controlling the abuse of these compounds in equine sports [13514].

Dermorphin is a unique opioid peptide that is 30-40 times more potent than morphine. It was misused and went undetected in horse racing until 2011 when intelligence obtained from a few North American race tracks suggested its use. To prevent such misuse, a reliable analytical method became necessary for detection and identification of dermorphin in post-race horse samples. This paper describes the first liquid chromatography-tandem mass spectrometry (LC-MS/MS) method for such a purpose. Equine plasma and urine samples were pre-treated with ethylenediamine tetra-acetic acid and urea prior to solid-phase extraction (SPE) on Oasis MCX cartridges. Resulting eluates were dried under vacuum and analyzed by LC-MS/MS for dermorphin. The matrix effect, SPE efficiency, intra-day and inter-day accuracy and precision, and stability of the analyte were assessed. The limit of detection was 10 pg/mL in plasma and 20 pg/mL in urine, and the limit of confirmation was 20 pg/mL in plasma and 50 pg/mL in urine. Dermorphin in plasma is stable at ambient temperature, but its diastereomer is unstable. With isotopically labeled dermorphin as an internal standard, the quantification range was 20-10,000 pg/mL in plasma and 50-20,000 pg/mL in urine. The intra-day and inter-day accuracy was from 91 % to 100 % for the low, intermediate, and high concentrations. The intra-day and inter-day coefficients of variation were less than 12 %. The method differentiates dermorphin from its diastereomer. This method is very specific for identification of dermorphin in equine plasma and urine, as assessed by BLAST search and targeted SEQUEST search, and by MS/MS spectrum library search. The method has been successfully applied to analysis of samples collected following dermorphin administration to research horses and of official post-race samples [13515].
The use of thin-film solid-phase microextraction (SPME) as the sampling preparation step before direct analysis in real time (DART) was evaluated for the determination of two prohibited doping substances, cocaine and methadone, in urine samples. Results showed that thin-film SPME improves the detectability of these compounds: signal-to-blank ratios of 5 (cocaine) and 13 (methadone) were obtained in the analysis of 0.5 ng/mL in human urine. Thin-film SPME also provides efficient sample cleanup, avoiding contamination of the ion source by salt residues from the urine samples. Extraction time was established in 10 min, thus providing relatively short analysis time and high throughput when combined with a 96-well shaker and coupled with DART technique [13516].
Cannabis

Overviews

Since 2004, cannabis has been prohibited by the World Anti-Doping Agency for all sports competitions. In the years since then, about half of all positive doping cases in Switzerland have been related to cannabis consumption. In doping urine analysis, the target analyte is 11-nor-9-carboxy-delta9-tetrahydrocannabinol (THC-COOH), the cutoff being 15 ng/mL. However, the wide urinary detection window of the long-term metabolite of delta9-tetrahydrocannabinol (THC) does not allow a conclusion to be drawn regarding the time of consumption or the impact on the physical performance. The purpose of one study on light cannabis smokers was to evaluate target analytes with shorter urinary excretion times. Twelve male volunteers smoked a cannabis cigarette standardized to 70 mg THC per cigarette. Plasma and urine were collected up to 8 h and 11 days, respectively. Total THC, 11-hydroxy-delta9-tetrahydrocannabinol (THC-OH), and THC-COOH were determined after hydrolysis followed by solid-phase extraction and gas chromatography/mass spectrometry. The limits of quantitation were 0.1-1.0 ng/mL. Eight puffs delivered a mean THC dose of 45 mg. Plasma levels of total THC, THC-OH, and THC-COOH were measured in the ranges 0.2-59.1, 0.1-3.9, and 0.4-16.4 ng/mL, respectively. Peak concentrations were observed at 5, 5-20, and 20-180 min. Urine levels were measured in the ranges 0.1-1.3, 0.1-14.4, and 0.5-38.2 ng/mL, peaking at 2, 2, and 6-24 h, respectively. The times of the last detectable levels were 2-8, 6-96, and 48-120 h. Besides high to very high THC-COOH levels (245 ± 1,111 ng/mL), THC (3 ± 8 ng/mL) and THC-OH (51 ± 246 ng/mL) were found in 65 and 98 percent of cannabis-positive athletes' urine samples, respectively. In conclusion, in addition to THC-COOH, the pharmacologically active THC and THC-OH should be used as target analytes for doping urine analysis. In the case of light cannabis use, this may allow the estimation of more recent consumption, probably influencing performance during competitions. However, it is not possible to discriminate the intention of cannabis use, i.e. for recreational or doping purposes. Additionally, pharmacokinetic data of female volunteers are needed to interpret cannabis-positive doping cases of female athletes [10193].

The aim of one study was to examine prospective memory impairments associated with cannabis use in young adults. An independent measures design utilising pre-existing groups of users and non-users was employed in which an opportunity sample of 90 undergraduates studying at universities in the north east of England participated. The number of prospective memory failures reported on the Prospective Memory Questionnaire and the number of location-action combinations correctly recalled during a video-based prospective memory task were measured. The number of strategies used to assist memory, level of anxiety and depression, and use of alcohol, nicotine and any other recreational drugs in addition to cannabis were also measured and controlled during the analysis. Analysis revealed no significant differences in the number of self-reported prospective memory failures; however, cannabis users recalled significantly fewer location-action combinations than non-users in the video-based prospective memory task. The findings from the present study suggest that cannabis use has a detrimental effect on prospective memory ability in young adults but users may not be aware of these deficits [10194].

Referred to as "spice", several new drugs, advertised as herbal blends, have appeared on the market in the last few years, in which the synthetic cannabinoids JWH-018 and a C(8) homologue of CP 47,497 were identified as major active ingredients. Due to their reported
cannabis-like effects, many European countries have banned these substances. The World Anti-Doping Agency has also explicitly prohibited synthetic cannabinoids in elite sport competition. Since urine specimens have been the preferred doping control samples, the elucidation of the metabolic pathways of these substances is of particular importance to implement them in sports drug testing programmes. In a recent report, an in vitro phase-I metabolism study of JWH-018 was presented yielding mainly hydroxylated and N-dealkylated metabolites. Due to these findings, a urine sample of a healthy man declaring to have smoked a “spice” product was screened for potential phase-I and -II metabolites by high-resolution/high-accuracy mass spectrometry in the present report. The majority of the phase-I metabolites observed in earlier in vitro studies of JWH-018 were detected in this urine specimen and furthermore most of their respective monoglucuronides. As no intact JWH-018 was detectable, the monohydroxylated metabolite being the most abundant one was chosen as a target analyte for sports drug testing purposes; a detection method was subsequently developed and validated in accordance to conventional screening protocols based on enzymatic hydrolysis, liquid-liquid extraction, and liquid chromatography/electrospray tandem mass spectrometry analysis. The method was applied to approximately 7500 urine doping control samples yielding two JWH-018 findings and demonstrated its capability for a sensitive and selective identification of JWH-018 and its metabolites in human urine [10380].

In one study, it was investigated the effect of delta(9)-tetrahydrocannabinol (THC), the principal psychoactive component of marijuana, on immobility time during the forced swim test. THC (2 and 6 mg/kg, i.p.) significantly prolonged the immobility time. In addition, THC at the same doses did not significantly affect locomotor activity in the open-field test. The selective cannabinoid CB(1) receptor antagonist rimonabant (3 mg/kg, i.p.) significantly reduced the enhancement of immobility by THC (6 mg/kg). Similarly, the selective serotonin (5-HT) reuptake inhibitor (SSRI) citalopram (10 mg/kg, i.p.) and 5-HT(1A/7) receptor agonist 8-hydroxy-2-(di-n-propylamino) tetralin (8-OH-DPAT, 0.3 mg/kg, i.p.) significantly reduced this THC-induced effect. These findings suggest that the 5-HT(1A) receptors are involved in THC-induced enhancement of immobility [08365].

As recently reported, the synthetic cannabinoid JWH-018 is the subject of extensive phase I and II metabolic reactions in vivo. Since these studies were based on LC-MS/MS and/or GC-MS identification and characterisation of analytes, the explicit structural assignment of the metabolites was only of preliminary nature, if possible at all. It was reported the chemical synthesis of five potential in vivo metabolites of JWH-018 derivatives featuring an alkylcarboxy (M1), a terminal alkylhydroxy (M2), a 5-indolehydroxy (M3), an N-dealkylated 5-indolehydroxy (M4) and a 2'-naphthylhydroxy (5) analogue, respectively, and their characterisation by nuclear magnetic resonance spectroscopy. The collision-induced dissociation (CID) patterns of the protonated compounds were studied by high-resolution/high-accuracy tandem mass spectrometry (MSn) applying an LTQ Orbitrap with direct infusion and electrospray ionisation of target analytes. An unusual dissociation behaviour including a reversible ion-molecule reaction between a naphthalene cation (m/z 127) and water in the gas phase of the MS was shown to be responsible for nominal neutral losses of 10 u in the course of the CID pathway. LC-MS/MS-supported comparison of synthesised reference standards with an authentic urine sample using an API 4000 QTrap mass spectrometer identified the synthetic JWH-018 analogues M1-M4 as true in vivo metabolites, presuming a chromatographic separation of potentially present regioisomeric analogues. Existing doping control methods were expanded and validated according to international guidelines in order to allow for the detection of the carboxy and the alkylhydroxy metabolites, respectively, as urinary markers for the illegal intake of the synthetic cannabinoid JWH-018. Both metabolites were quantified in authentic doping control urine samples that had been suspicious of JWH-018 abuse after routine screening procedures,
and a stable isotope-labelled $^{13}$C$_6$-$^{15}$N-carboxy metabolite was synthesised for future analytical applications [11223].

To estimate the prevalence of youth who use cannabis but have never been tobacco smokers and to assess the characteristics that differentiate them from those using both substances or neither substance a total of 5263 students (2439 females) aged 16 to 20 years divided into cannabis-only smokers ($n=455$), cannabis and tobacco smokers ($n=1703$), and abstainers ($n=3105$) were investigated regarding regular tobacco and cannabis use; and personal, family, academic, and substance use characteristics. Compared with those using both substances, cannabis-only youth were younger (adjusted odds ratio, AOR 1.33), to be students (AOR 2.56), and to have good grades (AOR 1.57) and less likely to have been drunk (AOR 0.55), to have started using cannabis before the age of 15 years (AOR 0.71), to have used cannabis more than once or twice in the previous month (AOR 0.64), and to perceive their pubertal timing as early (AOR 0.59). Compared with abstainers, they were more likely to be male (AOR 2.10), to have a good relationship with friends (AOR 1.62), to be sensation seeking (AOR 1.32), and to practice sports (AO, 1.37) and less likely to have a good relationship with their parents (AOR 0.59). They were more likely to attend high school (AOR 1.43), to skip class (AOR 2.28), and to have been drunk (AOR 2.54) or to have used illicit drugs (AOR 2.28). It was concluded that cannabis-only adolescents show better functioning than those who also use tobacco. Compared with abstainers, they are more socially driven and do not seem to have psychosocial problems at a higher rate [07204].

If the doors of perception were cleansed, everything would appear to man as it is, infinite. Ingestion of perception-altering substances dates back millennia, when they may have been used routinely as a dietary source of neurotransmitters, which are energetically expensive to synthesize. It has been suggested that there is a “deep-time” relationship (co-evolution) between hominids and psychotropic plants, their premise based on the synthesis by plants of defensive chemicals that mimic mammalian neurotransmitters, and the ability of mammals to metabolize and/or utilize these phytochemicals to their advantage. Ingestion of these compounds as a routine component of early hominid diets, even if this is no longer necessary, may explain in part the current propensity for the widespread use/abuse of these compounds. Almost all recreational drugs (cocaine, nicotine, amphetamines, tetrahydrocannabinol – THC) are plant toxins that induce changes in dopaminergic circuitry. Marijuana is widely recognized as the most used recreational drug, at least in Europe and North America; however, this is a generalization when dealing with specific countries, regions, or neighborhoods. For instance, members of the Los Angeles and San Francisco Police Department Narcotics Divisions confirmed that in many neighbourhoods in those cities the impact of cannabis is minimal compared with crack, methamphetamine, and/or heroin. This is undoubtedly true for many neighborhoods in major metropolitan areas in the USA and elsewhere. It is generally accepted that the addiction potential of the psychoactive components (primarily THC) of cannabis is limited to psychological habituation, although heavy users may experience slight to moderate short-term physical withdrawal symptoms. There are no documented instances of mortality due solely to cannabis poisoning. Most adverse health effects involve respiratory problems due to ingestion of particulates and other components associated with heavy smoking of any substance, psychoactive or not; nevertheless, legal and illegal use of THC and analogs has and will continue to have a significant impact on society. Even with current restrictions in the USA, the medicinal marijuana market is estimated to be 1.7 billion dollars in 2011, 92 percent accounted for by California and Colorado. This is dwarfed by estimates of the illicit market, for example, a commonly quoted figure from the US Drug Enforcement Agency (DEA) is USD 35 billion. Statistics from the NHTSA/FARS (US National Highway Traffic Safety Administration/Fatality
Analysis Reporting System) from 2009 state that 32% of all traffic fatalities in the USA (33,808) could be directly attributed to alcohol impairment, while those involving use of marijuana are essentially identical to those in which no drug use is suspected. This is not an anomaly. This is not a defense of using cannabinoids and their mimetics, or a denigration of current laws regulating their use; rather, it is to emphasize the need for a rational approach to drug enforcement policies which can be abetted in part by increased understanding of the physiological and psychological bases of their effects on human behaviour. There is a grey area when dealing with many recreational drugs including cannabinoids, steroids, opiates, and tropane alkaloids (scopolamine, atropine), since they have legitimate medicinal uses. One spotlight article explored the current knowledge of THC receptors, computational approaches to development of THC receptor analogues and other designer drugs for medicinal and recreational use, and the unexpected synergistic effects of tropane (belladonna) alkaloids on smoking cannabinoids [11555].

Despite a history of being used for thousands of years, and the subject of numerous chemical investigations dating back to the 1800s, it was not until 1964 that the correct structure for THC was identified. THC is the major psychoactive component of about 85 estimated cannabinoids synthesized by Cannabis sativa. Like the majority of popular recreational drugs – including nicotine, cocaine, amphetamines, and opiates – THC is a plant neurotoxin that affects dopaminergic circuitry primarily through G protein coupled receptors (GPCR). Receptors for cannabinoids were difficult to identify due to the highly lipophilic nature of THC. During the 1980s, Pfizer embarked on a major effort to synthesize analogues based on the THC structure, one of which, CP55,940, a high affinity CB1 ligand, led to identification of two receptors for THC in the early 1990s. CB1 is primarily localized in the central nervous system, and CB2 in cells associated with the immune system; however, there are exceptions, and tentative evidence for additional receptors. Identification of these receptors renewed efforts to synthesize THC analogues, to date numbering over 3000, with the goals of enhancing activity and/or specifically targeting either CB1 or CB2 [11555].

Since over 3000 compounds that bind to CB1 and/or CB2 have been synthesized, it is not surprising that some of these have been exploited for recreational drug use. Some strains of Cannabis have a significant muscle relaxing effect (CB2-mediated), while others are almost entirely euphoric (CB1-mediated). Since THC has similar binding affinities for CB1 and CB2, synergistic compounds have to be invoked to explain these differences. There are four main classes of cannabinoid mimetics: analogues of endogenous ligands related to anandamide (N-arachidonylethanolamine), especially oleamide; THC analogues based on the dibenzopyran ring, including HU-210 with reported 100 times the potency of THC; the cyclohexylphenol series; and the JWH series named after the eponymous John W. Huffman, a structurally diverse group that includes indenes, indoles, and pyrenes. Cannabinoid analogs first became a significant market in Europe sometime in the mid-2000s (and in the USA several years later) with the emergence of Spice, K2, Green Buddha and similar products marketed as “exotic incense blends”. Spice and its spin-offs consist of mixtures of up to 10 or 12 dried herbs (onlabel) and (apparently) one or more designer drugs (including compounds from the four groups listed previously) added for the psychoactive effects. Sometime between 2006 and 2008, Spice and its cousins triggered notice from the Psychonaut Web Mapping Project and the Early Warning System (EWS), which are coordinated by the European Monitoring Centre for Drugs and Drug Addiction. EWS links police, customs, regulatory agencies, and other illegal drug specialists, while Psychonaut (now defunct) trawled the Web for novel recreational drugs. Specific mimetics have subsequently been banned or otherwise regulated in European and Scandinavian countries beginning in 2009 [11555].

Since the World Anti-Doping Agency (WADA) was conceived in 1999 by the sport movement and governments of the world to fight against doping in sport in all its forms, the prohibition of
cannabis in sport has been one of the controversial issues debated by the scientific and political anti-doping authorities. Prior to 2004 and the establishment of the World Anti-Doping Code by WADA, cannabinoids were prohibited only in certain sports. The decision was left to the governing international sport federation as to whether cannabinoids were prohibited in their discipline(s) and whether anti-doping tests were conducted. Consequently, a limited population of athletes was tested and sanctioned for cannabis anti-doping rule violations. In 2004, WADA assumed responsibility for establishing the list of prohibited substances and methods in sport (the Prohibited List). In the first Prohibited List, published under the auspices of WADA that same year, prohibition of cannabinoids was extended to all sports in competition. At the second World Conference on Doping in Sport, held in Copenhagen in March 2003, extension of the cannabinoids ban to all sports was one of the most controversial issues. Some delegates strongly argued that cannabinoids should not be included in sport regulations because consumption of cannabis is not performance enhancing in sports and therefore it should remain a social issue. In this context, it is discussed the potential of cannabis to enhance sports performance, the risk it poses to the athlete's health and its violation of the spirit of sport. Although these compounds are prohibited in-competition only, it may explain why the pharmacokinetics of their main psychoactive compound, delta(9)-tetrahydrocannabinol, may complicate the results management of adverse analytical findings. Passive inhalation does not appear to be a plausible explanation for a positive test [11584].

Cannabis contains over 400 different chemical compounds, including at least 61 cannabinoids. During smoking, more than 2000 compounds may be produced by pyrolysis. Eighteen different classes of chemicals, including nitrogenous compounds, amino acids, hydrocarbons, sugars, terpenes, and simple and fatty acids, contribute to the known pharmacological and toxicological properties of cannabis. The main psychoactive drug in cannabis is delta9-tetrahydrocannabinol (THC), but other cannabinoids also contribute to its pharmacological effects. Cannabidiol (CBD) lacks psychoactivity but possesses anxiolytic, antipsychotic and alerting properties, and it is the basis of pharmacotherapies with multiple indications. CBD content in cannabis is believed to modulate the effects of THC. Other cannabinoids include cannabinol, which is approximately 10 percent as psychoactive as THC, and cannabigerol, cannabichromene and multiple minor cannabinoid components. Over the last 20 years, the knowledge of cannabinoid pharmacology has increased tremendously. Discoveries include identification of CB1 and CB2 cannabinoid receptors, multiple endogenous neurotransmitters (e.g. N-arachidonoyl ethanolamine (anandamide), 2-arachidonoylglycerol, 2-arachidonoyl glyceryl ether,N-arachidonoyldopamine and virodhamine); synthetic pathways, enzymes for neurotransmitter inactivation (fatty acid amide hydrolase and monoacylglycerol lipase), and transport across cell membranes. CB1 receptors are primarily located in the CNS, in high density in the cerebral cortex, hippocampus, amygdala, striatum and cerebellum and functional areas associated with the most prominent behavioural effects of cannabinoids [11584].

The most common neurocognitive deficit observed during acute intoxication is short-term memory impairment. Deficits in motor inhibition, decision making and inhibitory control are also prominent. Less consistent results are available for risk taking after cannabis use. After chronic cannabis exposure, it appears that cannabinoid receptors are desensitized and internalized. The distinct CB2 cannabinoid receptor, primarily located in the periphery, has a critical role in immunomodulation. The endogenous cannabinoid system is highly conserved throughout evolution; it modulates important functions including locomotion, emotional behaviour, cognition, cardiovascular response, pain, feeding behaviour and drug dependence. The stimulating effects of THC on the brain reward system are characteristic of drugs with abuse liability and are similar to other drugs of abuse such as heroin, cocaine, methamphetamine and nicotine. Cannabis produces substantial changes in human
behaviour as well as physiological and biochemical changes. The behavioural and subjective effects of cannabis are highly dose-dependent and include euphoria, enhancement of sensory perception, sedation, relaxation, altered perceptions of time, lack of concentration, impairment of learning/memory, mood changes, panic reaction, paranoia and impaired psychomotor activity. Well described physiological effects include tachycardia, conjunctival injection, dry mouth and throat, increased appetite, vasodilation, bronchodilation, increased sleep and analgesia. This spectrum of behavioural effects is unique, preventing classification of the drug as a stimulant, sedative, tranquilizer or hallucinogen. Subjective and physiological effects of cannabis appear after the first puff of a THC-containing product. Although cannabis smoking produces rapid changes in heart rate, pronounced hypotension and dizziness is observed in approximately 25 percent of individuals approximately 10 minutes after smoking. Cannabis does not produce death directly, as there are few cannabinoid receptors in the brain stem, other than the vomiting centre, limiting cannabis' effects on respiratory function. Around-the-clock, high-dose THC is needed to produce tolerance to the physiological and behavioural effects of cannabinoids. Controversy exists as to whether long-term exposure produces irreversible changes in brain function. Abstinence may permit elimination of cannabinoids from the brain and a return to baseline performance. There are conflicting reports in the literature on the chronic toxic effects of cannabis. Impaired health including lung damage, behavioural changes and reproductive, cardiovascular and immunological effects are associated with cannabis use [11584]

Acute effects of cannabis include increased heart rate, followed in many individuals by hypotension, dizziness and disorientation, increased subjective feelings of euphoria or being “high” and a state of intoxication or being “stoned”, and sometimes psychosis, panic reactions and paranoia. Additional effects that could harm the athlete during competition are loss of vigilance, increased reaction times and short-term memory loss. A different spectrum of effects occurs with chronic daily cannabis use. Multiple studies report decreased cognitive performance after long-term cannabis exposure. Other chronic effects include pulmonary toxicity following smoking and cannabis smoke may induce bronchial irritation, chronic cough and wheeze. Cardiovascular damage, liver steatosis and negative reproductive effects are all associated with chronic cannabis exposure. The exacerbation of symptoms of schizophrenia and the early initiation of the disease has been noted by several investigators. The cannabis withdrawal syndrome is characterized by psychological rather than physical symptoms, including restlessness, anxiety, insomnia, muscle tremor and increased aggression. THC increases dopamine release in the nucleus accumbens and prefrontal cortex similar to other reinforcing drugs of abuse such as cocaine and amphetamines. Synthetic cannabinoid agonists and antagonists at CB1 and CB2 cannabinoid receptors are approved or under development as pharmacotherapies. Cannabinoid agonists are approved for the treatment of nausea and vomiting from cancer chemotherapy and as an appetite stimulant in patients with HIV/AIDS wasting disease [11584].

Cannabis is often portrayed as a substance that has detrimental effects on performance. Cannabis decreases coordination, distorts spatial perception and alters perception and awareness of the passage of time. It has been found that cannabis smoking did not increase vital capacity or grip strength, and maximal exercise performance in 12 cyclists reduced from 16 to 15 minutes at 10 minutes after smoking a THC 1.7 percentcigarette. However, in this study vasodilation and bronchodilation were increased, suggesting that cannabis could also improve oxygenation to the tissues. Cannabis is presented as a drug that has significant positive effects in sports, such as improvement of vision for goalkeepers and muscle relaxation. Smoked cannabis can decrease anxiety, fear, depression and tension. THC is anxiolytic at low doses, the doses reportedly consumed by athletes. It has been suggested that cannabis smoking reduces anxiety, allowing athletes to better perform under pressure and to alleviate stress experienced before and during competition. Furthermore,
cannabinoids play a major role in the extinction of fear memories by interfering with learned aversive behaviors. The endocannabinoid system is also involved in the modulation of mood. Animal studies demonstrate antidepressant-like effects in models based on inescapable or chronic stress. In adolescents and young adults, cannabis also helps in coping with negative mood and emotional distress. Clearly, cannabis induces euphoria, improves self-confidence, induces relaxation and steadiness and relieves the stress of competition. Cannabis improves sleep and recovery after an event, reduces anxiety and fear and aids the forgetting of negative events such as bad falls and so forth. Cannabis increases risk taking and this perhaps improves training and performance, yielding a competitive edge [11584].

In urine, the presence of THCCOOH equal to or greater than the threshold value of 15 ng/mL is reported by WADA-accredited laboratories as an adverse analytical finding (AAF). THC, the primary psychoactive component of cannabis, is rapidly absorbed into the bloodstream following inhalation and is extensively metabolized in the liver into multiple metabolites. The equipotent metabolite 11-hydroxy-THC (11-OH-THC) of THC is further oxidized to THCCOOH and THCCOOH-glucuronide and sulphate. THC is extensively metabolized to multiple other alcohols and acids, but THCCOOH was selected as the analyte monitored in urine for virtually all drug-testing programs. After alkaline hydrolysis of urine to free THCCOOH from its conjugates, THCCOOH is the most abundant urinary marker of cannabis use. THC is distributed initially to the highly perfused organs including the brain, heart, liver and kidneys, with secondary distribution into adipose tissue, because of its high lipophilicity. With chronic daily THC exposure, the THC body burden in fat is large; the rate-limiting step in THC elimination is the slow release of stored drug from the tissues. Cannabinoid concentrations in body fluids depend upon the cannabis potency, smoking topography, frequency of cannabis use and time since last use. In plasma, for example, THC was detected for 6–27 hours after smoking a single cannabis joint containing approximately THC 34 mg (gas chromatography/mass spectrometry limit of quantification 0.5 ng/mL) in individuals who smoked less frequently than daily. Mean (range) peak plasma THC concentrations were 162 (76–267) ng/mL. The mean detection time for THCCOOH in plasma was longer, from 3 to 7 days at the same LOQ. Recently, nondaily cannabis users smoked THC 69 mg and achieved similar mean peak serum THC concentrations of 190 – 106 ng/mL, despite twice the available dose. This is consistent with other reports of cannabis smokers who titrate their dose to the desired level of intoxication and tolerable cardiovascular response. Mean peak urinary THCCOOH concentrations were 90 → 32 ng/mL and 153 → 49 ng/mL approximately 8 and 14 hours after smoking cigarettes containing THC 16 mg and 34 mg, respectively. All urine specimens were collected and individually analysed. THCCOOH was detected in urine at a concentration of 15 ng/mL for 34 → 9 hours (range 8 to 69 hours) and 89 → 10 hours (range 57–122 hours) after these doses. When subjects smoked a cannabis cigarette containing THC 20-25 mg; mean detection time for the last positive urine specimen was 58 – 6 hours (range 16–72 hours). Thus, in cannabis users smoking less frequently than daily, a positive urine cannabinoid test would likely be positive for <4 days. However, when an individual smokes cannabis daily for an extended period, it is possible to have a positive urine specimen for at least 4 weeks. When cannabis is smoked daily, the body burden of cannabinoids is high. It was reported cannabinoid excretion data based on creatinine-normalized urine concentrations from 60 cannabis smokers who resided on a closed research unit under 24-hour monitoring for up to 30 days. All urine specimens were collected and individually analysed for THCCOOH. When urinary cannabinoid excretion data are normalized to urinary creatinine, the individual’s state of hydration is taken into account and the excretion curve is smoothed. Cannabinoid excretion data were divided into three groups based on the initial cannabinoid to creatinine ratio in ng/mg. The three groups were <50 ng/mg, 51-150 ng/mg and >150 ng/mg. In the <50 ng/mg group, normalized cannabinoid/creatinine concentrations on admission ranged from 0 to 47 ng/mg. These
individuals reported smoking cannabis from 2 to 30 days per month for up to 25 years. The first negative urine specimen (<50 ng/mL by immunoassay screen) in this group occurred from 0 to 2.2 days after admission, and the last positive specimen occurred up to 8.6 days after admission, except for one individual who was positive 21.8 days later. The latter individual reported smoking daily for 5 years. In the >150 ng/mg group, normalized cannabinoid/creatinine concentrations on admission ranged from 155 to 1165 ng/mg. These individuals reported cannabis use from 12 to 30 days per month for up to 28 years. There were statistically significant correlations between groups and number of days until first negative and last positive urine specimens; mean number of days were 0.6 and 4.3, 3.2 and 9.7, and 4.7 and 15.4 days, respectively, for the three groups. In individuals generally smoking cannabis on a daily basis, creatinine normalized urine specimens would on average be negative after 15.4 days; however, the urine specimens of many cannabis smokers remained positive for up to 30 days after long-term use. Thus, for athletes who are occasional cannabis smokers, abstinence for 1 week prior to competition should result in negative cannabinoid urine tests and no AAFs, while chronic cannabis use would require abstinence of 1 month or longer. Based on the documented cognitive impairment and toxicity that occurs following chronic use, it is not expected that a significant number of elite athletes would be chronic daily cannabis smokers [11584].

When chronic cannabis users test positive, it is not possible to differentiate new cannabis use from residual cannabinoid excretion from a single urine specimen. Models were developed to predict whether new cannabis use has occurred between two urine specimens collected up to 21 days apart from cannabis users smoking less frequently than daily. These models require the creatinine-normalized cannabinoid concentrations and the time between specimen collections. Minimum, median and maximum ratios between the later urine specimen normalized concentration to that of the first specimen are provided to guide interpretation of whether or not new cannabis use has occurred between the two urine collection dates. Others suggested that measurement of the psychoactive components of cannabis, THC and/or 11-OH-THC, in urine could also indicate recent cannabis use, even in chronic cannabis smokers. Following Escherichia coli b-glucuronidase hydrolysis of urine, THC and 11-OH-THC could be found for up to 8 hours after cannabis smoking. It was evaluated cannabinoid excretion in blood, plasma and urine from the heaviest chronic daily cannabis users encountered in more than 15 years of research. Cannabis smokers resided in a closed research unit for up to 30 days of continuously monitored abstinence. Surprisingly, THC was quantified in blood and plasma from some chronic users for at least 7 days and in the urine for up to 24 days after initiation of abstinence with LOQs of 0.25, 0.25 and 2.5 ng/mL, respectively. Interestingly, 11-OH-THC was present in urine for as long as THCCOOH was throughout the 30-day monitoring period. Thus, neither THC nor 11-OH-THC in urine identify recent cannabis smoking. Another approach to identifying recent cannabis smoking is to monitor drug biomarkers in an alternative matrix other than urine. Oral fluid (saliva) testing offers a simple, fully observed specimen collection method, thereby reducing the potential for adulteration, and it does not require clinical personnel or same-sex doping control officers. THC appears immediately in oral fluids in high concentrations after cannabis smoking, because of the exposure of the oral mucosa to the drug in the cannabis smoke. It has been found that approximately 30-45 minutes after the end of smoking, THC concentrations in oral fluid decreased considerably, correlating temporally with blood concentrations. To date, there are no data on the window of THC detection in oral fluid after chronic cannabis smoking, and oral fluid is not an approved matrix for anti-doping testing. It has been argued that passive inhalation of cannabinoids can yield urinary THCCOOH concentrations >15 ng/mL. Under realistic exposure conditions, passive inhalation of cannabis or hashish smoke does not produce detectable levels of urinary cannabinoids. However, under extreme conditions in laboratory settings with high cannabis smoke concentrations, measurable THCCOOH is possible. Thus, passive inhalation is used as a
line of defence following positive drug tests in the workplace. Scientific data document that THCCOOH concentrations following passive THC inhalation under less than extreme experimental conditions do not exceed the threshold value of THCCOOH 15 ng/mL by GCMS. More recently, another experiment proved the low probability of detecting THCCOOH in the urine of subjects exposed to passive inhalation. The scientific evidence on passive inhalation was reviewed and it was noted that only when the air volume was extremely low and the THC smoke amount unrealistically high, bordering on intolerable discomfort, was it possible to detect the presence of cannabinoids in the urine of participants smoking passively for more than 24 hours. Based on the review of all published articles on the topic, they concluded that ignorant passive cannabis smoking can be excluded with high certitude as a cause of positive samples. Most studies on passive inhalation of cannabis smoke were, however, conducted more than 20 years ago. THC cannabis content increased from 2.8 to as high as 40 percent in some preparations sold in Dutch coffee shops. It could, therefore, be argued that since THC content is higher, there is a greater chance of testing positive if passively exposed to high-content cannabis. However, the average THC content in most street cannabis is 6-7 percent and the passive exposure conditions required to produce positive urine tests are unrealistic. When ingested, peak concentrations are much lower and peak later than after smoking. Less euphoria is experienced and exposure to the more toxic ingredients produced from burning cannabis is avoided [11584].

The consumption of substances derived from cannabis, such as hashish (resin) and marijuana ("grass", "pot"), particularly in the form of joints, is widespread. The relatively high incidence of cannabinoids detection in urine reflects the high prevalence of cannabis use among young adults. Various studies carried out in Europe and elsewhere have shown an impressive increase in the frequency and quantity of consumption, essentially in the younger population, with an earlier onset of use. In a report by the European Monitoring Center for Drugs and Drug Addiction, 1.2–16 percent of young people aged 15–24 from 18 European countries indicated cannabis consumption during the last month whereas 16 percent of young US adults aged 18–25 reported past month use of cannabis. As cannabis smoking impairs cognition, and psychomotor and exercise performance, it is considered to be an ergolytic drug. It has been shown that marijuana smoking reduce maximal exercise performance; when 12 healthy young adults cycled to exhaustion 10 minutes after smoking, exercise duration decreased from 16 to 15 minutes. Driving and piloting skills are also negatively affected, and point to the dangers of cannabis exposure when high level of alertness and quick reflexes are required, such as in automobile sports. Thus it can be inferred from the psychological effects of marijuana that cannabis is effective only in allowing an athlete to relax and to escape from social pressures. However, cannabis is on the list of prohibited substances in the practice of sport, although its performance enhancing effect has not yet been proved. Its popularity among the younger generations as a social drug puts cannabis at the top of the list of compounds detected by the anti-doping laboratories accredited by the World Anti-Doping Agency worldwide. The management of the results of urine analysis is quite difficult for the medical and disciplinary committees not only because of the social use of the substance, but also because of the interpretation of the analytical data from urine samples. One paper gave an overview of what is presently known about cannabis in relation with the practice of sport [06226].

Cannabis species has been used for a variety of purposes for thousands of years, and has been the subject of chemical investigations since the 1800s; however, it was not until 1964 that the correct structure for tetrahydrocannabinol (THC) was characterized. THC is the major psychoactive component of about 85 cannabinoids estimated to be synthesized by Cannabis sativa. Receptors for cannabinoids were difficult to identify because of their highly lipophilic nature. During the 1980s, Pfizer embarked on a major effort to synthesize analogues based on the THC structure, one of which, CP55,940, a high affinity CB1 ligand,
led to identification of two receptors for THC in the early 1990s. CB1 is primarily localized in the central nervous system, and CB2 in cells associated with the immune system. Today many studies state that the palliative benefits of marijuana outweigh the adverse effects of the drug, and recommend that marijuana be administered to patients who have failed to respond to other therapies. Differentiation between direct agonists (including THC), which directly bind to and stimulate cannabinoid receptors, and indirect agonists, which indirectly stimulate these receptors by increasing levels of endogenous CB transmitters, is central. The literature reveals that behavioural animal models yield inconsistent and often contradictory results; however, all drugs of abuse increase dopamine levels in the nucleus accumbens; a convincing argument is made that the degree of abuse potential of a very diverse group of compounds acting on completely different targets via independent mechanisms can reliably be predicted by monitoring dopamine release [12349].

A well-documented, rational case is that while cannabinoid intoxication can have some effects (decreased performance in critical tracking and divided attention tasks, reduced speed, and decreased reaction time), these are minimal compared to alcohol and benzodiazepines, especially among chronic, heavy users of THC and analogues. The average marijuana potency has progressively and substantially increased over the last four decades in the United States. A number of reasons for this trend have been presented, including a shift from foreign to domestic cultivation; advances in cultivation techniques; and cultivars with enhanced tetrahydrocannabinol (THC) levels, especially the switch to higher quality sinsemilla products. Broken down by decade, the 1970s were characterized by poor quality, and low potency kilobrick marijuana; the 1980s and 1990s by a mid-quality mix of kilobrick products; and the 2000s with a dramatic increase in market share by high quality, high potency sinsemilla products. This has led to the widespread belief that potency has increased by a factor of 10 during the last four decades; however, when adjusted for artefacts introduced by substantially reduced seizure-to-analysis times and modified analytical techniques with increased sensitivity, the actual increase is a factor of 6-7 [12349].

The discussion regarding whether cannabinoids such as delta^9-tetrahydrocannabinol (THC) and the synthetic cannabimimetics (e.g. JWH-018, HU-210, etc.) necessitate consideration by anti-doping authorities has been debated for years. Based on the growing knowledge concerning cannabinoid pharmacology, the reasoning for the prohibition of this class of compounds was revisited and reviewed in comprehensive contributions recently. One of the cannabimimetics explicitly mentioned in the WADA Prohibited List is HU-210, the in vitro metabolism of which was studied by means of LC-MS/MS. Using human liver microsomal preparations, 24 phase-I metabolites were obtained, resulting predominantly from oxygenation, hydroxylation, and a combination of both. Although assigning the modifications to either the tricyclic nucleus or the alkyl side chain of HU-210 was accomplished by diagnostic product ions and high resolution/high accuracy mass spectrometry, unambiguous characterization e.g. by chemical synthesis, complementary analytical strategies including for instance (selective) derivatization, GC-MS or NMR was not obtained [0012].

The synthetic cannabinoid JWH-200 (1-[2-(4-morpholinyl)ethyl]-3-(1-naphthoyl)-indole) appeared on the market around 2009. In order to identify markers for misuse of this compound and allow for the development of adequate routine methods, the metabolism of this compound was investigated using two models. In vitro and in vivo (both with and without enzymatic hydrolysis) samples were purified by solid-phase extraction and analyzed using liquid chromatography. Electrospray ionization high-resolution Orbitrap mass spectrometry was used for the identification of the metabolites. To confirm the results in vivo, triple-quadrupole mass spectrometry was employed. In the in vitro model, using human liver microsomes, 22 metabolites were detected which could be divided into 11 metabolite classes. By using the chimeric mouse model with humanized liver, most of these metabolites
were confirmed in vivo. It was found that all metabolites are excreted in urine as conjugates, mostly as glucuronides with varying conjugation rates. The metabolite formed by consecutive morpholine cleavage and oxidation of the remaining side chain to a carboxylic group was detected in the highest amounts with the longest detection time. Therefore, it is the best candidate metabolite to detect JWH-200 abuse in urine [13488].

Recent debate and cases involving elite athletes raised the question whether or not Cannabis sativa (cannabis) should be considered doping in sports. Results from a 2010 report in the United States showed that cannabis is the most used illicit drug, with 17.4 million users smoking cannabis and 6.9 million users smoking cannabis on a daily or near daily basis. The World Anti-Doping Agency (WADA) included cannabis in its Prohibited List in 2004, claiming that cannabis may improve performance in some sports and is an illegal drug in most countries; however, the inclusion of a substance in the Code is complex, requiring intense debate among delegates and the fulfillment of specific criteria. For instance, Section 4 of the Code establishes that a substance be considered for inclusion in the Prohibited List if it is a masking agent or meets two of the three following criteria [13489]:

- potential to enhance performance in sports – smoked cannabis affects cognition and performance, causes memory loss, executive function, and motor impairment, among other undesirable effects. Cannabis smoking may be helpful for some activities such as extreme sports, as it improves muscle relaxation, reduces anxiety, and extinguishes fear memories (e.g. negative experiences) leading to enhanced performance. It is also worthwhile to note that cannabis smoking improves sleep time and recovery, which may favor performance when an athlete is facing multiple competitions in a short period of time. In light of these positive effects, one can assume cannabis is a doping substance that relaxes the mind and improves recovery.
- potential or actual health risk – cannabis’ cognitive effects in chronic users are still unclear, but it may downregulate CB1 receptors, affect executive functions, and cause motor impairment, reversed only after weeks of abstinence. It seems unlikely that athletes are chronic cannabis smokers due to the detrimental effects of chronic use including inconsistent performance, concentration, and motivation. Cyclists who smoked cannabis had a 1-min decrease in maximal exercise performance at 10 min after smoking. These negative effects on cognition and performance can impair critical skills (e.g. decision making, vigilance, alertness) required in high-risk sports to avoid accidents and/or injuries.
- violation of the spirit of sport – doping is essentially contrary to the spirit of sport, which is the principle of Olympism, characterized by several values, such as ethics, fair play and honesty, health, respect for rules and laws, and respect for self and other participants.

The performance of the previously validated LUCIO(®)-Direct-enzyme linked immunosorbent assay (direct ELISA) screening tests according to forensic guidelines is compared to that of cloned enzyme donor immunoassays (CEDIA) test for drugs of abuse in urine as defined in the new re-licensing German medical and psychological assessment (MPA) guidelines. The MPA screening cut-offs correspond to 10 ng/ml 11-nor-delta-9-tetrahydrocannabinol-9-carboxylic acid (THC-COOH), 50 ng/ml amphetamine and designer amphetamines, 25 ng/ml morphine, codeine and dihydrocodeine, 30 ng/ml benzylecgonine, 50 ng/ml methadone metabolite, 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP) and metabolites of diazepam, oxazepam, bromazepam, alprazolam, flunitrazepam and lorazepam at 50 ng/ml. Average relative sensitivities and relative specificities were 99.7 and 98.4 percent for direct ELISA and 66 and 91 percent for CEDIA, respectively [13490].
Cannabis (Cannabis sativa) is known for its widespread use worldwide. In total, more than 400 different compounds, distributed by 18 chemical groups, including its most active substance delta⁹-THC have been detected in different species of cannabis plants. Consumption of THC-containing cannabis products, such as marijuana (herbal cannabis) and hashish (resinous cannabis) are commonly consumed in the form of cigarettes or even in small pipes. In addition, dronabinol, a THC synthetic product, has been approved in many countries to treat medical conditions such as HIV and cancer. The widespread popularity of use of substances derived from cannabis, such as marijuana among young athletes has led to its high detection frequency. In 2012, 7.6 million individuals 12 years of age or older used marijuana on 20 or more days in the past month [13008].

Long-term use

Cannabis is the most widely used illicit drug in the US, and the number of illicit and licit users is rising. Lasting neurocognitive changes or deficits as a result of use are frequently noted despite a lack of clarity in the scientific literature. In an effort to resolve inconsistencies in the evidence of lasting residual effects of cannabis use, we conducted two meta-analyses. First, it was updated a previous meta-analysis on broad nonacute cognitive effects of cannabis use through inclusion of newer studies. In a second meta-analysis, it was focused on evidence for lasting residual effects by including only studies that tested users after at least 25 days of abstinence. In the first meta-analysis, 33 studies met inclusion criteria. Results indicated a small negative effect for global neurocognitive performance as well for most cognitive domains assessed. Unfortunately, methodological limitations of these studies prevented the exclusion of withdrawal symptoms as an explanation for observed effects. In the second meta-analysis, 13 of the original 33 studies met inclusion criteria. Results indicate no significant effect of cannabis use on global neurocognitive performance or any effect on the eight assessed domains. Overall, these meta-analyses demonstrate that any negative residual effects on neurocognitive performance attributable to either cannabis residue or withdrawal symptoms are limited to the first 25 days of abstinence. Furthermore, there was no evidence for enduring negative effects of cannabis use [12350].

Epidemiology of use of cannabis

In 2010, an estimated 22.6 million Americans age 12 or older self-identified as current (past month) illicit drug consumers. A majority of these respondents, some 17.4 million, acknowledged having consumed cannabis. Year 2010 survey data further estimates that some 10.6 million persons, or 4.2 percent of the population age 12 or older, reported driving under the influence of an illicit drug during the past year. Those respondents who were age 18 to 25 were most likely to have reported engaging in this behavior. A previous US government analysis estimated that among those who acknowledge having driven following the consumption of an illicit substance, a majority of respondents, 70 percent, affirm having done so following the ingestion of cannabis. While this total is far from negligible, it is far fewer than the number of respondents who acknowledge having driven while under the influence of alcohol [12351].

Mechanism of action

The structure of THC was described long before its receptors, CB₁ and CB₂ were discovered. CB₁, which has been primarily found in the CNS, likely explains the central psychotropic effects of marijuana. CB₂ receptors, on the other hand, are mainly found in sensory tissue mediating an analgesic effect. Anandamide, an endogenous ligand binds to these receptors. Anandemide, however, appears to also signal via other receptors than CB₁ and CB₂. Future
studies should investigate the effects of exercise on the cannabinoid receptor system and how this is modulated by marijuana use. Numerous cannabimimetics (cannabis receptor agonists) are being developed that have similar pharmacologic effects but limited negative side effects. However, illicit cannabimimetics such as Spice and K2 (synthetic cannabis) with dangerous side effects are on the rise, which is a concerning issue [13008].

**Synthetic cannabinoids**

A number of synthetic cannabinoids such as JWH-018 and JWH-073 have been incorporated into “spice” products. Despite having labels warning against human consumption, the products are smoked for their cannabinoid-like effects and the extent of their use by athletes has not been adequately described. Urine samples collected from 5,956 athletes were analyzed by high-performance liquid chromatography-tandem mass spectrometry for the presence of JWH-018, JWH-073, and their metabolites. Metabolites of JWH-018 and/or JWH-073 were detected in 4.5 percent of the samples. Metabolites of JWH-018 and JWH-073, only JWH-018, and only JWH-073 were detected in 50 percent, 49 percent, and approximately 1 percent of positive samples, respectively. In total, JWH-018 metabolites were detected in 99 percent (50 % + 49 %) and JWH-073 metabolites were detected in approximately 50 percent (49 % + 1 %) of the positive samples. Parent JWH-018, JWH-018-2-OH-indole, and JWH-018-4-OH-indole were not detected in any of the samples. All samples in which JWH-073 metabolites were detected contained JWH-073-N-butanoic acid. Parent JWH-073 and its N-(4-OH-butyl), 4-OH-indole, 5-OH-indole, and 7-OH-indole metabolites were not detected. Given the number of synthetic cannabinoids that have been synthesized, their limited regulation, and the prevalence of JWH-018 and JWH-073 metabolites detected in the athletes, these compounds should remain a priority for anti-doping programs [12352].

**Medical use**

In the first half of the twentieth century, a number of pharmaceutical companies marked cannabis for indications such as asthma and pain, but since then its use has sharply declined, mainly due to its unpredictable effects, but also for socio-political issues. Recently, great attention has been directed to the medical properties of phytocannabinoids present in the cannabis plant alongside the main constituent delta9-tetrahydrocannabinol (THC); these include cannabinoids such as cannabidiol (CBD), cannabigerol (CBG), and tetrahydrocannabivarin (THCV). Evidence suggests an association between cannabis and schizophrenia: schizophrenics show a higher use of marijuana as compared to the healthy population. Additionally, the use of marijuana can trigger psychotic episodes in schizophrenic patients, and this has been ascribed to THC [12353].

**Duration of detection in blood**

The presence of THC may be detectable in the blood of occasional cannabis consumers for several hours after past use. In more chronic users, THC may be present at relatively low blood levels for a period of days after past use, long after any performance impairing effects have dissipated. Carboxy THC may be present for far longer periods of time. In some cases, the presence of carboxy THC has been identified in the urine of chronic cannabis consumers for periods of 30 to 100 days postabstinence [12351].

**Effects**
The main feature of recreational use of cannabis is that it produces a feeling of euphoria with decreased anxiety and increased sociability, which may alleviate the stress generated by competition. However, cannabis can also produce dysphoric reactions, including severe anxiety and panic disorders, paranoia, and psychosis. These undesirable reactions are commoner in naïve, anxious subjects and psychologically vulnerable individuals and occur more frequently after oral use than after smoking. Because cannabis diminishes alertness, and has relaxing and sedative properties, it may be used to improve sleeping time and sleep quality. Lorente and coworkers reported that relaxing, pleasure, and improved sleeping were the main motives to use cannabis as indicated by students from French sport science universities. A good sleep before competition should improve performance. Athletes engaged in “X-treme” sports are more likely to use cannabis. A relation between drug use and “sensation seeking” behaviour has been often reported. Competition level must be also considered as an increased risk factor for cannabis use for coping with stress and anxiety.

There has been an increase in the use of cannabis and cannabis derivatives in some countries, both in society in general and also among members of football clubs, even those at top professional level. However, the issue is not restricted to football; it affects all sports. This has led to increasing concern and uncertainty among young players, parents, coaches, and managers. Sportspeople who consume cannabis derivatives usually restrict themselves to low doses. Consumption usually takes place outside sports facilities and so is beyond the control of team coaches and/or doctors. The lack of control is accentuated by the fact that testing for the substance is only done during competitions. Data gathered from WADA-accredited laboratories show that cannabis is easily the commonest drug leading to positive results, in particular, it is ahead of testosterone and nandrolone. Positive results only relate to competition testing. They do not take into account any positive results found in urine samples taken out of competition; these are not reported by the laboratories. With development of cultivation methods it has become possible to grow cannabis plants that have significantly higher levels of THC than before. These high THC levels may reinforce and change the immediate effects of consumption. The effects of high levels of THC in terms of long term damage to health have not been well documented, although any activity requiring concentration and energy will be affected by its use. The effects of cannabis derivatives are varied with physical and psychological repercussions as well as influencing a player’s social behaviour. Isolated or infrequent consumption can lead to:

- mild intoxication
- sedative effect on behaviour
- slower reaction times
- memory problems
- tendency towards drowsiness

In terms of the effects on the body, although heightened sensory perception can be expected, THC also engenders a certain heaviness, marked relaxation, and excessive fatigue of the limbs. As the dose increases, the user may experience hallucinations, an alteration of the perception of reality, and a marked reduction in concentration. Furthermore, as these products are generally smoked, this can only have a negative effect on sporting performance and the player’s health (detrimental effects on the lungs, oral cavity, and upper respiratory tract). As regards psychological and social behaviour, cannabis accentuates the mood. So a user may become carefree, happy, and relaxed, but also risks becoming stressed, depressed, or paranoid. Other effects on a user include reduced inhibition and developing a certain indifference. Regular consumption leads to psychological dependence, a chronic sedative effect, and even social detachment.
Exercise increases THC levels

The major psychoactive ingredient of cannabis, delta(9)-tetrahydrocannabinol (THC) accumulates in fat tissue from where it slowly diffuses back into blood. THC pre-treated rats can show elevated plasma cannabinoid levels when subjected to conditions that promote fat utilization, such as fasting. Here we examine whether fasting and exercise increase plasma THC concentrations in regular cannabis users. Fourteen regular cannabis users completed 35 min of exercise on a stationary bicycle in either a fed or overnight fasted state. Plasma cannabinoid levels were assessed prior to exercise, immediately post-exercise and 2 h post-exercise. Plasma samples were also analyzed for indices of lipolysis (free fatty acids (FFA) and glycerol). Exercise induced a small, statistically significant increase in plasma THC levels accompanied by increased plasma FFA and glycerol levels. Exercise-induced increases in plasma THC concentrations were positively correlated with body mass index. Fasting induced a significant increase in plasma FFA levels, and a lowering of blood glucose, but did not significantly alter plasma cannabinoid levels. Thus it was demonstrated that exercise enhances plasma THC levels in regular cannabis users. The lack of a fasting effect may reflect the modest duration of fasting used which was associated with only a modest increase in fat utilization relative to exercise. Overall, these results suggest that exercise may elevate blood THC levels by releasing dormant THC from fat stores. These data suggest the interpretation of blood THC levels in roadside and workplace tests might be complicated by recent exercise [13497].

Influence on psychomotor performance

In closed course and driving simulator studies, cannabis’s acute effects on psychomotor performance may include increased break latency, variation in lateral positioning (weaving), increased headway (leaving greater distance between the subject’s vehicle and the car in front of them), decreased performance in critical tracking and divided attention tasks, reduced speed, and decreased reaction time. Notably, these changes in performance are more likely to be manifested by subjects’ performance on driver simulator tests as compared to assessment of subjects’ actual on-road driving performance. In general, cannabis-influenced variations in driving behavior are often the opposite of those effects exhibited by subjects under the influence of alcohol. Unlike subjects impaired by alcohol, individuals influenced by cannabis are typically aware of their impairment and “tend to compensate effectively” for it, either by driving more cautiously or by expressing an unwillingness to drive altogether. Further, numerous studies report that experienced cannabis users develop tolerance to many of the changes in cognitive or psychomotor performance associated with acute cannabis intoxication. The peak THC blood levels following inhalation do not consistently correspond with levels of peak behavioural impairment. Rather, subjects who inhale THC typically ascertain their highest THC blood levels within minutes, well before the substance’s adverse cognitive or psychomotor effects are at their most significant. Also, cannabis’ effect on psychomotor performance varies widely among individual subjects, particularly among those who are cannabis experienced versus those who are naïve. Experts have cautioned that an accumulation of THC in chronic consumers leads to cannabinoid concentrations in sober phases that resemble concentrations found in occasional users after acute cannabis use, therefore making the universal application of a specific blood/THC impairment standard in many cases inappropriate. However, because inhaled cannabis’ influence on psychomotor behaviour is often subtle, particularly in contrast to those associated with alcohol, and short-lived, consumers of the substance can greatly reduce their risk by refraining from driving for a period of several hours immediately following their cannabis use. Past use of cannabis, as defined by the detection solely of inactive cannabis metabolites in the urine of drivers, is not associated with an increased accident risk [12351].
Cannabis use in sports

Cannabinoids accounted for 13-14 percent of all AAFs reported by the IOC between 1998 and 2003. Since the enforcement of the 2004 WADA Code, when cannabinoids were prohibited in all sports, a significant decrease in cannabinoid-related AAFs from 16 percent to 8 percent was observed. These percentages place cannabinoids as the third most reported prohibited substance in 4 of the last 7 years of compiled WADA laboratory statistics (2003–9) and the second most reported in 2008–9 following anabolic agents. In a social context, cannabis is the most prevalent illicit drug abused in many countries. The use of cannabinoids peaks during the late teens to early twenties, decreasing thereafter to half peak prevalence by age 30. Based on these statistics, cannabis in sport would appear to reflect levels of recreational use reported in many countries, as elite athletes are in general young adults. Sanctions for a first positive result for cannabinoids range from a warning to a 2-year ban, with positive results on repeated occasions leading to a potential lifetime ban. In recent positive cannabinoid cases, there were serious consequences for the athlete’s image and sponsorship endorsement, even if the elite athlete stated the use was out of-competition. Based on WADA statistics, some sports report higher percentages of cannabis use than others, but there does not appear to be a pattern of abuse related to the degree of risk inherent in the sport, the abilities required for each type of sport or the psychological pressure related to exposure to the public. A specific culture of a sport and/or the athlete’s personal decision appears to be the primary motivation for using cannabis in sport. The significant decrease in AAFs for cannabinoids in-competition also stresses the importance of implementing such a tight anti-doping regulation in sport [11584].

Influence of nandrolone on cannabinoid dependence

The identification of the possible factors that might enhance the risk of developing drug addiction and related motivational disorders is crucial to reduce the prevalence of these problems. Here, it was examined in mice whether the exposure to the anabolic-androgenic steroid nandrolone would affect the pharmacological and motivational effects induced by Delta(9)-tetrahydrocannabinol (THC), the principal psychoactive component of Cannabis sativa. Mice received nandrolone using pre-exposure (during 14 days before THC treatment) or co-administration (1h before each THC injection) procedures. Both nandrolone treatments did not modify the acute antinociceptive, hypothermic and hypolocomotor effects of THC or the development of tolerance after chronic THC administration. Nandrolone pre-exposure blocked THC- and food-induced conditioned place preference and increased the somatic manifestations of THC withdrawal precipitated by the CB1 cannabinoid antagonist rimonabant (SR141617A). The aversive effects of THC were not changed by nandrolone. Furthermore, nandrolone pre-exposure attenuated the anxiolytic-like effects of a low dose of THC without altering the anxiogenic-like effects of a high dose in the lit/dark box, open field and elevated plus-maze. Biochemical experiments showed that chronic nandrolone treatment did not modify CB1 receptor binding and GTP-binding protein activation in the caudate-putamen and cerebellum. Taken together, the results suggest that chronic nandrolone treatment alters behavioural responses related to cannabinoid addictive properties [06227].

Cannabis in urine

The active substance in cannabis is tetrahydrocannabinol (THC). It is metabolised into its main metabolite carboxy-THC and conjugated, and then excreted chiefly in the urine. According to the World Anti-Doping Agency (WADA) standards, urine samples are considered positive for cannabis exposure if the sum of the concentrations of free and
conjugated carboxy-THC is greater than 15 microg/l, when determined by gas-chromatography/mass spectrometry. This threshold value distinguishes active users from passive smokers. It makes also less likely a positive result due to intake of commercial foods containing traces of cannabinoids. Since the mid-1990s, the ingestion of food products containing seeds or hemp seed oil has increased considerably in several Western countries. However, several US states have enacted regulatory limits for THC in foodstuffs and beverages, thus lowering THC intake from hemp containing foods and reducing the risk of a positive urine test. Regulations in Canada, the main supplier of hemp seeds to the USA, limit THC levels in hemp seed products to 10 parts per million (ppm). There are several other problems with carboxy-THC analysis in urine. The relevance of the 15 ng/ml cut-off value could be improved by correcting the THC concentration with the creatinine level. With this approach, the quantitative results would be corrected for urine dilution and possible adulteration. It will also be possible to predict repetitive or new marijuana use by analysis of the urinary cannabinoid to creatinine ratio in two consecutive urine samples collected at least 24 hours apart. Quantitation of carboxy-THC in urine alone cannot predict time of last marijuana use or suggest any relation between urine concentration and psychomotor effects. It has been found that occasional users of marijuana had positive urine specimens for three to four days after receiving a standard dose of marijuana. In heavy smokers, urine specimens have been shown to remain positive for seven to ten days after last drug use. It has also been reported an average time until the last positive result of 32 days (4–77 days) in urine for THC metabolites screened by immunoassay with a cut-off value of 20 ng/ml. According to some researchers determination of the time of last cannabis use is possible by measuring total THC in urine. Significant levels of THC could be measured by including a hydrolysis step in the extraction protocol. A concentration greater than 1.5 ng/mL would suggest marijuana use within a five hour time window, a time during which psychological and performance effects are known to occur [06226].

An abnormal result must be announced for cannabis if the main metabolite of THC, carboxy-THC, is discovered in a player's urine at a level in excess of 15 microg/l as a result of competition testing. This limit has been established to distinguish between active consumers and smokers of cannabis and players who may have been passively exposed to cannabis smoke. The limit also reduces the risk of a positive urine result after the consumption of some commercial products which contain traces of cannabis. The use of hemp seed and oil in food products has increased considerably in some Western countries since the mid-1990s. The authorities have acted to impose limits on THC levels such that the consumption of these commercial products will not bring about positive urine results. It should be noted that the elimination of THC metabolites from urine is a slow process and depends on individual physiology. In this way, a simple quantification of the urinary concentration of carboxy-THC reveals little information on the time elapsed since consumption. The quantity discovered in urine depends on various factors:

- dosage of the most recent consumption
- time elapsed between the most recent consumption and taking the urine sample
- manner of consumption (single dose or regular consumption)
- individual metabolism

When these factors are taken into account, it is extremely difficult to establish a relation between urinary concentration and the effects on an individual's psychomotor skills. Despite these considerations, some scientific studies have shown that on the occasional consumption of a normal dose (a "joint"), the user will have a positive result for carboxy-THC for three, four or even five days, depending on the smoker's body mass. In this way consuming marijuana with friends a few days before a match could be disastrous for a football player as there would be a considerable risk of failing a doping test. The pretext of
recreational use is no longer valid. Even if cannabis is taken without the intention of improving performance, the outcome will be a positive result if the urinary level exceeds the authorised threshold. For regular users – for example, those who smoke cannabis several times a week – urine samples would remain positive for a much longer time after the most recent consumption. Scientific research published on this subject has shown that the time until urine samples return negative outcomes can be as much as four weeks (two weeks on average) after the most recent consumption [06226].

Does cannabis have a doping effect?

The question often asked in the case of a positive result for cannabis is whether it was consciously used for doping purposes. The answer is that this substance can only indirectly improve performance – it can have a euphoric effect, reducing anxiety and increasing the sociability of a player who may be particularly nervous before an important match. It can also have a relaxing effect after the game. In this way, cannabis can be considered as a doping product that calms the mind. It has already been described that use of cannabis in sporting environments is basically motivated by the effects of relaxation and wellbeing, allowing the user to sleep more easily. However, if consumed regularly, it risks harming performance and motivation. It is when cannabis is consumed regularly that the signs become apparent in young athletes. There may be changes in behaviour during training as well as inconsistent performance, concentration, or motivation. Particular care should be taken when a player is vulnerable, for example if lacking support, during prolonged or repeated injury, when isolated from family or if subject to excessive pressure for results on the pitch. In these cases it is up to the club coaches and doctors to look out for any symptoms that may appear and to intervene tactfully, although firmly, when necessary. In some cases referral to a psychologist will be necessary [06226].

The ergogenic effects of marijuana are questionable, as its performance enhancing effect, if any, has yet to be established. Along these lines, very few studies have tested the effects of marijuana on performance. One of the first studies to evaluate the effects of marijuana tested the effects of marijuana smoking compared to placebo on several indices of exercise performance. Resting heart rate and both systolic and diastolic blood pressure were significantly elevated at rest after marijuana consumption compared to both control and placebo. Although there was no significant decrease in grip strength, physical work capacity at a heart rate of 170 decreased by 25 percent compared to placebo. It was tested subjects 10 min after smoking a marijuana cigarette (containing 1.7 % of delta⁹-THC) of 7 mg/kg of body weight, and noted a slight, but significant decrease in cycle ergometry time to exhaustion. It was demonstrated that double-blind administration of marijuana as 7.5 mg of delta⁹-THC or placebo did not affect blood pressure, ventilation or oxygen uptake during submaximal exercise (15 min at 50 % of VO₂max), however did increase heart rate and the rate-pressure product at rest and during both exercise and recovery. In another study it was hypothesized that the decrease in exercise performance may be due to its chronotropic effect leading to achievement of maximum heart rate at reduced workloads. Furthermore, detrimental effects on other aspects of performance have also been demonstrated. When subjects were acutely given THC orally (215 microg/kg) acutely, significant deficits in general performance, standing steadiness, reaction time and psychomotor performance were observed over a 5 hour period post-ingestion. Interestingly, in a case report, it was documented that in a patient with asthma, a condition characterized by bronchoconstriction, smoking marijuana prior to exercise testing led to bronchodilation and no defect in pulmonary function. Thus, if there is any positive effect of marijuana, it likely only indirectly improves performance. It is conceivable that cannabis may reduce an athlete’s feelings of pre-competition stress and anxiety as a result of the euphoric effect it may produce. Also, because cannabis diminishes alertness and has relaxing and sedative properties, use may
be driven by the effects of relaxation, well-being and improved sleep quality. For example, it has been reported that relaxing, pleasure, and improved sleeping were the main motives to use cannabis, with the rationale that adequate sleep and being relaxed before competition may lead to optimal performance. However, due to the trade-off of decreased exercise performance, possibly secondary to increases in heart rate and blood pressure, which may alter perceived exertion, marijuana may be considered an ergolytic agent [13008].

Overall, it appears that cannabis does not have ergogenic potential in sports activities and thus, its inclusion on the banned list is likely a function of its illicitness. As cannabis smoking impairs exercise and psychomotor performance (such as sedative effect, slower reaction times and other psychomotor effects), its ability to serve as an ergogenic aid has been questioned, and is generally considered to be an ergolytic drug. This is likely due to increase in heart rate and blood pressure, decline of cardiac output and reduced psychomotor activity that have been demonstrated in prior studies [13008].

### Endogenous

Marijuana is the most commonly used illegal drug, particularly in Western societies. The discovery of an endogenous cannabinoid system (ECS) highlighted new molecules in various physiological processes. The ECS consists of G-protein-coupled cannabinoid receptors that can be activated by small lipid mediators, termed endocannabinoids (eCBs) and cannabis-derived drugs, plus the associated biochemical machinery (precursors, synthesis and degradative enzymes, and transporters). Several biochemical, pharmacological and physiological studies have shown that endocannabinoid system elements are widely distributed throughout the body, with regional variations and organ-specific actions. This review portrays the endocannabinoid "family" on new studies concerning eCB storage, release and functional roles and on the growing importance of its bioactive metabolites. Those findings reinforce and confirm the importance of ECS. Strategies for manipulating the system for the treatment of human disease will require a thorough understanding of the roles of the different eCBs and their sources [13491].
The endocannabinoid system has been implicated in the regulation of a variety of physiological processes, including a crucial involvement in brain reward systems and the regulation of motivational processes. Behavioral studies have shown that cannabinoid reward may involve the same brain circuits and similar brain mechanisms with other drugs of abuse, such as nicotine, cocaine, alcohol and heroin, as well as natural rewards, such as food, water and sucrose, although the conditions under which cannabinoids exert their rewarding effects may be more limited. The purpose of one review was to briefly describe and evaluate the behavioral and pharmacological research concerning the major components of the endocannabinoid system and reward processes. Special emphasis is placed on data received from four procedures used to test the effects of the endocannabinoid system on brain reward in animals; namely, the intracranial self-stimulation paradigm, the self-administration procedure, the conditioned place preference procedure and the drug-discrimination procedure. The effects of cannabinoid 1 (CB1) and cannabinoid 2 (CB2) receptor agonists, antagonists and endocannabinoid modulators in these procedures are examined. Further, the involvement of CB1 and CB2 receptors, as well the fatty acid amid hydrolase (FAAH) enzyme in reward processes is investigated through presentation of respective genetic ablation studies in mice. We suggest that the endocannabinoid system plays a major role in modulating motivation and reward processes. Further research will provide us with a better understanding of these processes and, thus, could lead to the development of potential therapeutic compounds for the treatment of reward-related disorders [13492]

“Spice”

Over 60 cannabinoids are present in cannabis, with delta9-tetrahydrocannabinol (THC) the main psychoactive constituent and responsible for the observed toxic effects after smoking, while other cannabinoids are responsible for minor effects, such as cannabiol (CBN), which is 10 percent as psychoactive as THC. THC is lipophilic and stores in several organs, especially in adipose tissue; this extensive body burden explains the prolonged cannabinoid detection rate in blood and urine for at least 4 weeks in chronic daily cannabis smokers. The WADA establishes a 15 ng/mL urinary 11-nor-9-carboxy-THC (THCCOOH) threshold; urine analyses involves THCCOOH-glucuronide conjugates cleavage, which significantly increases free THCCOOH concentrations and detection time. Urinary THCCOOH concentrations above the 15 ng/mL threshold are considered Adverse Analytical Findings and may be interpreted as a violation of anti-doping rules. Studies showed that even occasional and single cannabis smoking might yield a THCCOOH positive result (≥15 ng/mL) for up to 5 days. Thus, consuming cannabis even weeks before a match may imply a considerable risk of being detected in a doping test. In light of this considerable risk, some users started using a new preparation of herbal smoking blends named “Spice.” Such substances are highly potent cannabinoid analogs, with unknown and potentially harmful toxicological properties that may cause prolonged intoxication. These substances mimic or worsen cannabis’ toxic effects provoking cognitive and motor impairment [13489].

CP 47,497, a potent cannabinoid receptor type 1 agonist, is the main active ingredient in the herbal mixture "Spice" sold in European countries. The illegal use of "Spice" for its psychoactive effects has become a social issue. In this study, the in vitro metabolism of CP 47,497 was investigated in human liver microsomes to characterize the metabolic fate of CP 47,497. CP 47,497 was incubated with human liver microsomes, and the reaction mixture was analyzed using liquid chromatography-tandem mass spectrometry. A total of eight metabolites were detected in human liver microsomes and structurally characterized based on mass spectral data. The main metabolic pathways involved hydroxylations or oxygenations. The identified metabolites were mono-oxygenated metabolites (M1 and M4), mono-hydroxylated metabolites (M3, M5, M6, M7, and M8), and a di-oxygenated metabolite
The detection of these metabolites could confirm the presence of CP 47,497 in biological samples; therefore, collectively, they would be excellent indicators of "Spice" drug abuse [13493].

Synthetic cannabinoid receptor agonists are becoming increasingly popular with adolescents as an abused substance. Chronic use of these drugs can lead to addiction syndrome and withdrawal symptoms similar to cannabis abuse. Due to their potential health risk, several countries have banned these substances. It was reported the clinical presentation and legislation status of synthetic cannabinoids in “Spice” products and alert the health care community about the identification and risk assessment problems of these compounds. It was retrospectively reviewed cases presenting to our Emergency Department (ED) during a 3-month period with chief complaints of Spice drug use before arrival. Six cases presented to our ED after using Spice drugs. Two patients were admitted after reporting seizures. All but one presented with tachycardia. Two patients had hallucinations. The average length of ED observation was 2.8 h. No patient with seizures had recurrent episodes. Spice drugs can cause potentially serious health care conditions that necessitate ED evaluation. Most cases can be discharged from the ED after a period of observation. Legal issues surrounding these drugs are yet to be finalized in the United States [13494].

The non-psychoactive cannabidiol (CBD) is anxiolytic in humans following a single dose; decreased anxiety and fear memories extinction after oral CBD intake may enhance sports performance with no “violation” of the Code, as no THCCOOH is detected in urine. One way to protect athletes’ health and to promote health, fairness, and equality in sports is to include any illicit drugs, their constituents and analogs in the anti-doping program. The sports may assist to create educational program for youth and athletes as an alternative to keep them away from drugs and to preserve the intrinsic value about the “spirit of sport” [13489].

**Occasional or frequent smokers**

There is extended urinary excretion of delta9-tetrahydrocannabinol (THC), 11-hydroxy-THC (11-OH-THC), and 11-nor-9-carboxy-THC (THCCOOH) in abstinent frequent cannabis smokers. It was characterized THC, 11-OH-THC, THCCOOH, cannabidiol, cannabinol, THC-glucuronide, and THCCOOH-glucuronide disposition in urine of frequent and occasional cannabis smokers, and we propose a model to predict recent cannabis smoking. Frequent and occasional smokers resided on a closed research unit and smoked one 7 percent THC cannabis cigarette ad libitum. Urinary cannabinoids were quantified in each void by liquid chromatography-tandem mass spectrometry within 24 h of collection. No urine samples had measureable THC, 11-OH-THC, cannabidiol, or cannabinol. THCCOOH, THC-glucuronide, and THCCOOH-glucuronide were measurable in all frequent smokers’ urine and 60, 100, and 100 percent of occasional smokers’ urine samples, respectively. Pre- and postdose maximal concentrations (non- and creatinine normalized) and probability of being positive were significantly higher in frequent smokers' samples. THC-glucuronide concentrations peaked 0.6-7.4 h after smoking; THCCOOH and THCCOOH-glucuronide concentrations were highly variable. At the newly adopted THCCOOH 175 microg/L World Anti-Doping Agency decision limit, only 50 percent of frequent smokers were positive 0-6 h postdose; no occasional smokers' samples were positive. An absolute percentage difference of ≥50 percent between 2 consecutive THC-glucuronide-positive samples with a creatinine-normalized concentration of ≥2 microg/g in the first sample predicted cannabis smoking with efficiencies of 93 percent in frequent and 77 percent in occasional smokers within 6 h of first sample collection. These controlled urinary cannabinoid data provide a possible means of identifying recent cannabis intake in cannabis smokers' urine within a short collection time frame after smoking [13500].
Side effects

In March 2012, the Wyoming Department of Health was notified by Natrona County public health officials regarding three patients hospitalized for unexplained acute kidney injury (AKI), all of whom reported recent use of synthetic cannabinoids (SCs), sometimes referred to as "synthetic marijuana." SCs are designer drugs of abuse typically dissolved in a solvent, applied to dried plant material, and smoked as an alternative to marijuana. AKI has not been reported previously in users of SCs and might be associated with a previously unrecognized toxicity, a contaminant or a known nephrotoxin present in a single batch of drug, or a new SC compound entering the market. After the Wyoming Department of Health launched an investigation and issued an alert, a total of 16 cases of AKI after SC use were reported in six states. Review of medical records, follow-up interviews with several patients, and laboratory analysis of product samples and clinical specimens were performed. The results of the investigation determined that no single SC brand or compound explained all 16 cases. Toxicologic analysis of product samples and clinical specimens (available from seven cases) identified a fluorinated SC previously unreported in synthetic marijuana products: (1-(5-fluoropentyl)-1H-indol-3-yl)(2,2,3,3-tetramethylcyclopropyl) methanone, also known as XLR-11, in four of five product samples and four of six patients' clinical specimens. Public health practitioners, poison center staff members, and clinicians should be aware of the potential for renal or other unusual toxicities in users of SC products and should ask about SC use in cases of unexplained AKI [13495].

Marijuana is the most widely used illicit drug by pregnant women in the world. In utero exposure to 79-tetrahydrocannabinol (79-THC), a major psychoactive component of marijuana, is associated with an increased risk for anencephaly and neurobehavioural deficiencies in the offspring, including ADHD (attention deficit hyperactivity disorder), learning disabilities and memory impairment. The developing central nervous system (CNS) is susceptible to the effects of 79-THC and other cannabimimetics, including the psychoactive ingredients of “Spice”. These exocannabinoids interfere with the function of an endocannabinoid (eCB) system [12349].

Heart

As with cocaine, marijuana and hashish are used by athletes, not so much for their ergogenic action, as because of addiction. Cases of acute myocardial infarction, arrhythmias, and sudden death have been described among athletes who use them. The cardiovascular complications are mainly due to sympathomimetic action and to suppression of peripheral vasoreflexes. These pathophysiological mechanisms lead to increased demand and at the same time decreased supply of oxygen, as well as the presence of arrhythmias [12126].

Coronary artery disease (CAD) remains a major public health problem in the world. Acute coronary syndromes (ACS) mainly affect patients with cardiovascular risk factors. It was reported a case of an exercise-induced ACS in a 24-year-old soccer player without any classic cardiovascular risk factor, but with a history of massive cannabis addiction. Coronary angiography showed complete occlusion of the proximal right coronary artery and intravascular ultrasound revealed an atherosclerotic plaque disruption. Thromboaspiration and antithrombotic treatment were successful and coronary stenting was not performed. The respective roles of cannabis toxicity and physical activity as triggers for ACS in young people are discussed [13498].

Ischemic stroke. It was reported on a 16-year-old body builder who suffered from an acute ischemic stroke. In the urine, cannabis metabolites as well as metabolites of the oral androgenic-anabolic steroid methandrostenolone were detected, both known to be
associated with stroke events. One report highlights the role of cannabis and steroid abuse that induce strokes in the absence of arteriopathy, cardioembolism or thrombophilia. Owing to new upcoming socio-behavioral aspects of late childhood and early adolescent life, this formally rare abuse of cannabis and/or anabolic steroids as well as their associations with strokes becomes more current than ever [13496].

**Laboratory techniques**

Testing for cannabis in the form of marijuana, hashish or other cannabis containing products is performed by urine analysis. The target molecule detected in urine analysis is 11-nor-9-carboxy-delta²⁷-THC, with the limit for a positive test at >15 ng/mL. Detection is determined by gas-chromatography/mass spectrometry, and this threshold distinguishes active users from passive smokers and foods that contain traces of cannabinoids [13008].

The identification of 11-nor-delta9-tetrahydrocannabinol-9-carboxylic acid (THCCOOH) in hair represents an exceptional forensic analytical challenge due to low target concentrations in a complex matrix. Several dedicated techniques (gas chromatography – negative chemical ionization-tandem mass spectrometry (GC-NCI-MS/MS) or GC-GC-MS couplings) were specifically introduced into forensic toxicology aiming to a selective and sensitive identification of THCCOOH in hair. The combination of liquid-chromatography (LC) and MS/MS gained an outstanding relevance in forensic toxicology (including the detection of cannabinoids). However, its application to hair matrix is characterized by a lack of specificity which is due to the unspecific decarboxylation as most abundant fragmentation reaction. Therefore, various chemical modifications of the carboxyl and/or phenolic hydroxyl groups were examined to improve the selectivity. The selective methylation of the 9-carboxyl-group proved to be the most efficient derivatization procedure. Hair extracts were redissolved in acetonitrile and after addition of few milligrams of solid sodium carbonate derivatized with 25 microL methyl iodide. The resulting THC-9-carboxymethylester was separated by conventional reverse phase LC and selectively detected using negative electrospray ionization by recording the fragmentation reactions 357➔325 and 357➔297. Resulting limits of quantification were below 100 fg/mg. A further significant improvement was achieved by application of the multistage MS3 fragmentation 357➔325➔297. To verify the validity of this procedure, a systematic quantitative comparison of THCCOOH concentrations in hair with data from a well established GC-NCI-MS/MS technique was performed. Both techniques proved to be in good accordance and equally suitable for hair testing of THCCOOH [13499].

A rapid and sensitive determination of cannabinoids in urine is important in many fields, from workplace drug testing over toxicology to the fight against doping. The detection of cannabis abuse is normally based on the quantification of the most important metabolite 11-nor-Δ⁹-tetrahydrocannabinol-9-carboxylic acid (THCA) in urine. In most fields THCA needs to be present at a concentration of exceeding 15 ng/mL before a positive result can be reported. The method described in this paper, combines a 4min GC-MS/MS method with a fast sample preparation procedure using microwave assisted derivatisation in order to complete the quantification of THCA in urine in 30 min, using only 1 mL of urine. The method is selective, linear over the range 5-100 ng/mL and shows excellent precision and trueness and hence, the estimated measurement uncertainty at the threshold level is small. The method also complies with applicable criteria for mass spectrometry and chromatography. Therefore the method can be used for rapid screening and confirmatory purposes [12354].
Most substances on WADA’s Prohibited List are banned at all times; however, compounds belonging to the sections S6-S9 or P1 and P2 are not relevant for doping controls in out-of-competition periods. Within a two-year monitoring program (2006 and 2007), the prevalence of so-called non-specified stimulants in athletes’ urine samples was assessed yielding 0.36% adverse analytical findings in approximately 25 000 analyzed specimens, demonstrating that cocaine was by far the most frequently detected “prohibited” substance. These numbers led to the conclusion that no systematic abuse of stimulants during out-of-competition periods prevails [12017].

Tropane alkaloids like atropine are antidotes applied against organophosphorus intoxications. Atropine is toxic itself and should be closely monitored during treatment. Hence, simple, fast, and sensitive determination methods for tropane alkaloids in serum are desirable. Mostly adopted methods of analysis are gas chromatography (GC); high performance liquid chromatography (HPLC), and capillary electrophoresis (CE). Various liquid and solid capillary fillings used in micellar electrokinetic chromatography, microemulsion electrokinetic chromatography, capillary electrophoresis, and enantioseparation provide high versatility to CE applications. In HPLC, specialised columns enhance separation efficacy. Ultraviolet light detection is common practise, but recently sensitivity and analyte identification were enhanced by coupling GC, HPLC, and CE to mass spectrometry. Apart from medical treatment, tropane alkaloids, cocaine in particular, are abused with various intentions. Forensic analysis of tropane alkaloids and their metabolites comprises the additional difficulty of unequivocal drug identification. Because of severe legal consequences, sophisticated analytical methods were developed and may provide additional techniques for therapeutic drug monitoring. Examples from forensic cocaine analysis and from doping analysis were included in the review [10195].

An accurate and precise method for the quantification of 11-nor-delta9-tetrahydro-cannabinol-9-carboxylic acid (THCA) in urine by liquid chromatography/tandem mass spectrometry (LC/MS/MS) for doping analysis purposes has been developed. The method involves the use of only 200 microL of urine and the use of D9-THCA as internal standard. No extraction procedure is used. The urine samples are hydrolysed using sodium hydroxide and diluted with a mixture of methanol/glacial acetic acid (1:1). Chromatographic separation is achieved using a C8 column with gradient elution. All MS and MS/MS parameters were optimised in both positive and negative electrospray ionisation modes. For the identification and the quantification of THCA three product ions are monitored in both ionisation modes. The method is linear over the studied range (5-40 ng/mL), with satisfactory intra- and inter-assay precision, and the relative standard deviations (RSDs) are lower than 15 percent. Good accuracy is achieved with bias less than 10% at all levels tested. No significant matrix effects are observed. The selectivity and specificity are satisfactory, and no interferences are detected. The LC/MS method was applied for the analysis of 48 real urine samples previously analysed with a routine gas chromatography/mass spectrometry (GC/MS) method. A good correlation between the two methods was obtained) with a slope close to 1 [10196].

It is frequently questioned whether cannabinoids are detectable in urine from individuals having been passively exposed to hashish or marihuana smoke. Literature was reviewed to shed light on an issue that is often debated in the health services, judicial system and in sports. A Medline search with the index terms "cannabis", "hashish", "marihuana" was conducted in September 2007. Summaries, abstracts and reference lists of selected articles were screened for relevancy. Seven experimental studies with humans were identified. Cannabinoids were detected in urine in two studies where the subjects had been exposed to high smoke levels. In studies conducted under less extreme conditions no urine samples were positive for more than a few hours after exposure and the measured cannabinoid levels
were low. When cannabinoids are detected in urine with conventional methods and limits of quantification the results are commensurate with active smoking [09291].

One study was designed to determine the effect of delta-9-tetrahydrocannabinol (THC) on susceptibility to stress. It was reported that THC significantly prolonged the immobility time during the forced swim-stress. The selective cannabinoid CB1 receptor antagonist O-2050 significantly reduced the enhancement of immobility by THC. It was investigated the effect of THC on levels of stress hormone corticosterone under non-stress and forced swim-stress conditions. THC did not affect plasma corticosterone levels under non-stress conditions. However, THC, together with forced swim-stress, significantly increased plasma corticosterone levels. This effect was inhibited by O-2050. This evidence suggests that THC, under stressful conditions, enhances the susceptibility of the hypothalamus-pituitary-adrenal-axis to stress via the CB1 receptor, thereby increasing the risk of depression [09292].

Cocaine has been used as a medicine for many years. It was also one of the original ingredients of Coca-Cola until it was removed in 1903. Its therapeutic indication is as a local anaesthetic, although misuse is linked to its euphoric effects and feeling of decreased fatigue. Its potential for use as a recreational drug emphasises the lifestyle pressures faced by some athletes. In some disciplinary sports, such as sprinting, cocaine is likely to increase production of heat and lactic acid, which, coupled with vasoconstriction, could contribute to fatal cardiac arrest [06171].

Cocaine is the most potent stimulant of natural origin. As opposed to amphetamines, which are pure synthetic compounds, cocaine is primarily obtained from Coca species and its notoriety belies the fact that the drug has been used as a stimulant for thousands of years. The Incas used to chew Coca leaves to fight against tiredness; cocaine was used in a number of patent medicines and even in soft drinks. In its pure form, cocaine is a white crystalline powder extracted from the leaves of the South American Coca plant. Pure cocaine was first used medicinally in the 1880s as a local anaesthetic in eye, nose, and throat surgery because of its ability to provide anaesthesia as well as to constrict blood vessels and limit bleeding. Many of its therapeutic applications are obsolete due to the development of safer drugs. Cocaine can be snorted, smoked, or injected. When snorted, cocaine powder is inhaled through the nose and absorbed into the bloodstream through the nasal tissues. When injected, a needle is used to release the drug directly into the bloodstream. Smoking involves inhaling cocaine vapour or smoke into the lungs, from where absorption into the bloodstream is as rapid as by injection. Each of these methods of administration pose great risks to the user. Crack is cocaine that has been processed from cocaine hydrochloride to a free base for smoking. The most popular route of administration is snorting, which produces peak effect in 5-15 minutes, lasting for up to one hour. Inhalation of free-base cocaine produces peak effects in less than one minute and a short lived physiological effect measured in minutes [06171].

Most substances on WADA's Prohibited List are banned at all times; however, compounds belonging to the sections S6-S9 or P1 and P2 are not relevant for doping controls in out-of-competition periods. Within a two-year monitoring program (2006 and 2007), the prevalence of so-called non-specified stimulants in athletes' urine samples was assessed yielding 0.36 percent adverse analytical findings in approximately 25 000 analyzed specimens, demonstrating that cocaine was by far the most frequently detected "prohibited" substance. These numbers led to the conclusion that no systematic abuse of stimulants during out-of-competition periods prevail and that the current structures of the Prohibited List (considering two scenarios with in- and out-of-competition testing) are justified [13012].

**Environmental factors important for abuse**
Decades of experimentation with a variety of pharmacological treatments have identified some effective therapy for heroin addiction but not for cocaine addiction. This may be due, at least in part, to our incomplete understanding of the factors involved in the differential vulnerability to these addictions. Cocaine addiction and heroin addiction are often considered mere variations of the same disorder, and the preference for one drug or another has been variously attributed to factors such as drug availability or price, to the addict's lifestyle, or even to chance. Yet there is evidence of substance-specific influences on drug taking. In particular, data from twin registries suggest that a sizeable portion of the variability in the susceptibility to drug abuse is due to environmental factors that are unique to opiates or to psychostimulants. Very little is known about the underpinnings of these epidemiological data. We report here original data indicating that the setting of drug taking exert a differential influence on heroin versus cocaine use in human addicts. It was also reviewed additional clinical and pre-clinical data pointing to fundamental differences in the way in which the environment interacts with cocaine relative to heroin and other addictive drugs. These findings – as well as other evidence, including the lack of pharmacological treatments effective for both cocaine and heroin addiction – support the notion that much is to be gained by taking into account the substance-specific aspects of drug addiction. At a therapeutic level, for example, it appears reasonable to propose that cognitive-behavioral approaches should be tailored in a substance-specific manner in order to allow the addict to anticipate, and cope with, the risks associated to the various environmental settings of drug use [13520].

**Effects**

Cocaine is a strong CNS stimulant and is probably the most addictive agent known. Its recreational use is widespread, and it is highly addictive with its effect mediated through dopamine release. For ethical and practical reasons, most of the knowledge of the pharmacology of cocaine comes from animal studies or from addict reports. Classic physical effects of cocaine use include constricted blood vessels, dilated pupils and increased temperature, heart rate and blood pressure. It also increases motor activity and talkativeness and is a strong inducer of euphoria. The duration of cocaine's immediate euphoric effects (hyperstimulation, reduced fatigue, and mental clarity) depends on the route of administration. The faster the absorption, the more intense are the effects and the shorter the duration of action. The effects from snorting may last 15-30 minutes whereas the effects from smoking may last 5-10 minutes. Increased use can reduce the period of time a user feels high and increases the risk of addiction. Cocaine users usually feel an initial “rush” or sense of well-being, of having more energy and being more alert. This effect quickly wears off, often leaving the user feeling more “down” or depressed than before. This down feeling leads the addict to use more cocaine, sometimes just to feel “normal”. Over a period of time, the amount of cocaine needed and the frequency of use to achieve a “high” have to be increased. Cocaine is more addictive than amphetamine and the increasingly higher doses used by addicts may lead to a state of irritability, restlessness, anxiety, and paranoia. Other complications associated with cocaine use include disturbances in heart rhythm and heart attacks, chest pain and respiratory failure, strokes, seizures and headaches, and gastrointestinal complications such as abdominal pain and nausea. Cocaine misuse is strongly associated with cerebrovascular accidents arising either from rupture or spasm of cerebral blood vessels. Different means of taking cocaine can produce different adverse effects. Regular snorting, for example, can lead to loss of sense of smell, nosebleeds, problems with swallowing, hoarseness, and a chronically runny nose. Ingesting cocaine can cause severe bowel gangrene due to reduced blood flow. People who inject cocaine can experience severe allergic reactions and, as with any injecting drug user, are at increased
risk for contracting human immunodeficiency virus (HIV) infection and other bloodborne diseases [06171].

**Cocaine in sport**

Despite the popular myth, cocaine does not really enhance performance, whether in the job, in sports, at school, or during sex. On the contrary, long term use can lead to loss of concentration, irritability, loss of memory, paranoia, loss of energy, anxiety, and a loss of interest in sex. In particular, several studies have shown that cocaine has no beneficial effect on running times and reduces endurance performance. Furthermore, at all doses, cocaine significantly increases glycogen degradation while increasing plasma lactate concentration without producing consistent changes in plasma catecholamine levels. The controlling effect of cocaine on an addict's life can lead to exclusion of all other facets of life. Nevertheless, despite these apparently detrimental effects, cocaine continues to be misused in sport. It may be that cocaine only affects activities of short duration requiring a burst of high intensity energy output. It is possible that the central nervous stimulatory effect may be more important than its action on peripheral metabolism. It has been suggested that athletes are drawn to cocaine because of the effects of heightened arousal and increased alertness, achieved principally at low doses. Federal regulations for cocaine were introduced in December 1914. This act banned non-medical use of cocaine, prohibited its importation and selling. Cocaine can currently be administered by a doctor for legitimate medical use, such as for local anaesthetic use for some eye, ear, and throat surgeries. Cocaine is banned by both WADA and IOC, including its use as a local anaesthetic. Like amphetamines, it comes under category S6 of the prohibited substances in competition. The presence of cocaine and/or its metabolites (benzoylecgonine and methylecgonine) in urine can be described as severe doping offence [06171].

**Side effects**

A number of dramatic fatalities associated with coronary occlusion have occurred in athletes misusing cocaine, usually those who have been exercising intensely following drug administration. Many sportspeople who misuse cocaine complain of negative central effects such as perceptual misjudgments and time disorientation that sometime reduce their athletic performance. Furthermore, cocaine addicts frequently turn to other drugs to relieve the down feeling when more cocaine is not available. When used together, these drugs and cocaine can prove even more deadly than when used alone. Some fatalities have also occurred when cocaine misuse has been mixed with alcohol or anabolic steroids. The joint misuse of alcohol and cocaine is extremely cardiotoxic. These practices increase the risk of sudden death by cardiac arrest or seizures followed by respiratory arrest [06171].

**Heart**

Cocaine is a particularly toxic substance for the cardiovascular and respiratory system, so its use can lead to serious complications. Among these, the most tragic is SCD, which may be due to coronary artery vasospasm, lethal arrhythmia, direct toxic action on the myocardium, or severe suppression of the respiratory centre. Ischaemia and/or acute myocardial infarction are common complications, both in individuals with normal coronary vessels and, to a greater extent, on a substrate of atherosclerosis, and are not always related to the cocaine dosage. The main pathophysiological mechanism that leads to the appearance of ischaemia is the strong sympathomimetic and parasympatholytic effects of the drug, which are enhanced by the increased adenylate cyclase activity. The consequence of this is an increase in oxygen demand, because of the tachycardia, and in blood pressure, and at the same time a reduction in oxygen supply because of the vasospasm, while also promoting the
thrombogenic process. Also common is the manifestation of rhythm disorders, because of sudden vasospasm, or its local anaesthetic effect from obstruction of the Na⁺/K⁺ pump, or its toxic effect on the myocardium. Because of this there is an increase in endothelial permeability in the pulmonary capillaries, which can result in pulmonary oedema. Finally, other complications that have been described are infective endocarditis, myocarditis and dilated cardiomyopathy (chemical cardiomyopathy), rupture of aortic aneurysms, arterial and pulmonary hypertension, and thromboembolic vascular episodes [12126].

The use of cocaine has been associated with acute and chronic cardiovascular disease. Cocaine inhibits norepinephrine reuptake in the sympathetic system leading to overstimulation and may cause release of catecholamines from central and peripheral stores. Acute coronary syndromes (including myocardial ischemia and infarction) are the commonest cardiac events secondary to cocaine abuse. This may be due to coronary artery spasm, increase in myocardial oxygen consumption from increases in heart rate and blood pressure, and a prothrombotic state. Most myocardial infarctions occur in the absence of atherosclerotic coronary disease and are unrelated to the dose and frequency of cocaine use. Cocaine abuse may however also lead to premature coronary disease sometimes with quite rapid onset. Cocaine abuse may also lead to coronary artery aneurysms, aortic dissection, rupture, vasculitis and stroke. Arrhythmias are not common with cocaine use, but sinus tachycardia, sinus bradycardia, supraventricular, ventricular arrhythmias and bundle branch blocks have been reported. A dilated cardiomyopathy can be caused by cocaine use and a cocaine-induced myocarditis has been reported at postmortem in 20-30 percent of cases. Myocarditic changes, however, may be fully reversible if identified early and abstinence from further cocaine abuse occurs. In the case study detailed the ECG changes with a significant cardiac event are shown in a young professional athlete who has a cocaine abuse history [12114].

Brain projections of cardiovascular disease induced by cocaine

Neural plasticity has been observed in the bed nucleus of the stria terminalis (BNST) following exposure to both cocaine and androgenic-anabolic steroids. Here we investigated the involvement of the BNST on changes in cardiovascular function and baroreflex activity following either single or combined administration of cocaine and testosterone for 10 consecutive days in rats. Single administration of testosterone increased values of arterial pressure, evoked rest bradycardia and reduced baroreflex-mediated bradycardia. These effects of testosterone were not affected by BNST inactivation caused by local bilateral microinjections of the nonselective synaptic blocker CoCl2. The single administration of cocaine as well as the combined treatment with testosterone and cocaine increased both bradycardiac and tachycardiac responses of the baroreflex. Cocaine-evoked baroreflex changes were totally reversed after BNST inactivation. However, BNST inhibition in animals subjected to combined treatment with cocaine and testosterone reversed only the increase in reflex tachycardia, whereas facilitation of reflex bradycardia was not affected by local BNST treatment with CoCl2. In conclusion, the present study provides the first direct evidence that the BNST play a role in cardiovascular changes associated with drug abuse. Our findings suggest that alterations in cardiovascular function following subchronic exposure to cocaine are mediated by neural plasticity in the BNST. The single treatment with cocaine and the combined administration of testosterone and cocaine had similar effects on baroreflex activity, however the association with testosterone inhibited cocaine-induced changes in the BNST control of reflex bradycardia. Testosterone-induced cardiovascular changes seem to be independent of the BNST [13522].

Laboratory techniques

1449
The use of thin-film solid-phase microextraction (SPME) as the sampling preparation step before direct analysis in real time (DART) was evaluated for the determination of two prohibited doping substances, cocaine and methadone, in urine samples. Results showed that thin-film SPME improves the detectability of these compounds: signal-to-blank ratios of 5 (cocaine) and 13 (methadone) were obtained in the analysis of 0.5 ng/ml in human urine. Thin-film SPME also provides efficient sample cleanup, avoiding contamination of the ion source by salt residues from the urine samples. Extraction time was established in 10 min, thus providing relatively short analysis time and high throughput when combined with a 96-well shaker and coupled with DART technique [13523].

In doping controls, the detection of cannabinoid misuse is based on the analysis of the non-psychoactive metabolite 11-nor-9-carboxy-delta-9-tetrahydrocannabinol (carboxy-THC). The determination of values greater than 15 ng/mL in urine represents an adverse analytical finding; however, no accurate prediction of the time of application is possible as the half-life of carboxy-THC ranges between three and four days. Consequently the detection of carboxy-THC in doping control urine samples collected in competition might also result from cannabis use in out-of-competition periods. The analysis of the glucuronide of the pharmacologically active delta 9-tetrahydrocannabinol (THC-gluc) may represent a complementary indicator for the detection of cannabis misuse in competition. An assay for the determination of THC-gluc in human urine was established. The sample preparation consisted of liquid-liquid extraction of urine specimens, and extracts were analysed by liquid chromatography/tandem mass spectrometry (LC-MS/MS). Authentic doping-control urine samples as well as specimens obtained from a controlled smoking study were analysed and assay characteristics such as specificity, detection limit (0.1 ng/mL), precision (>90 %), recovery (approximately 80 %), and extraction efficiency (90 %) were determined [09293].

**MALDI-TOF/TOF mass spectrometry**

The analysis of doping agents in biological fluids is of top significance in clinical and forensic toxicology. Herein it was described the study of a screening method for the detection of a mixture of drugs of potential abuse including cocaine and its metabolites. By using matrix-assisted laser desorption/ionization MALDI-TOF/TOF mass spectrometry. This screening procedure to detect the presence of different drugs, avoiding time consuming procedures could be useful in different fields of forensic analytical toxicology, including antidoping analysis [12348].

**Analysis of hair**

In forensic toxicology, apart from urine and blood samples, different complex matrices are also of interest such as various tissues or especially hair samples. Mass spectrometry coupled with gas or liquid chromatography (GC-MS or LC-MS) has been utilized to analyze drugs of abuse in such matrices. A large number of biomolecules ranging from large proteins to small pharmaceuticals have been visualized by matrix-assisted laser desorption/ionization-mass spectrometry (MALDI-MS) or MALDI MS Imaging (MALDI-MSI) in cells and tissues. MALDI-MS combined with spatial information in which the total ion current (TIC) or extracted ion current (XIC) is sorted with respect to the individual x/y-positions on the sample allow one to create MS images of various compounds in the sample, for example, tissue or hair. This technique has demonstrated to be a widely applicable tool for the description and elucidation of the spatial distribution of various compounds (peptides/proteins, but also small molecules) within biological tissues. MALDI-MSI has turned out to be a powerful tool to investigate the distribution of proteins and small molecules within biological systems by in situ analysis of tissue sections. In a preliminary test, four single hairs of a drug abuser were analyzed for the presence of drugs by MALDI Fourier transform mass spectrometry (MALDI-FTMS). Washed hair strains were directly fixed on a sample plate using pressure stable, double-sided adhesive tape; α-cyano-4-hydroxycinnamic acid matrix was manually spotted onto the hair.
strains. FTMS full scans were obtained moving from the hair root region towards the hair tip. Cocaine (accurate m/z ratio 304.15433) was identified mostly from the root of the hair and then later again towards the hair tip. This was confirmed by analysis of a second hair. Additionally cocaine metabolites with m/z ratio 290.13868 (benzoylecgonine), and m/z 318.16998 (cocaethylene) were detected for plausibility control. Using the MALDI technique, time-related information was obtained concerning the behavioural pattern of the consumer with high resolution compared to conventional procedures. However, in two hairs of the same individual which were analyzed under the same conditions, negative results were achieved. These preliminary results confirm the applicability of MALDI-MS for the determination of drugs and pharmaceuticals in hair samples being useful in forensic toxicology. The high chronological resolution allows an enhanced interpretation concerning the periods of drug administration. However, the negative results with two negative hairs have also demonstrated that hair analysis of single hairs can lead to misinterpretation. Different growth rates have to be considered, and particularly the phenomenon of different growth phases (anagen, catagen, telogen) require attention [13521].

**Methylenedioxymethamphetamine (MDMA; Ecstasy)**

The recreational and illicit use of amphetamine designer compounds, specially 3,4-methylenedioxymethamphetamine (MDMA; Ecstasy), is of concern worldwide. Such psychostimulating drugs are frequently present as complex mixtures in “rave' pills” making concomitant polysubstance use a common trend. However, the understanding of possible combination effects with these substances is still scarce. The present study was aimed at predicting the cytotoxic effects of mixtures of four amphetamine derivatives: MDMA, methamphetamine, 4-methylthioamphetamine and d-amphetamine in a human hepatoma cell line. Concentration-response curves for all single-mixture components were recorded by the MTT assay. Data obtained for individual agents were then used to compute the additivity expectations for mixtures of definite composition, using the pharmacological models of concentration addition (CA) and independent action. By comparing the predicted calculations with the experimentally observed effects, we concluded that CA accurately predicts the combination of amphetamines, which act together to generate additive effects over a large range of concentrations. Notably, we observed substantial mixture effects even when each drug was present at low concentrations, which individually produced unnoticeable effects. Nonetheless, for all tested mixtures, a small deviation from additivity was observed towards higher concentrations, particularly at high effect levels. A possible metabolic interaction, which could explain such deviation, was investigated, and it was observed that at higher mixture concentrations increased MDMA metabolism could be contributing to divergences from additivity. In conclusion, the present work clearly demonstrates that potentially harmful interactions among amphetamine drugs are expected when these drugs are taken concomitantly [13487].

3,4-Methylenedioxymethamphetamine (MDMA) is a racemic drug of abuse and its R- and S-enantiomers are known to differ in their dose-response curve. The S-enantiomer was shown to be eliminated at a higher rate than the R-enantiomer most likely explained by stereoselective metabolism that was observed in various in vitro experiments. The aim of this work was the development and validation of methods for evaluating the stereoselective elimination of phase I and particularly phase II metabolites of MDMA in human urine. Urine samples were divided into three different methods. Method A allowed stereoselective determination of the 4-hydroxy-3-methoxymethamphetamine (HMMA) glucuronides and only achiral determination of the intact sulfate conjugates of HMMA and 3,4-dihydroxymethamphetamine (DHMA) after C18 solid-phase extraction by liquid
chromatography-high-resolution mass spectrometry with electrospray ionization. Method B allowed the determination of the enantiomer ratios of DHMA and HMMA sulfate conjugates after selective enzymatic cleavage and chiral analysis of the corresponding deconjugated metabolites after chiral derivatization with S-heptafluorobutyrylpromyl chloride using gas chromatography-mass spectrometry with negative-ion chemical ionization. Method C allowed the chiral determination of MDMA and its unconjugated metabolites using method B without sulfate cleavage. The validation process including specificity, recovery, matrix effects, process efficiency, accuracy and precision, stabilities and limits of quantification and detection showed that all methods were selective, sensitive, accurate and precise for all tested analytes [13351].

The serotonin transporter (SERT) has been associated to diverse functions and diseases, though seldom to memory. Therefore, we made an attempt to summarize and discuss the available publications implicating the involvement of the SERT in memory, amnesia and anti-amnesic effects. Evidence indicates that Alzheimer's disease and drugs of abuse like d-methamphetamine (METH) and (+/-)3,4-methylenedioxymethamphetamine (MDMA, “ecstasy”) have been associated to decrements in the SERT expression and memory deficits. Several reports have indicated that memory formation and amnesia affected the SERT expression. The SERT expression seems to be a reliable neural marker related to memory mechanisms, its alterations and potential treatment. The pharmacological, neural and molecular mechanisms associated to these changes are of great importance for investigation [13352].

To improve our understanding of the pharmacology of “ecstasy” in recreational environments; in particular, to describe the composition of ecstasy pills, patterns of ecstasy use and the relationship between dose of 3,4-methylenedioxymethamphetamine (MDMA) and resulting plasma concentrations. A naturalistic observational study of 56 experienced “ecstasy” users in recreational settings in Australia was performed. Drug use patterns (number of pills consumed, other drugs consumed). drug content of pills and resultant plasma concentrations of MDMA and related drugs were assessed by gas chromatography/mass spectrometry (GC/MS). Ecstasy pills generally contained MDMA, but this was often combined with other drugs such as 3,4-ethylendioxyethylamphetamine (MDEA) and methamphetamine. The dose of MDMA per pill ranged from 0 to 245 mg and users consumed from one-half to five pills, with the total dose consumed ranging up to 280 mg. Plasma concentrations of MDMA increased with number of pills consumed and cumulative MDMA dose. Use of larger numbers of pills was associated with extended exposure to the drug. It was concluded that MDMA is the major active drug in ecstasy pills, but there is a high degree of variation in doses. Use of multiple pills over the course of one session is common and results in a sustained increase in MDMA plasma concentrations over a number of hours. This is likely to lead to a much greater exposure of the brain to MDMA than would be predicted from controlled single-dose pharmacokinetic studies [13353].

Metabolites

3,4-Methylenedioxymethamphetamine (MDMA) is excreted in human urine as unchanged drug and phase I and II metabolites. Previous urinary excretion studies after controlled oral MDMA administration have been performed only after conjugate cleavage. Therefore, it was investigated intact MDMA glucuronide and sulfate metabolite excretion. It was used LC-high-resolution MS and GC-MS to reanalyze blind urine samples from 10 participants receiving 1.0 or 1.6 mg/kg MDMA orally. It was determined median C(max),t(max), first and last detection times, and total urinary recovery; calculated ratios of sulfates and glucuronides; and performed in vitro-in vivo correlations. Phase II metabolites of 3,4-
dihydroxymethamphetamine (DHMA), 4-hydroxy-3-methoxymethamphetamine (HMMA), 3,4-dihydroxyamphetamine (DHA), and 4-hydroxy-3-methoxymethamphetamine were identified, although only DHMA sulfates, HMMA sulfate, and HMMA glucuronide had substantial abundance. Good correlation was observed for HMMA measured after acid hydrolysis and the sum of unconjugated HMMA, HMMA glucuronide, and HMMA sulfate. More than 90 percent of total DHMA and HMMA were excreted as conjugates. The analytic with the longest detection time was HMMA sulfate. Median HMMA sulfate/glucuronide and DHMA 3-sulfate/4-sulfate ratios for the first 24 h were 2.0 and 5.3, respectively, in accordance with previous in vitro calculations from human liver microsomes and cytosol experiments. It was concluded that human MDMA urinary metabolites are primarily sulfates and glucuronides, with sulfates present in higher concentrations than glucuronides. This new knowledge may lead to improvements in urine MDMA and metabolite analysis in clinical and forensic toxicology, particularly for the performance of direct urine analysis [11509].

Laboratory testing

Qualitative urinalysis can verify abstinence of drug misuse but cannot detect changes in drug intake. For drugs with slow elimination, such as methamphetamine (MA), a single episode of abuse can result in up to 5 days of positive urine drug screens. Thus, interventions that produce substantial decreases in drug use but do not achieve almost complete abstinence are classified as ineffective. Using nonpharmacologic doses of deuterium-labeled l-methamphetamine (l-MA-d3) we have developed a simple, robust method that reliably estimates changes in MA intake. Twelve subjects were dosed with 5 mg of l-MA-d3 daily and challenged with 15, 30, and 45 mg of nonlabeled d-MA (d-MA-d0) after reaching plasma steady status of l-MA-d3. Urinary concentration ratios of d-MA-d(0) to l-MA-d(3) provided clear separation of the administered doses with as little as 15-mg dose increments. Administered doses could not be resolved using d-MA-d0 concentrations alone. In conclusion, the urinary concentration of d-MA-d0 l-MA-d3 provides a quantitative, continuous measure of illicit MA exposure. The method reliably detects small, clinically relevant changes in illicit MA intake from random urine specimens, is amenable to deployment in clinical trials, and can be used to quantify patterns of MA abuse [13354].

There is evidence that the use of MDMA (methylenedioxymethamphetamine), colloquially known as “ecstasy” particularly among late adolescents and young adults is increasing. Despite recent government-sponsored public education programs, there is a perception that recreational use of MDMA is much less harmful than other illicit substances like heroin. Recent seizures by police in Australia underline the extent of the demand for MDMA and how lucrative trafficking in MDMA has become. In two recent Australian cases, appellate courts considered the legislative intent of both State and Commonwealth legislation and held that a quantity-based penalty regime applied which distinguished between “traffickable” and “commercial” quantities of illicit drugs and that no distinction turned on the relative “harmfulness” of MDMA. In examining the question of harmfulness, this column summarises the pharmacology and morbidity of MDMA and considers the links between MDMA and other substances of abuse and the implications for further prevention programs [09294].

The abuse of ecstasy-type drugs such as 3,4-methylenedioxyamphetamine (MDMA) and 3,4-methylenedioxymethamphetamine (MDA) is generally associated with young adults attending "Rave" parties. Little toxicological information has been reported regarding ecstasy usage by individuals undergoing monitoring in other settings in the United States. The goal of this study was to determine the prevalence and patterns of licit and illicit drugs in urine specimens of ecstasy users. A survey of laboratory data over the years 2005-2007 revealed that 198 urine specimens were confirmed positive (cutoff concentration 100 ng/mL) for
MDMA and/or MDA from the following types of donors (positive specimens): correctional (159); sports (19); workplace (9); pain patients (8); and special test requests (3). Of these, 122 (62 %) were positive for MDMA and MDA, 70 (35 %) were positive for MDMA, and 6 (3 %) were positive for MDA. A majority (84 %) of the specimens contained multiple drugs and/or metabolites in addition to MDMA and MDA. The median number of drugs/metabolites reported for these ecstasy users was 5 (range, 1-9). In addition to MDMA/MDA, the most commonly identified drug groups (%) were cannabis (THCCOOH) (62 %); amphetamine/methamphetamine (38 %); benzylecgonine (31 %); diazepam-related (10 %); opiates (7 %); alprazolam (6 %); and others (6%). Although multidrug ingestion appears to be common amongst ecstasy users, caution is recommended in interpretation. Illicit ecstasy in the United States and Canada frequently contains methamphetamine and other active substances, and multidrug use may not have been intentional [09295].

Bruxism is a recognized side effect of several licit and illicit drugs. In one report, this phenomenon was illustrated in three patients suffering from 3,4-methylenedioxymethamphetamine (ecstasy) abuse [10491].

The aim of this study was to investigate the influence of ecstasy (MDMA) administration on body temperature and soleus muscle histology in exercised and non-exercised mice. Charles-River mice were distributed into four groups: Control (C), exercise (EX), MDMA treated (M), and M + EX. The treated animals received an i.p. injection (10 mg/kg) of MDMA (saline for C and EX), and the exercise consisted of a 90 min level run at a velocity of 900 m/h, immediately after the MDMA or saline administration. Body temperature was recorded every 30 min via subcutaneous implanted transponder. Animals were sacrificed 1.5, 25.5, and 49.5 h after i.p. injection and the soleus muscles were removed and processed for light and electron microscopy. The MDMA-treated animals showed a significant increase in body temperature (similar in M and M + EX groups), reaching the peak 90 min after i.p. administration; their temperature remained higher than control for more than 5 h. The EX group evidenced a similar and parallel, yet lower temperature increase during exercise and recovery. Morphological signs of damage were rarely encountered in the EX group; they were more pronounced in M group and even aggravated in M + EX group. In conclusion, MDMA and exercise per se increased body temperature but in conjunction did not have a cumulated effect. However, ecstasy and concomitant physical activity might severely accumulate with regard to skeletal muscle toxicity and may lead to rhabdomyolysis [10492].

3,4-Methylenedioxymethamphetamine (MDMA, ecstasy) is one of the most widely abused illegal drugs. Some users self-report euphoria and an increased perception and feeling of closeness to others. When taken in warm environments, MDMA users may develop acute complications with potential fatal consequences. In rodents, MDMA increases locomotor activity and, depending on ambient temperature, may produce a dose-dependent, potentially lethal hyperthermia. Like most other recreational drugs, MDMA is frequently taken in combination with other substances including tobacco, EtOH, marijuana, amphetamines, cocaine and, caffeine. Although polydrug use is very common, the understanding of the effects of this multiple substance use, as well as the analysis of consequences of different drug-drug associations, received rather little attention. The purpose of one review was to summarize our current knowledge about the changes on MDMA-related behavior, pharmacology, and neurotoxicity associated with co-consumption of other drugs of abuse and psychoactive agents [11508].

**gamma-Aminobutyric acid (GABA)**
gamma-Aminobutyric acid, GABA, is synthesized through the decarboxylation of glutamate by the enzyme glutamic acid decarboxylase. Glutamate is the main excitatory neurotransmitter, and GABA is the major inhibitory neurotransmitter in the mature brain. GABA became a popular supplement with bodybuilders in the early 1980s after a study showed it increased plasma growth hormone (GH) levels in man. GABA acts primarily by activating Cl⁻ channels called GABAₐ receptors, and by eliciting metabotropic G-protein mediated responses by GABAₐ receptors. GABA is considered to act as a natural tranquilizer and antiepileptic agent in the brain. GABAₐ receptors are the site of action of benzodiazepines, barbiturates and anaesthetics and known to mediate sedation. GABAₐ agonists may be useful for the treatment of pain and drug dependence. Baclofen, the first synthetic GABAₐ receptor agonist, is used clinically for the treatment of spasticity and skeletal muscle rigidity. GABAₐ antagonists on the other hand have shown antidepressant and cognition-enhancing effects. Baclofen, in rats, has been shown to prolong time to fatigue, possibly because of a boost in glycogen owing to the effect of interleukin 6 release in the muscle. Recently it was shown that GABA ingestion at rest increases immunoreactive GH (irGH) and immunofunctional GH (ifGH) secretion, which may enhance the skeletal muscle response to resistance training. Moreover, when GABA ingestion was combined with exercise, concentrations of irGH and ifGH rose even higher. Although some effects have been found, specifically for the response to resistance training, much more research regarding the effects of GABAergic manipulations on exercise performance is needed to elucidate the role of GABA [10527].

Influence of anabolic steroids

Anabolics androgenic steroids (AAS) comprise a large and growing class of synthetic androgens used clinically to promote tissue-building in individuals suffering from genetic disorders, injuries, and diseases. Despite these beneficial therapeutic applications, the predominant use of AAS is illicit: these steroids are self-administered to promote athletic performance and body image. Hand in hand with the desired anabolic actions of the AAS are untoward effects on the brain and behavior. While the signaling routes by which the AAS
impose both beneficial and harmful actions may be quite diverse, key endpoints are likely to include ligand-gated and voltage-dependent ion channels that govern the activity of electrically excitable tissues. It was reviewed the known effects of AAS on molecular targets that play critical roles in controlling electrical activity, with a specific focus on the effects of AAS on neurotransmission mediated by GABA<sub>A</sub> receptors in the central nervous system [12336].

Anabolic androgenic steroids (AAS), synthetic testosterone derivatives that are used for ergogenic purposes, alter neurotransmission and behaviors mediated by GABA<sub>A</sub> receptors. Some of these effects may reflect direct and rapid action of these synthetic steroids at the receptor. The ability of other natural allosteric steroid modulators to alter GABA<sub>A</sub> receptor-mediated currents is dependent upon the phosphorylation state of the receptor complex. Here we show that phosphorylation of the GABA<sub>A</sub> receptor complex immunoprecipitated by beta<sub>2</sub>/beta<sub>3</sub> subunit-specific antibodies from the medial preoptic area (mPOA) of the mouse varies across the estrous cycle; with levels being significantly lower in estrus. Acute exposure to the AAS, 17alpha-methyltestosterone (17alpha-MeT), had no effect on the amplitude or kinetics of inhibitory postsynaptic currents in the mPOA of estrous mice when phosphorylation was low, but increased the amplitude of these currents from mice in diestrus, when it was high. Inclusion of the protein kinase C (PKC) inhibitor, calphostin, in the recording pipette eliminated the ability of 17alpha-MeT to enhance currents from diestrous animals, suggesting that PKC-receptor phosphorylation is critical for the allosteric modulation elicited by AAS during this phase. In addition, a single injection of 17alpha-MeT was found to impair an mPOA-mediated behavior (nest building) in diestrus, but not in estrus. PKC is known to target specific serine residues in the beta<sub>3</sub> subunit of the GABA<sub>A</sub> receptor. Although phosphorylation of these beta<sub>3</sub> serine residues showed a similar profile across the cycle, as did phosphoserine in mPOA lysates immunoprecipitated with beta<sub>2</sub>/beta<sub>3</sub> antibody (lower in estrus than in diestrus or proestrus), the differences were not significant. These data suggest that the phosphorylation state of the receptor complex regulates both the ability of AAS to modulate receptor function in the mPOA and the expression of a simple mPOA-dependent behavior through a PKC-dependent mechanism that involves the beta<sub>3</sub> subunit and other sites within the GABA<sub>A</sub> receptor complex [12337].

gamma-Butyrolactone (GBL)
The aim of one report was to describe morbidity associated with gamma-butyrolactone (GBL) dependence, and outcomes of withdrawal. The setting was a specialist out-patient clinic and affiliated in-patient detoxification unit. Patients with home support were offered the option of out-patient withdrawal management, based on high-dose diazepam and baclofen, titrated against withdrawal severity in an initial session lasting approximately 4 hours. Patients were then reviewed daily during the first 3 days of treatment, offered weekly follow-up for 4 weeks, and telephoned 2-4 months later. Drug history and social functioning were obtained by self-report in clinical interviews with a single clinician. Treatment completion, outcomes and adverse events associated with withdrawal are reported. Patients reported impaired social functioning associated with GBL dependence and difficulty in accessing treatment. Nineteen patients commenced detoxification; 17 initially declined admission and were treated as outpatients. Mean diazepam dose in the first 24 hours was 75 mg (range 40-110 mg). Sixteen patients completed withdrawal, although several had lapses to GBL use during treatment. One patient developed delirium and required transfer to the in-patient detoxification unit. Most patients had persisting insomnia, anxiety and depression for weeks after withdrawal. GBL withdrawal can be managed in ambulatory settings, but needs to be backed up with seamless access to in-patient treatment if required [11235].

Popularity of gamma-hydroxybutyric acid (GHB) is fairly stable among drug users, while the consumption of its chemical precursor, gamma-butyrolactone (GBL), is a growing phenomenon. Although conventional analytical methods allow to detect this substance in various matrices, linking a trace and a source is still a difficult challenge. However, as several synthesis pathways and chemical precursors exist for the production of GBL, its carbon isotopic signature may vary extensively. For that purpose, a method has been developed to determine the carbon isotopes content of GBL by means of gas chromatography/combustion/isotope ratio mass spectrometry (GC/C/IRMS). The delta$^{13}$C-values of 19 bulk samples purchased worldwide were in the range from -23.1 to -45.8 per thousand (SD<0.3 per thousand). Furthermore, testing on the purification of GBL by distillation has not been found to be consistent with such a large range of delta$^{13}$C-values, which are likely to result from the isotopic composition of the organic precursors used to produce GBL together with the kinetic isotope effect associated with the synthesis routes. Finally, inter- and intra-variability measurements of the delta$^{13}$C-values demonstrated the high potential of IRMS for discriminating between seizures of GBL and for source determination [10197].

Popularity of gamma-hydroxybutyric acid (GHB) is fairly stable among drug users, while the consumption of its chemical precursor, gamma-butyrolactone (GBL), is a growing phenomenon. Although conventional analytical methods allow to detect this substance in various matrices, linking a trace and a source is still a difficult challenge. Finally, inter- and intra-variability measurements of the delta$^{13}$C-values demonstrated the high potential of IRMS for discriminating between seizures of GBL and for source determination [10198].

**gamma-Butyrolactone and gamma-butyrolactone**
Gamma-hydroxybutyrate (GHB) and its precursor gamma-butyrolactone (GBL) are commonly abused drugs with a narrow therapeutic index. Therefore, overdoses occur readily with recreational use, and severe poisoning can occur after deliberate self-poisoning. It was reported the sequelae in a patient who ingested a massive dose of GBL, with suicidal intent. Severe metabolic acidosis and an asystolic cardiac arrest were successfully treated with standard resuscitation, supportive care, and continuous venovenous hemodiafiltration. Plasma GHB concentrations were the highest reported to date. The acidosis was attributed to rapid systemic absorption of GBL, followed by rapid metabolism to GHB [11360].

Gamma-hydroxybutyrate (GHB) is naturally present in the human body, but may also be used as an intoxicating drug. Information from several sources has suggested its increased availability and use in Norway. There have also been reports of an increasing use of the chemical precursor gamma-butyrolactone (GBL). There is currently a need for knowledge on symptoms, addictiveness and overdoses, as well as targeted preventive measures. One article was based on a discretionary selection of articles resulting from a literature search in PubMed, as well as reports from Norwegian and European authorities and research institutions. An intake of small amounts of GHB produces an intoxicating effect, whereas higher doses can result in poisoning. Deaths have been reported. The effect may be variable, due to a steep dose-response curve and interaction with alcohol and other intoxicants. Treatment of poisoning is symptomatic and supportive. Treatment of abstinence is also supportive, while delirium may be treated as delirium tremens [11510].

Gamma-hydroxybutyric acid (GHB) was first synthesized in 1960 as a derivative of the endogenous neurotransmitter gamma-aminobutyric acid (GABA) to pass the blood-brain barrier. In some European countries, GHB is used as an anaesthetic drug, but it has insufficient analgesic effects that necessitate its combination with an analgesic; adverse effects, such as seizures or vomiting, frequently occur. Moreover, controlling dosage and duration of effects is difficult. Later, GHB was also used in the treatment of alcohol and heroin withdrawal. Since studies have shown that GHB has a positive effect on patients with narcolepsy and cataplexy, the substance was licensed for their use in the United States in 2002 and in Europe in 2005, despite the fact that these therapies have many side-effects. As early as the 1980s, GHB was offered in the USA as a dietary supplement. Bodybuilders, in particular, used GHB because of its suggested anabolic muscle-building effects through the increased release of growth hormones. It was also consumed for its supposed aphrodisiac and weight-loss effects, and as a sleeping aid. After numerous cases of intoxication occurred over the following years, the US Food and Drug Administration (FDA) banned its sale to consumers in 1990. However, this did not put a stop to misuse of the drug. GHB gained in popularity; its users consumed “liquid ecstasy” or “soap” on the club scene as a party drug or at private events, as an alternative to, or in combination with, alcohol [11585].

Abuse of gamma-hydroxybutyric acid (GHB) has been known since the early 1990’s, but is not as widespread as the consumption of other illegal drugs. However, the number of severe intoxications with fatal outcomes is comparatively high; not the least of which is brought about by the consumption of the currently legal precursor substances gamma-butyrolactone (GBL) and 1,4-butanediol (1,4-BD). In regards to previous assumptions, addiction to GHB or its analogues can occur with severe symptoms of withdrawal. Moreover, GHB can be used for drug-facilitated sexual assaults. Its pharmacological effects are generated mainly by interaction with both GABAB and GHB receptors, as well as its influence on other transmitter systems in the human brain. Numerous analytical methods for determining GHB using chromatographic techniques were published in recent years, and an enzymatic screening method was established. However, the short window of GHB detection in blood or urine due to its rapid metabolism is a challenge. Furthermore, despite several studies addressing this problem, evaluation of analytical results can be difficult: GHB is a metabolite of GABA.
(gamma-aminobutyric acid); a differentiation between endogenous and exogenous concentrations has to be made. Apart from this, in samples with a longer storage interval and especially in postmortem specimens, higher levels can be measured due to GHB generation during this postmortem interval or storage time [11585].

Illicit forms of GHB have come under narcotics law in the USA since 2000 and are subject to the strictest categorization (Schedule I). In some parts of Europe (Germany, for example), GHB is still approved for treatment as an anaesthetic and for the treatment of narcolepsy. In March 2001, GHB was added to Schedule IV of the 1971 UN Convention on Psychotropic Substances, thereby binding all EU member states to control it under their legislation addressing psychotropic substances. However, GHB is not yet fully under national control in all countries [11585].

Quantitative data on the prevalence of GHB abuse is incomplete, but various qualitative measures indicate that a mini-epidemic of abuse began in the late 1980s and continues up to the present. Undoubtedly, the easy availability and low costs of GHB and its precursors have contributed to its popularity. According to a study by the European Monitoring Centre for Drugs and Drug Addiction, consumption of GHB or GBL is not as widespread as consumption of other illegal drugs. Studies have shown that the prevalence of young people’s leisure use of GHB in the past month rarely exceeds 3 percent. However, there are also signs that consumption is becoming more common in private spheres, especially in certain population subgroups and certain social environments or geographical areas. Depending on the particular study and target group interviewed, the lifetime prevalence is 3 percent to 19 percent (six studies were included from the UK, the Netherlands, and Austria with data from years 1999 to 2007). According to various national reporting systems in the USA, there has been an emergence of a problem with GHB abuse beginning no later than 1994 or 1995. Quantitative data on the prevalence in the population is not available due to the fact that the use of GHB is not queried specifically, but is included under “other drugs” in most surveys since 2001. Since the final active agent in the body is GHB, even in cases of GBL or 1,4-BD consumption, an exact discrimination between these drugs is not possible in most cases. In spite of the comparatively low popularity of GHB, cases of intoxication, somewith a lethal result, have been increasing. Since GHB is not yet detected in routine toxicological screening, the prevalence of GHB abuse is thought to be underestimated [11585].

GHB is a naturally occurring hydroxy carboxylic acid in the human brain, blood, urine, and peripheral tissue. It appears both as a metabolic product and as a precursor of GABA. In spite of numerous studies, its function has not yet been clarified in detail, but there is evidence that GHB has different effects on the balance of neurotransmitters. One possible mechanism of action in discussion is that GHB acts as a neuromodulator in the GABA system. Moreover, GHB causes a dose-response increase or decrease of dopamine levels in the brain and affects the cholinergic system (via GABAB receptors), as well as neurosteroids and, indirectly, opioids. Furthermore, GHB potentiates brain serotonin turnover and increases the secretion of growth hormones. In millimolar concentrations (above endogenous concentrations), GHB already activates GABAB receptors itself or by conversion to GABA and thereby inhibits the influx of Ca\(^{2+}\) and opens K\(^+\)-channels, as GABA does. In addition, the existence of a separate G-protein coupled GHB receptor in the brain has been proven. This receptor is thought to be stimulated already by endogenous concentrations of GHB (micromolar range). It is suggested that after exogenous admission, GHB will act both as a GABAB- and GHB-receptor agonist. GHB is administered intravenously for the purpose of sedation, and orally for most other indications. Misuse occurs mostly by oral administration in liquid form, neat or diluted in drinks. Occasionally, capsules are ingested, which often contain GHB in the form of its sodium salt (sodium oxybate). GHB induces abiphasic time profile with
an initial stimulant-like effect related to the simultaneous rise of plasma concentrations and a latter sedative effect not related to GHB kinetics. GHB has a narrow therapeutic index: the symptoms of poisoning are dose-dependent and partly similar to those of alcohol poisoning. Headache, nausea, vomiting, vertigo, and speech impairment may be present. Higher concentrations may lead to bradycardia, seizures, respiratory depression to the point of respiratory arrest, and impaired consciousness to the point of coma. In severe intoxication, myoclonus or seizures followed by loss of consciousness have often been described. A typical characteristic is a rapid onset and sudden clinical picture. Owing to the extremely fast metabolism of GHB, usually the effects last only 1-4 h, depending on the dose. This phenomenon is known as the “fast-in, fast-out” effect and causes a sudden awakening from (near) coma in most cases, with patients usually recovering within 6-8 h after receiving symptom-oriented treatment. Patients who developed coma (Glasgow Coma Scale. GCS, > 3) had serum levels that ranged from 72 to 300 mg/L with a median of 193 mg/L and regained consciousness as levels decreased to the range of 75 to 150 mg/L. In 15 patients with GCS <8, blood concentrations of 112 to 430 mg/L were determined (most of them co-ingested other drugs or ethanol). One patient was in a state of coma (GCS 7) after ingestion of 1,4-BD, corresponding blood levels were 82 mg/L for 1,4- BD and 103 mg/L for GHB. A woman who was admitted to an emergency department in a comatose state had 161 mg/L GHB in serum after ingestion of GBL from nail polish remover pads. After oral administration, GHB is absorbed very rapidly; maximum plasma concentrations are reached after 25-45 min. The distribution throughout the body is fast and follows a two-compartment model. The apparent distribution volume is reported with 0.19 to 0.4 L/kg and was not significantly affected by gender, food, or liver cirrhosis. GBL has potentially a higher intestinal flux after oral administration and a shorter onset, therefore causing higher C_max of GHB. 1,4-butanediol is also quickly absorbed and metabolized. It is extensively converted to GHB after oral administration, but significant inter-individual variability in the rate of metabolism, possibly related to genetic variants in the alcohol dehydrogenase, was observed. Moreover, conversion of 1,4-BD is blocked competitively by ethanol [11585].

Endogenous GHB is formed from GABA by means of succinic semialdehyde reductase via the intermediate product succinic semialdehyde (SSA). Via the enzyme GHB dehydrogenase, GHB can be oxidated back into SSA. After a further oxidation step, SSA reaches the citric acid cycle, mainly as succinic acid. Only a small proportion of GHB is excreted in an unchanged form through the kidneys (<2 %). GHB is eliminated rapidly; the terminal elimination half-life in plasma averages 20-60 min after single oral doses, but there are indications that the elimination kinetics of GHB is not linear after administration of therapeutic doses. Moreover, in some cases after ingestion of large doses, zero order kinetics seems to be more appropriate than first-order kinetics. Drug facilitated sexual assaults/chemical submission GHB and its precursors are colourless liquids, transparent, and almost entirely without taste. They can thus be mixed with drinks to administer to unsuspecting victims without their noticing, and are used with criminal intent to weaken the resistance of individuals, for example to exploit their property or body without their consent and without them having the slightest recollection afterwards of what happened (anterograde amnesia). Criminals tend to use substances such as GHB to facilitate the commitment of their offences. They also tend to use substances currently not under international control, such as ketamine, 1,4-BD and GBL, since they are easily available through legitimate channels. GHB can result in impaired consciousness, including coma with anterograde amnesia. Studies have shown that GHB is one of the substances most often used for the purpose of drug facilitated sexual assault (DFSA) in the USA.[5,36,37] Similar cases have also been reported in Germany and other European countries. Because of its depressant effect on the central nervous system, the use of GHB and its analogues is also important in cases of driving under the influence of drugs (DUID). For example, Jones et al. identified in their database 548 DUID cases with GHB (alone or together with other recreational drugs)
for the years 1997 to 2007 in Sweden. Fatalities have been reported with accidental overdoses of GHB, suicidal intent, or trauma as a result of impaired driving. Fatal overdoses occur also with the precursors GBL or 1,4-BD. Especially post-mortem analytical GHB results should be interpreted with caution. Furthermore, it should be recognized that abrupt GHB withdrawal can cause life-threatening clinical courses which can even lead to death. Initial studies after clinical administration of GHB in patients with narcolepsy have not shown any cases of misuse or of a developing tolerance. More recent studies, however, indicate the potential for the drug as mentally and physically addictive and suggest a high abuse liability. GHB abuse can lead to addiction with severe withdrawal complications; the same is valid for its precursors. GHB addiction is characterized by round-the-clock dosing, typically every 1-3 h. According to our experience, typical doses are 20 to 70 mL per day; reported doses of patients with GBL/1,4-BD withdrawal in the literature ranged from “two sips every night” up to 900 mL/day during five weeks to four years. Addiction can develop within a few weeks. Withdrawal symptoms after abrupt GHB discontinuation manifested very quickly within 2-6 h. Withdrawal complications of dependence can be associated with a range of neurological phenomena including tremor, anxiety attacks, confusion, epileptic fits, and memory loss. These initial symptoms may progress to severe delirium with auditory and visual hallucinations and autonomic instability. Cardiovascular effects included severe tachycardia and hypertension. Life-threatening clinical courses with admission to the intensive care unit have been documented. Most patients typically requested medical assistance for continued withdrawal symptoms from three days to up to 14 days or more after the last dose. Benzodiazepines, barbiturates, and antipsychotic medication are the most used drugs in the treatment of GHB withdrawal symptoms. However, in many cases, high doses of benzodiazepines and barbiturates proved ineffective. A sufficient medical treatment of the GHB withdrawal syndrome comparable to the treatment of alcohol or benzodiazepine addiction is not yet clearly defined [11585].

**gamma-Butyrolactone and 1,4-butanediol**

Since GHB is subject to the Narcotics Act, legal substitutes such as gamma-butyrolactone (GBL) or 1,4-butanediol (BD), the most commonly used GHB analogues, are currently being consumed. These substances are metabolized into GHB after oral administration or they are transformed into GHB before ingestion by means of a simple chemical reaction, either by the dealers or the users themselves. Instructions on how to synthesize these substances, as well as complete “chemistry kits”, are available on the Internet. Since the actual effective substance is GHB, consumption of these precursors results in the same effects, side effects, and symptoms of intoxication. In most countries, the GHB precursors (GBL and 1,4-BD) are not controlled under current drug or medicine legislation owing to their widespread use as solvents and the associated consequences for the chemical industry. Although three EU member states (Sweden, Italy, and Latvia) have chosen to control them under the same or similar legislation as that affecting GHB, this is not done all over EU. Recently in Germany, several dealers of GBL were punished based on the pharmaceutical law. They were accused of selling so-called “precarious pharmaceuticals” with a reasonable suspicion of harmful effects (on the basis of § 5 and § 95 of the German pharmaceutical act) [11585].

**gamma Hydroxybutyrate (GHB)**

GHB is a short-chain 4-carbon fatty acid found endogenously in the brain, mainly in the hypothalamus and basal ganglia, in the form of γ-hydroxybutyric acid. GHB has several precursors, including gamma-butyrolactone, which are metabolised into GHB upon ingestion through various pathways. Concurrently, GHB is transformed into the inhibitory
neurotransmitter GABA, with preference for the GABA\textsubscript{B} receptor. The precise mechanism of action of GHB remains unclear. Its properties indicate a role in the brain as a neurotransmitter or neuromodulator. Additional research has shown it could influence serotonergic and dopaminergic activity, both directly and indirectly through interaction with other systems (e.g. GABA\textsubscript{B} receptors). Primary effects include lowered inhibition, induced feelings of euphoria and increased libido. GHB was identified and synthesised more than 40 years ago as a central nervous system depressant: it has been used as an anaesthetic adjuvant and to improve sleep patterns. Links to athletic performance came from a study proposing that GHB administration increased GH release. The drug was then marketed as a nutritional supplement alleging enhanced muscle growth, better sleep quality and improved sexual performance. Simultaneously, GHB became popular during the 1980s with body builders due to the potential anabolic and performance-enhancing properties. These benefits have never been proven in athletic populations but, interestingly, a recent study that examined the effects of GHB on sleep and sleep-related GH release found that low-dose supplementation (2.5–3.5 g/day) caused a twofold increase in GH secretion during sleep. An exact mechanism was not identified, but it was suggested that GHB augments GH release by inducing deeper phases of sleep. GHB and its precursors are not typically present in the diet, but can be found in flavouring agents. It is typically taken as a liquid or powder, and dosages range hugely from 12.5–100 mg/kg/day. It is rapidly absorbed and metabolised, and effects occur almost instantaneously. After a single dose (12.5–50 mg/kg), maximal plasma concentrations are reached after approximately 30–40 min, and its elimination half-life ranges from 30–50 min. Side effects include drowsiness, alcohol-like inebriation, dizziness and induction of sleep. Overdose can cause coma, respiratory depression and death. Frequent and prolonged use has resulted in increased tolerance, and dependence. Currently, no available evidence supports the use of GHB in the athletic population [10527].

GHB, a short-chain 4-carbon fatty acid found in the brain, has also been promoted as a nutritional supplement alleging enhanced muscle growth, better sleep quality and improved sexual performance. GHB is found endogenously in the brain, mainly in the hypothalamus and basal ganglia, in the form of gamma-hydroxybutyric acid. GHB has several precursors, including γ-butyrolactone, which are metabolised into GHB upon ingestion through various pathways. Concurrently, GHB is transformed into the inhibitory neurotransmitter GABA, with preference for the GABA\textsubscript{B} receptor. The precise mechanism of action of GHB remains unclear. Its properties indicate a role in the brain as a neurotransmitter or neuromodulator. Additional research has shown it could influence serotonergic and dopaminergic activity, both directly and indirectly through interaction with other systems (e.g. GABA\textsubscript{B} receptors). Primary effects include lowered inhibition, induced feelings of euphoria and increased libido. GHB was identified and synthesised more than 40 years ago as a central nervous system depressant: it has been used as an anaesthetic adjuvant and to improve sleep patterns. Links to athletic performance came from a study proposing that GHB administration increased GH release. The drug was then marketed as a nutritional supplement alleging enhanced muscle growth, better sleep quality and improved sexual performance. Simultaneously, GHB became popular during the 1980s with body builders due to the potential anabolic and performance-enhancing properties. These benefits have never been proven in athletic populations but, interestingly, a recent study that examined the effects of GHB on sleep and sleep-related GH release found that low-dose supplementation (2.5–3.5 g/day) caused a twofold increase in GH secretion during sleep. An exact mechanism was not identified, but it was suggested that GHB augments GH release by inducing deeper phases of sleep. GHB and its precursors are not typically present in the diet, but can be found in flavouring agents. It is typically taken as a liquid or powder, and dosages range hugely from 12.5–100 mg/kg/day. It is rapidly absorbed and metabolised, and effects occur almost instantaneously. After a single dose (12.5–50 mg/kg), maximal plasma concentrations are reached after approximately 30–40 min, and its elimination half-life ranges from 30–50 min.
Side effects include drowsiness, alcohol-like inebriation, dizziness and induction of sleep. Overdose can cause coma, respiratory depression and death. Frequent and prolonged use has resulted in increased tolerance, and dependence. Currently, no available evidence supports the use of GHB in the athletic population [11232].

Gamma hydroxybutyrate (GHB), also known as fantasy, liquid ecstasy, and was initially introduced as a general anesthetic. Due to dosing difficulty and side effects, regular use was discontinued. It was also used as a nutritional supplement for sleep inducement and to increase muscle mass, however, its use as a “club drug” and “date rape drug” led to US federal regulation of GHB. GHB analogs such as GBL (gamma-butyrolactone), BD (1,4-butanediol), GHV (gamma-hydroxyvalerate), and GVL (gamma-valerolactone), which are found legitimately in industrial solvents and paint strippers, are used for illicit consumption in an effort to produce effects similar to GHB. GHB is often used to increase feelings of euphoria, relaxation, sociability, and sexuality and to explore altered states of consciousness. However, consequences of use include loss of consciousness, overdose, amnesia, emotionality, loss of motor control, withdrawal, hospital admittance, sexual assault victimization, and engaging in risky behaviors, such as driving while under the influence and polysubstance use. Despite possible adverse effects, GHB has been used to treat sleep and addictive disorders including alcohol withdrawal. In the 1990s, it was promoted as a supplement and taken to improve mood and sex. GHB and its analogs (gamma butyrolactone and butanediol) were widely available until federal regulations were put into effect with mounting evidence of adverse events. One survey (n= 61) study was conducted to assess patterns, experiences, and functions of use. Much of what is understood regarding GHB treatment is based on hospital case studies for overdose and withdrawal. This study found that most respondents who began this web-based survey completed it without incident. It is possible to obtain a relatively diverse sample of GHB/analog users via the Internet, although most were men. Results indicate that over 76 percent of respondents had used these substances one or more times per day, and that it is not uncommon for GHB/analogs to be obtained through persons not known well to the consumer. Furthermore, results indicate that 42 to 58 percent of persons consuming these substances did not know there were government warnings regarding adverse events associated with these drugs. The sample generally endorsed use of GHB/analogs for recreational purposes, to improve health, and to assist with sleep difficulty. Respondents also generally appeared to have significant withdrawal symptoms including mood disturbance and insomnia. Although the sample reported relatively few consequences due to use, the dollar amounts associated with arrests, jail time, hospital care, and annual purchase cost of the drug are exorbitant and range from USD 900 to USD 36,000. Of note, 50 respondents had engaged in driving under the influence. Had these 50 respondents been arrested even once, at USD 10,000 per episode, the costs of for the entire sample would have been USD 500,000 (without injury or accident costs). A substantial proportion of participants are unmotivated to alter use. Relaxation and having fun were seen as important in making decisions to use, and similarly, not wanting to disappoint others was seen as important to making decisions to not use. A substantial proportion of participants associate with friends who encourage use, as compared to their family members who discourage use. Although many respondents were thinking about changing use or working on changing use, they are more vulnerable to using GHB/analogs when socializing, when feeling pressured by others, when they feel an urge to use, or when they are physically uncomfortable. What’s more, respondents seemed overly reliant on cognitive coping skills to avoid use, rather than on more active behavioral coping strategies. These findings suggest that the public needs to be better informed of the potential adverse events associated with GHB/analogs. The data also suggest that efforts to reduce use might focus on increasing contacts with family members who are nonusers, and increasing efficacy and behavioral skills to cope with social pressure, urges, and physical discomfort. Motivation to reduce use is associated with acknowledging more use-related problems, more coping
skills, and fewer dependence symptoms. More withdrawal symptoms are associated with fewer coping skills, and more lifetime dependence symptoms. Most frequent use in the past 12 months is associated with more use-related problems and lower confidence to resist use; whereas having more confidence to resist is associated with fewer problems. Confidence to resist is associated with 12-month dependence symptoms, which may suggest that persons are over-confident in their ability to resist use or alternatively, that previous symptoms abated with recently improved confidence to resist. As expected, most frequent use in the last 12 months is associated with most frequent lifetime use, and surprisingly, it is also related to low dependence symptom count for both 12-month and lifetime. Similarly, most frequent lifetime use was related to low 12-month and lifetime dependence symptom count. In addition, 12-month and lifetime dependence are associated with acknowledging fewer use-related problems. It is difficult to reconcile these findings, and more research is needed to see if results are spurious or if there are subsets of users with varying vulnerabilities to development of dependence symptoms. Persons using in relation to socializing have fewer dependence symptoms, and see more benefits to use. Tentatively this suggests that there may be a portion of users who do not experience difficulties with GHB/analogs when used in the context of social settings; however more detailed studies are needed to understand if this is true and potential mediating factors. Persons using in relation to perceived heath benefits employ fewer coping skills and have more 12-month dependence symptoms. The view that GHB/analogs should be legal and freely accessible is associated with perceiving fewer use-related problems, use of fewer coping skills, and more 12-month dependence symptoms. This suggests that persons more vulnerable to developing dependence symptoms begin to use for health benefits and do not believe in limiting access; however, again, more detailed studies are needed to determine if this is true as well as potential mediating factors [11233].

Gamma-hydroxybutyric acid (GHB) is an endogenous short-chain fatty acid popular as a recreational drug due to sedative and euphoric effects, but also often implicated in drug-facilitated sexual assaults owing to disinhibition and amnesic properties. Whilst discrimination between endogenous and exogenous GHB as required in intoxication cases may be achieved by the determination of the carbon isotope content, such information has not yet been exploited to answer source inference questions of forensic investigation and intelligence interests. However, potential isotopic fractionation effects occurring through the whole metabolism of GHB may be a major concern in this regard. Thus, urine specimens from six healthy male volunteers who ingested prescription GHB sodium salt, marketed as Xyrem®, were analysed by means of gas chromatography/combustion/isotope ratio mass spectrometry to assess this particular topic. A very narrow range of delta^{13}C values was observed, whilst mean delta^{13}C value of Xyrem® corresponded to -2.5 percent. Since urine samples and prescription drug could not be distinguished by means of statistical analysis, carbon isotopic effects and subsequent influence on delta^{13}C values through GHB metabolism as a whole could be ruled out. Thus, a link between GHB as a raw matrix and found in a biological fluid may be established, bringing relevant information regarding source inference evaluation. Therefore, the study supports a diversified scope of exploitation for stable isotopes characterized in biological matrices from investigations on intoxication cases to drug intelligence programmes [11234].

Gamma-hydroxybutyrate (GHB) is naturally present in the human body, but may also be used as an intoxicating drug. Information from several sources has suggested its increased availability and use in Norway. There have also been reports of an increasing use of the chemical precursor gamma-butyrolactone (GBL). There is currently a need for knowledge on symptoms, addictiveness and overdoses, as well as targeted preventive measures. One article was based on a discretionary selection of articles resulting from a literature search in PubMed, as well as reports from Norwegian and European authorities and research institutions. An intake of small amounts of GHB produces an intoxicating effect, whereas
higher doses can result in poisoning. Deaths have been reported. The effect may be variable, due to a steep dose-response curve and interaction with alcohol and other intoxicants. Treatment of poisoning is symptomatic and supportive. Treatment of abstinence is also supportive, while delirium may be treated as delirium tremens [11510]

Gamma-hydroxybutyric acid (GHB) was first synthesized in 1960 as a derivative of the endogenous neurotransmitter gamma-aminobutyric acid (GABA) to pass the blood-brain barrier. In some European countries, GHB is used as an anaesthetic drug, but it has insufficient analgesic effects that necessitate its combination with an analgesic; adverse effects, such as seizures or vomiting, frequently occur. Moreover, controlling dosage and duration of effects is difficult. Later, GHB was also used in the treatment of alcohol and heroin withdrawal. Since studies have shown that GHB has a positive effect on patients with narcolepsy and cataplexy, the substance was licensed for their use in the United States in 2002 and in Europe in 2005, despite the fact that these therapies have many side-effects. As early as the 1980s, GHB was offered in the USA as a dietary supplement. Bodybuilders, in particular, used GHB because of its suggested anabolic muscle-building effects through the increased release of growth hormones. It was also consumed for its supposed aphrodisiac and weight-loss effects, and as a sleeping aid. After numerous cases of intoxication occurred over the following years, the US Food and Drug Administration (FDA) banned its sale to consumers in 1990. However, this did not put a stop to misuse of the drug. GHB gained in popularity; its users consumed “liquid ecstasy” or “soap” on the club scene as a party drug or at private events, as an alternative to, or in combination with, alcohol [11585].

Abuse of gamma-hydroxybutyric acid (GHB) has been known since the early 1990’s, but is not as widespread as the consumption of other illegal drugs. However, the number of severe intoxications with fatal outcomes is comparatively high; not the least of which is brought about by the consumption of the currently legal precursor substances gamma-butyrolactone (GBL) and 1,4-butanediol (1,4-BD). In regards to previous assumptions, addiction to GHB or its analogues can occur with severe symptoms of withdrawal. Moreover, GHB can be used for drug-facilitated sexual assaults. Its pharmacological effects are generated mainly by interaction with both GABAB and GHB receptors, as well as its influence on other transmitter systems in the human brain. Numerous analytical methods for determining GHB using chromatographic techniques were published in recent years, and an enzymatic screening method was established. However, the short window of GHB detection in blood or urine due to its rapid metabolism is a challenge. Furthermore, despite several studies addressing this problem, evaluation of analytical results can be difficult: GHB is a metabolite of GABA (gamma-aminobutyric acid); a differentiation between endogenous and exogenous concentrations has to be made. Apart from this, in samples with a longer storage interval and especially in postmortem specimens, higher levels can be measured due to GHB generation during this postmortem interval or storage time [11585].

Illicit forms of GHB have come under narcotics law in the USA since 2000 and are subject to the strictest categorization (Schedule I). In some parts of Europe (Germany, for example), GHB is still approved for treatment as an anaesthetic and for the treatment of narcolepsy. In March 2001, GHB was added to Schedule IV of the 1971 UN Convention on Psychotropic Substances, thereby binding all EU member states to control it under their legislation addressing psychotropic substances. However, GHB is not yet fully under national control in all countries [11585].

Quantitative data on the prevalence of GHB abuse is incomplete, but various qualitative measures indicate that a mini-epidemic of abuse began in the late 1980s and continues up to the present. Undoubtedly, the easy availability and low costs of GHB and its precursors have contributed to its popularity. According to a study by the European Monitoring Centre for
Drugs and Drug Addiction, consumption of GHB or GBL is not as widespread as consumption of other illegal drugs. Studies have shown that the prevalence of young people’s leisure use of GHB in the past month rarely exceeds 3 percent. However, there are also signs that consumption is becoming more common in private spheres, especially in certain population subgroups and certain social environments or geographical areas. Depending on the particular study and target group interviewed, the lifetime prevalence is 3 percent to 19 percent (six studies were included from the UK, the Netherlands, and Austria with data from years 1999 to 2007). According to various national reporting systems in the USA, there has been an emergence of a problem with GHB abuse beginning no later than 1994 or 1995. Quantitative data on the prevalence in the population is not available due to the fact that the use of GHB is not queried specifically, but is included under “other drugs” in most surveys since 2001. Since the final active agent in the body is GHB, even in cases of GBL or 1,4-BD consumption, an exact discrimination between these drugs is not possible in most cases. In spite of the comparatively low popularity of GHB, cases of intoxication, somewhith a lethal result, have been increasing. Since GHB is not yet detected in routine toxicological screening, the prevalence of GHB abuse is thought to be underestimated.

GHB is a naturally occurring hydroxy carboxylic acid in the human brain, blood, urine, and peripheral tissue. It appears both as a metabolic product and as a precursor of GABA. In spite of numerous studies, its function has not yet been clarified in detail, but there is evidence that GHB has different effects on the balance of neurotransmitters. One possible mechanism of action in discussion is that GHB acts as a neuromodulator in the GABA system. Moreover, GHB causes a dose-response increase or decrease of dopamine levels in the brain and affects the cholinergic system (via GABAB receptors), as well as neurosteroids and, indirectly, opioids. Furthermore, GHB potentiates brain serotonin turnover and increases the secretion of growth hormones. In millimolar concentrations (above endogenous concentrations), GHB already activates GABAB receptors itself or by conversion to GABA and thereby inhibits the influx of Ca\(^{2+}\) and opens K\(^{-}\)-channels, as GABA does. In addition, the existence of a separate G-protein coupled GHB receptor in the brain has been proven. This receptor is thought to be stimulated already by endogenous concentrations of GHB (micromolar range). It is suggested that after exogenous admission, GHB will act both as a GABAB- and GHB-receptor agonist. GHB is administered intravenously for the purpose of sedation, and orally for most other indications. Misuse occurs mostly by oral administration in liquid form, neat or diluted in drinks. Occasionally, capsules are ingested, which often contain GHB in the form of its sodium salt (sodium oxybate). GHB induces biphasic time profile with an initial stimulant-like effect related to the simultaneous rise of plasma concentrations and a latter sedative effect not related to GHB kinetics. GHB has a narrow therapeutic index; the symptoms of poisoning are dose-dependent and partly similar to those of alcohol poisoning. Headache, nausea, vomiting, vertigo, and speech impairment may be present. Higher concentrations may lead to bradycardia, seizures, respiratory depression to the point of respiratory arrest, and impaired consciousness to the point of coma. In severe intoxication, myoclonus or seizures followed by loss of consciousness have often been described. A typical characteristic is a rapid onset and sudden clinical picture. Owing to the extremely fast metabolism of GHB, usually the effects last only 1-4 h, depending on the dose. This phenomenon is known as the “fast-in, fast-out” effect and causes a sudden awakening from (near) coma in most cases, with patients usually recovering within 6-8 h after receiving symptom-oriented treatment. Patients who developed coma (Glasgow Coma Scale. GCS, > 3) had serum levels that ranged from 72 to 300 mg/L with a median of 193 mg/L and regained consciousness as levels decreased to the range of 75 to 150 mg/L. In 15 patients with GCS <8, blood concentrations of 112 to 430 mg/L were determined (most of them co-ingested other drugs or ethanol). One patient was in a state of coma (GCS 7) after ingestion of 1,4-BD, corresponding blood levels were 82 mg/L for 1,4- BD and 103 mg/L for GHB. A
woman who was admitted to an emergency department in a comatose state had 161 mg/L GHB in serum after ingestion of GBL from nail polish remover pads. After oral administration, GHB is absorbed very rapidly; maximum plasma concentrations are reached after 25-45 min. The distribution throughout the body is fast and follows a two-compartment model. The apparent distribution volume is reported with 0.19 to 0.4 L/kg and was not significantly affected by gender, food, or liver cirrhosis. GBL has potentially a higher intestinal flux after oral administration and a shorter onset, therefore causing higher C\text{max} of GHB. 1,4-butanediol is also quickly absorbed and metabolized. It is extensively converted to GHB after oral administration, but significant inter-individual variability in the rate of metabolism, possibly related to genetic variants in the alcohol dehydrogenase, was observed. Moreover, conversion of 1,4-BD is blocked competitively by ethanol [11585].

Endogenous GHB is formed from GABA by means of succinic semialdehyde reductase via the intermediate product succinic semialdehyde (SSA). Via the enzyme GHB dehydrogenase, GHB can be oxidated back into SSA. After a further oxidation step, SSA reaches the citric acid cycle, mainly as succinic acid. Only a small proportion of GHB is excreted in an unchanged form through the kidneys (<2 %). GHB is eliminated rapidly; the terminal elimination half-life in plasma averages 20-60 min after single oral doses, but there are indications that the elimination kinetics of GHB is not linear after administration of therapeutic doses. Moreover, in some cases after ingestion of large doses, zero order kinetics seems to bemore appropriate than first-order kinetics. Drug facilitated sexual assaults/chemical submission GHB and its precursors are colourless liquids, transparent, and almost entirely without taste. They can thus be mixed with drinks to administer to unsuspecting victims without their noticing, and are used with criminal intent to weaken the resistance of individuals, for example to exploit their property or body without their consent and without them having the slightest recollection afterwards of what happened (anterograde amnesia). Criminals tend to use substances such as GHB to facilitate the commitment of their offences. They also tend to use substances currently not under international control, such as ketamine, 1,4-BD and GBL, since they are easily available through legitimate channels. GHB can result in impaired consciousness, including coma with anterograde amnesia. Studies have shown that GHB is one of the substances most often used for the purpose of drug facilitated sexual assault (DFSA) in the USA.[5,36,37] Similar cases have also been reported in Germany and other European countries. Because of its depressant effect on the central nervous system, the use of GHB and its analogues is also important in cases of driving under the influence of drugs (DUID). For example, Jones et al. identified in their database 548 DUID cases with GHB (alone or together with other recreational drugs) for the years 1997 to 2007 in Sweden. Fatalities have been reported with accidental overdoses of GHB, suicidal intent, or trauma as a result of impaired driving. Fatal overdoses occur also with the precursors GBL or 1,4-BD. Especially post-mortem analytical GHB results should be interpreted with caution. Furthermore, it should be recognized that abrupt GHB withdrawal can cause life-threatening clinical courses which can even lead to death. Initial studies after clinical administration of GHB in patients with narcolepsy have not shown any cases of misuse or of a developing tolerance. More recent studies, however, indicate the potential for the drug as mentally and physically addictive and suggest a high abuse liability. GHB abuse can lead to addiction with severe withdrawal complications; the same is valid for its precursors. GHB addiction is characterized by round-the-clock dosing, typically every 1-3 h. According to our experience, typical doses are 20 to 70 mL per day; reported doses of patients with GBL/1,4-BD withdrawal in the literature ranged from “two sips every night” up to 900 mL/day during five weeks to four years. Addiction can develop within a few weeks. Withdrawal symptoms after abrupt GHB discontinuation manifested very quickly within 2-6 h. Withdrawal complications of dependence can be associated with a range of neurological phenomena including tremor, anxiety attacks, confusion, epileptic fits, and memory loss. These initial symptoms may progress to severe delirium with auditory and visual
hallucinations and autonomic instability. Cardiovascular effects included severe tachycardia and hypertension. Life-threatening clinical courses with admission to the intensive care unit have been documented. Most patients typically requested medical assistance for continued withdrawal symptoms from three days to up to 14 days or more after the last dose. Benzodiazepines, barbiturates, and antipsychotic medication are the most used drugs in the treatment of GHB withdrawal symptoms. However, in many cases, high doses of benzodiazepines and barbiturates proved ineffective. A sufficient medical treatment of the GHB withdrawal syndrome comparable to the treatment of alcohol or benzodiazepine addiction is not yet clearly defined [11585].

The discovery of gamma-hydroxybutyrate (GHB) over 40 years ago led to its immediate use as a general anesthetic agent. Subsequent research demonstrated that GHB is an endogenous compound in the mammalian brain and current research suggests that GHB is a probable neurotransmitter. In the United States, reports of anabolic effects lead to its misuse among body builders during the 1980's while the intoxicating properties of the drug lead to its popularization as a substance of abuse during the 1990's. GHB became associated with reports of drug-facilitated sexual assault and cases of physical dependence and withdrawal. Efforts to ban GHB caused increased use of GHB analogues and pro-drugs. Against this backdrop, GHB was being developed for the treatment of narcolepsy, leading to the approval of Xyrem (sodium oxybate) oral solution in 2002 for the treatment of cataplexy in patients with narcolepsy. A risk management program permits the safe handling and distribution of the approved product, minimizes the risk for diversion, provides professional and patient education about the risks and benefits of sodium oxybate, and includes physician and patient registries. Post-marketing surveillance indicates sodium oxybate has an acceptable safety profile and presents minimal risk for the development of physical dependence [06228].

Gamma-hydroxybutyrate (GHB) is a naturally occurring compound present in the brain and peripheral tissues of mammals. It is a minor metabolite and precursor of gamma-aminobutyric acid (GABA). Just as GABA, GHB is believed to play a role in neurotransmission. GHB was first synthesized in vitro in 1960, when it revealed depressive and hypnotic effects on the central nervous system. In 1960s it was used as an anaesthetic and later as an alternative to anabolic steroids, in order to enhance muscle growth. However, after it was shown that it caused strong physical dependence and severe side effects, GHB was banned. For the last fifteen years, GHB has been abused for its intoxicating effects such as euphoria, reduced inhibitions and sedation. Illicitly it is available as white powder or as clear liquid. Paradoxically GHB can easily be manufactured from its precursor gamma-butyrolactone (GBL), which has not yet been banned. Because of many car accidents and criminal acts in which it is involved, GHB has become an important object of forensic laboratory analysis. One paper described gas and liquid chromatography, infrared spectroscopy, microscopy, colourimetry and nuclear magnetic resonance as methods for detection and quantification of GHB in urine and illicit products [06229].

Gamma-hydroxybutyrate (GHB) is a drug of abuse that causes euphoria, anxiolysis, and hypnosis. The recent rise in the recreational intake of GHB, as well as its association with 'drug rape', has turned the attention to GHB in acute hospital settings. Acutely admitted GHB intoxicated patients may display various levels of sedation or coma, but may also show paradoxical agitation, combativeness, or self-injurious behaviors. The symptoms can be nonspecific and the definite diagnosis therefore normally relies on the detection of GHB in blood or body fluids, which is an analysis that may not be promptly available. As a basis for understanding the clinical features of GHB intoxication and abuse, it was reviewed the pharmacological and neurophysiological knowledge about GHB, which stems from decades of clinical and basic GHB research. In addition, it was discussed the latest discoveries in the quest for distinct GHB receptors in the brain, and their possible implications for future
therapies of GHB abuse [06230].

Gamma-hydroxybutyric acid (GHB; sodium oxybate) is approved for narcolepsy symptom treatment, and it is also abused. One study compared the participant-rated, observer-rated effects, motor/cognitive, physiological, and reinforcing effects of GHB and ethanol in participants with histories of sedative (including alcohol) abuse. Fourteen participants lived on a residential unit for 1 month. Sessions were conducted Monday through Friday. Measures were taken before and repeatedly up to 24 hours after drug administration. Participants were administered GHB (1, 2, 4, 6, 8, and 10 g/70 kg), ethanol (12, 24, 48, 72, 96, and 120 g/70 kg), or placebo in a double-blind, within-subjects design. For safety, GHB and ethanol were administered in an ascending dose sequence, with placebos and both drugs intermixed across sessions. The sequence for each drug was stopped if significant impairment or intolerable effects occurred. Only 9 and 10 participants received the full dose range for GHB and ethanol, respectively. The highest doses of GHB and ethanol showed onset within 30 minutes, with peak effects at 60 minutes. GHB effects dissipated between 4 and 6 hours, whereas ethanol effects dissipated between 6 and 8 hours. Dose-related effects were observed for both drugs on a variety of measures assessing sedative drug effects, abuse liability, performance impairment, and physiological effects. Within-session measures of abuse liability were similar between the two drugs. However, postsession measures of abuse liability, including a direct preference test between the highest tolerated doses of each drug, suggested somewhat greater abuse liability for GHB, most likely as a result of the delayed aversive ethanol effects (e.g. headache) [13534].

To avoid the detection of small fragmentation products of gamma-hydroxybutyrate (GHB), a liquid chromatography-tandem mass spectrometry GHB quantification method in human serum supported by adduct formation was developed and validated. The continuous infusion of GHB/GHB-D6 made the identification of two adducts possible and GHB/GHB-D6 sodium acetate adduct fragmentation was used as target mass transition. A Luna 5 μm C18 (2) 100 A, 150 mm × 2 mm analytical column and elution with a programmed flow of the mobile phase consisting of 10 percent A (H₂O/methanol = 95/5, v/v) and 90 percent B (H₂O/methanol = 3/97, v/v), both with 10 mM ammonium acetate and 0.1percent acetic acid (pH = 3.2), were used. Protein precipitation with 1 mL of the mobile phase B was used as the sample preparation. The calculated limit of detection/quantification was 1 microg/mL. The presented study shows that the fragmentation of GHB sodium acetate adducts is an effective way of quantification of this small molecule and is an interesting alternative to other methods based on the detection of ions smaller than 85 Da. This fact together with the short analysis time of 3 min and the fast sample preparation make this method very attractive for forensic/clinical application [13535].

Gamma-hydroxybutyric acid and gamma-butyrolactone are illegal drugs with potentially fatal outcomes that are entering wider use in Scandinavia. Gamma-hydroxybutyric acid-dependent persons with withdrawal symptoms often require forceful withdrawal treatment provided in psychiatric units. Data were collected from interviews with 15 registered nurses working in specialised dependency units in psychiatric wards. The data collected were analysed through a descriptive, qualitative analysis. The registered nurses' narratives revealed four main areas of convergence: feelings of anxiety and despair, preparation for unpredictable and precarious situations, striving for good relationship and striving to optimise and develop nursing care. The interviews revealed that registered nurses reflect on and discuss their feelings about their patients' situations with colleagues; prepare themselves for potential aggressiveness and unpredictable situations; improve their care through conscious attitude adjustment and relationship-forming behaviours; and strive to increase their personal knowledge, maintain a hopeful outlook and exhibit a positive approach. These themes were found in all nine categories and sixteen subcategories. The findings based on the registered
nurses' narratives indicated that the registered nurses experienced their work situation when caring for these patients to be very complex and demanding. It was concluded that the study revealed that registered nurses worked extensively to craft their approach and attitude towards their patients. It is clear that registered nurses use themselves as tools or instruments for the creation of good relationships, thus providing the best care possible. Registered nurses should be given more education, clearer guidelines and better guidance to assist them in facing such challenging and often problematic situations. One-on-one shadowing provides the possibility to create and develop relationship [135].

GHB occurs naturally in the human body primarily in the central nervous system. It is a metabolite of brain neurotransmitter GABA. Chemically, GHB is called gamma-hydroxybutyric acid, 4-hydroxybutyric acid, or gamma-hydroxybutyrate. GHB has a structure that consists of a chain of four carbon atoms, with an alcohol group (-C-OH) at one end and a carboxylic acid group (-C-OOH) at the other end. GHB is usually exists either as a free acid, or as a sodium salt. The sodium salt is called Sodium Oxybate and is soluble in water and methanol. It is available as tablet, light-colored powder; colorless liquid, odorless, tasteless in small vials. It was first developed for its calming actions and was found out to have the ability to induce sleep. This made it to be used as an anesthetic in 1960s but was withdrawn due to its side effects like seizures and coma. Due to its euphoric effects, it is nowadays used as “recreational drugs”. The vials contain as much as 10 hits and are often slipped into an unknowing victim's drink when they aren’t noticing GHB is most commonly available in liquid form and is taken orally. It is also available in powder, putty, capsule and gel forms. Street names are Liquid ecstasy, Fantasy, GBH, Georgia Homeboy, Great hormones at bedtime, Liq. E, Liq. X, salty water, Soap, Everclear, Sodium Oxybate, Scoop, Poor man heroine. Trade names include Alcover (Italy), GammaOH (France), Somsanit (Germany) and Xyrem (US, Canada). GHB was used clinically as an anesthetic in the 1960s but was withdrawn due to side effects that included seizures and coma. GHB has been implicated in a number of crime types; most notably in drug-facilitated sexual assault. GHB is abused by three main groups of users: Body builders who use the substance believing that it stimulated the release of growth hormone; sexual predators who covertly administer the drug for its sedative and amnesic effects and club-goers (rave parties) who take the drug for its euphoric effects. The short-lived hypnotic effects, relative safety and widespread availability of the drug have made it particularly well suited to this role. The drug has an addictive potential if used for long term. The primary effects of GHB use are those of a CNS depressant and therefore range from relaxation, to euphoria, confusion, amnesia, hallucinations, and coma. Despite the increased regulation, GHB remains widely available through the Internet where one can easily purchase the necessary reagents as well as recipes for home production. There are reports of patients being unresponsive to painful stimuli and cases of oral self-mutilations linked to the abuse of GHB, though quiet rare. Such cases should remind odontologists that intra-oral lesions may be the result of self-mutilation either due to mental illness or altered states caused by the use of prescription or non-prescription drugs. It is well documented in the dental literature that certain cultures practice deliberate mutilation and non-therapeutic extractions of the dentition to satisfy a variety of social, religious and cultural imperatives. Reasons for such activities include esthetic adornment, class identification and a means of facilitating oral sex. In Western cultures, deliberate mutilation however is considered pathologic. Oral self-mutilation may be classified as either organic or functional. In organic self-mutilation, the person injures himself unknowingly and compulsively. The occurrence of oral self-mutilation resulting from a functional cause may be motivated by secondary gains, facultial or neurotic self-excoriations and self-mutilation during a psychotic episode. The purpose of this article is to highlight the fact that though, oral self-mutilation, particularly auto-extraction, is rare, such cases should remind odontologists that intra-oral lesions, such as extraction sockets, may be the result of self-mutilation either due to mental illness or altered states caused by the use of prescription or non-prescription drugs [130].
**Metabolism and neuromodulatory properties**

The most important synthetic pathway for GHB involves conversion of GABA to succinic semialdehyde by the molecule GABA aminotransferase, followed by reduction of succinic semialdehyde to GHB by cytosolic succinic semialdehyde reductase. Mitochondrial succinic semialdehyde dehydrogenase converts succinic semialdehyde to succinate. A minor pathway for GHB production involves partial oxidation of 1, 4 butanediol. Systemically administered gamma-butyrolactone (GBL) is converted by a circulating lactonase to GHB. The lactonase is not present in brain tissue. The most significant catabolic pathway for GHB degradation is the oxidation of GHB to succinic semialdehyde by NADP⁺-linked succinic semialdehyde reductase. The resultant succinic semialdehyde undergoes further metabolism to either GABA or succinate. There is disagreement as to whether there is significant metabolism of GHB through a beta oxidation scheme. GHB exerts ubiquitous pharmacologic and physiological effects when it is administered systemically to animals. However, GHB also has many of the vital properties of a neurotransmitter or neuromodulator and neurodepressant. This neurodepressant effect may be mediated by a specific GHB receptor, binding to GABA receptors, modulation of GABA levels, or interactions with other neurotransmitters. There is compelling evidence that a novel GHB receptor exists in the CNS. These receptors are saturated at the levels of GHB achieved after exogenous administration. In addition to its own receptor; GHB is known to bind to the GABA₆ receptor, although with a much lesser affinity. Physiologic levels of GHB would not bind this receptor sufficiently to cause pharmacologic effect. However, supraphysiologic levels achieved after exogenous administration could cause considerable binding of the GABA₆ receptor leading to membrane hyperpolarization and depression of the CNS. Thus, experimental evidence to date suggests that the high concentrations of GHB in brain tissue that would be predicted to mount up from exogenous administration of this compound as occurs in the clinical scenarios of GHB intoxication, addiction and abuse may wield their protean pharmacologic, toxicologic and behavioral effects chiefly through mechanisms mediated by the GABA₆ receptor [13010].

**Positive aspect of GHB**

GHB can be easily manufactured at home with very little knowledge of chemistry, as it only involves the mixing of its two precursors, GBL and an alkali hydroxide (such as sodium hydroxide) to form the resulting GHB salt. Due to the ease of manufacture, it can even be produced in private homes by low level producers. It can be purchased overseas via Internet and then shipped to the purchaser. GHB is generally taken orally and is rapidly absorbed from the gastrointestinal tract. The onset of GHB’s effects is delayed and systemic effects occur generally within 15 min [13010].

**Cardiovascular and respiratory effects**

It was observed a constant but short drop in blood pressure in rabbits after administration of GHB, but in dogs there was either no effect or a slight progressive increase in blood pressure. In all animals, a constant bradycardia was observed. It was also observed a strong hepatic and renal vasodilating action, particularly during hemorrhagic shock in animals, indicating that GHB has “antishock activity”. In man, there appeared to be no effect on blood pressure. Laborit also observed that at low hypnotic doses of GHB, a decrease in ventilatory rate was reported with an increase in amplitude. At high (sleep-inducing) doses of GHB, a Cheyne-Stokes rhythm appeared [13010].

1471
Central nervous system effects

Based on behavioral and electroencephalographic criteria, GHB-induced sleep has been described as being indistinguishable from natural sleep, i.e. unlike coma, the natural stages of sleep 1-2-3-4-REM (rapid eye movement) all occur in their normal sequence. The effect of GHB-enhanced sleep appears to wear off after 3-4 hours at “normal” doses [13010].

GHB in obstetrics

GHB had a spectacular action on the dilation of the cervix and furthermore was beneficial in obstetric surgery due to the absence of respiratory depression in the infant and its antishock property against possible cardiac anoxia [13010].

Sexual enhancing effects of GHB

GHB is “aphrodisiac” in man. It has four sexual-enhancing effects; disinhibition (e.g. relaxation), heightened sense of touch, enhancement of male erectile capacity and increased power of orgasm. These drugs also appear to promote high-risk sexual behaviors that have been associated with increased HIV infection [13010].

GHB use in alcohol and opiate withdrawal

The use of GHB in alcohol withdrawal has been investigated by various researchers and was found to reduce tremors after consumption of alcohol. GHB has also been shown to inhibit voluntary ethanol consumption. The exact mechanism of GHB-enhanced alcohol and opiate withdrawal is unknown. However, a profound inhibition of dopamine output in the nucleus accumbens and ventral caudate nucleus has been associated with alcohol and opiate withdrawal syndromes, and increased dopamine output is known to be involved in the rewarding effects of morphine and alcohol. Therefore, it is possible that GHB suppresses these symptoms as it increases the dopamine levels in these regions of the brain and maintains the dopamine reward pathway [13010].

Interaction with alcohol

Gamma-hydroxybutyrate (GHB) is a common drug of abuse that can produce serious toxicity, particularly when used with other sedatives. It was examined the individual and combined effects of GHB and ethanol in human volunteers. Sixteen healthy adults (7 men) were given 50 mg/kg GHB (Xyrem), 0.6 g/kg ethanol in 2 doses, alone and combined in a double-blind, placebo-controlled, crossover study. Plasma concentrations, heart rate (HR), blood pressure (BP), and oxygen saturation (O_{2sat}) were serially monitored for 24 hours. Adverse events included 2 instances of hypotension and 6 episodes of vomiting with GHB-plus-ethanol ingestion. Oxygen saturation was decreased by GHB and ethanol individually, and maximally decreased by the drugs combined. Compared with baseline, systolic and diastolic BP were significantly decreased, and HR was increased by ethanol but not affected by GHB alone. Ethanol coingestion resulted in 16 percent higher GHB maximal plasma concentration and 29 percent longer elimination half-life, indicating possible enhanced bioavailability or reduced clearance of GHB caused by ethanol, however, these effects were not statistically significant. It was concluded that modest doses of GHB do not affect hemodynamic function, but O_{2sat} was decreased. Gamma-hydroxybutyrate-plus-ethanol resulted in more adverse effects, including gastrointestinal disturbances, hypotension, and decreased O_{2sat}, but only minimal pharmacokinetic interactions were observed [06231].
Pharmacokinetics and pharmacodynamics

gamma-Hydroxybutyrate (GHB) is a potent sedative/hypnotic and drug of abuse. Tolerance develops to GHB's sedative/hypnotic effects. It is hypothesized that GHB tolerance may be mediated by alterations in central nervous system pharmacokinetics or neurotransmitter response. Rats were dosed daily with GHB (548 mg/kg s.c. q.d. for 5 days), and sleep time was measured as an index of behavioral tolerance. Plasma and brain GHB pharmacokinetics on days 1 and 5 were monitored using blood and microdialysis sampling. Extracellular (ECF) striatal dopamine levels were measured by microdialysis as a pharmacodynamic endpoint of tolerance. Pharmacokinetic (PK)/pharmacodynamic (PD) modeling was performed to describe the plasma and brain disposition using an indirect response model with inhibition of dopamine synthesis rate to describe the pharmacodynamic response. GHB plasma and brain ECF concentration versus time profiles following acute or chronic exposure were not significantly different. GHB sedative/hypnotic tolerance was observed by day 5. Acute GHB administration resulted in a decrease in striatal ECF dopamine (DA) levels compared with baseline levels. GHB tolerance was reflected by a 60% decrease in dopamine area under the curve (effect and baseline): acute, 10.1 ± 15.3 percent basal DA/min/10^−3 versus chronic, 4.73 ± 1.49 percent basal DA/min/10^−3. The PK/PD model revealed an increase in the IC50 following chronic exposure indicating decreased dopaminergic sensitivity toward the inhibitory effects of GHB. The findings indicate that GHB pharmacokinetics do not contribute to behavioral tolerance; however, changes in neurotransmitter responsiveness may suggest specific neurochemical pathways involved in the development and expression of tolerance [06232].

Despite gamma-hydroxybutyrate (GHB) therapeutic uses and the increasing concern about its toxicity, few studies have addressed GHB dose-related effects under controlled administration and their relationship with its pharmacokinetics. The study design was double-blind, randomized, crossover, and controlled. As a pilot pharmacology phase I study, increasing doses of GHB were given. Single oral sodium GHB doses (40, 50, 60, and 72 mg/kg) were administered to eight volunteers. Plasma and urine were analyzed for GHB by gas chromatography-mass spectrometry. Physiological effects, psychomotor performance, and subjective effects were examined simultaneously. GHB produced dose-related changes in subjective effects as measured by questionnaires and VAS. GHB showed a mixed stimulant-sedative pattern, with initially increased scores in subjective feeling of euphoria, high, and liking followed by mild-moderate symptoms of sedation with impairment of performance and balance. Mean peak GHB plasma concentrations were 79.1, 83.1, 113.5, and 130.1 mug/L for 40, 50, 60, and 72 mg/kg, respectively. GHB-mediated physiological and subjective effects were dose dependent and related to GHB plasma concentrations. GHB urinary excretion was mainly related to administered doses. GHB-mediated subjective and physiological effects seem dose dependent and related to GHB plasma concentrations. Results suggest a high abuse liability of GHB in the range of dose usually consumed [06233].

1,4-Butanediol (BD) is converted to gamma-hydroxybutyrate (GHB) after ingestion, and is associated with cases of dependence, coma, and death. The pharmacology of BD after oral ingestion has not been described in humans. Eight healthy volunteers (five men) were administered 25 mg/kg BD in a single oral dose after an overnight fast in a double-blinded, placebo-controlled, crossover study. Vital signs were monitored, and serial blood samples collected over 24 h for gas chromatography-mass spectrometry analysis of BD and GHB levels. Subjective mood and symptoms responses were assessed by visual analog scale. All subjects completed the study without significant adverse effects. BD was quickly absorbed and cleared, with time to maximal plasma concentration of 24+/−12 min, and elimination half-
life ($T_{1/2}$) of 39 ± 11 min. BD was extensively converted to GHB, with a mean maximum GHB concentration of 46 ± 20 mg/l reached 39 ± 11 min after BD ingestion. GHB $T_{1/2}$ averaged 32 ± 7 min. Some subjects exhibited slow oral clearance of BD, which tended to correlate with a variant haplotype of the alcohol dehydrogenase gene ADH-IB G143A. Mean CL/F was 152 ± 177 mL/min kg for four subjects with variant haplotype versus 599 ± 447 mL/min kg for four wild-type subjects. Subjects reported feeling less awake and alert, less able to concentrate, and more lightheaded in the first 90 min after BD ingestion. Pulse oximetry readings were lower 45 min after BD dosing with a mean oxygen saturation of 98.5 percent with BD versus 99.6 percent with placebo. Transient increases in mean systolic and diastolic blood pressure were observed, but other vital signs remained unchanged. BD was extensively converted to GHB after oral administration, but significant inter-individual variability in the rate of metabolism, possibly related to variants in ADH-IB, was observed. At the modest dose studied, significant clinical effects were not seen [06234].

In the urine
Gamma-hydroxybutyric acid (GHB) is used as an illicit drug and is implicated in drug-facilitated sexual assault, but it also has some therapeutic uses. Detection of GHB in urine is important for forensic testing and could be of clinical benefit in overdose management. Urine GHB concentration-time profiles have not been well-characterized or correlated with doses used therapeutically. GHB levels were measured by gas chromatography-mass spectrometry in urine collected over 24 h from 16 adults administered single doses of 50 mg/kg GHB (Xyrem) alone and combined with 0.6 g/kg ethanol. Peak GHB urine concentrations averaged 150-200 mg/L and occurred in the 0-3 h urine collection. Significant variability in GHB urine levels between individuals was observed. Caucasians had lower urine concentrations than other races/ethnicities. Men had lower GHB levels than women in the first 3 h after dosing. Coingestion of ethanol did not significantly affect renal clearance of GHB, but urine GHB concentrations were lower in the first 3 h when ethanol and GHB were coingested. At a proposed cut-off of 10 mg/L to distinguish endogenous versus exogenous GHB levels, 13 percent of the samples collected from 3 to 6 h, 81 percent of samples collected from 6 to 12 h, and 100 percent of urine specimens collected from 12 to 24 h were below this level. It was concluded that the detection time for GHB in urine may be shorter than the previously reported 12-h window in some people taking therapeutic doses of GHB [06235].

One study was designed to supplement previous studies that documented in vitro production of gamma-hydroxybutyrate (GHB) in urine samples. Urine samples were provided by subjects who reported that they had never used GHB (n=31). The specimens were stored under standard conditions of refrigeration (5 degrees C) without any preservatives added. All specimens were repeatedly analyzed for the presence of endogenous GHB over a 6-month period using a previously reported headspace GC-MS method. Significant elevations in GHB were observed in many of the urine samples as storage time increased. As a result, the in vitro production of GHB may increase the apparent GHB concentrations in urine during storage. This potential for an artificial increase in GHB concentration must be appreciated when establishing the threshold between endogenous and exogenous concentrations of GHB [06236].

Other negative aspect of GHB

GHB is an extremely dangerous drug as the dose range between safe and toxic is very narrow. After being swallowed the Ecstasy pill begins to disintegrate. It starts to enter the bloodstream through the lining of the small intestine. Once in the bloodstream the active ingredient of GHB will be pumped into the heart. After about 30 minutes, the GHB will be small enough to cross the capillaries into the brain and the “high” will start to be felt. GHB
makes nerves in the brain release serotonin. This serotonin then causes a gland in the brain to release oxytocin also known as ‘the cuddle chemical’. Oxytocin creates the feeling of euphoria and the illusion of strong connection with others. The brain also releases dopamine which allows the user to focus hard on one thing, like beat of a song in a club. It also affects the hypothalamus which controls the body temperature. GHB users are a high risk for overheating. GHB makes you high but it also drags you down. The way the drug affects a person can be compared to the swinging pendulum. The “feel good” emotions for the abuser go far beyond their usual boundaries. But the person feels far worse than usual as the pendulum of emotions swings back in the other direction. The main adverse effects include respiratory depression, amnesia, apnea, hypotonia, aggressiveness, hallucinations, dizziness, euphoria, confusion and seizures. Resolution of CNS depression occurs abruptly with patients going from unresponsive to agitated and combative over very short period of time [13010].

GHB abuse

Due to the various effects of GHB and the various groups of people using the compound, it has a wide-ranging abuse potential. Various myths have come up from time to time which has made the usage of GHB even more adverse. Many people use it for weight lifting. A few credit GHB for keeping them young. According to some it is the safest of all euphoric drugs, in terms of having zero negative side effects. However some are of opinion that it is good!!! Better than alcohol as you need not overload the liver with processing excess amounts of alcohol. A few even use it as a vitamin supplement. Physical dependence has been observed at prolonged high dosage. Reports indicate that GHB is abused for various reasons and by various sections of society [13010].

Body builders who believe that by taking this drug could improve muscle mass or improve exercise performance but there is no evidence of such effects. Therefore it is illicitly sold and distributed in gymnasiums. Some people erroneously refer to GHB as an anabolic steroid, which is not the case, as its chemical structure does not resemble a steroid. Conversely, other people sometimes use GHB as an apparent appetite suppressant or weight loss product, although there is very little definite scientific data to support these claims. Second group includes the sexual predators who covertly administer drug for its sedative and amnesic effects and lastly club goers who take the drug for its euphoric effects. GHB use is very often in night clubs and is an alternative to ecstasy. Most patients are transported from night clubs with 84 [13010].

GHB withdrawal is similar to withdrawal from other sedative/hypnotic agents such as ethanol. GHB’s significant “likelihood of abuse” is evident with its sixth place ranking out of 19 hypnotic drugs compared. It is ranked second only to pentobarbital with respect to toxicity taking into account withdrawal severity. Onset of withdrawal symptoms typically occurs within a few hours after cessation of GHB or its prodrugs. The withdrawal symptoms include: insomnia, anxiety, tremor, delirium, seizures and in extreme cases even, death. Wernicke-Korsakoff syndrome has also been associated with GHB withdrawal. In the majority of GHB-related deaths, the concentration in post mortem blood has been found to be high. Furthermore, in living persons, similar concentrations have been detected in unconscious patients who awake a few hours later with no obvious side effects. Due to the rapid absorption and metabolism of GHB, however, it is difficult to predict how much of the original dose such post mortem concentrations represent. Hence more research and thorough analysis of GHB in fatalities and poisonings are still required before the true involvement of GHB can be established and accurate mortality and morbidity figures produced [13010].
**GHB detection**

GHB can be detected in hair even months after GHB ingestion. To detect GHB in urine, the sample must be taken within 8-12 hours of GHB ingestion. In some cases, however, extensive drug screening is performed and presence of GHB has been confirmed by gas chromatography and mass spectrometry [13010].

**Laboratory technique**

A gas chromatographic-tandem mass spectrometric (GC-MS-MS) method for determining trace concentrations of gamma-hydroxybutyrate (GHB) in blood and urine has been developed. Multiple reaction monitoring was used to detect parent and daughter ions of GHB, 233 and 147, respectively, following liquid-liquid extraction with acetonitrile and derivatisation with N,O-bis[trimethylsilyl]trifluoroacetamide (BSTFA). Deuterated GHB was used as an internal standard. The assay produced excellent linearity and sensitivity without conversion to gamma butyrolactone. The lower limit of quantitation (LLOQ) in 50 microL of sample was 2.5 microg/mL. The expanded uncertainty values for intra- and interassay results were ± 0.097 and ± 0.123 ng/mL at a confidence level of 95 percent for blood and urine, respectively. Endogenous concentrations of GHB were found to be in the range of 0.3 to 6 microg/mL in urine and 0.5 to 2.3 microg/mL in blood, confirming previously suggested cut-off values for forensic analysis [06237].

One study was designed to supplement previous attempts to establish an accurate range of normal endogenous gamma-hydroxybutyrate (GHB) concentrations in random antemortem urine samples. Furthermore, its purpose was to ascertain the effect of gender, race, age, medications, and select medical conditions on endogenous concentrations of GHB in urine and the proposed endogenous urinary GHB cutoff of 10 microg/mL. Urine samples (n=207) were provided by subjects who reported that they had never used GHB. As part of the collection process, subjects also completed a short survey to collect information about gender, race, age, orally ingested medications, and select medical conditions. All specimens were analyzed in duplicate for the presence of endogenous GHB using a previously reported headspace gas chromatography-mass spectrometry method. The data were analyzed for tendencies among different population groups. GHB concentrations ranged from 0.00 to 2.70 microg/mL in all specimens, with a median concentration of 0.24 microg/mL. Males (n=130) had an average endogenous GHB concentration of 0.27 microg/mL (0.00-2.70 microg/mL), whereas females (n=77) averaged 0.29 microg/mL (0.00-0.98 microg/mL). Select medical conditions and participants’ race, age ranges, and medications that were used within 48 h prior to collection were also evaluated. The results of this study will aid the interpretation of low GHB concentrations measured in urine samples, particularly in investigations of drug-facilitated crimes [06238].

**beta-Hydroxy-beta-methylbutyrate (HMB)**

HMB is a byproduct of leucine metabolism in the human body. HMB is currently marketed as calcium-HMB-monohydrate. Although the ergogenic mechanism is unknown, investigators speculate that HMB may be incorporated into cell components or may influence cellular enzyme activity, in some way inhibiting the breakdown of muscle tissue during strenuous exercise. Several animal studies involving poultry, cattle, and pigs have indicated HMB supplementation may increase lean muscle mass and decrease body fat. Studies on humans are limited, but the first published report indicated that HMB supplementation (1.5-3.0 g/day)
significantly increased lean tissue and strength in untrained males who initiated a resistance-training program for three weeks. Research was limited in the following years. In a year 2000 review of research evaluating claims that HMB supplementation can enhance exercise performance, it was indicated that at that time there were only two reports published in peer-reviewed journals, and the remaining eight papers were published as abstracts only and had not undergone the peer-review process. Based on these data, they indicated that although there is some support for the claims, at least in young, untrained individuals, the response of resistance-trained individuals is less clear and that there is a need for more tightly controlled, longer duration studies to evaluate the ergogenic effect of HMB supplementation. Peer-reviewed studies published subsequent to year 2000 are equivocal regarding the ergogenic effect of HMB supplementation on exercise performance in untrained individuals. For example, it was reported that short-term HMB supplementation (3 grams daily for 4 weeks) during resistance training significantly increased upper body strength in both untrained males and females. In another report older subjects engaged in 8 weeks of resistance training and consuming 3 grams HMB daily experienced a significant decrease in body fat, but no significant change in fat-free mass. In a placebo-controlled study, compared the effects of HMB (3 grams daily) and creatine (20 grams for 10 days; 10 grams for 14 days), both separately and in combination, on body composition and strength of subjects undergoing resistance training for 3 weeks. All subjects gained body mass and strength with training, but the supplement groups gained more than the placebo group. However, the only significant effect on body mass was that of the creatine group compared to the placebo group. Overall these findings with untrained individuals are equivocal, meriting additional research. In general, studies using resistance-trained individuals as subjects report no significant effects of HMB supplementation. In one study it was provided forty experienced strength-trained athletes with 0, 3, or 6 grams of HMB daily during four weeks of resistance training, and reported no significant effects of HMB on muscle tissue breakdown, fat-free body mass, or strength gains in the bench press and leg press. It was also studied the effect of daily HMB supplementation on body composition, muscular strength, and markers of muscle damage and muscle protein turnover following 3 and 6 weeks of training. While both the placebo and HMB groups increased lean body mass and strength with the training, the HMB supplementation provided no additional benefits. In a review, it was indicated that studies of HMB supplementation have shown minimal gains in strength and lean body mass in specific populations, mainly untrained athletes. However, HMB use in athletes involved in regular high-intensity exercise has not been proven to be beneficial when multiple variables are evaluated. It was concluded that HMB cannot be recommended as an ergogenic until further studies in larger groups reproduce early data [06239].

One study investigated the effects of 6 weeks of dietary supplementation of beta-hydroxy-beta-methylbutyrate (HMB) and HMB combined with creatine monohydrate (HMBCr) on the muscular strength and endurance, leg power, and anthropometry of elite male rugby league players. The subjects were divided into a control group (n=8), a HMB group (n=11; 3 g/day)) or a HMBCr group (n=11; 12 g/day with 3 g HMB, 3 g Cr, 6 g carbohydrates). Three repetition maximum lifts on bench press, deadlifts, prone row, and shoulder press, maximum chin-up repetitions, 10-second maximal cycle test, body mass, girths, and sum of skinfolds were assessed pre- and postsupplementation. Statistical analysis revealed no effect of HMB or HMBCr on any parameter compared with presupplementation measures or the control group. HMB and HMBCr were concluded to have no ergogenic effect on muscular strength and endurance, leg power, or anthropometry when taken orally by highly trained male athletes over 6 weeks [07214].

The aim of one study was to determine the effects of oral beta-hydroxy-beta-methylbutyrate (HMB) supplementation (3 g/d) on selected components of aerobic performance and body composition of active college students. Subjects were randomly assigned to either an HMB
(n=8) or a placebo (PLA) group (n=8) for a 5-weeks supplementation period during which they underwent interval training 3 times a week on a treadmill. Aerobic-performance components were measured using a respiratory-gas analyzer. Body composition was determined using dual-energy X-ray absorptiometry. After the intervention, there were significant differences between the 2 groups in gains in maximal oxygen consumption (+8% for PLA and +13% for HMB). Regarding body composition, there were no significant differences. The authors concluded that HMB supplementation positively affects selected components of aerobic performance in active college students [07215].

The purpose of one study was to determine the effects of short-term supplementation with the free acid form of beta-hydroxybeta-methylbutyrate (HMB-FA) on indices of muscle damage, protein breakdown, recovery and hormone status following a high-volume resistance training session in trained athletes. A total of twenty resistance-trained males were recruited to participate in a high-volume resistance training session centred on full squats, bench presses and dead lifts. Subjects were randomly assigned to receive either 3 g/d of HMB-FA or a placebo. Immediately before the exercise session and 48 h post-exercise, serum creatine kinase (CK), urinary 3-methylhistadine (3-MH), testosterone, cortisol, and perceived recovery status (PRS) scale measurements were taken. The results showed that CK increased to a greater extent in the placebo (329%) than in the HMB-FA group (104%). There was also a significant change for PRS, which decreased to a greater extent in the placebo than in the HMB-FA group. Muscle protein breakdown, measured by 3-MH analysis, numerically decreased with HMB-FA supplementation and approached significance. There were no acute changes in plasma total or free testosterone, cortisol or C-reactive protein. In conclusion, these results suggest that an HMB-FA supplement given to trained athletes before exercise can blunt increases in muscle damage and prevent declines in perceived readiness to train following a high-volume, muscle-damaging resistance-training session [13524].

Beta-hydroxy-beta-methylbutyrate (HMB), a metabolite of the branched-chain amino acid leucine, is extensively used by athletes and bodybuilders in order to increase strength, muscle mass and exercise performance. It was performed a systematic review of the clinical literature on the effectiveness of HMB supplementation in healthy and pathological conditions (i.e. training programs, aging, acute and chronic diseases, and after bariatric surgery). It was reviewed all clinical trials indexed in Medline that tested HMB supplementation as well as all the experimental data regarding HMB intracellular mechanisms of action. Search terms included: randomized controlled trials, controlled clinical trials, single- and double-blind method, HMB, proteolytic pathways, muscle atrophy, cachexia, and training. It was found out 13 studies testing HMB in healthy young trained subjects, 11 in healthy young untrained subjects, 9 in patients affected by chronic diseases (i.e. cancer, HIV, chronic obstructive pulmonary disease), and 6 in elderly subjects. The indexed studies support that HMB is effective in preventing exercise-related muscle damage in healthy trained and untrained individuals as well as muscle loss during chronic diseases. Most of the selected studies showed the effectiveness of HMB in preventing exercise-related muscle damage in healthy trained and untrained individuals as well as muscle loss during chronic diseases. The usual dose of 3 g/day may be routinely recommended to maintain or improve muscle mass and function in health and disease. The safety profile of HMB is unequivocal. Further, well-designed clinical studies are needed to confirm effectiveness and mode of action of HMB, particularly in pathological conditions [13525].

Beta-hydroxy-beta-methylbutyrate (HMB) is a five-carbon organic acid and a derivative, in vivo, of the essential amino acid leucine (LEU) via its metabolite alpha-ketoisocaproate (alpha-KIC). LEU is a potent anti-catabolic compound and a regulator of protein metabolism. In fact, muscle loss in atrophic conditions can be reversed by LEU supplementation. High
LEU doses counteract muscle proteolysis, while low LEU doses enhance muscle protein synthesis. Almost 80 percent of LEU is normally employed for protein synthesis while the remainder is converted to α-KIC and only a small proportion of LEU (5%) is converted into HMB. LEU may be transaminated to alpha-KIC by two different pathways. The first one consists of transformation of alpha-KIC into HMB by the liver cytosolic enzyme KIC dioxygenase with cytosolic HMB subsequently converted into beta-hydroxy-beta-methylglutaryl-CoA (HMG-CoA) which can be directed for cholesterol synthesis in liver and in muscle. The second pathway consists of liver α-KIC oxidation into isovaleryl-CoA by the mitochondrial branched-chain ketoacid dehydrogenase (BCKD); finally, HMG-CoA is produced by the HMG-CoA synthase. HMB supplementation is claimed to exert positive effects both in healthy (i.e., increasing sport performance as well as reducing exercise-related muscle damage) and pathological conditions (i.e., preserving and increasing muscle mass) perhaps by reducing protein degradation and enhancing protein synthesis. In cachectic conditions (i.e., cancer, sepsis, acquired immunodeficiency syndrome, malnutrition, myopathies, congestive heart failure, renal failure, and chronic obstructive pulmonary disease) skeletal muscle loss is mainly consequent to a shift towards protein breakdown. The proteolytic systems, i.e. the ubiquitin–proteasome and the caspase systems, may initiate myofibrillar proteolysis thus playing a pivotal role in muscle wasting diseases. HMB may influence protein metabolism as shown by changes in proteasome dependent proteolysis and protein synthesis in experimental models. HMB administration to murine cell culture attenuated the tumor factor proteolysis-inducing factor (PIF)-induced activation of protein kinase C (PKC), the subsequent degradation of nuclear factor-kappaB inhibitor-alpha (IκBα) and nuclear accumulation of nuclear factor kappaB (NFκB). HMB also attenuated PIF-induced phosphorylation of p24/44 mitogen-activated protein kinase (MAPK) thereby interfering with proteasome expression. Moreover, expression of the proteasome 20S alpha or beta subunits was reduced by 50 percent as well as the ATPase subunits of the 19S proteasome regulatory subunit and the E2 ubiquitin-conjugating enzyme [13525].

Muscle protein degradation also occurs following activation of caspase-3 and caspase-8 by tumor necrosis factor-alpha (TNF-alpha), interferon-gamma (IFN-gamma), angiotensin II (ANG II) and lipopolysaccharide (LPS). The subsequent autophosphorylation and activation of protein kinase R (PKR) increases reactive oxygen species (ROS) formation via activation of p38 MAPK. ROS formation stimulates NF-κB-mediated induction of the ubiquitin–proteasome pathway. HMB completely attenuated the increase in ROS formation, caspase-3 and caspase-8 activity and PKR autophosphorylation in murine myogenic cell culture. In addition, HMB stimulated protein synthesis in murine myotubes treated with cachectic stimuli (PIF, TNF-alpha/IFN-gamma, ANG II and LPS) through enhancement of the phosphorylation and activation of the mammalian target of rapamycin (mTOR) that, in turn, phosphorlates and activates the 70-kDa ribosomal S6 kinase (p70S6k). Cachectic stimuli also depress protein synthesis by activating PKR with subsequent phosphorylation of eukaryotic initiation factor 2 (eIF2) on the α-subunit and eukaryotic elongation factor 2 (eEF2). HMB attenuated phosphorylation of eEF2 by increasing phosphorylation of mTOR and attenuated phosphorylation of eIF2alpha by preventing autophosphorylation and activation of PKR. In presence of HMB, phosphorylation of the initiation factor 4E-binding protein 1 (4EBP1) was increased; so, the increased association of eukaryotic initiation factor 4E (eIF4E) with eIF4G resulted in the increase of the active eIF4G-eIF4E complex consequently to the reduction of the inactive 4E-BP1-eIF4E complex. Together, these effects active the translation machinery and attenuate PIF-induced depression of protein synthesis in murine myotubes. Thus, HMB attenuation of muscle and body weight loss in experimental cancer cachexia may rely on HMB-mediated decrease in phosphorylated eIF2α and increase in phosphorylated p70S6k and phosphorylated mTOR. The HMB anabolic properties are consistent with muscle hypertrophy and increase in serum insulin levels, expression of mTOR and phosphorylation...
of p70S6k in healthy and sedentary rats. In addition to the anabolic properties above, the increase of muscle glycogen, ATP content and citrate synthase (CS) activity after HMB supplementation to Wistar rats confirm HMB-related changes in oxidative metabolism improving muscle strength generation and performance during intense contractions [13525].

Tumor weight and tumor cell proliferation, ex vivo, were reduced in Walker 256 tumor-bearing rats treated with HMB. These animals also expressed significant increase in IκBα, Bax/Bcl-2 protein expression ratio, phagocytic capacity and H2O2 production rates in blood polymorphonuclear cells, decrease in NFκB p65 subunit content, and an intense infiltration of leukocytes and activated granulocytes in tumor necrotic regions. HMB also decreased the extent of human peripheral blood mononuclear cell proliferation and cytokine production, in vitro. However, when added to human serum-starved myoblasts HMB induced cell proliferation, MyoD (a marker for activated satellite cells) expression, the phosphorylation of mitogen-activated protein kinase/extracellular signal-regulated protein kinase (MAPK/ERK), muscle differentiation factors (myogenin and MEF2) expression, an increase in insulin-like growth factor-1 (IGF-1) mRNA levels and accelerated cell fusion. HMB also reduced serum-starvation- or staurosporine-induced cell apoptosis and myonuclear apoptosis during recovery from hind limb suspension-induced muscle fiber atrophy in aged rats, perhaps via a reduction in pro-apoptotic protein (Bax and cleaved caspase-3) levels and increase in anti-apoptotic protein levels (Bcl-2 and Bcl-X). As the myoblast proliferation would be related to the mediation of MAPK/ERK pathway, the promotion of cell differentiation and fusion as well as the prevention of apoptosis would be related to the activation of phosphoinositide 3′-kinase (PI3 K)/Akt pathway. In fact, HMB enhances the association of the p85 subunit of PI3 K with tyrosine-phosphorylated proteins and PI3 K-dependent Akt phosphorylation thereby conditioning cell survival via inhibition of pro-apoptotic proteins. Because HMB administration increased growth hormone (GH) and IGF-I mRNA levels in vitro and in vivo models, GH/IGF-I axis may mediate some of HMB’s effects on myoblasts proliferation, differentiation and survival [13525].

Some of HMB’s reparative effects on damaged tissues may be due to its metabolite HMG-CoA which represents a carbon source for cholesterol synthesis allowing for cell growth, function and regenerative capability of the cell membrane. Therefore, HMB may prevent leakage of muscle enzymes by repairing the cell membranes damaged after physical exercise. In addition, HMB supplementation was recently shown to be effective in attenuating dexamethasone-induced muscle atrophy and to reduce total and low-density lipoprotein cholesterol in humans. Noteworthy, despite the increase in cholesterol synthesis HMB supplementation does not influence serum testosterone levels in healthy males [13525].

Supplementing the diet with the amino acid leucine in combination with resistance training may increase lean body mass (LBM), strength and decrease body fat. Moreover, leucine appears to decrease skeletal muscle soreness following eccentric exercise, and prevent declines in both circulating testosterone and skeletal muscle power following an overreaching cycle. Leucine has been thought to augment adaptations to strength training by acting as the primary signal to activate protein synthesis (e.g. regulation of translation initiation). Additionally, for over three decades this amino acid has been known to exert antiproteolytic effects. However, the effects of leucine on muscle proteolysis are maximized at 10–20 times (5-10 mM/L) the concentration required to maximally stimulate muscle protein synthesis. Thus, it is probable that these effects are partly mediated by the conversion of leucine to a specific metabolite. One strong candidate is the leucine-derived metabolite, beta-hydroxy-beta-methylbutyrate (HMB). In 1996, it was first demonstrated that supplementation with HMB lowered muscle proteolysis following resistance training, and augmented gains in LBM and strength in a dose-dependent manner. Since that time HMB has been studied in a variety of anaerobic and aerobic training conditions. While numerous studies have supported
the efficacy of HMB supplementation for enhancing recovery, LBM, strength, power, and aerobic performance, there have also been conflicting results. The International Society of Sports Nutrition (ISSN) therefore bases the following position stand on a critical analysis of the literature on the use of beta-hydroxy-beta-methylbutyrate (HMB) as a nutritional supplement. The ISSN has concluded the following [13526]:

- HMB can be used to enhance recovery by attenuating exercise induced skeletal muscle damage in trained and untrained populations
- If consuming HMB, an athlete will benefit from consuming the supplement in close proximity to their workout
- HMB appears to be most effective when consumed for 2 weeks prior to an exercise bout
- 38 mg/kg bodymass daily of HMB has been demonstrated to enhance skeletal muscle hypertrophy, strength, and power in untrained and trained populations when the appropriate exercise prescription is utilized
- Currently, two forms of HMB have been used: Calcium HMB (HMB-Ca) and a free acid form of HMB (HMB-FA). HMB-FA may increase plasma absorption and retention of HMB to a greater extent than HMB-Ca. However, research with HMB-FA is in its infancy, and there is not enough research to support whether one form is superior
- HMB has been demonstrated to increase LBM and functionality in elderly, sedentary populations
- HMB ingestion in conjunction with a structured exercise program may result in greater declines in fat mass
- HMB’s mechanisms of action include an inhibition and increase of proteolysis and protein synthesis, respectively
- Chronic consumption of HMB is safe in both young and old populations

beta-Hydroxy-beta-methylbutyrate (HMB), a metabolite of the branched-chain amino acid leucine, is extensively used by athletes and bodybuilders in order to increase strength, muscle mass and exercise performance. It was performed a systematic review of the clinical literature on the effectiveness of HMB supplementation in healthy and pathological conditions (i.e. training programs, aging, acute and chronic diseases, and after bariatric surgery). We reviewed all clinical trials indexed in Medline that tested HMB supplementation as well as all the experimental data regarding HMB intracellular mechanisms of action. Search terms included: randomized controlled trials, controlled clinical trials, single- and double-blind method, HMB, proteolytic pathways, muscle atrophy, cachexia, and training. We found out 13 studies testing HMB in healthy young trained subjects, 11 in healthy young untrained subjects, 9 in patients affected by chronic diseases (i.e. cancer, HIV, chronic obstructive pulmonary disease), and 6 in elderly subjects. The indexed studies support that HMB is effective in preventing exercise-related muscle damage in healthy trained and untrained individuals as well as muscle loss during chronic diseases. Most of the selected studies showed the effectiveness of HMB in preventing exercise-related muscle damage in healthy trained and untrained individuals as well as muscle loss during chronic diseases. The usual dose of 3 g/day may be routinely recommended to maintain or improve muscle mass and function in health and disease. The safety profile of HMB is unequivocal. Further, well-designed clinical studies are needed to confirm effectiveness and mode of action of HMB, particularly in pathological conditions [13525].

Metabolism

HMB is naturally produced in animals and humans from the amino acid leucine. The first step in production of HMB is the reversible transamination of leucine to alpha-keto-isocaproate (KIC) by the enzyme branched chain amino acid transferase. After leucine is metabolized to
KIC, KIC is either metabolized into isovaleryl-CoA by the enzyme α-ketoacid dehydrogenase in the mitochondria, or into HMB in the cytosol, by the enzyme α-ketoisocaproate dioxygenase. KIC is primarily metabolized into isovaleryl-CoA, with only approximately 5 percent of leucine being converted into HMB. To put this into perspective, an individual would need to consume over 600 g of high quality protein to obtain the amount of leucine (60 grams) necessary to produce the typical 3 g daily dosage of HMB used in human studies. Since consumption of this amount of protein is impractical, HMB is typically increased via dietary supplementation. As a dietary supplement, HMB has been commercially available as a mono-hydrated calcium salt, with the empirical formula Ca(HMB)$_2$$\cdot$H$_2$O (HMB-Ca). The magnitude and rate of appearance of HMB following ingestion is dependent on the dose, and whether or not it is consumed with additional nutrients. It is likely that the addition of glucose slowed gastric emptying, or improved HMB clearance. Recently a new delivery method of HMB, administered as a free acid, has been investigated. The free acid form is called beta-hydroxy-beta-methylbutyric acid and can be designated as HMB-free acid (HMB-FA). The initial research studies have utilized HMB-FA associated with a gel, containing a buffering mechanism (K$_2$CO$_3$) that raises the pH to 4.5. Commercially, HMB has only been available in the calcium salt form (HMB-Ca) as a powder, which has generally been supplemented in capsule form. Moreover, it was previously thought that because calcium dissociated relatively easily from HMB-Ca (10-5 minutes in the gut), there would be no difference in digestion kinetics between HMB-Ca and HMB-FA. The half-life of HMB in plasma when given as HMB-FA and HMB-Ca were found to be approximately three- and two and a half hours, respectively [13526]

**HMB safety**

The safety of HMB has been widely studied. In a study conducted in compliance with Food and Drug Administration Good Laboratory Practice, rats consuming a diet of up to 5 percent HMB-CA for 91 days did not exhibit any adverse effects vis a vis clinical observations, hematology, clinical chemistry or organ weights. In addition, two meta-analyses, one with HMB supplementation alone and another with HMB supplementation combined with glutamine and arginine, have concluded that HMB is safe and does not result in any adverse effects. Evidence to date indicates that that consumption of HMB is safe in both young and old populations; however, future studies examining the effects of HMB on insulin sensitivity in humans are warranted [13526].

**Effects on skeletal muscle damage, protein breakdown, and recovery**

HMB is presently thought to work by speeding regenerative capacity of skeletal muscle following high intensity or prolonged exercise. Researchers have used a number of dependent measures to examine this attribute including serum indices of skeletal muscle damage (creatine kinase [CK], and lactate dehydrogenase [LDH]), and urinary indicators of protein breakdown (3-methyl-histidine [3-MH] and urea nitrogen). Perceived recovery and skeletal muscle soreness have also been investigated following training with, and without HMB supplementation. However, results across studies have not been consistent [13526].

**Effects of training status**

Training status has been a variable that has received a great deal of interest in the literature. When training and/or diet are controlled, a number of studies have demonstrated that HMB can lower indices of skeletal muscle damage and protein breakdown in a dose dependent fashion in untrained populations. However, research indicates that in trained populations it is critical that the exercise stimulus is of adequate intensity and volume to cause skeletal muscle damage. If these conditions are lacking, HMB is not likely to be It has been found
effects of pre exercise administration of HMB-FA to resistance trained athletes on muscle damage, and perceived recovery following a high volume resistance training bout centered around squats, deadlifts, and bench press. HMB-FA supplementation blunted the rise in CK levels and protein breakdown following a workout compared to the placebo group. Moreover, HMB-FA improved the perceived recovery score, suggesting that HMB-FA enhanced recovery [13526].

Duration of supplementation, dose, and timing

The duration, dosage, and timing of HMB supplementation have notably varied in the literature. The effects appeared to be greater when ingesting 3 g of HMB-CA compared to lower doses of the supplement (1.5 g of HMB-CA). Other investigations who have supplemented with HMB-Ca for two or more weeks have generally reported that the supplement lowers indices of skeletal muscle damage and soreness, while those supplementing for shorter periods of time have not. These findings suggest that HMB-Ca supplementation may be optimized when ingestion begins two weeks prior to the onset of a new training period or change in training workload. In the majority of studies, however, researchers have had subjects consume HMB-Ca with breakfast, lunch, and dinner, without any regard to how the supplement is timed relative to exercise. Currently only two studies have reported HMB’s acute effects on skeletal muscle damage and recovery. Collectively these findings lead us to suggest the following: HMB supplementation appears to speed recovery in untrained and trained individuals if the exercise stimulus is high intensity, and/or high volume in nature. For untrained individuals this would likely occur with the introduction of most exercise regimens; however, in a trained population the exercise stimulus will likely need to center on free weights and compound movements. In regards to optimizing HMB supplementation, it appears that HMB has both acute and chronic effects. HMB’s acute effects likely depend upon supplementation pre-exercise. If taking HMB-Ca, the recommendation would be to consume 3 g, at least 60 minutes prior to intense exercise. If consumed with glucose it may need to be taken as long as two hours prior to training. HMB in the HMB-FA form may have an overall faster and greater effect based upon the rise in plasma levels. Thus, athletes could consume the supplement in HMB-FA form 30-60 minutes prior to exercise. Finally, in order to optimize HMB’s chronic effects, the recommendation would be to consume 3 g daily, divided into three equal servings for a minimum of two weeks prior to a potentially damaging skeletal muscle event [13526].

The effects on skeletal muscle hypertrophy in healthy untrained and trained adults

Similar to its reported effects on skeletal muscle damage, a wide range of subject populations (untrained vs resistance trained; male vs female) and training protocols have been examined. Training protocols have varied in duration (10 days to 12 weeks), periodization scheme, and training modalities (machines and free weights vs free weights only). To confound the situation further, some researchers have designed and monitored the resistance-training protocol, while others have left it up to subjects to train on their own. In other cases, subjects have participated in unspecified training protocols reportedly provided by various team coaches or training camps. In addition, studies have provided a variety HMB doses ranging from 1.5 to 6 g daily. Moreover, some studies have supplemented HMB along with creatine monohydrate or arginine and glutamine. Further, some researchers have controlled for diet, while the majority have not. Lastly, the outcome measures for indices of skeletal muscle mass have varied from less accurate indirect indices (skin fold and bioelectrical impedance measures), to dual x-ray absorptiometry (DXA) to determine fat free mass (FFM) and LBM, respectively. Thus, in order to make any overall conclusions on HMB’s effectiveness, the validity and reliability of each of these measures needs to be considered. In both trained and untrained individuals the majority of studies using HMB have
lasted four weeks or less. In untrained individuals supplementation with HMB has been demonstrated to increase FFM, as well as strength in as little as three weeks. These findings are not surprising if HMB operates through speeding recovery of damaged skeletal muscle tissue. In particular, research indicates that the initial weeks of training result in the highest magnitude of damage in an untrained population. Research supports that rate of improvement in novice lifters decline as their training experience increases, however, the majority of studies using HMB were not periodized. For these reasons HMB’s magnitude of effect over a placebo in novices only slightly increases when analyzing results over eight weeks versus three to four weeks utilizing a linear resistance training model. Finally, in untrained individuals it appears that 3 g of HMB per day produces greater gains than 1.5 g of HMB per day; though, 6 g of HMB per day was not shown to further increase HMB’s effectiveness over 3 g of HMB per day. However, only one study has examined a daily dose of 6 g HMB, therefore no definitive recommendation on (upper limit) dosing can be provided until additional research is conducted. According to the available science, the effectiveness of HMB appears to be optimized under conditions of continually changing loading patterns. The rate of adaptation in strength, power, and hypertrophy in trained and untrained individuals markedly differs. For example it was found that 21 weeks of resistance training resulted in 21 and 4 percent increases in strength in untrained and highly strength trained athletes, respectively. In these subjects, HMB appears to augment adaptations following unaccustomed high intensity training protocols. Because the rate of adaptation is markedly slowed in trained populations it is likely that HMB’s effects in this population will be optimized over longer duration protocols (>6 weeks). To date, few studies have examined monitored resistance training in trained athletes. Collectively the findings lead us to the following conclusions [13526]:

- In untrained individuals, HMB can enhance muscle hypertrophy and dynamic strength in as little as three weeks
- For trained individuals it is important to realize that adaptations occur at a slower rate than in untrained individuals. For this reason, HMB will likely be most beneficial over longer training durations (> 6 weeks) in trained individuals.
- HMB supplementation has been demonstrated to result in modest increases in strength during unsupervised, resistance training programs greater than six weeks in duration.
- Presently, available literature suggests 38 mg/kg BM daily, divided into two to three servings provides an adequate amount of HMB to enhance adaptive processes in muscle.

**HMB in athletes training in an energy restricted state**

The effects of HMB supplementation on regenerative capacity and fat metabolism make it a unique candidate for a number of special situations in which skeletal muscle wasting is indicated. One situation in particular concerns caloric (energy) restriction. Restricting calories prior to competition is commonly used by bodybuilders and those in weight-classified sports. However, research demonstrates that calorie restriction can cause decreases in lean mass and exercise performance. Findings suggest that individuals who are moderately calorically restricted may augment fat loss and prevent declines in LBM by supplementing with HMB [13526]

**HMB supplementation in youth and adolescent populations**

Research in infants using HMB has yet to be done using human models. However, there is recent epigenetic data in animal models to suggest that HMB given during pregnancy can result in prenatal programming of skeletal muscle tissue. Specifically, maternal
supplementation of HMB during pregnancy resulted in greater weight and lean mass gain in piglets than those not under maternal treatment. Moreover, research in growing, pre-adolescent rats suggests that HMB supplementation was able to stimulate skeletal muscle hypertrophy in the extensor digitorum longus and soleus muscles. There is little research examining the effects of HMB in human adolescent populations. However, this population may be an ideal model for HMB supplementation as resources required to augment their training adaptations compete with resources needed for normal growth of organs, bones, and muscle tissue. No changes in hormone status (testosterone, cortisol, IGF-1, growth hormone) or inflammatory mediators (IL-6 and IL-1 receptor antagonist) occurred with HMB-Ca supplementation [13526].

**HMB supplementation in aging and masters athletes**

Skeletal muscle loss is a part of the aging process and approximately 30 percent of skeletal muscle mass is lost between the 5th and 8th decades of life. This reduction in skeletal muscle mass occurs for several reasons, including maintaining a sedentary lifestyle, malnutrition, insulin resistance, oxidative stress, and alterations in skeletal muscle metabolism and repair. In addition, the elderly exhibit impaired anabolic and anti-catabolic responsiveness to resistance exercise and amino acid feeding, termed anabolic resistance. Anabolic resistance can be overcome by supplementation of leucine, and it has been hypothesized that this may be due to the conversion of leucine to HMB. These data suggest a potential benefit of HMB supplementation in aging individuals. HMB supplementation was able to prevent the loss of skeletal muscle fiber size in very old as compared to young rats. These studies suggest that HMB alone can decrease body fat and increase skeletal muscle mass and strength in aging populations. The efficacy of HMB supplementation in conjunction with a strength-training program has also been investigated in aging populations. Considering the paucity of available research on HMB ingestion and resistance exercise in older adults, additional investigations are warranted [13526].

**HMB improves indices of aerobic performance, fat loss, and energy metabolism**

While HMB has long been touted as an anti-catabolic agent that may aid recovery and improve performance, recent evidence has identified additional metabolic benefits of HMB supplementation related to energy metabolism. The mechanisms for these benefits of HMB on aerobic performance and fat loss are poorly understood. However, recent evidence demonstrated that HMB supplementation improves fatty acid oxidation, adenosine monophosphate kinase (AMPK), Sirt1 (Silent information regulator transcripts) and Sirt3 activity in 3T3-L1 adipocytes and in skeletal muscle cells. Consequently, this recent evidence has shown that HMB supplementation increases mitochondrial biogenesis and fat oxidation. Exactly how HMB induces changes in Sirt proteins, AMPK, and mitochondria remains unclear. However, these results could have implications for obesity, insulin resistance, and diabetes, as well as for athletes seeking to improve body composition and aerobic performance [13526].

**Proposed mechanisms of action**

Skeletal muscle protein turnover is the product of skeletal muscle protein synthesis and skeletal muscle protein degradation. When protein synthesis exceeds protein degradation, there is a net synthesis of skeletal muscle protein. However, when protein degradation exceeds protein synthesis, there is a net breakdown of skeletal muscle protein. HMB has been shown to affect both protein synthesis and degradation pathways in skeletal muscle. HMB has been shown to stimulate protein synthesis in skeletal muscle. This has been hypothesized to occur through stimulation of mTOR, a protein kinase responsive to
mechanical, hormonal, and nutritional stimuli. Mammalian target of rapamycin has a central role in the control of cell growth, primarily by controlling mRNA translation efficiency. Indeed, previous studies have observed that HMB supplementation increases phosphorylation of mTOR and its downstream targets ribosomal protein S6 kinase (S6K) and eukaryotic initiation factor-4 binding protein-1. The growth hormone (GH) and insulin-like growth factor 1 (IGF-1) axis may also play a key role in the stimulation of protein synthesis, and it is possible HMB may stimulate protein synthesis through changes in the activity of GH/IGF-1 axis. It is possible that the GH/IGF-1 axis signaling may require a large change in plasma HMB levels. At this point, it is not clear whether a threshold response to a specific concentration of plasma HMB exists [13526].

Skeletal muscle regeneration

In addition to the direct effects on protein synthesis, HMB has been shown to affect satellite cells in skeletal muscle. When myoblasts were cultured with HMB, the mRNA expression of myogenic regulatory factor D (MyoD), a marker of cell proliferation, was increased in a dose responsive manner. Moreover, the addition of various concentrations of HMB (25-100 microg/mL) to the culture medium for 24 hours resulted in a marked increase of myogenin and myocyte enhancer factor-2 (MEF2) expression, markers of cell differentiation. As a result, there was a significant increase in the number of cells, suggesting a direct action of HMB upon the proliferation and differentiation of myoblasts [13526].

Skeletal muscle proteolysis

Skeletal muscle proteolysis is increased in catabolic states such as fasting, immobilization, aging, and disease. HMB has been shown to decrease skeletal muscle protein degradation both in vitro and in vivo. The ubiquitin-proteasome system is an energy-dependent proteolytic system that degrades intracellular proteins. The activity of this pathway is significantly increased in conditions of exacerbated skeletal muscle catabolism, such as fasting, immobilization, bed rest and disease. Therefore, inhibition of this proteolytic system could explain the attenuation of skeletal muscle protein losses observed during treatment with HMB [13526].

HMB in young trained subjects

Several studies tested the metabolic effects of HMB supplementation to young trained subjects. Augmentation of muscle mass, strength and anaerobic properties with no effects on aerobic capacity and hormonal and inflammatory mediators during the initial phases of the training season by HMB administration to elite adolescent volleyball players. Pre-exercise HMB supplementation significantly lowered lactate dehydrogenase (LDH) and creatine kinase (CK) activities thus mitigating exercise-induced muscle damage. Maximal oxygen consumption (\(\text{VO}_{2\text{peak}}\)) and lactate accumulation peak were unaffected by HMB administration to endurance-trained cyclists, but HMB resulted in a greater time to reach \(\text{VO}_{2\text{peak}}\) and an increase in the onset of blood lactate accumulation (OBLA). Also HMB free acid supplementation was shown to improve markers of exercise-induced muscle damage and ameliorated recovery in resistance-trained men. On the contrary, a trivial effect on combined averaged strength measures, FM, BM and FFM was observed with HMB supplementation during resistance training. Moreover, no short duration HMB-related ergogenic benefit during high-intensity training, nor significant differences between supplemental and placebo groups as for anaerobic power, CK, cortisol, testosterone and myoglobin levels were shown. Additionally, three different studies failed to demonstrate HMB-related influences on muscle function and damage parameters during a strenuous
exercise program [13525].

Three g/day of HMB supplementation to untrained subjects promoted a greater increase in FFM and peak isometric torque while a larger dose (6 g/day) produced a greater increase in peak isokinetic torque without compromising liver function, renal function, immune system or lipid profile during resistance training. HMB supplementation increased maximal oxygen consumption (VO\textsubscript{2max}) and respiratory compensation point (RCP), i.e. components of aerobic performance, suggesting increased capacity to tolerate intense physical activity over a long period of time. Subjects receiving HMB as a free acid gel presented quicker and greater plasma concentrations and improved clearance of plasma HMB versus those receiving calcium HMB (CaHMB) gelatine capsules. This new gel formulation could improve HMB availability and efficacy to tissue. Short-term HMB supplementation had no effect on the severity of swelling, muscle soreness or the subsequent recovery of muscle torque measures following an eccentric exercise bout [13525].

**HMB in trained versus untrained subjects**

A significant HMB-related increase in FFM and weight lifted with resistance training was associated with reduced 3-methylhistidine (3-MH), i.e. a marker of exercise-induced muscle proteolysis, and CK, a marker of muscle damage has been noticed demonstrated a greater increase in upper body strength when combined with an exercise program; plasma CK levels tended to be suppressed in the HMB group. Moreover, the HMB group tended to increase FFM and decrease percent fat. These studies found no significant influence of prior training status (trained versus untrained) or gender on the effects of HMB on body composition, strength and muscle damage [13525].

**HMB mixed with other molecules in young trained subjects**

In two different studies, no ergogenic effect of HMB or HMB/CR supplementation on muscular strength, endurance, leg power, aerobic and anaerobic ability or anthropometry were measured in rugby players over a 6-weeks resistance training program. There were no adverse effects on indices of health although blood bicarbonate, blood monocytes and lymphocytes that were significantly different from the control but still within normal ranges [13525].

**HMB mixed with other molecules in young untrained subjects**

An amino acid-based formula (containing HMB, ARG, GLN, taurine and dextrose) significantly augmented the positive benefits (improved FFM, muscle strength and muscle power) by 12 weeks of resistance exercise when compared with the placebo group. This nutritional formula promoted increased resting and exercise-induced testosterone and resting GH concentrations and reduced pre-exercise cortisol concentrations thereby improving the anabolic-to-catabolic hormone ratio. Moreover, it was associated with a decrease in plasma CK, malondialdehyde (MDA, i.e. a marker of free radical formation and lipid peroxidation which are responsible for exercise-induced membrane disruption) and percent body fat. Another study revealed a significant effect in FFM gains with CR supplementation and a trend with HBM supplementation during a weight-training program; CR- and HBM-related effects on FFM were additive. Creatine, HMB, CR/HMB supplementation caused accumulative strength increases above the placebo group. HMB alone significantly suppressed the exercise-induced rise in serum CK but CR antagonized this effect. HMB also decreased urine urea nitrogen (UUN) and blood urea nitrogen (BUN) which were not affected by CR supplementation. HMB/KIC supplementation for 14 days before a single bout of
eccentrically biased resistance exercise significantly attenuated the CK response, the percentage decrement in concentric one repetition maximum (1RM), the percentage increase in limb girth and delayed onset muscle soreness (DOMS) that are signs and symptoms of exercise-induced muscle damage [13525].

Dose and safety of treatment

Normally, an individual metabolizes 60 g of L-LEU to obtain 3 g of HMB but a 70 kg person produces 0.2-0.4 g of HMB per day, depending on the dose of LEU in the diet. The dose of HMB provided to the treatment groups varied between trials but in the majority 3 g/day of HMB were provided. Up to 3 g of HMB could improve strength and FFM and reduce muscle damage in a dose dependent manner, while higher doses, such as 6 g, had no additional benefits. The 3 g (or 38 mg/kg of body weight per day) dose may be an optimal dosage but too few studies have investigated the efficacy of higher dosages of HMB. Currently, all studies reported no adverse effects from the daily use of HMB. Renal, hematological, hepatic, endocrine functions were not negatively affected as a result of the intake of the nutrient supplement as well as any marker of tissue damage. BUN increase was reported in only two studies. This effect was possibly caused by the additional nitrogen consumed or perhaps ureagenesis induced by arginine and glutamine supplementation. It was determined the influence of oral glucose ingestion upon the time course kinetics of HMB in humans. That study reported no major differences between concomitant glucose/HMB and HMB supplementation alone, except for the longer interval required for the HMB concentration to peak and the longer plasma half-life when HMB was consumed with glucose. All studies employed capsule, drink or powder form of CaHMB salt. Two studies used HMB free acid form, which produced a different plasma kinetic profile. CaHMB has a potential role as a phosphate binder in uremia as demonstrated in vitro. It might contribute to the management of hyperphosphatemia in uremic patients. In one recent experimental study it was observed that HMB supplementation induced hyper-insulinemia [13525].

HMB versus glucocorticoids

Glucocorticoid (GC) excess alters glucose homeostasis and promotes modifications in murinometric and anthropometric parameters in rodents and humans, respectively. beta-Hydroxy-beta-methylbutyrate (HMB), a leucine metabolite, has been proposed as a nutritional strategy for preventing muscle wasting, but few data regarding its effects on glucose homeostasis are available. Here, it was analyzed whether the effects of GC excess on glucose homeostasis may be attenuated or exacerbated by the concomitant ingestion of HMB. Adult Wistar rats (90-days-old) were assigned to four groups: (1) vehicle treated (Ctl), (2) dexamethasone (DEX) treated (Dex), (3) HMB treated (Hmb), and (4) DEX plus HMB treated (DexHmb). Dex groups received DEX (1 mg/kg body weight (BW), intraperitoneal) for 5 consecutive days. HMB groups ingested HMB (320 mg/kg BW, oral gavage) for the same 5 days. HMB ingestion did not attenuate the effects of DEX on food intake and body weight loss, changes in masses of several organs, insulin resistance, and glucose intolerance. In fact, in DexHmb rats, there was increased fasting glycemia and exacerbated glucose intolerance with the main effect attributed to DEX treatment. HMB exerted no attenuating effect on plasma triacylglycerol levels from DexHmb rats, but it seems to attenuate the lipolysis induced by bwta-adrenergic stimulation (20 micromol/L isoproterenol) in fragments of retroperitoneal adipose tissue from DexHmb rats. Therefore, HMB does not attenuate the diabetogenic characteristics of GC excess. In fact, the data suggest that HMB may exacerbate GC-induced glucose intolerance [13527].
**Attenuation of muscle loss during sustained energy deficit**

To investigate the efficacy and underlying mechanisms of beta-hydroxy-beta-methylbutyrate (HMB) on body composition, muscle mass and physical performance under catabolic versus normal training conditions mice were divided into four groups (n=10/group): (1) ALT=ad libitum+trained (1 h/d for 3 d/wk); (2) ALTH=ALT+HMB (0.5 g/kg BW/d); (3) C=calorie restricted (-30%)+trained (6 h/d, 6 d/wk); and (4) CH=C+HMB. Repeated in vivo assessments included body composition, grip strength and sensorimotor coordination before and after the experimental protocol, while in vitro analyses included muscle wet weights, expression of selected genes and proteins regulating muscle mass, and myofiber cross-sectional area. ALTH had greater lean mass than ALT and sensorimotor function increased in ALTH, but decreased in ALT under normal training conditions. Grip strength decreased only in C, but was maintained in CH. Gastrocnemius mass and myofiber CSA were greater in CH than C following catabolic conditions. Gastrocnemius atrogin-1 mRNA expression was elevated in C but not in CH compared to all other groups whereas atrogin-1 protein levels showed no significant changes. It was concluded that HMB improves body composition and sensorimotor function during normal training and attenuates muscle mass and strength loss during catabolic conditions [13528].

**Influence of HMB on protein synthesis**

Many low-birth-weight infants experience failure to thrive. The amino acid leucine stimulates protein synthesis in skeletal muscle of the neonate, but less is known about the effects of the leucine metabolite beta-hydroxy-beta-methylbutyrate (HMB). To determine the effects of HMB on protein synthesis and the regulation of translation initiation and degradation pathways, overnight-fasted neonatal pigs were infused with HMB at 0, 20, 100, or 400 micromol/kg body wt/h for 1 h (HMB 0, HMB 20, HMB 100, or HMB 400). Plasma HMB concentrations increased with infusion and were 10, 98, 316, and 1,400 nmol/ml in the HMB 0, HMB 20, HMB 100, and HMB 400 pigs. Protein synthesis rates in the longissimus dorsi (LD), gastrocnemius, soleus, and diaphragm muscles, lung, and spleen were greater in HMB 20 than in HMB 0, and in the LD were greater in HMB 100 than in HMB 0. HMB 400 had no effect on protein synthesis. Eukaryotic initiation factor (eIF)4E-eIF4G complex formation and ribosomal protein S6 kinase-1 and 4E-binding protein-1 phosphorylation increased in LD, gastrocnemius, and soleus muscles with HMB 20 and HMB 100 and in diaphragm with HMB 20. Phosphorylation of eIF2α and elongation factor 2 and expression of system A transporter (SNAT2), system L transporter (LAT1), muscle RING finger 1 protein (MuRF1), muscle atrophy F-box (atrogin-1), and microtubule-associated protein light chain 3 (LC3-II) were unchanged. Results suggest that supplemental HMB enhances protein synthesis in skeletal muscle of neonates by stimulating translation initiation [13529].

**Influence on free acids**

The purpose of this study was to examine the effect of beta-hydroxy-beta-methylbutyrate-free acid (HMB-FA) and cold-water immersion (CWI) on circulating concentrations of TNF-alpha and monocyte TNF-alpha receptor 1 (TNFR1) expression. Forty resistance-trained men (22 ± 2 years) were randomized into four groups [placebo (PL), HMB-FA, CWI, and HMB-FA-CWI] and performed an acute, intense exercise protocol (four sets of up to 10 repetitions of the squat, dead lift, and split squat). Participants also performed four sets of up to 10 repetitions of the squat at 24 and 48 h following the initial exercise bout. Blood was sampled before exercise (PRE), immediately postexercise (IP), and 30 min, 24 h, and 48 h postexercise (30P, 24P, and 48P, respectively). Circulating TNF-α was assayed, and TNFR1 expression on CD14+ monocytes was measured by flow cytometry. The exercise protocol
significantly elevated TNF-alpha in only PL and CWI IP. Mean percent changes show that TNF-α significantly increased from PRE to IP for only PL and CWI groups, whereas the percent change of TNF-alpha for HMB-FA and HMB-FA-CWI was not significant. TNFR1 expression was elevated in PL and CWI at 30P compared with PRE, whereas both HMB-FA-treated groups did not increase significantly. In conclusion, HMB-FA attenuated circulating TNF-alpha IP and TNFR1 expression during recovery compared with PL and CWI. HMB-FA supplementation may attenuate the initial immune response to intense exercise, which may reduce recovery time following intense exercise [13530].

Laboratory testing

For the quantification of beta-hydroxybutyrate (BHB) and beta-hydroxy-beta-methylbutyrate (HMB) in human whole blood, a method using hydrophilic interaction liquid chromatography tandem mass spectrometry (HILIC-MS/MS) was developed, which does not require chemical modification of the analytes. Samples were deproteinised by a mixture of methanol and acetonitrile, and the extracts were cleaned-up using both polymeric strong cation exchange and strong anion exchange sorbents. The analytes and their structural isomers were separated using a column with a zwitterionic stationary phase. Isotope dilution of both analytes was used for quantitative analysis. Separation of BHB from isobaric interferences was achieved through chromatography. The relative intra-laboratory reproducibility standard deviations were better than 10 percent for blood samples at concentration levels of 10-20 microM BHB and 1 microM HMB and better than 5 percent at concentration levels 10 times higher. The mean true extraction recoveries were close to 100 percent. The trueness expressed as the relative bias of test results was within ±5 % at concentration levels of 10-1000 microM BHB and 1-20 microM HMB. The lower limits of quantification were estimated to be 3 microM for BHB and 0.4 microM for HMB. A simple and highly sensitive and selective HILIC-MS/MS method was developed that is suitable for the quantification of BHB and HMB in whole blood [13531].

For the quantification of beta-hydroxybutyrate (BHB) and beta-hydroxy-beta-methylbutyrate (HMB) in human whole blood, a method using hydrophilic interaction liquid chromatography tandem mass spectrometry (HILIC-MS/MS) was developed, which does not require chemical modification of the analytes. Samples were deproteinised by a mixture of methanol and acetonitrile, and the extracts were cleaned-up using both polymeric strong cation exchange and strong anion exchange sorbents. The mean true extraction recoveries were close to 100 percent. The trueness expressed as the relative bias of test results was within ±5 percent at concentration levels of 10-1000 microM BHB and 1-20 microM HMB. The lower limits of quantification were estimated to be 3 microM for BHB and 0.4 microM for HMB [13532].

Experimental

To investigate the efficacy and underlying mechanisms of beta-hydroxy-beta-methylbutyrate (HMB) on body composition, muscle mass and physical performance under catabolic versus normal training conditions. Mice were divided into four groups (n=10/group): 1) ALT=ad libitum+trained (1h/d for 3d/wk); 2) ALTH=ALT+HMB (0.5g/kg BW/d); 3) C=calorie restricted (-30 %)+trained (6h/d, 6d/wk); and 4) CH=C+HMB. Repeated in vivo assessments included
body composition, grip strength and sensorimotor coordination before and after the experimental protocol, while in vitro analyses included muscle wet weights, expression of selected genes and proteins regulating muscle mass, and myofiber cross-sectional area. ALTH had greater lean mass than ALT and sensorimotor function increased in ALTH, but decreased in ALT under normal training conditions. Grip strength decreased only in C, but was maintained in CH. Gastrocnemius mass and myofiber CSA were greater in CH than C following catabolic conditions. Gastrocnemius atrogin-1 mRNA expression was elevated in C but not in CH compared to all other groups whereas atrogin-1 protein levels showed no significant changes. It was concluded that HMB improves body composition and sensorimotor function during normal training and attenuates muscle mass and strength loss during catabolic conditions [13533].

**Summarised aspects of HMB in sports**

High intensity resistance training is essential for athletes seeking to add strength and hypertrophy. However, high intensity resistance training that results in skeletal muscle damage may take a number of days to recover from; in this case, overall training frequency may be reduced. HMB appears to speed recovery from high intensity exercise. These effects on skeletal muscle damage appear to be reliant on the timing of HMB relative to exercise, the form of HMB, the length of time HMB was supplemented prior to exercise, the dosage taken, as well as the training status of the population of interest. In particular, the supplement should be taken at 1-2 grams 30-60 minutes prior to exercise if consuming HMB-FA, and 60-120 minutes prior to exercise if consuming HMB-Ca. Finally, it is likely that HMB will work ideally if consumed at a dosage of 3 grams for two weeks prior to a high intensity bout that induces muscle damage [13526].

**1,4-Butanediol (1,4-BD)**

1,4-Butanediol (1,4-BD) is a gamma-hydroxybutyrate (GHB) pro-drug, with multiple commercial uses, and a drug of abuse. Although there are case reports of a withdrawal syndrome following 1,4-BD use, no studies have evaluated the physical dependence potential of 1,4-BD and characterized the time course of withdrawal. Vehicle and then 1,4-BD were administered continuously 24 h/day via intragastric catheters in male baboons (Papio anubis, n=3). Dosing was initiated at 100 mg/kg and increased by 100 mg/kg/day to 400 mg/kg. After a stabilization period, doses of 500 and then 600 mg/kg/day were each maintained for 3-4 weeks. Plasma levels of 1,4-BD and GHB were determined for each dose condition. Physical dependence was assessed via administration of a GABA-B antagonist (precipitated withdrawal test) during administration of the 600 mg/kg dose and via abrupt termination of chronic 1,4-BD administration (spontaneous withdrawal test). Outcome measures included the number of food pellets earned, performance on a fine-motor task, observed behaviors, and plasma levels of GHB and 1,4-BD. Following maintenance of 1,4-BD 600 mg/kg for 3 weeks, the number of food pellets earned was significantly decreased. At the end of chronic 1,4-BD dosing, the levels of GHB in plasma ranged from 1290 to 2300 μmol/L and levels of 1,4-BD in plasma ranged from 13.1 to 37.9 μmol/L. Signs of physical dependence were observed following precipitated and spontaneous withdrawal tests. Seizures were not observed. These data indicate chronic 1,4-BD produced physical dependence in baboons and the withdrawal syndrome can be characterized as mild to intermediate [13537].

**gamma-Oryzanol and ferulic acid**

1491
Gamma-oryzanol, a mixture of a plant sterol and ferulic acid ester first isolated from rice bran oil in the early 1950s, has since been found to be in the lipid fraction of many other plants, and can be identified in various vegetable oils and products. The phytosterol base, structurally similar to cholesterol, has been promoted as having cholesterol-lowering and testosterone-enhancing activities, but these have not been substantiated in humans. Like other plant sterols, gamma-oryzanol is poorly absorbed from the gastrointestinal tract. However, ferulic acid is well absorbed and has been proposed to be the active agent in gamma-oryzanol, with activities including antioxidant properties. As a result, ferulic acid has been isolated and marketed as a separate supplement. Despite a lack of evidence or consistent explanation of mechanisms underpinning claimed benefits, gamma-oryzanol and ferulic acid have been marketed to, and used by, body builders and strength-training athletes in the hope of boosting strength, increasing muscle gain, reducing body fat, speeding recovery and reducing postexercise soreness. These supplements also claim to promote endorphin release. Only three studies, of which only one was published in a peer-reviewed publication, have tested these supplement claims on athletic performance. A double-blind, placebo-controlled study of 22 recreationally weight-trained male college students involved a 9-week resistance exercise training protocol, combined with a daily intake of 500 mg of gamma-oryzanol or placebo. Improvements in muscle strength and vertical jump power, increased body mass and decreased skinfold thickness were observed in both groups. A significant decrease in resting testosterone and cortisol concentrations was also observed at the end of the testing period in both groups, with no other alterations in hormone, lipid or blood parameters. These findings support the benefits of a training programme but do not find additional benefits from gamma-oryzanol ingestion in terms of functional gains or alterations of various hormone concentrations. An abstract describes a double-blind crossover study of six highly trained male distance runners who were supplemented with either placebo or 50 mg of ferulate daily for 3 weeks. Although workouts increased blood concentrations of cortisol, testosterone and β-endorphins, there were no differences in the response between ferulate and placebo trials, with the exception of an increase in postexercise beta-endorphin concentrations during some sessions in the final week of intensified training. A further study reported in abstract form described a multicentre double-blind, placebo-controlled trial in which weight lifters received either a placebo or ferulate treatment (15 mg twice daily) for 8 weeks. Using small numbers of participants, the authors reported a significant increase in body weight and shoulder press strength in the supplemented group (n=6) compared with the placebo group (n=4), but no differences in leg and chest strength. In summary, the effects of supplementation with gamma-oryzanol and ferulic acid on athletic performance have not been well studied, and there is no current evidence to support their use in sport [10527].

Gamma-Oryzanol, a mixture of a plant sterol and ferulic acid ester, also marketed to body builders and strength training athletes, was used in hopes of boosting strength, increasing muscle gain, reducing body fat, speeding recovery and reducing postexercise soreness. It was first isolated from rice bran oil in the early 1950s, has since been found to be in the lipid fraction of many other plants, and can be identified in various vegetable oils and products. The phytosterol base, structurally similar to cholesterol, has been promoted as having cholesterol-lowering and testosterone-enhancing activities, but these have not been substantiated in humans. Like other plant sterols, gamma-oryzanol is poorly absorbed from the gastrointestinal tract. However, ferulic acid is well absorbed and has been proposed to be the active agent in gamma-oryzanol, with activities including antioxidant properties. As a result, ferulic acid has been isolated and marketed as a separate supplement. Despite a lack of evidence or consistent explanation of mechanisms underpinning claimed benefits, gamma-oryzanol and ferulic acid have been marketed to, and used by, body builders and strength-training athletes in the hope of boosting strength, increasing muscle gain, reducing body fat, speeding recovery and reducing postexercise soreness. These supplements also
claim to promote endorphin release. Only three studies, of which only one was published in a peer-reviewed publication, have tested these supplement claims on athletic performance. A double-blind, placebo-controlled study of 22 recreationally weight-trained male college students involved a 9-week resistance exercise training protocol, combined with a daily intake of 500 mg of gamma-oryzanol or placebo. Improvements in muscle strength and vertical jump power, increased body mass and decreased skinfold thickness were observed in both groups. A significant decrease in resting testosterone and cortisol concentrations was also observed at the end of the testing period in both groups, with no other alterations in hormone, lipid or blood parameters. These findings support the benefits of a training programme but do not find additional benefits from gamma-oryzanol ingestion in terms of functional gains or alterations of various hormone concentrations. An abstract describes a double-blind crossover study of six highly trained male distance runners who were supplemented with either placebo or 50 mg of ferulate daily for 3 weeks. Although workouts increased blood concentrations of cortisol, testosterone and β-endorphins, there were no differences in the response between ferulate and placebo trials, with the exception of an increase in postexercise beta-endorphin concentrations during some sessions in the final week of intensified training. A further study reported in abstract form describes a multicentre double-blind, placebo-controlled trial in which weight lifters received either a placebo or ferulate treatment (15 mg twice daily) for 8 weeks. Using small numbers of participants, the authors reported a significant increase in body weight and shoulder press strength in the supplemented group (n=6) compared with the placebo group (n=4), but no differences in leg and chest strength. In summary, the effects of supplementation with gamma-oryzanol and ferulic acid on athletic performance have not been well studied, and there is no current evidence to support their use in sport [11279].

Gamma-oryzanol, a mixture of ferulic acid esters of sterol and triterpene alcohols occurs in rice (Oryza stavia) bran oil at a level of 1-2 percent. Gamma oryzanol is used in the belief that they may elicit anabolic effects via increased testosterone production. Although limited, the available research does not support an ergogenic effect of gamma-oryzanol supplementation in humans. Compared to a placebo group, weight-trained males who consumed 500 mg/day of gamma-oryzanol for 9 weeks of resistance exercise training experienced no significant differences in circulating concentrations of hormones (testosterone, human growth hormone, insulin), nor was there any improvement in muscular power or strength [06297].
ALCOHOL

The use of alcohol is often intimately associated with sport. As well as providing a source of energy, alcohol (ethanol) has metabolic, cardiovascular, thermoregulatory, and neuromuscular actions that may affect exercise performance. Strength is minimally affected, and performance impairments depend on the dose of alcohol and subject habituation to alcohol intake, exercise duration, environmental conditions, and other factors. Central nervous system function is impaired at high doses, resulting in decrements in cognitive function and motor skill, as well as behavioral changes that may have adverse effects on performance. Effects may persist for hours after intoxication [06223].

Alcohol is not an essential part of the human diet, but various alcohols, of which the only one of quantitative significance is ethanol, are regularly consumed by a large part of the world’s population. In addition to being a significant source of energy, providing about 7 kcal (29 kJ) per gram, ethanol has a number of effects that have implications for athletic performance. There are reasons to believe that acute alcohol intake may impair performance of endurance exercise because of effects on metabolic, cardiovascular, and thermoregulatory function. Performance of skilled tasks may be impaired because of effects on reaction time, fine motor control, levels of arousal, and judgment. All of these elements are important components of sports performance, but there are relatively few well-controlled studies of performance itself. The limited amount of experimental evidence is at least in part because institutional ethics review boards are reluctant to condone the administration of high doses of ethanol to volunteers. There have been rather few studies in this area in recent years, and there is an urgent need for further studies, particularly investigations involving measurement of sport-specific performance. In the past few years there appear to have been more review articles published on the effects of alcohol on sporting performance than original research papers. There is evidence that at least some groups of athletes consume more alcohol than nonathletes, but separating fact from anecdote can be difficult. Reports that include only average intakes can be misleading, as binge drinking is commonly found in some team sports, and some athletes will abstain from alcohol in training but will drink copious amounts after competition [06223].

Alcohol consumption control policies at U.S. intercollegiate sports events, and their association with student drinking, were assessed using data from a 2001 nationally representative survey of students and administrators (n=7,261 students, n=117 colleges). Alcohol was available to sports event attendees through in-stadium sales, tailgating parties, and allowing spectators to bring in alcohol. Policies varied by college, with fewer restrictions at large public schools with NCAA Division I athletics. Permitting alcohol at tailgate parties was associated with more students drinking at sports events. Future research should evaluate whether enacting policy restrictions can reduce drinking and related problems at intercollegiate sports events [10504].

The potential influence of alcohol consumption on endogenous steroids has already been described in the literature. In those studies the ethanol level after ingestion was monitored using its concentration in blood, urine or saliva. Corresponding methods are not commonly used in anti-doping laboratories. Ethylglucuronide (EtG), which can be easily detected by liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS), appears to be a more suitable parameter for this purpose. It is slowly excreted into the urine and indicates alcohol intake for a much longer period than blood or urinary alcohol and it is therefore routinely used for legal purposes as an alcohol consumption marker. In pharmacokinetic studies that aimed to establish calculation models after ethanol intake, the formation of EtG
was observed to coincide with elevated urinary testosterone/epitestosterone (T/E) ratios. Similarly, large amounts of EtG were correlated with abnormal steroid profiles found in routine doping samples. In this pilot study, several cases with significantly elevated T/E ratios were associated with urinary EtG concentrations higher than 50 microg/mL. These findings confirmed recent intake of ethanol in considerable amounts and suggest a connection to changes in specific steroid profile parameters. Owing to the ease with which procedures to determine EtG can be carried out, and the potential for such procedures to be introduced into screening schemes, the inclusion of this marker in the final evaluation of suspicious outliers in T/E ratio longitudinal studies would seem to be very useful [09301].

One study investigated the relationships among sports-specific factors, perceived peer drinking, and alcohol-related behaviors among adolescents, examining sex differences in the relationship between perceived peer drinking and alcohol-related behaviors. A questionnaire assessing demographics, sports-specific factors, perceived peer drinking, and alcohol-related behaviors was administered among 378 adolescents who were mostly male (76 %) and non-Hispanic black (70 %). Varsity sports participants reported significantly higher levels of perceived peer drinking compared to those who participated in sports at other levels (0.64, 95 % confidence interval 0.28 to 0.99). Participants in both sports offering team- and individual-level competition reported greater perceived peer drinking, compared to those who only participated in individual sports. Perceived peer drinking was associated with alcohol-related behaviors and there were no significant differences between males and females in this relationship. Suggestions for future research include examining factors contributing to the low prevalence of drinking behaviors, and investigating factors related to sports that impact perceived peer drinking and alcohol-related behaviors [09302].

One study investigated the effects of acute moderate alcohol intake on muscular performance during recovery from eccentric exercise-induced muscle damage. Eleven healthy males performed 300 maximal eccentric contractions of the quadriceps muscles of one leg on an isokinetic dynamometer. They then consumed a beverage containing 1g/kg bodyweight ethanol (as vodka and orange juice). On another occasion they performed an equivalent bout of eccentric exercise on the contralateral leg after which they consumed an isocaloric quantity of orange juice. Measurement of maximal isokinetic (concentric and eccentric) and isometric torque produced across the knee, plasma creatine kinase (CK) concentrations and muscle soreness were made before and at 36 and 60 h following each exercise bout. All measures of muscle performance were significantly reduced at 36 and 60h post-exercise compared to pre-exercise measures. The greatest decreases in peak strength were observed at 36 h with losses of 12, 28 and 19 percent occurring for orange juice isometric, concentric, and eccentric contractions, respectively. However, peak strength loss was significantly greater in alcohol group with the same performance measures decreasing by 34 percent, 40 percent and 34 percent, respectively. Post-exercise plasma creatine kinase activity and ratings of muscle soreness were not different between conditions. These results indicate that consumption of even moderate amounts of alcohol following eccentric-based exercise magnifies the normally observed losses in dynamic and static strength. Therefore, to minimise exercise related losses in muscle function and expedite recovery, participants in sports involving eccentric muscle work should avoid alcohol-containing beverages in the post-event period [09303].

One study was conducted to examine the effect of consuming a dilute alcohol solution (weak beer) on urine production in euhydrated and hypohydrated individuals. Twelve males completed an intermittent cycle protocol in hot, humid conditions to dehydrate by 1.9 ± 0.3 percent body mass in the evening. Twice they were then fed and rehydrated, while on two other occasions they were fed the same meal but remained hypohydrated. The following morning they were given 1 l of beer to drink. On two occasions the beer was alcohol-free,
while on the other two occasions the same beer contained 4 percent ethanol. Participants remained in the laboratory for monitoring over the subsequent 4 h. Blood and urine samples were taken prior to dehydration, prior to drink administration and once every hour of the monitoring period. No difference existed in the volume of urine produced between the alcohol and non-alcohol beer when hypohydrated, but there was a significant difference when euhydrated. Unsurprisingly, more urine was produced on both euhydrated trials than either of the hypohydrated trials. Blood alcohol concentration was elevated 1 h after drinking on the alcohol trials. Serum osmolality was higher 1 h after drinking on both the alcohol trials than on their non-alcohol, equivalent hydration trials. These results suggest that the diuretic action of alcohol is blunted when the body is hypohydrated [10394].

Sports participation, while offering numerous developmental benefits for adolescents, has been associated with alcohol use in prior research. However, the relationship between sports participation and alcohol use among adolescents remains unclear, particularly how research design elements impact evidence of this relationship. It was reviewed the evidence regarding sports participation and alcohol use among adolescents, with a focus on examining the potential impact of research design elements on this evidence. Studies were assessed for eligibility and coded based on research design elements including: study design, sampling method, sample size, and measures of sports participation and alcohol use. Fifty-four studies were assessed for eligibility, 29 of which were included in the review. Nearly two-thirds used a cross-sectional design and a random sampling method, with sample sizes ranging from 178 to 50,168 adolescents (median = 1,769). Sixteen studies used a categorical measure of sports participation, while 7 applied an index-type measure and 6 employed some other measure of sports participation. Most studies assessed alcohol-related behaviors (n=18) through categorical measures, while only 6 applied frequency only measures of alcohol use, 1 study applied quantity only measures, and 3 studies used quantity and frequency measures. It was concluded that sports participation has been defined and measured in various ways, most of which do not differentiate between interscholastic and community-based contexts, confounding this relationship. Stronger measures of both sports participation and alcohol use need to be applied in future studies to advance our understanding of this relationship among youths [11224].

Moderate, acute alcohol consumption after eccentric exercise has been shown to magnify the muscular weakness that is typically associated with exercise-induced muscle damage (EIMD). As it is not known whether this effect is dose-dependent, the aim of this study was to investigate the effect of a low dose of alcohol on EIMD-related losses in muscular performance. Ten healthy males performed 300 maximal eccentric contractions of the quadriceps muscles of one leg on an isokinetic dynamometer. They then consumed either a beverage containing 0.5 g of alcohol per kg bodyweight (as vodka and orange juice) or an isocaloric, isovolumetric non-alcoholic beverage. At least 2 weeks later, they performed an equivalent bout of eccentric exercise on the contralateral leg after which they consumed the other beverage. Measurement of peak and average peak isokinetic (concentric and eccentric) and isometric torque produced by the quadriceps was made before and 36 and 60 h post-exercise. Significant decreases in all measures of muscular performance were observed over time under both conditions; however, no difference between treatments was evident at any of the measured time points. Therefore, consumption of a low dose of alcohol after damaging exercise appears to have no effect on the loss of force associated with strenuous eccentric exercise [11225].

Alcohol expectancies have been associated with drinking behaviors among college students. Few studies, however, have focused on researcher-labeled "positive" and "negative" expectancies as well as the valuations (i.e. desirability) of these expectancies. Moreover, research on the correlates of heavy drinking among female college athletes remain relatively
sparse, despite the prevalence of elevated alcohol use in this population. It was examined the associations of expectancies and valuations with frequency of heavy drinking and context-specific drinking behaviors. The sample consisted of 145 female college athletes (mean age 20 years) who completed self-report surveys and indicated alcohol use in the past 30 days. Regression analyses indicated that favorable valuations of negative expectancies were related to heavy drinking, and that valuations accounted for significant proportions of variance in the model. Elevated endorsement of negative expectancies was also associated with the perceived likelihood of heavy use in convivial and personal-social drinking contexts, and favorable valuations of these expectancies accounted for significant variance in these models. These findings highlight the relevance of negative expectancies and valuations with respect to heavy drinking and context-specific drinking behaviors among female college athletes. The perception of “negative” effects of alcohol as “positive” could help explain the high rates of problematic drinking among female athletes [07205].

The authors examined alcohol use among students involved in recreational sports. To the authors' knowledge, this was the first study of alcohol use in which researchers separate recreational sports participants from intercollegiate athletes and examine them as a separate group of interest. The authors generated a random sample of 494 students from the undergraduate population at a 4-year university. They used a Web-based survey to collect data and stratified and weighted the sample by residence status to more accurately reflect the population. Students who participated in recreational sports used alcohol at a greater frequency and intensity than did those who were not involved in recreational sports across a variety of measures, even alongside other variables, including race, sex, and Greek membership. It was concluded on the basis of these findings, that alcohol consumption among those participating in recreational sports appears to be an area worthy of consideration in future research [07206].

Community-based sporting clubs in Australia are often sites of unregulated, problematic and unsafe drinking. The Good Sports program, initiated in Victoria in 2001, offers such clubs a model of incremental change designed to eliminate harmful drinking practices and establish safer norms of alcohol use. The Good Sports model was developed in situ over a period of 5 years and is currently operating in 1600 sporting clubs across Australia. It has strong face validity and is supported by sporting organizations and key stakeholders including public health, law enforcement, road safety, and local government. The article outlined the model, explains early evaluation results, and identifies challenges for the future [07207].

One study examined alcohol use among college students, focusing on variation in binge drinking based on involvement in athletics. Prior research indicates that college students who participate in athletics are more likely to report binge drinking than are students who are not involved in athletics. However, existing research has not offered an explanation why college athletes are at a greater risk for binge drinking. Using data from the 1999 Harvard School of Public Health College Alcohol Study, a national study examining substance use and other health risk behaviors of college students in the United States, the current research examines social norms as a possible source of the elevated levels of binge drinking among college athletes. Findings indicate that athletes are more likely to report binge drinking, in part, because they view alcohol use as being more normative [07208].

The aim of one study was to explore the associations of physical activity with smoking and alcohol consumption. It examined whether these associations are due to people participating in organized sports (the sport hypothesis), and/or reflect the concentration of drinking and smoking in manual occupational groups (the occupation hypothesis). Data from the 2003 Health Survey for England (n=11,617) were analyzed from a multilevel perspective. Four models were specified to examine the variation of heavy drinking, smoking, sports activity,
and occupational activity across different sociodemographic groups; and four sets of analyses further explored the associations of sports and occupational activity with heavy drinking and smoking. Some support was found for both the sport and occupation hypothesis. Sports activity and heavy drinking were more prevalent among sportsclub members, and occupational activity and heavy drinking were more prevalent among manual occupational groups. Sportsclub membership accounted for some of the association between sports activity and heavy drinking; and occupational position partly accounted for the association between occupational activity and heavy drinking. The occupation hypothesis is the more likely explanation for the association between physical activity and smoking. The study shows that it is worthwhile to distinguish between different types of physical activity; and that multiple processes underlie the clustering of health behaviors [07209].

The relationship between perceived alcohol use among peers and personal alcohol use was assessed in a sample of collegiate athletes. Data were collected on 109 intercollegiate athletes during the competitive season and 119 athletes during the off-season at a large, state university in the Northeastern United States. Participants were asked to estimate the normative alcohol use of four reference groups (closest athlete friend, closest nonathlete friend, typical athlete, and typical nonathlete). Results of both in-season and off-season analyses indicated that athletes estimated that others consumed more drinks per week than they did, and perceptions of these social norms predicted personal use. Although the typical athlete norm emerged as the strongest predictor of personal alcohol use, the relative strength of the relationships between individual behavior and the athlete and nonathlete norms varied according to seasonal status. Results have implications for the content and timing of prevention and intervention programs aimed at reducing high-risk alcohol use among intercollegiate athletes [07210].

To examine the relationship between athlete drinking motives and hazardous drinking across differing levels of sporting participation (club vs elite-provincial vs elite-international). Data from 1214 New Zealand sportspeople was collected. It was assessed hazardous drinking with the WHO's AUDIT questionnaire and sportspeople's psychosocial reasons for drinking with the ADS. Level of sporting participation (club/social, provincial/state, or international/olympic level) was also assessed. Hazardous drinking behaviours differed across levels of sporting participation, with elite-provincial sportspeople showing the highest level of hazardous drinking, club/social sportspeople the next highest and elite-international sportspeople the lowest. Sportspeople who placed a greater emphasis on drinking as a reward for participating in their sports tended to display more hazardous drinking behaviours, but other ADS motives differed over level of sporting participation. Elite-provincial sportspeople and elite-international sportspeople placed more emphasis on drinking as a way to cope with the stresses of participating in their sports. A relationship between team/group motives and AUDIT scores was fully mediated by positive reinforcement motives, and partially mediated by stress-related coping motives. These findings have implications for alcohol education programs targeted at sportspeople and sport administration, and may help improve the efficacy and focus of intervention programs [07211].

Chronic alcohol abuse has adverse effects on skeletal muscle, and reduced muscle strength is frequently seen in chronic alcoholics. In this study the acute effects of moderate alcohol intoxication on motor performance was evaluated in 19 non-alcoholic healthy subjects (10 women, 9 men). A randomised double-blinded placebo controlled design was applied to subjects receiving alcohol in juice and pure juice at two separate test periods. Isokinetic and isometric muscle strength and endurance were determined before, during, 24 and 48 h after the ingestion of alcohol in juice and juice (placebo). To detect a reduced activation of the central motor pathways superimposed external electrical stimulations during voluntary contractions were applied. Creatine kinase (CK) was measured to detect any alcohol-
induced changes in sarcolemmal integrity. No change was seen in isokinetic as well as in isometric muscle performance during or following the alcohol intoxication as compared to the non-alcoholic condition. Also, no central activation failure was observed. No significant difference in CK increment was observed comparing the alcoholic- and non-alcoholic condition. In conclusion, a single episode of moderate alcohol intoxication (1.4 g/L) does not impair motor performance, and no accelerated exercise-induced muscle damage is seen.

The objective of one study is to describe energy drink consumption and health behaviors among college students attending a predominantly minority university. Undergraduate and graduate students attending a private, minority-serving university were invited to participate in an online survey between 2009 and 2010. Out of 2,500 students, 407 participated yielding a response of 16 percent. Analysis assessed energy drink consumption as well as participation in sport activities and high-risk behaviors. Energy drink consumption is significantly related with drinking alcohol to inebriation and driving and to riding with a drunk driver. Athletes were more likely to engage in drinking alcohol to inebriation and driving. Energy drink consumption is a common practice among racial minority university students. Tailored health promotion strategies and interventions are needed to address misconceptions of energy drink and alcohol mixing.

Excessive alcohol consumption is responsible for considerable harm from chronic disease and injury. Within most developed countries, members of sporting clubs participate in at-risk alcohol consumption at levels above that of communities generally. There has been limited research investigating the predictors of at-risk alcohol consumption in sporting settings, particularly at the non-elite level. The purpose of this study was to examine the association between the alcohol management practices and characteristics of community football clubs and at-risk alcohol consumption by club members. A cross-sectional survey of community football club management representatives and members was conducted. Logistic regression analysis (adjusting for clustering by club) was used to determine the association between the alcohol management practices (including alcohol management policy, alcohol-related sponsorship, availability of low- and non-alcoholic drinks, and alcohol-related promotions, awards and prizes) and characteristics (football code, size and location) of sporting clubs and at-risk alcohol consumption by club members. Members of clubs that served alcohol to intoxicated people (OR 2.23) conducted “happy hour” promotions (OR 2.84) or provided alcohol-only awards and prizes (OR 1.80) were at significantly greater odds of consuming alcohol at risky levels than members of clubs that did not have such alcohol management practices. At-risk alcohol consumption was also more likely among members of clubs with less than 150 players compared with larger clubs (OR 1.45) and amongst members of particular football codes. The findings of the study suggest a need and opportunity for the implementation of alcohol harm reduction strategies targeting specific alcohol management practices at community football clubs.

Little is known about how adolescents’ peer relations might alter whether sport participation is associated with alcohol use. Consistent with social learning theory, we found that sport participation was protective against alcohol use if these peers had low alcohol use, but athletes were likely to use alcohol if their sport friends and teammates had high alcohol use. Interestingly, those with no or low sport participation seemed to emulate the alcohol use of their non-sport friends, whereas adolescents in a high number of sports had elevated alcohol use regardless of their non-sport friends’ alcohol use.

Heavy episodic drinking (HED) (consumption of five or more drinks on the same occasion) among adolescents is related to several problems and partaking in sport or physical activities.
has been suggested as an option to prevent or reduce alcohol consumption among this population. The aim of this study was to investigate the relationship between soccer practice and heavy episodic drinking among high school students from Brazil. Data were obtained from a cross-sectional study among a representative sample of public and private high school students from all Brazilian state capitals (n=19,132). Only students aged from 14 to 18 who reported having taken part in soccer practice, other team sports or non-practicing sports in the last month were included. Characteristics of sport practice (frequency and motivation) and HED in the last month (type of drink; where and with whom they drank; frequency of HED) were also considered. Regression models were controlled for sociodemographic variables. For all groups studied most of the students reported drinking beer, with friends and at nightclubs or bars. Soccer practice was associated to HED when compared to non-practicing sports and to other team sports. Compared to other team sports, playing soccer for pleasure or profession, but not for keep fit or health reasons, were more associated to HED. Frequency of soccer practice from 1 to 5 days per month and 20 or more days per month, but not from 6 to 19 days per month, were also more associated to HED. It was concluded that the relationship between soccer and HED appears to be particularly stronger than in other team sports among adolescents in Brazil. Induced sociability of team sports practice cannot be assumed as the main reason for HED among soccer players. Possibly these results reflect the importance of a strong cultural association between soccer and beer in Brazil and these findings should be integrated to future prevention or intervention programs [13542].

Alcohol (ethanol; referred to as alcohol or EtOH) is and has been one the most commonly consumed and abused drugs for a substantial period in human history. Alcohol is a dependence-producing drug which affects a host of organ systems and one that increases the risk of morbidity and mortality from different diseases when abused. Indeed, some authors have suggested that alcohol is harmful similar to drugs such as heroin or cocaine and that excessive alcohol consumption is a serious world-wide health risk. Although the detrimental effects of alcohol on human physiology are well known, even elite athletes consume alcohol. When looking at the effects of alcohol on overall health, it is, however, important to distinguish between chronic, moderate alcohol consumption versus alcohol abuse. Alcohol consumption and sport have been inextricably linked since ancient times when alcohol was considered the elixir of life. To some extent that may be true, given that a substantial body of epidemiological evidence shows that moderate ingestion of alcohol may reduce the risk of cardiovascular disease. The link between alcohol consumption and mortality is subject to a J-shaped curve i.e. improved longevity with moderate consumption with increasing intake resulting in greater mortality risk. Indeed, dietary guidelines from the American Heart Association recommend moderation of alcohol intake as it has been associated with a lower risk of cardiovascular events [13008].

Alcohol use is fairly widespread among the athletic population with 88 percent of intercollegiate American athletes reporting the use of alcohol. It is also noteworthy that many athletes consume alcohol prior to sports events. However, it is important to note that scientific evidence suggests that the consumption of alcohol has some detrimental effects on exercise performance. It is fairly obvious that it is unlikely for competitive athletes to be alcohol abusers and most performance studies have focused on the acute ergolytic effects of EtOH consumption. The chronic studies merely reinforce the point that EtOH is profoundly ergolytic in the long term setting. They also serve to reinforce that chronic EtOH use can be toxic to cardiac and skeletal muscle [13008].
Epidemiology

Sport participation can play an important and positive role in the health and development of children and youth. One area that has recently been receiving greater attention is the role that sport participation might play in preventing drug and alcohol use among youth. The current study is a systematic review of 17 longitudinal studies examining the relationship between sport participation and alcohol and drug use among adolescents. Results indicated that sport participation is associated with alcohol use, with 82 percent of the included studies (14/17) showing a significant positive relationship. Sport participation, however, appears to be related to reduced illicit drug use, especially use of non-cannabis related drugs. Eighty percent of the studies found sport participation associated with decreased illicit drug use, while 50 percent of the studies found negative association between sport participation and marijuana use. Further investigation revealed that participation in sports reduced the risk of overall illicit drug use, but particularly during high school; suggesting that this may be a critical period to reduce or prevent the use of drugs through sport. Future research must better understand what conditions are necessary for sport participation to have beneficial outcomes in terms of preventing alcohol and/or illicit drug use. This has been absent in the extent literature and will be central to intervention efforts in this area [13543].

Motives and attitudes for alcohol use by athletes

One study aimed to explore the mediating effects of conscientiousness and alexithymia in the relationship between parental attachment style and alcohol use in a large sample of athletic young people. Participants included 434 French sport sciences students. Alcohol use, parental attachment style, conscientiousness and alexithymia were assessed. The hypotheses were tested by using regression and bootstrapping mediation analyses. Maternal insecure attachment style is positively associated with alcohol use. The current study highlights a multiple pathway in this relationship. The results reveal the mediating effect of low conscientiousness and alexithymia between maternal insecure attachment and alcohol use. Athletes' alcohol use seems to be the result of a complex association of underlying psychological factors [13544].

Intercollegiate athletes report greater alcohol consumption and more alcohol-related problems than their non-athlete peers. Although college athletes share many of the same problems faced by non-athletes, there are some consequences that are unique to athletes. Studies have demonstrated that alcohol negatively affects athletic performance including increased dehydration, impeded muscle recovery, and increased risk for injury. Beyond risk factors for alcohol misuse that may affect college students in general, research has begun to examine risk factors that are unique to collegiate athletes. For example, research has found that off-season status, the leadership role, and athlete-specific drinking motives are associated with increased alcohol use. Given these findings, it is possible that other athlete-specific variables influence alcohol misuse. One such variable may be sport achievement orientation. The purpose of one study was to examine the relationship between sport achievement orientation and alcohol outcomes. Given previous research regarding seasonal status and gender, these variables were examined as moderators. Varsity athletes (n=263) completed the Sport Orientation Questionnaire, which assesses sport-related achievement orientation on three scales (Competitiveness, Win Orientation, and Goal Orientation). In addition, participants completed measures of alcohol use and alcohol-related problems. Results indicated that Competitiveness, Win Orientation, and Goal Orientation were all significantly associated with alcohol use, but not alcohol-related problems. Moreover, these
relationships were moderated by seasonal status and gender. These interactions, clinical implications, and limitations are discussed [13545].

Mechanism of action

Chronic alcohol abuse has significant detrimental effects on the human cardiac muscle and one of the putative mechanisms via which alcohol may induce cardiac dysfunction is through the induction of increased oxidative stress. Interestingly, exercise training blunted the oxidative damage observed in a rat model of chronic alcohol consumption. The authors suggest that exercise training results in an up-regulation of cardiac antioxidants which may in turn reduce the deleterious effects of chronic alcohol induced oxidative stress. Acute alcohol use can also have effects on cardiovascular determinants of exercise performance. It was examined the effects of acute alcohol administration on left ventricular contractility using echocardiography and found that alcohol had a significant depressant effect on the myocardium. Specifically, acute alcohol consumption resulted in a decreased end-systolic pressure-dimension slope and reduced velocity of myocardial fiber shortening. Alcohol has significant effects on skeletal muscle substrate utilization during exercise. Specifically, it has been demonstrated that alcohol consumption decreases glucose and amino acid utilization, which can have adverse effects on energy supply to exercising muscle. Ethanol consumption induces hypoglycemia and decreases glucose appearance in plasma by decreasing hepatic gluconeogenesis. Ethanol administration has been shown to worsen skeletal muscle determinants of exercise performance such as muscle capillary density and muscle fiber cross-sectional area. It was shown in vitro that alcohol can inhibit sarcolemmal calcium channel actions thereby potentially impair excitation-contraction coupling and diminishing muscular performance. Muscle capillary density is closely related to the oxidative capacity of skeletal muscle. Greater capillary density also allows for a greater surface area for gas exchange and delivery of metabolic substrates. Long term alcohol consumption is associated with the development of alcoholic myopathy which is characterized by a reduction in skeletal muscle capillarity. Exercise training, however, appears to attenuate these adverse changes [13008].

Epidemiological data suggest that moderate alcohol consumption is associated with many salutary changes in blood coagulation and fibrinolysis. However, compelling experimental evidence is lacking and often conflicting. Alcohol can also lead to significant post-exercise perturbations in levels of clotting factors. Moderate post-exercise alcohol consumption resulted in significantly elevated levels of Factor VIII at 5 and 22 hours during the post-exercise milieu. Both circulating catecholamine and vasopressin levels have been implicated in up-regulation of Factor VIII. These factors in turn, have been implicated in the pathogenesis of atherosclerosis in prospective studies. Alcohol and exercise may interact with each other to induce disorders in platelet aggregation which are associated with an elevated risk of cardiovascular and cerebrovascular events. Alcohol intoxication has been shown to be linked to cerebrovascular infarctions in a few case-control studies. However, the exact pathological mechanisms of the same are currently unknown. Alcohol consumption following athletic participation is commonly observed and may be associated with disorders in platelet aggregation. It was demonstrated that alcohol ingestion following exercise was associated with a marked increase in platelet count 1-hour following exercise. Platelet aggregation induced by adenosine diphosphate was found to be reduced when exercise was followed by alcohol consumption. Thus, it appears that ingestion of a moderate quantity of alcohol is associated with delayed recovery of platelet aggregation. It is important to note however, that the performance impact of ethanol consumption mediated post-exercise coagulopathy is unknown. Acute alcohol consumption is associated with the deterioration of psychomotor skills. A significant difference exists in injury rates between drinkers and non-
drinkers in athletic populations. Athletes that consume alcohol at least once a week have almost a 2-fold higher risk of injury compared to non-drinkers and this elevated injury rate holds true for the majority of sports examined [13008].

Alcohol may also interfere with the body’s ability to recover from injury. It was also examined the effects of 1 g/kg body weight alcohol consumption on recovery from eccentric exercise-induced muscle injury. The authors measured peak and average peak isokinetic and isometric torque produced by the quadriceps. Alcohol consumption was associated with significantly greater decreases in torque production (40-44 %) 36 hours into recovery. The authors concluded that the consumption of a moderate amount of alcohol after damaging exercise magnified the loss of muscle force production potential. Finally, there is some evidence to suggest that chronic alcohol consumption may result in a positive energy balance and a potentially obesogenic state. It has also been reported that chronic alcohol consumption did not result in a reduction in lipid intake and that a dietary regimen that provided a large fraction of energy in the form of alcohol increased the risk for a positive energy balance in a free-living state. It appears that alcohol may have a fat-sparing effect similar to that of carbohydrates and may cause fat gain. It has also been suggested that alcohol could result in excess body fat gain especially in the upper body. There is some evidence to suggest that obese individuals may be more susceptible to weight gain and the hyperlipidemic effects of alcohol consumption as compared to lean individuals. This is in contrast to epidemiological studies that report a negative association between alcohol consumption and adiposity. This may be explained by the induction of unregulated futile metabolic cycles that appear to significantly aid in the disposal of excess calories. In general, it appears that the effects of alcohol on body weight are controversial and it is likely that moderate consumption of alcohol that replaces calories from carbohydrates and fat is unlikely to result in weight gain [13008].

**Studies on alcohol and performance**

Many of the studies on the effects of alcohol on athletic performance suffer from one of more defects. Subject numbers are often small, and the lack of a definite outcome may be the result of underpowered studies. The doses of alcohol that have been used in many studies are small relative to those reported to be consumed by athletes. The reluctance of investigators to induce inebriation in their subjects, and the reluctance of ethics committees to sanction such studies because of safety concerns, are understandable, but this nonetheless limits the application of the studies to the real world of sport. It is not always clear that subjects have been fully familiarized with experimental protocols prior to measurements of performance, especially when tasks involving complex skills have been used. These factors may lead to performance changes that are of significance to the athlete being dismissed as being of no consequence [06223].

Alcohol has direct and demonstrable effects on athletic performance which may be due to its cardiovascular effects. It has been demonstrated significant ergolytic effects in short and middle distance runners. The adverse effects were most prominent in events that were more dependent upon aerobic capacity (i.e. 800 m and 1500 m). However there were no adverse effects observed in the 100 m run. Similarly, it was demonstrated a significant impairment in 60-minute treadmill time trial performance in trained athletes following alcohol ingestion. Heart rate and VO\textsubscript{2} were significantly elevated in subjects after alcohol ingestion and only 1 out of 4 subjects could complete the run. This may be due, in part, to the significant hypoglycemia that the subjects experienced at the 60 minute time point. Acute alcohol consumption may also result in small but significant reductions in sustained power output. It
was also demonstrated that acute ethanol ingestion resulted in a about 4 percent reduction in average cycling power output during a 60 minute time-trial. However, the detrimental effect of alcohol on aerobic performance seems to be dose dependent with a threshold of 20 mmol/L, upon which the effect becomes significant. Consumption of alcohol 24 hours prior to exercise has also been shown to reduce aerobic performance by 11 percent. Some studies have failed to show reductions in exercise performance following alcohol consumption. However, this may be due to limitations in their experimental design as well as type of exercise used. For instance, the lack of ergolytic effects on exercise performance during bicycle ergometer testing may be due to the fact that using a stationary bicycle ergometer does not place significant motor coordination demands as compared to running [13008].

Alcohol can also impair recovery following exercise. It has been shown that alcohol can impair glycogen resynthesis after prolonged cycling. More importantly, alcohol seems to interfere with protein synthesis, most likely by suppressing the mTOR pathway, which is critical to facilitate repair and hypertrophy following strength training. Although alcohol seems to have an overall ergolytic effect on exercise performance, a well-known athlete reported consumed alcohol before a ski downhill competition. This is potentially a dangerous precedent especially since alcohol has significant effects on executive functions such as judgment and decision making while also having significant adverse effects on motor control and coordination. This has to be considered in sports requiring a high level of boldness (downhill skiing, downhill mountain biking) and may have implications for pre-participation testing. In addition, the effects of an alcohol-induced hangover are poorly quantified and as such are relatively unknown and subject to further investigation in humans [13008].

The American College of Sports Medicine (ACSM) concludes in its position stand that alcohol consumption adversely affects psychomotor skills and exercise performance while resulting in minimal reductions in maximal oxygen consumption. The ACSM also recommends that if an athlete must consume alcohol, that they should refrain from alcohol consumption for at least 48 hours prior to competition. Chronic alcohol abuse is associated with significant impairments in cardiac and skeletal muscle. It also slows post-exercise recovery by inhibiting protein synthesis. Thus, alcohol is a uniformly ergolytic agent that has significant detrimental effects on exercise performance and that use of the same during competitive activity should be minimized for athlete safety and so as to maximize athletic performance [13008].

Practical effects of energy drinks on alcohol priming
While several researchers have proposed a causal relationship between alcohol mixed with energy drink (AmED) consumption and subsequent alcohol intake, there is a dearth of research exploring the potential mechanisms underpinning this association. Marczinski and colleagues (in press) report the results of a double-blind, placebo-controlled, between-groups study assessing whether an initial AmED dose primes an increased motivation to drink relative to alcohol alone. Participants (n=80) received either alcohol (0.91 ml/kg vodka), energy drink (ED; 1.82 ml/kg Red Bull®), AmED, or a placebo beverage and then self-reported their motivation to drink via the Desire-for-Drug scale. Subjective ratings of "desire more alcohol" were significantly higher than predrink in the placebo, alcohol, and AmED conditions, with this effect apparent at more time points in the AmED condition. While it was concluded that EDs may increase alcohol priming, between-condition analyses revealed that ratings did not differ significantly in AmED and alcohol conditions, with moderate magnitude treatment effects at most, and ratings of desire generally closer to 0 (absence of desire) than 100 (very much desire) [13546].

Effects of ethanol on glycogen metabolism

Resynthesis of the glycogen stores in liver and muscle is one of the key goals of athletes after intensive training or competition, and it is well recognized that ethanol has a variety of effects on carbohydrate metabolism in skeletal muscle and liver. Much of the available evidence comes from older studies using animal models, showing that synthesis of glycogen in both liver and oxidative skeletal muscle is impaired in the presence of even relatively low levels of ethanol, though there seems to be no effect on type 2 muscle fibers. There is also evidence of impaired hepatic glucose output in the presence of even low doses of ethanol. This may be of particular concern during prolonged, moderate-intensity exercise when glucose output from the liver is an important source of energy. It has been reported the effects of alcohol intake on muscle glycogen storage in humans during recovery from a prolonged cycling bout that resulted in a substantial reduction of carbohydrate stores. Subjects undertook three different diets following their glycogen-depleting exercise: a high-carbohydrate diet intended to optimize recovery, an alcohol displacement diet (reduced carbohydrate, in which about 210 g of dietary carbohydrate was replaced by about 120 g alcohol), and an alcohol plus carbohydrate diet (about 120 g alcohol added to the high-carbohydrate diet). Muscle glycogen storage was significantly reduced (by almost 50 % at 8 hours and about 16 % at 24 hours) on the alcohol displacement diet when the amount of carbohydrate provided by the diet was less than optimal. When the high carbohydrate diet was eaten, however, there was no clear evidence that alcohol intake caused a reduction in muscle glycogen storage; there was a small, not statistically significant reduction at 8 hours and no effect at all at 24 hours. It should be noted that there was a large variability of the responses of different subjects, and it may well be that some individuals will be unable to effectively replenish their glycogen reserves between daily training sessions if substantial amounts of alcohol are consumed. Even if there is not a direct metabolic effect of ethanol on glycogen storage when dietary carbohydrate intake is high, it is likely that athletes who consume large amounts of alcohol during the recovery period after training or competition will have a reduced carbohydrate intake, either as a result of a decreased total (nonalcohol) energy intake or because of a failure to follow the recommended eating strategies at this time [06223].

Hydration and thermoregulatory function

The diuretic action of ethanol is well recognized. This effect as been quantified to an excess
urine production of about 10 mL for each gram of ethanol ingested. It was also reported that the diuretic action was greatly attenuated, or eliminated altogether, in individuals who were already hypohydrated. Subsequent studies showed that alcohol acts via suppression of the release of antidiuretic hormone from the pituitary gland. However, alcohol has a negligible diuretic effect when consumed in dilute solution following a moderate level of hypohydration induced by exercise in the heat. There appears to be no difference in recovery from dehydration whether the rehydration beverage is alcohol-free or contains up to 2 percent alcohol, but drinks containing 4 percent alcohol tend to delay the recovery process by promoting urine loss. Based on this it is apparent that concentrated alcohol solutions will result in net negative fluid balance; a 25-mL measure of spirits (40 % ethanol) contains 10 mL of alcohol and 15 mL of water, resulting in a urine output of about 100 mL and net negative water balance of 85 mL. Ingestion of large volumes of dilute alcohol will result in a water diuresis, but should promote restoration of fluid balance after sweat loss provided that there is also an intake of sodium, which is essential for restoration of euhydration [06223].

The 1982 American College of Sports Medicine Position Stand on the use of alcohol in sports identified perturbations of thermoregulatory mechanisms, especially in the cold, as one of the reasons to abstain from alcohol prior to exercise. Small doses of ethanol given to human volunteers at rest in the absence of a thermal stress have very little effect on body temperature, but large doses administered before exercise at low ambient temperatures result in increased peripheral vasodilatation and a marked fall in core temperature. In combination with the concomitant fall in blood glucose concentration that is normally observed in this situation, there is clear potential for an adverse effect on performance. It was shown that ingestion of alcohol (2.5 mL/kg) prior to prolonged (3 hours) exercise in the cold resulted in increased heat loss, though this effect was somewhat attenuated by co-ingestion of glucose. In animal studies, administration of alcohol to animals exposed to ambient temperatures both above and below the thermoneutral zone, has shown that alcohol acts to impair adaptation to both heat and cold [06223].

In an animal study, rats were given 0, 4, 8, 12, or 16 percent ethanol as the sole source of drinking water for 14 days. Time to fatigue in treadmill running in the heat (35°C) of rats drinking 4 percent ethanol was similar to that of rats consuming water (32 vs 33 min, respectively), but running time of rats drinking 16 percent ethanol was reduced [06223].

**Effects of acute alcohol consumption on neuromuscular function.**

Voluntary and electrically stimulated muscular performance was examined to identify the effects of acute alcohol consumption on neuromuscular function in the presence and absence of exercise-induced muscle damage (EIMD). After initial neuromuscular performance measures were made, 12 subjects completed a bout of eccentric exercise (EX) using the quadriceps muscles of 1 leg while the remaining 11 subjects did not exercise (NX). Subjects then consumed either an alcoholic beverage containing 1 g/kg body weight (ALC) or a nonalcoholic beverage (OJ). On another occasion the contralateral leg of both groups was tested and those in the EX group performed an equivalent bout of eccentric exercise after which the other beverage was consumed. Measurements of neuromuscular function were made pre-exercise and 36 and 60 h post-beverage consumption. Creatine kinase (CK) was measured pre-exercise and at 12, 36, and 60 h. Significantly greater decrements in maximal voluntary isometric contraction were observed with EX ALC at 36 and 60 h compared with EX OJ, and no change was seen in the NX group. Significant decreases in voluntary activation were observed at 36 h and 60 h with EX ALC only. Elevations in CK were observed at all posteccentric exercise time points under both EX OJ and ALC. No
change in electromyography or low-frequency fatigue was observed under either treatment in either group. These results suggest that decreased neural drive appears to contribute to alcohol's effect on the magnitude of EIMD-related decrements in voluntary force generation [12344].

**Effects of acute alcohol consumption on recovery from a match**

In one study, it was investigated the effects of acute post-exercise alcohol consumption on measures of physical performance, creatine kinase, and immunoendocrine function in the 48 h following a rugby game simulation. Ten male senior rugby union players completed a rugby game simulation after which they consumed either 1 g of alcohol per kilogram of body mass or a non-alcoholic control beverage. Agility, 15 m sprint, countermovement jump, and scrumming performance were assessed pre-simulation and 24 and 48 h post-simulation. White blood cell count, testosterone, cortisol, and creatine kinase were measured before the simulation and 30 min, 12, 24, 36, and 48 h after the simulation. One week after the first trial, participants completed the second simulation after which the other beverage was consumed. The acute consumption of alcohol after a rugby game simulation negatively affected countermovement jump performance in the days following the simulation. No differences between treatments were observed for the other criterion measures made in this study. In conclusion, after 80 min of a simulated rugby game, the consumption of 1 g of alcohol per kg body mass negatively impacts lower body vertical power output. However, performance of tasks requiring repeated maximal muscular effort is not affected [12345].

One study compared the effects of "normal" post-game behaviour with recommended behaviour on physical performance in the days after a rugby union game. Additionally, the habitual drinking habits of rugby players were identified. After a rugby game, 26 players were split by team into a customary behaviour group (CB), who carried out their usual post-game behaviour, or recommended behaviour group (RB), whose diet and activity was controlled in the hours after the game. Counter movement jump, lower-body strength, repeated sprint ability, CK and hydration status were measured prior to and in the days after the game. Twenty-four hour behaviour recall questionnaires were completed throughout the trial period. The Alcohol Use Disorders Identification Test (AUDIT) was also administered to participants. Compared to baseline values, large volumes of alcohol and a loss in sleep was reported by the CB group in the hours after the game. Measures of performance and hydration status were unchanged over time and no difference was evident between groups. Total AUDIT scores for all participants were 17.75. CK was elevated in the days following the game. It was concluded that physical performance was not affected by participation in a game of senior club rugby, irrespective of post-game behaviour and possible muscle damage. AUDIT scores indicate that club rugby players may be at risk of serious alcohol related harm, with post-game binge drinking likely to be a major contributor [13548].

**Effects on brain's white matter**

Chronic alcohol abuse is related to numerous deleterious neurobiological consequences, including loss of gray matter, damage to white matter (WM), and impairment of cognitive and motor functions. Aerobic exercise has been demonstrated to slow cognitive decline and decrease the negative neural changes resulting from normal aging and from several diseases. It is possible that exercise may also prevent or repair alcohol-related neurological damage. One study tested the hypothesis that aerobic exercise protects WM in anterior and dorsal areas of the brain from damage related to heavy alcohol use. Sixty individuals underwent a diffusion tensor imaging session and completed measures of alcohol
consumption, loss of control over drinking, and aerobic exercise participation. Analyses examined the relationship of exercise, alcohol, and their interaction to fractional anisotropy (FA) in the superior longitudinal fasciculus (SLF), external capsule (EC), superior and anterior corona radiata, and fornix. The relationship of aerobic exercise and alcohol consumption to self-reported loss of control over drinking were also examined. A significant interaction was observed between alcohol consumption and aerobic exercise participation on FA in the SLF and EC. In the models examining loss of control over drinking, a significant interaction between aerobic exercise and alcohol consumption was observed, such that alcohol consumption was associated with loss of control more strongly for low exercisers than high exercisers. These results indicate that the association between heavy alcohol consumption and WM damage in the EC and SLF and the association between alcohol consumption and loss of control over drinking are greater among individuals who do not exercise regularly. These results are consistent with the notion that exercise may protect WM integrity from alcohol-related damage [13547].

The aftermath of alcohol use

There is limited and conflicting evidence on the effects of postalcohol consumption and hangover on functional capacity, but there is sufficient evidence of adverse effects the day after a heavy drinking session for such activities to be discouraged. It was shown reductions in aerobic exercise performance of rugby players the day after an evening bout of drinking involving an intake of 1 to 38 units of alcohol (equivalent to 10-380 mL pure alcohol), though anaerobic performance was unaffected. The negative effect on aerobic performance was apparent at even the smallest dose of alcohol. For obvious reasons, there are few studies of the effects of high alcohol intakes on soccer-specific performance, and there appear to be no studies on well-trained football players. In spite of substantial efforts on the part of the alcoholic drinks industry, the causes of the symptoms of hangover are not well understood, but are thought to include dehydration, acid-base disturbances, disruption of cytokine and prostaglandin pathways, and alterations in glucose metabolism via effects on circulating insulin and glucagon levels. There are also disturbances of cardiovascular function during the hangover phase, including increased heart rate, decreased left ventricular performance, and increased blood pressure [06223].

Effects of alcohol on injury and incapacity

The ingestion of alcohol is likely to have a number of behavioral and other effects that may influence the risk of injury and the recovery process after injury. There are many reported instances of athletes in various sports competing while under the influence of alcohol, even though prior alcohol consumption appears to increase the risk of sports-related injury. The mechanisms by which this association may be mediated are not entirely clear, but the increased risk of injury, and the increased severity of injuries that do occur, may be a consequence of increased risk-taking behaviors as alcohol removes some of the restraints that normally control behavior. Increased levels of aggression are also often displayed by those under the influence of alcohol. Intoxication during competition is probably rather rare, at least at the higher levels of sport, though it is not completely absent. It is perhaps not so unusual, though, for athletes training the morning after a high alcohol intake the previous night to be still under the influence of alcohol, and several high-profile players from the various football codes have publicly admitted to alcohol addiction. Athletes often experience some degree of muscle damage, either of intrinsic or extrinsic origin, after hard training or competition. This is usually in the form of minor damage that results in some degree of pain
and disability that may persist for hours or days. Because alcohol can act as a peripheral vasodilator, it is often stated that alcohol intake should be avoided after any exercise that may have resulted in muscle damage. There appears, however, to be no experimental evidence to support these anecdotal observations. It remains prudent, however, to avoid intoxication, as this is likely to result in inappropriate behaviors that may exacerbate existing muscle damage and delay the recovery process [06223].

**Influence of sex**

Studies indicate greater sexual risk-taking behaviors and alcohol use in student-athletes compared with nonathletes, particularly in college samples. Although research has documented an association between drinking and risky sex, studies have not examined the role of sex motives in predicting risky sex in athletes. The purpose of one study was to extend previous research on athletes’ risk-taking behaviors by examining incoming college student-athletes and nonathletes’ alcohol consumption, risky sexual behavior, and sex motives. Participants included 2,123 (59% female) incoming college students attending a northwest university, 221 of whom reported intercollegiate athletic participation during their upcoming year. Hierarchical multiple regression analyses were conducted to examine associations between sex motives and risky sexual behaviors using a cross-sectional design. Results indicated greater weekly alcohol consumption, frequency of drinking before or during sex, and number of sexual partners in athletes compared with nonathletes. Athletes also reported greater levels of enhancement motives for sex and lower levels of intimacy motives than nonathletes, although no differences were found for coping motives. Significant interactions indicated that, for athletes, greater levels of enhancement sex motives predicted a greater number of sexual partners and more frequent drinking before or during sex, and greater levels of intimacy motives predicted less frequent drinking before or during sex. It was concluded that student-athletes are at risk for problematic outcomes associated with risky sex, including drinking before or during sex and having sex with multiple partners. Prevention efforts targeted at incoming college student-athletes should consider the role of sex motives [07213].

**Impact of alcohol on steroid profiles**

The impact of ethanol consumption on steroid profiles was investigated. In a comprehensive study with 21 male and 15 female volunteers, alterations in steroid profile parameters were correlated with urinary ethanol-glucuronide and ethanol-sulfate concentrations, and threshold values of 48 mg/mL and 16 mg/mL for men and women, respectively, were suggested. When exceeded, an influence on urinary steroid profiles due to ethanol-induced suppression of steroid biotransformation processes should be considered during data interpretation [12017].

**Cardioprotective effects**

It is well-known that the moderate use of alcohol has a cardioprotective effect, especially as regards the process of atherothrombosis. This is mainly due to an increase in levels of HDL cholesterol and apolipoproteins A-I and A-II, and a decrease in levels of LDL cholesterol, as well as its favourable action on fibrinolytic activity. However, the long-term use of large quantities of alcohol leads to cardiovascular complications, such as arterial hypertension, dilated cardiomyopathy, stroke, arrhythmias, and coronary artery spasm, because of its sympathomimetic action [12126].
Carbohydrate deficient transferrin (CDT)

The determination of carbohydrate deficient transferrin (CDT) concentration is primarily used in social security studies as a proof of regular alcohol consumption exceeding the amount of 60 grams per day. One study was performed to investigate into how carbohydrate deficient transferrin CDT values in serum are affected by the so-called food supplements and chemicals included in doping lists. The investigation was carried out in 15 bodybuilders of two sport clubs and in 10 boxers. All sportsmen were males. In both groups serum carbohydrate deficient transferrin (CDT %), median red blood cell volume and (MCV) gamma-glutamyl-transpeptidase (GGT) values were measured. The authors found a significant difference between the two groups only in carbohydrate deficient transferrin CDT% that was the CDT% value in bodybuilders was twice as high as in boxers. Thus, not all the details of the specificity of carbohydrate deficient transferrin (CDT) concentration are known, however, the remarkably high sensitivity of the method makes it suitable and probably economically effective as a pre-screening tool in doping tests [12341].

In football

The use of alcohol is often intimately associated with sport, and the association is particularly strong in football. As well as providing a source of energy, alcohol (ethanol) has metabolic, cardiovascular, thermoregulatory, and neuromuscular actions that may affect exercise performance. Its actions on the central nervous system, however, result in decrements in skill and behavioural changes that may have adverse effects on performance. There is also evidence of dose-dependent decrements in aerobic capacity. Although the mechanisms are not well understood, the aftermath of alcohol use (hangover) may also adversely affect performance for many hours after intoxication. Alcohol intoxication may adversely affect the player's dietary choices by displacing carbohydrate from the diet at a time when restoration of glycogen stores should be a priority [06224].

Consumption in US college sports

The purpose of one study was to examine the drinking patterns of club and intramural college athletes and compare their alcohol consumption, perceived norms around the excessive use of alcohol, experience of negative consequences, and employment of protective strategies with those of campus varsity athletes. A total of 442 undergraduate students attending a private, suburban institution in the Northeast participated in the American College Health Association National College Health Assessment-II Web survey in spring 2011. Thirty-five students identified themselves as varsity athletes, 76 identified as club sport athletes, and 196 students identified themselves as intramural athletes. Survey responses were analyzed using Statistical Package for the Social Sciences. The Pearson's correlation coefficient and test for independence were applied to identify significant relationships between athlete status and identified variables related to alcohol use. Results: Results indicated that there were significant correlations between athlete status and all variables, to varying degrees. These findings have implications for campus health promotion professionals and athletics program coordinators seeking to address high-risk alcohol use among college athletes [12346].
**Sponsorship**

Sports sponsorship is a significant marketing tool. As such, it can promote products that pose risks to health (e.g., high fat and high sugar foods) or it can promote health-supporting products (e.g., sporting equipment and services). However, there is a lack of data on the proportion of sponsorship associated with "unhealthy" and "healthy" products and no methodology for systematically assessing it. This research aimed to explore this proportion with an Internet survey of sports sponsorship in the New Zealand setting. A search methodology was developed to identify Internet-based evidence of sports sponsorship at the national level and at the regional and club level in one specific region (Wellington). The top eight sports for 5-17-year-olds were selected and products and services of sponsors were classified in terms of potential public health impact (using a conservative approach). Sponsorship of these popular sports was common at the national, regional and club levels (640 sponsors listed on 107 websites overall). Sports sponsorship associated with sponsors' products classified as "unhealthy" (e.g., food high in fat and sugar, gambling and alcohol) were over twice as common as sponsorship associated with sponsors' products classified as "healthy" (33% vs 16%). "Gambling" was the most common specific type of sponsorship (19%) followed by alcohol (11%). There were significantly more "alcohol" sponsors for rugby, compared to all the other sports collectively (rate ratio (RR) = 2.47), and for top male sports compared to female (RR = 1.83). Also there was significantly more "unhealthy food" sponsorship for touch rugby and for "junior" teams/clubs compared to other sports collectively (RR = 6.54 and RR = 14.72). A validation study gave an inter-rater reliability for number of sponsors of 95 percent (n= 87 sponsors), and an inter-rater reliability of classification and categorisation of 100 percent. The study found that the sponsorship of popular sports for young people is dominated by "unhealthy" sponsorship (i.e. predominantly gambling, alcohol and unhealthy food) relative to "healthy" sponsorship. Governments may need to consider regulations that limit unhealthy sponsorship and/or adopt alternative funding mechanisms for supporting popular sports [06225].

There is accumulating evidence supporting a link between alcohol industry sponsorship and alcohol-related problems in both community and elite-level sports. Little is known, however, about the current status of such sponsorship, particularly of community sport. One study aimed to assess associations between alcohol industry sponsorship and different community football clubs in Australia. The study involved 101 community football clubs across New South Wales, Australia. One representative from each club took part in a cross-sectional telephone survey designed to assess club (football code, number of players, socioeconomic and geographic descriptors) and alcohol industry sponsorship (money, equipment, free alcohol or discounted alcohol) characteristics. Chi-square analysis was used to test associations between club characteristics, and any alcohol industry sponsorship; and type of sponsorship. Eighty-eight per cent of clubs reported receiving sponsorship from the alcohol industry, and most clubs (82%) were sponsored by a licensed premises. There were no significant associations between club characteristics and source of alcohol industry sponsorship. However, small clubs were found to be significantly more likely to receive free or discounted alcohol sponsorship than larger clubs. This exploratory study suggests a significant presence of alcohol industry sponsorship among community football clubs in Australia [12342].

Although there is evidence that alcohol sponsorship in sport is related to greater drinking, there is no empirical research on whether alcohol sponsorship is associated with alcohol-related harms. It was examined whether there is an association between receipt of alcohol industry sponsorship, and attendance at alcohol sponsor's drinking establishments (e.g. bars), and alcohol-related aggression and antisocial behaviour in university students who
play sport. University sports-people (n=652) completed surveys (response rate >80 %) assessing receipt of alcohol industry sponsorship, attendance at sponsor's establishments and confounders [i.e. age, gender, sport type, location and alcohol consumption measured by Alcohol Use Disorders Identification Test-alcohol consumption (AUDIT-C) scores]. Participants also completed measures assessing displays and receipt of aggressive and antisocial behaviours (e.g. assaults, unwanted sexual advance, vandalism). Logistic regression models including confounders and reported attendance at alcohol sponsor's establishments showed that sportspeople receiving alcohol industry sponsorship were more likely to have been the victim of aggression (adjusted odds ratio 2.62, 95 % confidence interval 1.22 to 5.64). Attending an alcohol sponsor's establishment was not associated with higher rates of other aggressive or antisocial behaviour. However, significant associations where found between AUDIT-C scores and having displayed and received aggression, and having damaged or had property damaged. Male sportspeople were more likely to have displayed and received aggressive and antisocial behavior. Higher AUDIT-C scores, gender and receipt of alcohol industry sponsorship were associated with alcohol-related aggression/antisocial behaviours in university sportspeople. Sport administrators should consider action to reduce the harms associated with excessive alcohol consumption and alcohol industry sponsorship in sport [12343].

Prevention

To examine 12-year changes in alcohol use and cigarette smoking in response to community-based prevention activities among Icelandic adolescents a study used a quasi-experimental, non-randomized control group design to compare outcomes in 4 Icelandic communities (n=3117) that participated in community-based substance use prevention activities designed to increase levels of parental monitoring and adolescent engagement in healthy leisure-time activities and a matched group of 7 comparison communities (n=1,907). Annual, nationwide, population-based cross-sectional surveys of the prevalence of adolescent substance use were conducted among cohorts of Icelandic adolescents, aged 14-15 years (n=5,024), in all communities from 1997 to 2009. Parental monitoring and adolescent participation in organized sports increased in communities that adopted the intervention program compared to communities that did not, whereas unmonitored idle hours and attendance at unsupervised parties decreased. Over time, alcohol use and being intoxicated during the last 30 days decreased significantly more in the intervention than control communities. Community-based prevention designed to strengthen parental monitoring and participation in organized sports may confer some protection against adolescent substance use [10395].

Alcohol control strategies at large sports events

To assess the implementation and effectiveness of strategies and actions to eliminate and/or reduce alcohol-related problems at large sports and entertainment events in New Zealand it was conducted site visits and monitoring observations at venues before, during and after a variety of large events between 2009 and 2010. Thirteen events were attended at nine different venues. Events included rugby, rugby league and cricket matches, motor racing, rowing, horse racing, an outdoor music festival, and food and wine festivals. Most large events appeared to pass with few or no alcohol-related problems. The exceptions were one of the horse-race meetings, a rugby league match and one food and wine festival. Common contexts at events where alcohol-related problems were seen included: inadequate alcohol control and management by security staff; the ability to purchase four alcoholic drinks (rather than two) at a time; inexperienced bar staff untrained in responsible alcohol service; no or
little promotion of low and non-alcoholic drinks; and a lack of monitoring and enforcement of the law on intoxication. An important approach to prevent and reduce alcohol-related problems at large spots and entertainment events is the use of specific alcohol-control strategies. The management of alcohol consumption is a major part of event management that must be planned with harm-minimisation strategies well in advance of the event itself. If strategies and actions are not properly implemented to manage the sale and supply of alcohol at large events, there is significant risk of alcohol-related problems and harm resulting from them [12347].
NICOTINE

Nicotine, 3-(1-methyl-2-pyrrolidinyl)pyridine, is a potent activator of the sympathetic nervous system, and in healthy humans increases heart rate and blood pressure, cardiac stroke volume and output and coronary blood flow. Nicotine also causes cutaneous vasoconstriction associated with a decrease in skin temperature, systemic venoconstriction and increased muscle blood flow. Circulating levels of noradrenaline and adrenaline increase after nicotine consumption, as do concentrations of free fatty acids, glycerol and lactate. Although the cardiovascular and metabolic effects of nicotine are pronounced, it is likely that during moderate-intensity or prolonged exercise when sympathetic output is high, the peripheral effects of nicotine may be attenuated. Nicotine is widely reported to increase alertness, improve co-ordination and enhance cognitive performance; however, to our knowledge there have been no attempts to replicate these findings in relation to exercise endurance. The purpose of one study was to determine the effects nicotine might have on cycling endurance, perception of exertion and a range of physiological variables. With local ethics committee approval and having obtained informed consent, 12 healthy, non-smoking men (22 ± 3 years) cycled to exhaustion at 18 degrees C and 65 percent of their peak aerobic power, wearing either a 7 mg transdermal nicotine patch (NIC) or a colour-matched placebo (PLA) in a randomized cross-over design; water was available ad libitum. Subjects were exercising at approximately 75 percent of their maximal O₂ uptake with no differences in cadence between trials. Ten out of 12 subjects cycled for longer with NIC administration, and this resulted in a significant improvement in performance. No differences were observed for perceived exertion, heart rate or ventilation. There were no differences in concentrations of plasma glucose, lactate or circulating fatty acids. In the absence of any effect on peripheral markers, it was concluded that nicotine prolongs endurance by a central mechanism. Possible modes of action are suggested [06192].

Of the well-known stimulants, amphetamine and cocaine use is marginal compared to caffeine and nicotine, which are considered as the most widely consumed psychostimulants in the world, with more than 80 percent of the world population consuming caffeine and/or nicotine on a daily basis. There are research on nicotine has concentrated on the pharmacodynamics of the drug and improving smoking cessation, with no published studies having examined the effects of nicotine on exercise endurance/capacity. Nicotine administration during light physical activity has been shown to increase heart rate and blood pressure with no effect on ventilation, as well as having no effect on perceived exertion, however, protocols included smokers, sedentary subjects and work rates of cycling between 30 and 150 W for a maximum of 15 min. It has also been observed a significant increase in heart rate and a decrease in stroke volume together with an increase in blood lactate at rest and during treadmill exercise at 60 and 85 percent maximal O₂ uptake with oral smokeless tobacco (OST), compared to a placebo. The authors concluded that OST-induced increases in plasma nicotine concentrations augment anaerobic energy production and suggest a nicotine-induced sympathetic stimulation of the heart [06192].

Smoking and administration of nicotine are often associated with increased alertness, improved coordination and positive mood changes. It is likely that cortical arousal is a result of nicotine directly stimulating cholinergic neurotransmission in the basal forebrain. Nicotine has also been shown to increase dopamine release in the striatum and nucleus accumbens, the reward centre of the brain, and this effect is mediated by nicotinic acetylcholine receptors. It is therefore likely that administration of nicotine may enhance motivation during prolonged exercise owing to an increased release of dopamine, possibly involving similar pathways to those suggested for the central actions of caffeine [06192].
Despite the widespread use of nicotine and general acceptance that it promotes many of the characteristics provided by other stimulants, such as caffeine, cocaine and amphetamines, there has been no quantitative research about its benefits on endurance capacity during moderate and prolonged exercise, where the progressive development of central fatigue is believed to be a contributing factor in maintaining motivation. Whilst the present observation of a about 17 percent improvement in exercise duration may be the first demonstration of the efficacy of nicotine, others have shown improvements of this magnitude at a similar intensity for caffeine as well as amphetamine sulphate ingestion, which delays fatigue and improves time to exhaustion during short, intense bouts of exercise of < 10 min. It is likely that, as for caffeine, the maximal benefits of nicotine will be seen with exercise of 70-80 percent maximal aerobic capacity; depletion of muscle glycogen is likely to be the limiting factor during exercise below this intensity, whilst at higher intensities, cardiovascular and respiratory limitations, combined with peripheral muscle fatigue, will predominate [06192].

Consumption of nicotine in the form of smokeless tobacco (snus, snuff, chewing tobacco) or nicotine-containing medication (gum, patch) may benefit sport practice. Indeed, use of snus seems to be a growing trend and investigating nicotine consumption amongst professional athletes is of major interest to sport authorities. Thus, a liquid chromatography-tandem mass spectrometry (LC-MS/MS) method for the detection and quantification of nicotine and its principal metabolites cotinine, trans-3-hydroxycotinine, nicotine-N'-oxide and cotinine-N-oxide in urine was developed. Sample preparation was performed by liquid-liquid extraction followed by hydrophilic interaction chromatography-tandem mass spectrometry (HILIC-MS/MS) operated in electrospray positive ionization (ESI) mode with selective reaction monitoring (SRM) data acquisition. The method was validated and calibration curves were linear over the selected concentration ranges of 10-10,000 ng/mL for nicotine, cotinine, trans-3-hydroxycotinine and 10-5000 ng/mL for nicotine-N'-oxide and cotinine-N-oxide, with calculated coefficients of determination (R²) greater than 0.95. The lower limit of quantification (LLOQ) for all analytes was 10 ng/mL. Repeatability and intermediate precision were ≤9.4 and ≤9.9%, respectively. In order to measure the prevalence of nicotine exposure during the 2009 Ice Hockey World Championships, 72 samples were collected and analyzed after the minimum of 3 months storage period and complete removal of identification means as required by the 2009 International Standards for Laboratories (ISL). Nicotine and/or metabolites were detected in every urine sample, while concentration measurements indicated an exposure within the last 3 days for eight specimens out of ten. Concentrations of nicotine, cotinine, trans-3-hydroxycotinine, nicotine-N'-oxide and cotinine-N-oxide were found to range between 11 and 19,750, 13 and 10,475, 10 and 8217, 11 and 3396, and 13 and 1640 ng/mL, respectively. When proposing conservative concentration limits for nicotine consumption prior and/or during the games (50 ng/mL for nicotine, cotinine and trans-3-hydroxycotinine and 25 ng/mL for nicotine-N'-oxide and cotinine-N-oxide), about half of the hockey players were qualified as consumers. These findings significantly support the likelihood of extensive smokeless nicotine consumption. However, since such conclusions can only be hypothesized, the potential use of smokeless tobacco as a doping agent in ice hockey requires further investigation [10505].

Tobacco consumption is a global epidemic responsible for a vast burden of disease. With pharmacological properties sought-after by consumers and responsible for addiction issues, nicotine is the main reason of this phenomenon. Accordingly, smokeless tobacco products are of growing popularity in sport owing to potential performance enhancing properties and absence of adverse effects on the respiratory system. Nevertheless, nicotine does not appear on the 2011 World Anti-Doping Agency (WADA) Prohibited List or Monitoring Program by lack of a comprehensive large-scale prevalence survey. Thus, this work describes a one-year monitoring study on urine specimens from professional athletes of
different disciplines covering 2010 and 2011. A method for the detection and quantification of nicotine, its major metabolites (cotinine, trans-3-hydroxycotinine, nicotine-N'-oxide and cotinine-N-oxide) and minor tobacco alkaloids (anabasine, anatabine and nornicotine) was developed, relying on ultra-high pressure liquid chromatography coupled to triple quadrupole mass spectrometry (UHPLC-TQ-MS/MS). A simple and fast dilute-and-shoot sample treatment was performed, followed by hydrophilic interaction chromatography-tandem mass spectrometry (HILIC-MS/MS) operated in positive electrospray ionization (ESI) mode with multiple reaction monitoring (MRM) data acquisition. After method validation, assessing the prevalence of nicotine consumption in sport involved analysis of 2185 urine samples, accounting for 43 different sports. Concentrations distribution of major nicotine metabolites, minor nicotine metabolites and tobacco alkaloids ranged from 10 (LLOQ) to 32,223, 6670 and 538 ng/mL, respectively. Compounds of interest were detected in trace levels in 23 percent of urine specimens, with concentration levels corresponding to an exposure within the last three days for 18 percent of samples. Likewise, hypothesizing conservative concentration limits for active nicotine consumption prior and/or during sport practice (50ng/mL for nicotine, cotinine and trans-3-hydroxycotinine and 25 ng/mL for nicotine-N'-oxide, cotinine-N-oxide, anabasine, anatabine and nornicotine) revealed a prevalence of 15 percent amongst athletes. While this number may appear lower than the worldwide smoking prevalence of around 25 percent, focusing the study on selected sports highlighted more alarming findings. Indeed, active nicotine consumption in ice hockey, skiing, biathlon, bobsleigh, skating, football, basketball, volleyball, rugby, American football, wrestling and gymnastics was found to range between 19 and 56 percent. Therefore, considering the adverse effects of smoking on the respiratory tract and numerous health threats detrimental to sport practice at top level, likelihood of smokeless tobacco consumption for performance enhancement is greatly supported [11226].

Smokeless tobacco (ST) use is common in some sports. Nicotine is a psychomotor stimulant and this raises the issue of whether such use constitutes that of a performance-enhancing drug. Most of the data come from baseball players. Both adolescent and adult baseball players use ST. Among major league players, 45 percent have been reported to use ST. The amount of nicotine extracted from ST ranges between 20 and 45 percent and bioavailability is 40-60 percent of the extracted amount. Plasma levels peak after 30 minutes, with values which could reach an average of 20-30 ng/mL at the end of the day (similar to moderate to heavy smoking). ST users are thus exposed to a large amount of nicotine over a longer period than from smoking. Nicotine has been found in some studies to enhance information processing and attentional processes in humans. The robustness of this effect and whether in smokers it represents more than normalization of impairment experienced as a result of nicotine withdrawal has been debated. In baseball ST users there are only limited data. It has been assessed muscular force, reaction time and choice reaction time in athlete ST users (under abstinence) versus non-users. ST users showed a stronger force, a slower choice reaction time but no difference in simple reaction time. Another study compared field performance between ST users versus non-users by using common baseball statistics parameters. Indeed, higher values for parameters investigated are an expression of a better integration between cognitive and motor processes, such as perception, vigilance, divided attention, decision-making and executive outcome, in order to meet demanding game situations. These key moments of the match are also characterized by high alertness and arousal states, as well as by a higher stress condition. Also modest enhancement induced by ST use may make a difference in performance that could affect the outcome of a highly competitive match, where teams and players appear to be well balanced. Thus, while the limited set of available data suggests that some psychometric values are not changed in baseball ST users under abstinence, no data are available from the field, or even from the laboratory, under actual ST exposure. The question still remains: are those subjects who are taking ST benefiting from legal doping? At present, there is limited translation or modeling of
complex psychomotor performance – as in sports – into the laboratory. Although specific models have been developed to study sport performance in the laboratory, valid experimental paradigms are still lacking for investigations on the effects of addictive substances on complex psychomotor performance. A possible experimental approach is to begin by correlating the statistical data available on baseball performances in the United States with information on ST use of leading players. The results of such correlations may support experimental placebo-controlled studies on any enhancing effects of low- or high-nicotine ST. This is a difficult area, but it makes sense to begin the debate now and start collecting relevant data [07203].

Aerobic exercise can acutely reduce cigarette cravings during periods of nicotine deprivation. The primary aim of this study was to assess the differential effects of light and vigorous intensity aerobic exercise on cigarette cravings, subjective and physiological reactivity to smoking cues, and affect after overnight nicotine deprivation. A secondary aim was to examine cortisol change as a mediator of the effects of exercise on smoking motivation. 162 (55 female, 107 male) overnight nicotine-deprived smokers were randomized to one of three exercise conditions: light intensity, vigorous intensity, or a passive control condition. After each condition, participants engaged in a standardized cue reactivity assessment. Self-reported urges to smoke, affect, and salivary cortisol were assessed at baseline (i.e., before each condition), immediately after each condition, and after the cue reactivity assessment. Light and vigorous exercise significantly decreased urges to smoke and increased positive affect, relative to the control condition. In addition, those in the vigorous exercise condition demonstrated suppressed appetitive reactivity to smoking cues, as indexed by the startle eyeblink reflex. Although exercise intensity was associated with expected changes in cortisol concentration, these effects were not related to changes in craving or cue reactivity. Both light and vigorous exercise can reduce general cravings to smoke, whereas vigorous exercise appears especially well-suited for reducing appetitive reactions to cues that may precede smoking. Results did not support exercise-induced cortisol release as a mechanism for these effects [13549].

Nicotine or 3-(1-methyl-2-pyrrolidinyl)pyridine is a naturally occurring alkaloid and one of the most widely used psychostimulants in the world. Cigarettes are the most common source of nicotine. Smoked tobacco contains additional harmful constituents and chemicals, which have detrimental effects on the respiratory system. In summary, nicotine seems to have ergogenic potential. Athletes appear to benefit from activation of the sympathoadrenal system with increased catecholamine release and subsequent increases in muscle blood flow and lipolysis. One component of nicotine action seems to act via a central mechanism (by nicotine receptor activation and/or dopaminergic pathways. There is evidence for the abuse of nicotine by athletes. Although the sale of snuff is illegal within the European Union, anecdotal observations by coaches and research from Scandinavia shows a high prevalence of snus use among athletes [13008].

Mechanism of action

In general, nicotine has a psychostimulatory effect on the CNS at low doses via enhancing the actions of norepinephrine and dopamine in the brain. At higher doses, however, nicotine enhances the effect of serotonin and opiate activity, exerting a calming and depressing effect. Nicotine-induced stimulation of the sympathetic nervous system leads to increased heart rate and blood pressure, cardiac stroke volume and output and coronary blood flow. Although the results are conflicting and some authors report increases in cutaneous blood flow and skin temperature, others report a decrease in cutaneous blood flow and subsequent decline in skin temperature associated with nicotine consumption. These differences in
cutaneous blood flow are possibly related to differences in nicotine administration. Both snus and nicotine gums enable nicotine to diffuse across the mucous membranes and are taken up by the bloodstream or, when inhaled, diffuses across the alveolar membrane of the alveoli, and enters the bloodstream. Although the amount of nicotine inhaled is lower than with conventional cigarettes, the use of electronic cigarettes is becoming more and more popular. However, the amount taken up by smokeless tobacco users tends to be much greater than by smoking. Once in the bloodstream, nicotine is quickly (within seconds) delivered to the brain, where it interacts with neural nicotinic acetylcholine receptors (nAChRs). It is metabolized by the liver cytochrome P450 enzyme system and has a half-life of approximately 2 hours. Upon binding of ACh or its exogenous ligand nicotine, the ion channel is opened and causes an influx of sodium and calcium (Ca\(^{2+}\)). This local increase in intracellular Ca\(^{2+}\) can alter cellular functions. A mechanism termed Ca\(^{2+}\)-induced Ca\(^{2+}\) release can further boost intracellular calcium upon activation of nAChR. In vitro experiments using human neutrophils showed a dose-dependent rise in intracellular Ca\(^{2+}\) levels of 700% over baseline at a concentration of 10\(^{-2}\) M nicotine. In numerous pathways, Ca\(^{2+}\) acts as an intracellular messenger, setting the stage for nAChRs as potent candidates to influence a variety of Ca\(^{2+}\)-dependent neuronal processes, such as neurotransmitter release, synaptic plasticity or gene transcription [13008].

**Effect on performance**

While it is clear that smoking can lead to the development of respiratory, cardiovascular, and skin diseases as well as a number of tobacco-related cancers there are other forms of application such as the use of alternative smokeless tobacco (snuff), which is gaining popularity among athletes as it bypasses the respiratory system. Snuff and cigarette consumers show similar peak blood nicotine levels after use with a tendency for higher cotinine levels in the former. Nicotine activates the sympathoadrenal system, which leads to increased heart rate, contractility, vasoconstriction and a rise in blood pressure and the level of circulating catecholamines during light exercise. Nicotine also increases muscle blood flow and lipolysis due to enhanced circulating levels of norepinephrine and epinephrine as well as direct action on nicotinic cholinergic receptors in adipose tissue. The effects exerted by nicotine may be beneficial in a wide variety of sports and it is suggested that nicotine is abused by athletes. A cumulative exposure to nicotine metabolites were found in 26-56 percent of urine samples that were subjected to screening for tobacco alkaloids. After correcting for exposure to second-hand smoke, 15 percent of the athletes were considered active nicotine consumers. Among athletes, this is high considering the WHO's 25 percent worldwide estimate of smoking prevalence. It can be hypothesized that the metabolites stem mostly from smokeless tobacco due to the adverse effects of conventional cigarettes for athletes, which most severely affects athletes engaging in endurance type sports [13008].

A large number of human and animal studies have found nicotine-induced improvements in several aspects of cognitive function, including learning and memory, reaction time, and fine motor abilities. Studies addressing the question of a direct performance enhancing effect of nicotine are rare. Sports most affected include ice hockey, skiing, biathlon, bobsleigh, skating, football, basketball, volleyball, rugby, American football, wrestling and gymnastics. These sports seem to gain performance benefits from the stimulating effect of nicotine as evident from the use of other prohibited stimulants according to the Anti-Doping Database. It was found a 17 percent improvement in time to exhaustion after nicotine patch application compared to a placebo without affecting cardiovascular and respiratory parameters or substrate metabolism. In this sense, nicotine seems to exert similar effects as caffeine by delaying the development of central fatigue as impaired central drive is an important factor contributing to fatigue during exercise. To date, no improvement on anaerobic performance
(Wingate test) has been reported. It is important to note that, compared to rest, exercise can lead to increased drug absorption from transdermal nicotine patches, possibly due to exercise-induced increase in peripheral blood flow at the site of the transdermal patch. It was reported increased plasma nicotine levels and toxicity due to increased drug absorption during physical exercise. To prevent undesirable side effects, health professionals, trainers and coaches should therefore be aware of proper transdermal patch use, particularly while exercising. Athletes are encouraged to inform their physician about their exercise routine before beginning transdermal patch use. Athletes should further be familiar with signs and symptoms of drug toxicity related to the medication contained in the transdermal patch and consult their physician if signs or symptoms arise. Reducing exercise intensity and duration for the first 1-2 weeks until potential side effects are known might also help to minimize toxicity. To reduce increased exercise-induced drug absorption, athletes are encouraged to avoid exercising in extreme environmental and temperature conditions, wear appropriate breathable sports garments and drink plenty of fluids to prevent dehydration [13008].

Additionally, although nicotine may have ergogenic potential, it is also highly addictive, reportedly as addictive as heroin and cocaine. Therefore, detrimental effects on motor performance can be altered after a short abstinence duration. However, it was noted that motor performance declines in heavy smokers after a short period of abstinence appears, this decline being similar to the motor symptoms of Parkinsonism. The abstinence symptoms are ameliorated by cigarette smoking. It is important to consider the concerning addictive potential with following deterioration of motor performance upon abstinence. Interestingly, however, it was noted that moderate and vigorous exercise led to significant reductions of the desire to smoke among abstaining smokers, possibly via reductions in cortisol. A recent meta-analysis showed that exercise has the potential to acutely reduce cigarette cravings and could therefore be a promising strategy to attenuate withdrawal symptoms in smokers. It is also important to mention that the vasoconstriction mediated by nicotine could limit exercise performance in a hot environment. As skin blood flow increases during exercise to transfer heat impaired nicotine-induced skin blood flow may be ergolytic. A recent meta-analysis clearly suggests significant effects of nicotine on fine motor abilities, including attention and memory. Participants of the studies included in the meta-analysis were mainly nonsmokers, therefore avoiding confounding of nicotine withdrawal. Considering the importance of cognition in sport, such an optimization of neurobiological function in our view seems to be beneficial for a variety of sports such as sport games or track and field. Finally, nicotine’s effect on increased pain tolerance might be of advantage in a wide variety of sports [13008].

**Detection**

Nicotine use can be detected in urine samples based on its major metabolites (cotinine, trans-3-hydroxycotinine, nicotine-N0-oxide and cotinine-N-oxide) and tobacco alkaloids (anabasine, anatabine and nornicotine) which can be used as an indicator of a person’s exposure to nicotine [13008].
NON-STEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)

Non-steroidal anti-inflammatory drugs (NSAIDs) are widely consumed among athletes worldwide in relation to muscle injury and soreness. This review aims to provide an overview of studies investigating their effects on skeletal muscle, in particular the repair processes in injured muscle. Muscle injury occurs in diverse situations and the nature of muscle injuries varies significantly, complicating extrapolations between experimental models and “real life.” Classical muscle strain injuries occur at the interface between the muscle fibers and connective tissue, most often in the myotendinous junction, whereas contusion or overload injury can damage both myofibers and intramuscular connective tissue. The role of NSAIDs in muscle repair is complicated by differences in injury models used, variables evaluated, and time point(s) selected for evaluations. While the temporal pattern of the influence of NSAIDs on muscle repair is difficult to settle on, it appears that a potential beneficial effect of NSAIDs in the early phase after injury is not maintained in the long term, or is even negated by a long-term repair deficit. At the cellular level, evidence exists for a negative influence of NSAIDs on the muscle stem cell population (satellite cells). At a structural level, it is known that muscle connective tissue undergoes significant remodeling during muscle regeneration, but the potential of NSAID exposure to alter this response in humans needs investigation [12329].

Superstitions and rituals are commonplace in sports, and range from simple activities such as each player touching a special inanimate object before entering the field of play to more extreme behaviors such as not washing a uniform or wearing the same underwear during a winning streak. These practices are relatively harmless and may reduce pre-competition anxiety, but a concerning ritual that has recently developed in sports is the prophylactic use of non-steroidal anti-inflammatory drugs (NSAIDs) [09298].

Non-steroidal anti-inflammatory drugs (NSAIDs) are commonly used in sports medicine. NSAIDs have known anti-inflammatory, analgesic, antipyretic, and antithrombotic effects, although their in-vivo effects in treating musculoskeletal injuries in humans remain largely unknown. NSAIDs analgesic action is not significantly greater than paracetamol for musculoskeletal injury but they have a higher risk profile, with side-effects including asthma exacerbation, gastrointestinal and renal side-effects, hypertension, and other cardiovascular disease. The authors recommend an approach to NSAID use in sports medicine whereby simple analgesia is preferentially used when analgesia is the primary desired outcome. However, based both on the current pathophysiological understanding of most injury presentations, and the frequency that inflammation may actually be a component of the injury complex, it is premature to suppose that NSAIDs are not useful to the physician managing sports injuries. The prescribing of NSAIDs should be cautious, and both situation and pathology specific. Both dose and duration minimization should be prioritized and combined with simple principles of protection, rest, ice, compression, elevation (PRICE) which should allow NSAID-sparing. NSAID use should always be coupled with appropriate physical rehabilitation. NSAIDs are probably most useful for treating nerve and soft-tissue impingments, inflammatory arthropathies, and tenosynovitis. There are not generally indicated for isolated chronic tendinopathy, or for fractures. The use of NSAIDs in treating muscle injury is controversial. Conditions where NSAID use requires more careful assessment include; ligament injury, joint injury, osteoarthritis, haematoma, and post-operatively [09296].

Unaccustomed exercise leads to satellite cell proliferation and increased skeletal muscle protein turnover. Several growth factors and cytokines may be involved in the adaptive
responses. Non-steroidal anti-inflammatory drugs (NSAIDs) negatively affect muscle regeneration and adaptation in animal models, and inhibit the exercise-induced satellite cell proliferation and protein synthesis in humans. However, the cellular mechanisms eliciting these responses remain unknown. Eight healthy male volunteers performed 200 maximal eccentric contractions with each leg. To block prostaglandin synthesis locally in the skeletal muscle, indomethacin (NSAID) was infused for 7.5 h via microdialysis catheters into m. vastus lateralis of one leg. Protein synthesis was determined by the incorporation of 1,2-13C2-leucine into muscle protein from 24 to 28 h post-exercise. Furthermore, mRNA expression of selected genes was measured in muscle biopsies (5 h and 8 days post-exercise) by real-time reverse transcriptase PCR. Myofibrillar and collagen protein synthesis were unaffected by the local NSAID infusion. Five hours post-exercise, the mRNA expression of cyclooxygenase-2 (COX2) was sixfold higher in the NSAID leg compared with the unblocked leg. The expression of growth factors and matrix-related genes were unaffected by NSAID. Although NSAIDs inhibit the exercise-induced satellite cell proliferation, it was observed only limited effects on gene expression, and on post-exercise protein synthesis [11513].

Although athletes are young and generally healthy, they use a variety of non-doping classified medicines to treat injuries, cure illnesses and obtain a competitive edge. Athletes and sports medicine physicians try to optimize the treatment of symptoms related to extreme training during an elite athlete's active career. According to several studies, the use of antiasthmatic medication is more frequent among elite athletes than in the general population. Recent studies show that athletes use also NSAIDs and oral antibacterials more commonly than age-matched controls, especially athletes competing in speed and power sports. Inappropriately high doses and concomitant use of several different NSAIDs has been observed. All medicines have adverse effects that may have deleterious effects on elite athletes' performance. Thus, any unnecessary medication use should be minimized in elite athletes. Inhaled beta2-agonists may cause tachycardia and muscle tremor, which are especially harmful in events requiring accuracy and a steady hand. In experimental animal models of acute injury, especially selective cyclo-oxygenase-2 inhibitors have been shown to be detrimental to tissue-level repair. They have been shown to impair mechanical strength return following acute injury to bone, ligament and tendon. This may have clinical implications for future injury susceptibility. However, it should be noted that the current animal studies have limited translation to the clinical setting. Adverse effects related to the CNS and gastrointestinal adverse reactions are commonly reported in connection with NSAID use also in elite athletes. In addition to the potential for adverse effects, recent studies have shown that NSAID use may negatively regulate muscle growth by inhibiting protein synthesis [08366].

The World Anti-Doping Agency does not prohibit the use of nonsteroidal anti-inflammatory drugs (NSAIDs) because these agents are not performance enhancing, and their analgesic and anti-inflammatory effects are at best performance enabling. Consequently, athletes have relatively unrestricted access to NSAIDs, which are readily available as over-the-counter drugs. However, concern has been raised on athletes’ prophylactic use of these agents. Data from many sporting fields have consistently demonstrated that many individuals self-administer NSAIDs prior to athletic participation to prevent pain and inflammation before it occurs. However, scientific evidence for this approach is currently lacking, and athletes should be aware of the potential risks in using NSAIDs as a prophylactic agent. These agents are not benign, and can produce significant side effects, including gastrointestinal and cardiovascular conditions, as well as musculoskeletal and renal side effects. The latter side effects appear paradoxical to the rationale for prophylactic use of NSAIDs [10209].

Sports medicine physicians often treat athletes in pain with non-steroidal anti-inflammatory drugs (NSAIDs). However, there is a lack of high-quality evidence to guide NSAID use. Their
adverse effects have clinical relevance, and their possible negative consequences on the long-term healing process are slowly becoming more obvious. One article provides some practical management guidelines for the use of NSAIDs, developed to help sports medicine physicians deal with frequent sports-related injuries. NSAIDs are not recommended for muscle injuries, bone fractures (also stress fractures) or chronic tendinopathy. In all cases, if chosen, NSAID treatments should always be kept as short as possible and should take into account the specific type of injury, the level of dysfunction and pain [10210].

To examine the prescribing habits of NSAIDs among pediatric medical and surgical practitioners, and to examine concerns and barriers to their use a sample of 1289 pediatricians, pediatric rheumatologists, sports medicine physicians, pediatric surgeons and pediatric orthopedic surgeons in the United States and Canada were sent an email link to a 22-question web-based survey. 338 surveys (28 %) were completed, 84 were undeliverable. Of all respondents, 164 (50 %) had never prescribed a selective cyclooxygenase-2 (COX-2) NSAID. The most common reasons for ever prescribing an NSAID were musculoskeletal pain, soft-tissue injury, fever, arthritis, fracture, and headache. Compared to traditional NSAIDs, selective COX-2 NSAIDs were believed to be as safe (42 %) or safer (24 %); have equal (52 %) to greater efficacy (20 %) for pain; have equal (59 %) to greater efficacy (15 %) for inflammation; and have equal (39 %) to improved (44 %) tolerability. Pediatric rheumatologists reported significantly more frequent abdominal pain (81 % vs 23 %), epistaxis (13 % vs 2 %), easy bruising (64 % vs 8 %), headaches (21 % vs 1 %) and fatigue (12 % vs 1 %) for traditional NSAIDs than for selective COX-2 NSAIDs. Prescribing habits of NSAIDs have changed since the voluntary withdrawal of rofecoxib and valdecoxib; 3 percent of pediatric rheumatologists reported giving fewer traditional NSAID prescriptions, and while 57 percent reported giving fewer selective COX-2 NSAIDs, 26 percent reported that they no longer prescribed these medications [10211].

Nonsteroidal anti-inflammatory drugs (NSAIDs) are frequently used in sports medicine to reduce time of incapacity. To describe the frequency of NSAIDs use by athletes in the XV Pan-American Games all athletes who were tested by the anti-doping control filled a form. The voluntarily declared medications were recorded and categorised according to sport modality, gender, region and control situation according to the World Anti-Doping Agency. Among the 1261 athletes tested (231 out-competition (OC) and 1030 in-competition (IC); 733 men and 528 women), 63 percent reported use of drugs, NSAIDs being the most frequently (64% of users) used medications. The use of medications was not significantly different between sexes or among different regions of the world. The number of users of only one type of NSAID was higher than those who used more than one type of NSAIDs or a combination with analgesics (335 vs 168 cases). IC reports presented higher use of NSAIDs than OC. Athletes tested by the anti-doping control of the XV Pan-American Games reported a high frequency of NSAIDs use. The frequent utilisation in competition suggests that these medications might be used as ergogenic aid [11230].

Sports medicine physicians often treat athletes in pain with non-steroidal anti-inflammatory drugs (NSAIDs). However, there is a lack of high-quality evidence to guide NSAID use. Their adverse effects have clinical relevance, and their possible negative consequences on the long-term healing process are slowly becoming more obvious. This article provides some practical management guidelines for the use of NSAIDs, developed to help sports medicine physicians deal with frequent sports-related injuries. It was not recommend their use for muscle injuries, bone fractures (also stress fractures) or chronic tendinopathy. In all cases, if chosen, NSAID treatments should always be kept as short as possible and should take into account the specific type of injury, the level of dysfunction and pain [06220].

Nonsteroidal antiinflammatory drugs (NSAIDs) are frequently used in the treatment of acute
athletic injuries, often for analgesic purposes as the evidence to support enhanced healing is limited. However, the current evidence on NSAID use in athletic injury is slowly growing. On the basis of animal models and limited human studies, some practical management guidelines can be drawn to assist the sports physician. Specifically, NSAIDs are not recommended in the treatment of completed fractures, stress fractures at higher risk of nonunion, or in the setting of chronic muscle injury. The only exception may be very short-term use (e.g. a few days) for analgesic purposes only. Judicious use of NSAIDs may be more appropriate in the management of acute ligament sprains, muscle strains, tendinitis, and eccentric muscle injury. However, length of treatment should always be kept as short as possible, with consideration of the specific type of injury, level of dysfunction, and pain.

Non-steroidal anti-inflammatory drugs (NSAIDs) act by inhibiting cyclo-oxygenase-1 (COX-1) and COX-2 enzymes, which are involved in prostaglandin synthesis, resulting in their analgesic, anti-inflammatory, and antipyretic effects. Arachidonic acid is metabolised by the cyclo-oxygenase isoenzymes COX-1 and COX-2 to intermediate prostaglandins (PGG2, then PGH2), which are then converted to other prostaglandins that are mediators of pain, inflammation, and fever, and are gastroprotective. Thromboxane A2 causes platelet aggregation, and prostacyclin produces vasodilation. By blocking COX enzymes, NSAIDs inhibit the synthesis and thus the effects of prostaglandins, prostacyclin, and thromboxane A2. The clinical effects of NSAIDs depend largely on their selectivity for these enzymes. Aspirin works by irreversibly inhibiting COX-1 mediated synthesis of thromboxane A2, and is used to inhibit platelet aggregation. Although the boundary is blurred, there are two broad groups of NSAIDs: the older, traditional, nonselective NSAIDs that inhibit both COX-1 and COX-2 and the newer, selective COX-2 inhibitors that predominantly inhibit COX-2. The non-selective NSAID aspirin is used primarily for its antiplatelet effect, thus reducing the risk of myocardial re-infarction and stroke.

Non-selective (NSAIDs) and selective (COX-2) nonsteroidal anti-inflammatory drugs are commonly used for their analgesic and anti-inflammatory effects. Their role after orthopaedic surgery has been infrequently described and remains controversial because of unclear effects on soft tissue and bone healing. One study critically reviewed the available literature to describe the effects of NSAIDs and COX-2 inhibitors on soft tissue and bone healing. A Medline search was performed using NSAIDs or COX-2 inhibitors and tissue healing. The combined search yielded 637 articles. Following exclusion, 44 articles were deemed relevant with 9 articles on soft tissue healing and 35 articles on bone healing. The available evidence is based primarily on animal data (39 studies), with considerable variation in study methods. In regard to soft tissue healing, there is insufficient evidence of a detrimental effect when using either NSAIDs or COX-2 inhibitors at standard doses for ≤2 weeks. For soft tissue to bone healing, a limited number of studies demonstrate impairment in healing. However, with respect to bone healing, indomethacin appears to have a clear detrimental effect, with less substantial evidence for other NSAIDs. It was concluded that short-term, low-dose use of NSAIDs and COX-2 inhibitors does not appear to have a detrimental effect following soft tissue injury, but is inhibitory in cases involving bony healing. However, additional well-controlled human studies are necessary to draw more definitive conclusions regarding their role. Clinically, the prudent use of anti-inflammatory medications following sports medicine injuries and surgeries appears to be a reasonable option in clinical practice unless bone healing is required.

The indications and effectiveness of the various NSAIDs differs, although there is little difference in their mean efficacy, and although a review of individual patient data indicates that patients vary in their responses to different NSAIDs. Effectiveness may vary with different conditions.
- For acute pain and dysmenorrhoea, meta-analyses indicate that both classes of NSAIDs are highly effective analgesics compared with placebo.
- Both groups of NSAIDs play a useful but adjunctive anti-inflammatory role in rheumatoid arthritis, although disease control with antirheumatic drugs such as methotrexate and biological agents is critical.
- Both groups of NSAIDs are often used for osteoarthritis and low back pain; their effectiveness is generally small.

**Mechanism of action**

Mechanism of action is the first aspect of NSAIDs that should be considered prior to prescribing. Traditional NSAIDs act in the body by nonselectively blocking cyclooxygenase (COX). COX's primary mechanism of action is to catalyze the transformation of arachidonic acids to prostaglandins. There are two main forms, COX-1 and COX-2, each producing different prostaglandins. COX-1 is present at all times in the human body and is responsible for basal functions such as protection of the gastric mucosa and platelet aggregation. COX-2 is an inducible enzyme created and up-regulated during times of injury. Traditional NSAIDs inhibit both COX-1 and COX-2, leading to decreased inflammatory response, but the decrease in gastric mucosa protection also increases the risk of gastrointestinal irritation. COX-2–specific inhibitors were developed with the goal of suppressing the inflammation produced by up-regulation of COX-2 after injury while sparing the gastrointestinal tract. This is accomplished by not inhibiting prostaglandin secretion in the gastric wall mucosa. Unfortunately, that concept did not take into account the effects on prostacyclin produced in vascular endothelial cells. Without prostacyclin, thromboxane A2 (mediated by COX-1) is unopposed, creating a potential shift in the tissue balance away from prostacyclin's vasodilatory and antiplatelet effects and toward more deleterious vasoconstriction and platelet aggregation. This shift's end result theoretically promotes thrombosis; more than one COX-2 inhibitor has been removed from the market following an increase in cardiovascular events [07216].

**Ketoprofen**

Ketoprofen (KP), a nonsteroidal anti-inflammatory drug (NSAID), possesses analgesic, antipyretic and anti-inflammatory properties. Oral KP is widely used in musculoskeletal pain and inflammation in muscles and joints, including arthritis pain, osteoarthritis, stiffness of the joints, soft tissue rheumatism, and sports injuries. In common with all NSAIDs, oral KP has been associated with systemic adverse events and in particular gastrointestinal disorders. Topical application of the active ingredient is locally effective and at the same time minimises the risk of systemic adverse events. Pharmacokinetic studies show that serum levels of the active ingredient following topical KP 2.5 percent gel are less than 1 percent of those reported after oral dosing, thereby providing good levels of pain relief without the systemic adverse events normally associated with oral NSAIDs. In comparative studies, topical KP 2.5 percent gel twice daily showed clinical benefits in patients with a range of musculoskeletal conditions. KP 2.5 percent gel is generally well tolerated but the treated skin area should not be exposed to direct sunlight, including solarium (sunbeds), during the treatment and for 2 weeks afterwards as topical photosensitization has been reported [11369].

**Topical NSAID**
Use of topical NSAIDs to treat acute musculoskeletal conditions is widely accepted in some parts of the world, but not in others. Their main attraction is their potential to provide pain relief without associated systemic adverse events. To review the evidence from randomised, double-blind, controlled trials on the efficacy and safety of topically applied NSAIDs in acute pain it was searched MEDLINE, EMBASE, The Cochrane Library, and the own in-house database to December 2009. It was also sought unpublished studies by asking personal contacts and searching on-line clinical trial registers and manufacturers web sites. It was included randomised, double-blind, active or placebo (inert carrier)-controlled trials in which treatments were administered to adult patients with acute pain resulting from strains, sprains or sports or overuse-type injuries (twisted ankle, for instance). There had to be at least 10 participants in each treatment arm, with application of treatment at least once daily. Two review authors independently assessed trial quality and validity, and extracted data. Numbers of participants achieving each outcome were used to calculate relative risk and numbers needed to treat (NNT) or harm (NNH) compared to placebo or other active treatment. Forty-seven studies were included; most compared topical NSAIDs in the form of a gel, spray, or cream with a similar placebo, with 3455 participants in the overall analysis of efficacy. For all topical NSAIDs combined, compared with placebo, the number needed to treat to benefit (NNT) for clinical success, equivalent to 50% pain relief, was 4.5 (3.9 to 5.3) for treatment periods of 6 to 14 days. Topical diclofenac, ibuprofen, ketoprofen, and piroxicam were of similar efficacy, but indomethacin and benzydamine were not significantly better than placebo. Local skin reactions were generally mild and transient, and did not differ from placebo. There were very few systemic adverse events or withdrawals due to adverse events. There were insufficient data to reliably compare individual topical NSAIDs with each other or the same oral NSAID. Topical NSAIDs can provide good levels of pain relief, without the systemic adverse events associated with oral NSAIDs, when used to treat acute musculoskeletal conditions [06222].

Topical medications, including NSAIDs, hold a lot of promise by delivering medicines known to be effective, only without the associated risks when administered orally. Topical NSAID preparations have in some instances good evidence to support their use. A prospective, double-blind, randomized controlled trial of once-daily topical ketoprofen patch was performed in France and found a statistically significant decrease in pain for the topical ketoprofen group versus the placebo group. Treatment with topical NSAIDs can keep plasma levels low (thereby limiting systemic adverse events) while allowing penetration into soft tissues of an injured extremity [07216].

Creams, solutions, gels, sprays, and patches of non-selective NSAIDs are widely used for their local effects, low systemic absorption, and considerable safety. For acute soft-tissue injuries (sprains, minor injuries, etc), systematic reviews have shown that topical products are more effective than placebo products. For effects on osteoarthritis, the most comprehensive data have been obtained with diclofenac. Although the results of clinical trials are variable, systematic reviews indicate that the available gel formulations of diclofenac provide greater relief of pain than placebo, though the improvement is small [13559].

How safe are NSAIDs?

Gastrointestinal

Harm from both types of NSAID is a major problem in osteoarthritis because of their prolonged use in the treatment of this disease. The absolute risk of adverse effects increases substantially in patients over 70 years old and with duration of use and size of dose, and is
affected by individual risk factors. A major adverse effect of the non-selective NSAIDs is serious injury to the upper gastrointestinal tract (perforations, ulcers, bleeding). The COX-2 selective inhibitors are also associated with upper gastrointestinal toxicity, but large controlled and observational studies and meta-analyses indicate this is significantly less than with non-selective NSAIDs. Modelling indicates that adding a proton pump inhibitor to an NSAID reduces the rate of upper gastrointestinal adverse effects. Dyspepsia is common with both types of NSAID, although a meta-analysis indicates that the risk is slightly smaller (12%) with the selective COX-2 inhibitors [13559].

Cardiac

Overall, both NSAID classes, with the apparent exception of the non-selective NSAID naproxen, are associated with a significantly increased risk of myocardial infarction and coronary death. From a recent, very large meta-analysis of individual data from randomised trials, this translated to three more major vascular events (mainly major coronary events) occurring in 1000 patients taking a selective COX-2 inhibitor or diclofenac for one year than seen with placebo, one of these extra events being fatal. Thus, the higher the background risk, the higher the absolute risk will be on exposure to one of these drugs. These conclusions are supported by a cost effectiveness analysis of data from three large controlled clinical studies on NSAIDs. Naproxen seems to be the safest NSAID, with a similar rate of myocardial infarction as with no treatment. Of the non-selective NSAIDs, there is broad agreement that diclofenac seems to have the greatest risk of myocardial infarction, similar to COX-2 selective drugs [13559].

Renal and hypertension

As renal prostaglandins and prostacyclin are synthesised by both COX-1 and COX-2 both classes of NSAIDs increase the risk of further renal impairment and of worsening cardiac failure. All NSAIDs cause a dose dependent increase in blood pressure. The mean increase is around 2-3 mm Hg in systolic blood pressure, but it can be dramatic and may be greater in patients with hypertension or those taking angiotensin converting enzyme inhibitors, angiotensin II receptor blockers, or diuretics [13559].

Asthma

A systematic review showed that taking aspirin reduces forced expiratory volume in one second (FEV1) in about 20 percent of adults and 5 percent of children with asthma. There is almost total cross reactivity with the non-selective NSAIDs. However, asthma has not been produced by selective COX-2 inhibitors in double blind challenge tests on asthmatic patients sensitive to aspirin [13559].

Pregnancy

A large epidemiological study has found that both classes of NSAID may lead to abortion in the first trimester, with an odds ratio of 2.43 (95% confidence interval 2.1 to 2.8) compared with women not taking NSAIDs. Both classes of NSAID may also delay labour and lead to premature closure of the ductus arteriosus, while non-selective NSAIDs may increase blood loss at delivery. Pregnant patients should not take NSAIDs with misoprostol, which is a prostaglandin analogue used to prevent NSAID associated ulcers and may also induce miscarriage [13559].

Comparison with other analgesics
**Paracetamol**
For chronic conditions, such as osteoarthritis and back pain, paracetamol is generally recommended as first line treatment even though meta-analyses indicate that both groups of NSAID are, on average, superior in reducing pain. The reason for the preference of paracetamol is its superior tolerability compared with both classes of NSAID. Paracetamol has little gastrointestinal toxicity, minimal effect on blood pressure and renal function, no reported increase in the rate of myocardial infarction, and no effect on the antiplatelet effect of aspirin [13559].

**Opioids**
These drugs should not be used as first line treatment of milder pain because of their adverse effects such as constipation, drowsiness, and cognitive blunting. Use of opioids in elderly patients is also associated with a high incidence of falls and fractures [13559].

**In ultramarathon runners**
Despite increased 161-km ultramarathon participation in recent years, little is known about those who pursue such an activity. This study surveyed entrants in two of the largest 161-km trail ultramarathon runs in North America to explore demographic characteristics and issues that affected race performance. All entries of the 2009 Western States Endurance Run and the Vermont 100 Endurance Race were invited to complete a postrace questionnaire. There were 500 respondents among the 701 race entries (71% response). Finish time was found to have a significant negative association with training volume and was generally directly associated with body mass index. Among nonfinishers, the primary reason for dropping out was nausea and/or vomiting (23%). Finishers compared with nonfinishers were more likely to report blisters (40% vs 17%), muscle pain (37% vs 20%), and exhaustion (23% vs 14%) as adversely affecting race performance, but nausea and/or vomiting was similar between groups (37% vs 40%). Nausea and/or vomiting was no more common among those using nonsteroidal anti-inflammatory drugs (NSAIDs), those participating in the event with higher ambient temperatures, those with a lower training volume, or those with less experience at finishing 161-km races. Overall use of NSAIDs was high, and significantly greater among finishers (61%) than nonfinishers (46%). From this study, it was conclude that primary performance-limiting issues in 161-km ultramarathons include nausea and/or vomiting, blisters, and muscle pain, and there is a disturbingly high use of NSAIDs in these events [11231].

**Use in handicapped athletes**
Non-steroidal anti-inflammatory drugs (NSAIDS) are frequently used in sports medicine to reduce time of incapacity. To describe the frequency of NSAIDS use by athletes in the XVth Pan-American Games all athletes who were tested by the anti-doping control filled a form. The voluntarily declared medications were recorded and categorized according to sport modality, gender, region, and control situation according to the World Anti-doping Agency. Among the 1,261 athletes tested (231 out competition and 1030 in competition; 733 men and 528 women), 63 percent reported use of drugs, NSAIDS being the most frequently (64% of users) used medications. The use of medications was not significantly difference between genders or among different regions of the world. The number of users of only 1 type of NSAID was higher than those who used more than one type of NSAIDS or a combination with analgesics (335 cases vs 168 cases). In competition reports presented higher use of
NSAIDS than out competition. Athletes tested by the anti-doping control of the XVth Pan-American Games reported a high frequency of NSAIDS use. The frequent utilization in competition suggests that these medications might be used as ergogenic aid [09299].

Side effect

Nicolau Syndrome (also known as Embolia cutis medicamentosa and livedo-like dermatitis) is a rare but severe localized adverse drug reaction to a range of intra-muscular preparations. It manifests as acute pain, cutaneous, subcutaneous and intra-muscular inflammation and necrosis immediately following an injection, with potentially devastating sequelae. It was described the syndrome in a 21-year-old national level race walk athlete following an intramuscular diclofenac injection [09297].

Recommendations

Sports medicine physicians often treat athletes in pain with non-steroidal anti-inflammatory drugs (NSAIDs). However, there is a lack of high-quality evidence to guide NSAID use. Their adverse effects have clinical relevance, and their possible negative consequences on the long-term healing process are slowly becoming more obvious. One article provided some practical management guidelines for the use of NSAIDs, developed to help sports medicine physicians deal with frequent sports-related injuries. It was not recommend their use for muscle injuries, bone fractures (also stress fractures) or chronic tendinopathy. In all cases, if chosen, NSAID treatments should always be kept as short as possible and should take into account the specific type of injury, the level of dysfunction and pain [10213].

Non-steroidal anti-inflammatory drugs (NSAID) are commonly utilised in sports medicine. NSAID have known anti-inflammatory, analgesic, antipyretic and antithrombotic effects, although their in-vivo effects in treating musculoskeletal injuries in humans remain largely unknown. NSAID analgesic action does not appear to be significantly greater than paracetamol for musculoskeletal injury but they have a higher risk profile, with side-effects including asthma exacerbation, gastrointestinal and renal side-effects, hypertension and other cardiovascular diseases. Evidence-based working groups on pain management recommend using regular paracetamol as first-line treatment for acute and chronic musculoskeletal pain. Furthermore, intramuscular NSAID have additional risks with fluctuant drug levels, infection and muscle necrosis. NSAID works via cyclooxygenase (COX) inhibition, thus blocking prostaglandin production from arachadonic acid. Prostaglandin inhibition will decrease the cascading inflammatory response, but will also lead to increased leucotriene production through the “overflow” pathway for arachadonic acid. COX-2 inhibitors are a subclass of NSAID that specifically block the COX-2 enzyme, and subsequently have fewer gastrointestinal side-effects and renal side-effects but at a cost of an increased risk of cardiovascular side-effects. NSAID in sports medicine practice are delivered as topical, oral, intramuscular or, less commonly, intravenous preparations. Daily NSAID use in the general population is 1-4 percent and in elite athletes at Olympic games or during Fédération Internationale de Football Association World Cup football tournaments, the reported use of NSAID is as high as 25-35 percent. Given their availability, the use of NSAID to treat sporting injury in the general population is probably similar to that seen in elite sporting populations. As medical practitioners, sports physicians are obliged by the Hippocratic oath to “first do no harm”, and this discussion paper will attempt to address the utilisation of NSAID use in musculoskeletal injury pragmatically. Recent well-publicised adverse events surrounding COX-2 anti-inflammatories, in combination with an increased understanding of soft-tissue

1528
injury pathophysiology, have resulted in NSAID use in sports medicine being challenged. Early functional mobilisation is a key component to the rehabilitation and early return to sporting activity following many injuries, and pain management is integral to this. In addition to their well-documented anti-inflammatory action, NSAID are known to be moderately potent analgesics, and therefore when prescribing, one must consider whether they are being used for analgesic, anti-inflammatory or a combined benefit. Regarding muscle strain injury, concerns of increased bleeding from the anti-platelet effect of COX-1 inhibition of thromboxane A2 had traditionally led to NSAID use being a relative contraindication in the early phases, but with the advent of specific COX-2 inhibitor formulations, this became less relevant. Inflammation initiates macrophage action, with subsequent phagocytosis of necrotic tissue and stimulation of new capillary formation, vital aspects of muscle regeneration. In contrast to muscle strain injuries, the benefits of using NSAID in eccentrically induced muscle soreness is well established. The use of NSAID patches have recently been shown to be beneficial in the early management of contusion type injuries, and the risk of myositis ossificans has been shown to be reduced post-surgically by the expedient use of NSAID. NSAID are thus not contraindicated in muscle injury per se, but should be used with consideration of the specific pathology being treated. The majority of literature surrounding tendinopathy is specific to chronic tendinopathy. The histopathology of tendinopathy is typically degenerative, with an absence of inflammatory cells or biochemical markers of inflammation. The pain of tendinopathy thus not associated with bursitis, tenosynovitis or other inflammatory comorbidity could be rationally treated with paracetamol rather than NSAID. Whereas tendinopathies with an associated co-morbid inflammatory component may benefit from NSAID, it is also not uncommon for team physicians at the elite level to see the first presentation of a tendinopathy within 1-2 days of pain onset. In this situation, it may not be unreasonable to attempt to treat any suspected tendon or paratendon inflammatory-mediated symptoms with NSAID. COX-2 inhibitors have been shown to impair healing in ligament and bone, and probably should not be used to treat acute joint injuries. While several studies have shown enhanced functional recovery after ankle sprain when NSAID were employed in addition to standard rehabilitation techniques, it is suggested that while the decreased pain may allow an earlier return to army training, ultimately they have increased instability and a decreased range of motion. This may suggest that NSAID are having both an analgesic and antisynovitic benefit, rather than any effect on ligament healing. However, to uniformly exclude NSAID from the treatment armoury of ankle sprains would appear premature, based on the knowledge available, and when the predominant functional limitation may be synovitis. Inflammatory conditions such as rheumatoid arthritis clearly benefit from NSAID, and many of the co-morbidities of such conditions, in particular inflammatory bursitis, intra-articular synovitis and tenosynovitis, are common sporting presentations to the sports physician. A trial of oral NSAID before more aggressive interventions is considered acceptable practice and should not be excluded. It was recommended [09300]

- considering regular paracetamol as first-line treatment for acute and chronic musculoskeletal pain, due to comparable analgesic efficacy with NSAID but a lower side-effect profile
- NSAID are useful in treating inflammatory pathologies such as tenosynovitis and soft-tissue impingement, but not conditions such as chronic tendinopathies and fractures
- NSAID in treating muscle injury remains controversial

Medical ethics

NSAIDs are a commonly used class of drugs available both OTC and by prescription. NSAIDs are taken for a myriad of reasons, including treatment of pain, soft tissue swelling, fever, and sprains/strains, especially overuse strains. Given the easy OTC access, many
people assume that there is little risk involved in taking these medications. Although NSAIDs have shown promise in treating painful inflammatory conditions such as rheumatoid arthritis, beneficial effects of NSAIDs in common musculoskeletal injuries are not clearly established in the medical literature. The decision to use these medications should consider several issues regarding safe and appropriate use [07216].

Before prescribing NSAIDs, it also is important to consider the natural healing process when no extrinsic factors are in play and how these medicines may interfere with that process. Injuries that trigger the inflammatory cascade allow for signaling to increase blood flow to the area and recruitment of inflammatory cells that are an important part of the healing response. Although this process occurs in a predictable fashion, certain stages require a brisk inflammatory response to be successful and to prepare the injured tissue for the final reconstruction of elements to produce complete healing. NSAID inhibition of the early inflammatory response theoretically could impact or alter natural healing [07216].
AICAR (5-AMINO-4-IMIDAZOLECARBOXYAMIDE RIBONUCLEOSIDE)

AICAR (5-amino-4-imidazolecarboxyamide ribonucleoside) arguably provides performance-enhancing properties even in the absence of physical exercise and, therefore, the substance is banned in elite sports since 2009. Due to the natural presence of AICAR in human blood and urine, uncovering the misuse by direct qualitative analysis is not possible. Entering the circulation, the riboside is immediately incorporated into red blood cells (RBCs) and transformed into the corresponding ribotide (5'-monophosphate) form. Within the present study, an analytical method was developed to determine AICAR-ribotide concentrations in RBC concentrates by means of liquid chromatography-tandem mass spectrometry. The method was validated enabling quantitative result interpretation considering the parameters specificity, precision (intra- and interday), linearity, recovery, accuracy (LOD/LOQ), stability and ion suppression. By analysing 99 RBC samples of young athletes, normal physiological levels of AICAR-ribotide were determined (10-500 ng/mL), and individual levels were found to be stable for several days. Employing in vitro incubation experiments with AICAR riboside in fresh whole blood samples, the ribotide concentrations were observed to increase significantly within 30 min from baseline to 1-10 microg/mL. These levels are considered conserved for the lifetime of the erythrocyte and, thus, the results of the in vitro model strongly support the hypothesis that measuring abnormally high AICAR-ribotide concentrations in RBC of elite athletes has the potential to uncover the misuse of this substance for a long period of time [13575].
ANTICONVULSANTS

Although the World Anti-Doping Code (WADC) permits anticonvulsants in general, harmonization of antidoping permits an international sport federation (IF) to prohibit specific medications within that IF. The anticonvulsants levetiracetam, tiagabine, and lamotrigine may pose ethical dilemmas and could be considered violations of antidoping codes. Lamotrigine, with antiglutamatergic and sodium channel properties, is FDA-approved for maintenance treatment of bipolar disorder, in addition to its use in the treatment of major depression, anxiety disorders, and schizophrenia. Tiagabine, a selective GABA reuptake inhibitor, has mood-stabilizing and anxiolytic properties. Levetiracetam, whose unique mechanism involves the modulators beta-carboline and zinc, has anxiolytic and mood-stabilizing properties. Anxiolytics, antidepressants, and antipsychotics are banned in archery; under strict liability, all three anticonvulsants violate WADC/IF for that specific sport and could result in disqualification unless therapeutic use exemptions (TUEs) are obtained. Ethical issues regarding the use of anticonvulsants by athletes and the need to obtain TUEs are addressed. The WADC with harmonized IF policies are meant to prevent doping by athletes, but not appropriate medical treatment. When anticonvulsants have other psychotropic properties, ethical issues arise. Athletes should list all medications taken with diagnoses, obtain TUEs as indicated, and contact the appropriate IF or Olympic organization to determine the status of the proposed medication (banned, restricted, nonbanned). Further, clinicians should be knowledgeable regarding these issues when treating athletes [07024].
The World Antidoping Agency (WADA) has introduced some changes in the 2012 prohibited list. Among the leading innovations to the rules are that both 5-aminoimidazole-4-carboxamide-1-beta-D-ribofuranoside (peroxisome proliferator-activated receptor-delta [PPAR-delta]-5' adenosine monophosphate-activated protein kinase [AMPK] agonist) and GW1516 (PPAR-delta-agonist) are no longer categorized as gene doping substances in the new 2012 prohibited list but as metabolic modulators in the class "Hormone and metabolic modulators" [12333].

Since January 2009, the list of prohibited substances and methods of doping as established by the World Anti-Doping Agency includes new therapeutics such as the peroxisome-proliferator-activated receptor (PPAR)-delta agonist GW1516, which is categorized as a gene doping substance. GW1516 has completed phase II and IV clinical trials regarding dyslipidemia and the regulation of the lipoprotein transport in metabolic syndrome conditions; however, its potential to also improve athletic performance due to the upregulation of genes associated with oxidative metabolism and a modified substrate preference that shifted from carbohydrate to lipid consumption has led to a ban of this compound in elite sport. In a recent report, two presumably mono-oxygenated and bisoxygenated urinary metabolites of GW1516 were presented, which could serve as target analytes for doping control purposes after full characterization. Hence, in one study now, phase I metabolism was simulated by in vitro assays employing human liver microsomal fractions yielding the same oxygenation products, followed by chemical synthesis of the assumed structures of the two abundant metabolic reaction products. These allowed the identification and characterization of mono-oxygenated and bisoxygenated metabolites (sulfoxide and sulfone, respectively) as supported by high-resolution/high-accuracy mass spectrometry with higher-energy collision-induced dissociation, tandem mass spectrometry, and nuclear magnetic resonance spectroscopy. Since urine samples have been the preferred matrix for doping control purposes, a method to detect the new target GW1516 in sports drug testing samples was developed in accordance to conventional screening procedures based on enzymatic hydrolysis and liquid-liquid extraction followed by liquid chromatography, electrospray ionization, and tandem mass spectrometry. Validation was performed for specificity, limit of detection (0.1 ng/ml), recovery (72 %), intraday and interday precisions (8-15 %), and ion suppression/enhancement effects (<10 %) [10207].
Since urine samples have been the preferred matrix for doping control purposes, a method to detect the new target GW1516 in sports drug testing samples was developed in accordance to conventional screening procedures based on enzymatic hydrolysis and liquid-liquid extraction followed by liquid chromatography, electrospray ionization, and tandem mass spectrometry. Validation was performed for specificity, limit of detection (0.1 ng/ml), recovery (72 %), intraday and interday precisions (7.7-15.1 %), and ion suppression/enhancement effects (<10 %) [10208].

Peroxisome proliferator-activated receptor delta (PPARdelta) regulates expression of genes involved in lipid and carbohydrate metabolism. To examine the association of a functional +294T/C polymorphism of PPARD gene with human physical performance, it was studied the distribution of PPARD alleles and genotypes in a cohort of athletes (n=1256; stratified by specialty and skill level) and controls (n=610). It was found that the frequency of PPARD C allele (with higher transcriptional activity compared to T allele) in a group of endurance-oriented athletes (n=898) is significantly higher than in controls (18 % vs 12 %). Moreover, in the group of endurance-oriented athletes with cyclic activity it was revealed an increasing frequency of PPARD C allele with the rising of athletes' skill level. Thus, PPARD C allele is associated with predisposition to endurance performance [07217].

The elucidation of metabolic pathways and the detection of emerging therapeutics potentially enhancing athletic performance are of paramount importance to doping control authorities to protect the integrity of elite sports. A new drug candidate belonging to the family of the peroxisome proliferator-activated receptor-delta agonists termed GW1516 (also referred to as GW501516) has been prohibited by the World Anti-Doping Agency in 2009 due to its potential to artificially increase endurance. Consequently, sports drug testing laboratories need to establish detection methods enabling the identification of the intact substance and/or its metabolite(s) that unambiguously prove the presence or absence of the target substances in doping control specimens. Simulating human metabolic reactions using liver microsomal preparations, minute amounts of possible urinary metabolites were obtained that were characterized by mass spectrometry-based methods. Subsequently, the most abundant metabolic products were chemically synthesized and as well characterized by mass spectrometry and nuclear magnetic resonance spectroscopy. Finally, GW1516 and two oxidized metabolites were implemented in a routine doping control analytical assay based on liquid chromatography-(tandem) mass spectrometry (LC-MS/MS), which was tested for its fitness-for-purpose using spiked urine samples [13567].

Sensitive and robust bioassays able to detect nuclear receptor activation are very useful for veterinary and doping control, pharmaceutical industry and environmental scientists. Here, we used bioassays based on human leukemic monocyte lymphoma U937 and human liver hepatocellular carcinoma HepG2 cell lines to detect the ligand-induced activation of the peroxisome proliferator-activated receptor delta (PPAR-delta). Exposure of U937 cells to the PPAR-delta agonist GW501516 resulted in a marked increase in mRNA expression of the PPAR-delta target gene Angptl4 which was quantified by qRT-PCR analysis. Exposure of HepG2 cells transiently transfected with a PPAR-delta expression plasmid and a PPAR-response element-driven luciferase reporter plasmid to PPAR-delta agonists GW501516, GW610742 and L-165041 resulted in clear dose-response curves. Although the qRT-PCR resulted in higher fold inductions, the luciferase assay with transfected HepG2 cells is cheaper and quicker and about ten times more sensitive to GW501516 compared to analysis of Angptl4 mRNA expression in U937 cells by qRT-PCR. The HepG2-based luciferase assay was therefore used to screen GW501516-spiked supplements and feed and water samples. After liquid extraction and clean-up by solid phase extraction using a weak anion exchange column, extracts were screened in the HepG2 bioassay followed by confirmation with a newly developed UPLC-MS/MS method, using two transitions for each compound, i.e., for
Mitochondrial dysfunction has been linked to many diseases including metabolic diseases such as diabetes. Peroxisome proliferator-activated receptor gamma co-activator 1 (PGC-1) is a superfamily of transcriptional co-activators which are important precursors to mitochondrial biosynthesis found in most cells including skeletal muscle. The PGC-1 superfamily consists of three variants all of which are directly involved in controlling metabolic gene expression including those regulating fatty acid oxidation and mitochondrial proteins. In contrast to previous reviews on PGC-1, this mini-review summarizes the current knowledge of many known dietary stimulators of PGC-1 and the subsequent mitochondrial biosynthesis with associated metabolic benefit in skeletal muscle [13569].

Performing exercise in a glycogen depleted state increases skeletal muscle lipid utilization and the transcription of genes regulating mitochondrial beta-oxidation. Potential candidates for glycogen-mediated metabolic adaptation are the peroxisome proliferator activated receptor (PPAR) coactivator-1alpaha (PGC-1alpha) and the transcription factor/nuclear receptor PPAR-delta. It was therefore the aim of the present study to examine whether acute exercise with or without glycogen manipulation affects PGC-1alpha and PPAR-delta function in rodent skeletal muscle. Twenty female Wistar rats were randomly assigned to 5 experimental groups (n 4): control [CON]; normal glycogen control [NG-C]; normal glycogen exercise [NG-E]; low glycogen control [LG-C]; and low glycogen exercise [LG-E]. Gastrocnemius (GTN) muscles were collected immediately following exercise and analyzed for glycogen content, PPAR-delta activity via chromatin immunoprecipitation (ChIP) assays, AMPK alpha1/alpha2 kinase activity, and the localization of AMPK and PGC-1alpha. Exercise reduced muscle glycogen by 47 and 75 percent relative to CON in the NG-E and LG-E groups, respectively. Exercise that started with low glycogen (LG-E) finished with higher AMPK-alpha2 activity (147 %), nuclear AMPK-alpha2 and PGC-1alpha, but no difference in AMPK-alpha1 activity compared to CON. In addition, PPAR-delta binding to the CPT1 promoter was significantly increased only in the LG-E group. Finally, cell reporter studies in contracting C2C12 myotubes indicated that PPAR-delta activity following contraction is sensitive to glucose availability, providing mechanistic insight into the association between PPAR-delta and glycogen content/substrate availability. The present study is the first to examine PPAR-delta activity in skeletal muscle in response to an acute bout of endurance exercise. Our data would suggest that a factor associated with muscle contraction and/or glycogen depletion activates PPAR-delta and initiates AMPK translocation in skeletal muscle in response to exercise [13570].

Genetics

Peroxisome proliferator-activated receptor delta (PPAR-delta; encoded by the PPARD gene) plays a role in energy metabolism and mitochondrial function. It was investigated the distribution of PPARD rs2267668, rs2016520 and rs1053049 polymorphisms, individually and in haplotype, in a cohort of 660 elite athletes which was subdivided into four different groups based on the different metabolic demands of their respective sports and 704 healthy controls. PPARD rs2016529 and rs1053049 were individually significantly associated with overall elite athletic performance and also with athletes grouped as strength endurance. Furthermore, PPARD A/C/C haplotype (rs2267668/rs2016520/rs1053049) was significantly underrepresented in all athletes and each subgroup of athletes when compared with controls, suggesting that harboring this specific haplotype is unfavorable for becoming an
elite athlete. These results help to identify which genetic profiles may contribute to elite athletic performance, specifically the role of variants within the PPARD gene, and may be useful in talent identification or optimizing the response to training [13571].

Effect of lactate

The effects of exercise are not limited to muscle, and its ability to mitigate some chronic diseases is under study. A more complete understanding of how exercise impacts non-muscle tissues might facilitate design of clinical trials and exercise mimetics. Here, we focused on lactate's ability to mediate changes in liver and brain bioenergetic-associated parameters. In one group of experiments, C57BL/6 mice underwent 7 weeks of treadmill exercise sessions at intensities intended to exceed the lactate threshold. Over time, the mice dramatically increased their lactate threshold. To ensure that plasma lactate accumulated during the final week, the mice were run to exhaustion. In the liver, mRNA levels of gluconeogenesis-promoting genes increased. While peroxisome proliferator-activated receptor-gamma co-activator 1 alpha (PGC-1alpha) expression increased, there was a decrease in PGC-1beta expression, and overall gene expression changes favored respiratory chain down-regulation. In the brain, PGC-1alpha and PGC-1beta were unchanged, but PGC-1-related co-activator expression and mitochondrial DNA copy number increased. Brain tumor necrosis factor alpha expression fell, whereas vascular endothelial growth factor A expression rose. In another group of experiments, exogenously administered lactate was found to reproduce some but not all of these observed liver and brain changes. The data suggest that lactate, an exercise byproduct, could mediate some of the effects exercise has on the liver and the brain, and that lactate itself can act as a partial exercise mimetic [13572].

Pioglitazone

Peroxisome-proliferator-activated receptor (PPAR) delta and adenosine monophosphate (AMP)-activated protein kinases (AMPKs) regulate the metabolic and contractile characteristics of myofibres. PPAR proteins are nuclear receptors that function as transcription factors and regulate the expression of multiple genes. AMPK has been described as a master metabolic regulator which also controls gene expression through the direct phosphorylation of some nuclear proteins. Since it was discovered that both PPARdelta agonists (GW1516) and AMPK activators (5-aminoimidazole-4-carboxamide-1-β-D-ribofuranoside, known as AICAR) are very effective performance-enhancing substances in sedentary mice, the World Anti-doping Agency (WADA) included AICAR and GW1516 in the prohibited list of substances as metabolic modulators in the class “Hormone and metabolic modulators”. Thiazolidinediones are PPAR-gamma agonists that can induce similar biological effects to those of PPAR-delta and PPAR-delta-AMPK agonists. Thus in this study, the effects of pioglitazone on mitochondrial biogenesis and performance were evaluated. Blood glucose levels and the protein expression of the intermediates involved in the mitochondrial biogenesis pathway and the citrate synthase activity were determined in both gastrocnemius and soleus muscles. Maximal aerobic velocity (MAV), endurance capacity, and grip strength before and after the training period were also determined. The MAV endurance capacity and grip strength of trained animals significantly increased. It was found that the peroxisome proliferator-activated receptor-gamma coactivator-1alpha (PGC-1alpha) and the nuclear respiratory factor-1 (NRF-1) protein content and citrate synthase activity significantly increased in the soleus muscle of trained animals. No effect of treatment was found.
Therefore in the study, pioglitazone administration did not affect mitochondrial biogenesis signaling pathway [13573].

**Interaction with beta-adrenergic blocker**

Interaction of peroxisome proliferator-activated receptor gamma coactivator-1alpha (PGC-1alpha) with other cellular signalling pathways plays an important role in training-induced mitochondrial adaptations. The purpose of one study was to examine whether pyrrolidine dithiocarbamate (PDTC), a nuclear factor-kappaB inhibitor and antioxidant, and the beta-adrenergic blocker propranolol would affect the PGC-1alpha-induced mitochondrial transcription factors, enzymes and proteins involved in energy metabolism and antioxidant defense in response to endurance training. Female Sprague-Dawley rats (aged 8 weeks) were randomly divided into two groups (n=24), one subjected to 8 weeks of treadmill training and one remaining sedentary. The data indicates that nuclear factor-kappaB-inhibitory and antioxidant properties of PDTC can attenuate PGC-1alpha-mediated mitochondrial adaptation to endurance training, whereas the beta-adrenergic pathway has little adverse effect [13574].
PHOSPHODIESTERASE-4 INHIBITORS

The recent discovery of resveratrol's capability to inhibit cAMP-specific phosphodiesterases (PDEs) and, as a consequence, to enhance particularly the activity of Sirt1 in animal models has reinforced the interest of preventive doping research organizations, especially in PDE4 inhibitors. Among these, the archetypical PDE4-inhibitor rolipram significantly increased the number of mitochondria in laboratory rodents, which further demonstrated a performance increase in a treadmill-test (time-to-exhaustion) of approximately 40%. Besides rolipram, a variety of new PDE4-inhibiting substances including cilomilast, roflumilast, and numerous additional new drug entities were described, with roflumilast being the first-in-class having received clinical approval for the treatment of chronic obstructive pulmonary disease (COPD). Due to the availability of these substances, and the fact that a misuse of such compounds in sport cannot be excluded, it deems relevant to probe for the prevalence of these compounds in sports drug testing programs. Known urinary phase-I metabolites of rolipram, roflumilast, and cilomilast were generated by in vitro incubations employing human liver microsomal preparations. The metabolites obtained were studied by liquid chromatography with high-resolution/high-accuracy tandem mass spectrometry (LC/MS/MS) and the reference product ion mass spectra of established and most relevant metabolites were utilized to provide the information necessary for comprehensive doping controls. The analytical procedure was based on conventional routine doping control assays employing enzymatic hydrolysis followed by liquid-liquid extraction and subsequent LC/MS/MS measurement. Structures of diagnostic product ions and dissociation pathways of target analytes were elucidated, providing the information required for implementation into an existing test method for routine sports drug testing. The established method allowed for detection limits for the intact drugs of 1-5 ng/mL, and further assay characteristics (intraday precision 1.5-13.7 percent, interday precision 7.3-18.6 percent, recovery 20-100 percent, ion suppression/enhancement, and specificity) were determined. In addition, proof-of-concept analyses concerning roflumilast were conducted with a urine sample obtained from a COPD patient under roflumilast treatment [13517].

Another class of substances gained attention as to its potential to increase athletic performance, namely phosphodiesterase-4 (PDE4) inhibitors. A recent report on the ability of PDE4 inhibiting molecules to increase mitochondrial function and physical stamina in mice raised the question if PDE4 inhibitors are covered by the Prohibited List and if these substances are considered as banned. While one representative (roflumilast) is approved as therapeutic agent in several countries, the archetypical analog rolipram and the next-generation PDE4-inhibitor cilomilast have not (yet) received full clinical approval. In order to provide the required tools for preventive and proactive doping controls, a detection assay for these compounds and main metabolites (as generated by in vitro approaches) was developed in 2013. Also here, established sports drug test methods employing enzymatic deconjugation of substances followed by LLE and LC-MS/MS were expanded to comprise the additional target compounds. In addition to the active drugs of rolipram, roflumilast, and cilomilast, their main metabolites (dealkylated, hydroxylated, or oxo-derivatives) were included in the method and detected at 1-5 ng/mL of urine [13009].
NUTRITIONAL SUPPLEMENTS: GENERAL ASPECTS

The Oxford English Dictionary definition of supplement is: “Something added to supply a deficiency”. Yet many supplements, or their individual ingredients, are nutrients or food chemicals for which the body does not have an estimated or theoretical requirement. Thus there are clearly other factors that underpin their use by athletes. Athletes choose to consume a supplement for a number of reasons, including:

- to prevent or treat a perceived nutrient deficiency, especially when requirements for a nutrient are increased by their exercise programme
- to provide a more convenient form of nutrients in situations where everyday foods aren’t practical – particularly to address nutritional needs/goals around an exercise session
- to provide a direct ergogenic (performance-enhancing) effect
- because they believe every top athlete is consuming it and they can’t afford to miss out

Nutrition significantly influences sports performance; however, the efficacy of any nutritional supplement or strategy should be carefully considered in relation to the event and the sex, training and nutritional status of the participant. The causes of fatigue, mechanism of action, safety and legality of the supplement, together with the scientific evidence from studies with an appropriate experimental design, should all be taken into account before incorporating into the training and/or competition diet. The efficacy of ingesting nutritional supplements immediately before and/or during endurance exercise (duration 45-180 min) was reviewed. The ingestion of CES (carbohydrate-electrolyte solutions) have been shown to improve both exercise capacity and performance, either due to the maintenance of euglycaemia throughout exercise or the sparing of muscle glycogen early on in exercise. The addition of caffeine to CES may improve endurance performance as a consequence of a reduced perception of effort. Research suggests that the addition of protein to CES may only be effective when a suboptimal amount of CHO (carbohydrate) is ingested during exercise (<60 g of CHO per hour); however, recovery of performance may be enhanced due to a reduction in subsequent muscle soreness and the promotion of muscle protein synthesis after exercise. The findings from studies investigating the effects of ingesting MCTs (medium-chain triacylglycerols) and BCAAs (branched-chain amino acids), either on their own or in combination with CES, on endurance performance have been equivocal and therefore would not be recommended. Any nutritional strategy should be practised in training before being used during a competition.

Physical training and proper nutrition are paramount for success in sport. A key tissue is skeletal muscle, as the metabolic pathways that produce energy or ATP allow the muscles to complete the many activities critical to success in sport. The energy-producing pathways must rapidly respond to the need for ATP during sport and produce energy at a faster rate or for a longer duration through training and proper nutrition which should translate into improved performance in sport activities. There is also continual interest in the possibility that nutritional supplements could further improve muscle metabolism and the provision of energy during sport. Most legal sports supplements do not improve performance following oral ingestion. However, three legal supplements that have received significant attention over the years include creatine, carnitine and sodium bicarbonate. The ingestion of large amounts of creatine for 4-6 days increases skeletal muscle creatine and phosphocreatine contents. The majority of the experimental evidence suggests that creatine supplementation can improve short-term exercise performance, especially in sports that require repeated short-term

1539
sprints. It may also augment the accretion of skeletal muscle when taken in combination with a resistance-exercise training programme. Supplementary carnitine has been touted to increase the uptake and oxidation of fat in the mitochondria. However, muscle carnitine levels are not augmented following oral carnitine supplementation and the majority of well-controlled studies have reported no effect of carnitine on enhancing fat oxidation, V0\textsubscript{2max} or prolonged endurance exercise performance. The ingestion of sodium bicarbonate before intense exercise decreases the blood hydrogen to potentially assist the efflux of hydrogen from the muscle and temper the metabolic acidosis associated with intense exercise. Many studies have reported performance increases in laboratory-based cycling tests and simulated running races in the field following sodium bicarbonate ingestion where the need for ATP from substrate phosphorylation is high. However, other studies have reported no benefit and the incidence of negative side effects is high [08368].

There are indications that performance enhancing supplement use positively correlates with the probability of prohibited performance enhancing substance use [369]. Supplement taking has also been used as a proxy for attitude toward prohibited substances [08370]. It has also been found that supplement users have the need or desire to assist their performance but wish to do so by legal means, or alternatively, supplement use is the first step [08371].

In the world of athletes’ nutrition, there is a suspicion that in practice, large doses of supplements in athletes are not taken for nutritional purposes. Very often, the effects of supplements are hormone-related, or supplements influence hormone secretion. Examples of possible links between “supplements or ergogenic compounds” and the endocrine and metabolic system may be given [08372].

Although some supplements do enhance athletic performance, many have no proven benefits and have serious adverse effects. Caffeine, creatine, and sodium bicarbonate have been shown to enhance performance in certain contexts and have few adverse effects. No performance benefit has been shown with amino acids, beta-hydroxy-beta-methylbutyrate, chromium, human growth hormone, and iron. Carbohydrate-electrolyte beverages have no serious adverse effects and can aid performance when used for fluid replacement [08374].

Athletes often use supplements believing that they can help them to achieve sport success. The nutrition way of Polish athletes seems to be inappropriate. Diet contained too much fat and delivered too less nutritive constituents to cover daily dietary intake. Analysis also demonstrated differences between estimated and determined content of nutritive constituents in the food studied [08375].

Practitioners who work with elite athletes know that the pressure and considerable rewards involved with success provide a high level of motivation to look for any safe and legal strategy that might enhance performance, even by small margins. Dietary supplements operate in this space, whether they promise a large performance boost or just create the fear that an athlete cannot afford to miss out on what everyone else is using. It is often tempting to overlook the lack of evidence to support the claims made about a supplement on the basis that the stakes are higher for elite athletes; therefore the cost:benefit ratio favours experimentation in the absence of clear proof. Over the past decade, however, we have become aware that the cost of getting it wrong has also escalated for elite athletes. A new hazard related to supplement use has emerged: inadvertent ingestion of substances that are banned under the antidoping codes in place in elite sport, but present in supplement products. In some cases, the level of the presence, or contamination, of banned substances in supplements presents a health hazard for all consumers. In some cases, the concentration may be too small to achieve any health or performance effect but large enough to record an infringement for athletes who submit to doping tests. Newspapers, the internet and Courts of
Arbitration in Sport now bear stories of dedicated athletes whose careers have been or are being jeopardised because of the ingestion of a banned substance via a dietary supplement. It is clear that there is a real risk that athletes who use dietary supplements may unknowingly ingest a banned substance that will cause them to record a positive doping outcome. There are cases in which a doping infringement can be traced back to supplement use and for which the athlete has undertaken some strategies to reduce this risk. For example, the athlete has received written advice from a supplement manufacturer that their produce does not contain banned substances, but following a positive doping test, a sealed container of the dietary supplement has been examined and found to contain the banned ingredient. Unfortunately, strict liability applies to these situations and even if athletes have been successful in having the terms of their ban from sport reduced, a doping infringement will still be recorded against their name. The loss of a career, livelihood and reputation are stakes that an athlete must take into account when using dietary supplements [11010].

Many athletes use dietary supplements as part of their regular training or competition routine, including about 85 percent of elite track and field athletes. Supplements commonly used include vitamins, minerals, protein, creatine, and various "ergogenic" compounds. These supplements are often used without a full understanding or evaluation of the potential benefits and risks associated with their use, and without consultation with a sports nutrition professional. A few supplements may be helpful to athletes in specific circumstances, especially where food intake or food choice is restricted. Vitamin and mineral supplements should be used only when a food-based solution is not available. Sports drinks, energy bars, and protein-carbohydrate shakes may all be useful and convenient at specific times. There are well-documented roles for creatine, caffeine, and alkalinizing agents in enhancing performance in high-intensity exercise, although much of the evidence does not relate to specific athletic events. There are potential costs associated with all dietary supplements, including the risk of a positive doping result as a consequence of the presence of prohibited substances that are not declared on the label [07218].

Performance enhancing drugs, ergogenic aids, and supplements come in many forms. The financial, personal, social, and health-related impact of these substances has wide and varied consequences. This article reviews common substances and practices used by athletes. It discusses the history, use, effects, and adverse effects of androgenic anabolic steroids, peptide hormones, growth factors, masking agents, diuretics, volume expanders, β-blockers, amphetamines, caffeine, other stimulants, and creatine. The evidence base behind the use, safety, and efficacy of these items as well as testing for these substances is discussed [13577].

An athlete taking a spiked supplement with intent to dope may claim that he/she did not realise the product contained a prohibited substance. It is difficult to know the intent: nevertheless, the athlete will benefit from the ergogenic effect of the prohibited substance and have an unfair advantage over their competitor. There are many cautionary tales of athletes taking energy boosting supplements before or during the games and subsequently being sanctioned. Many dietary supplements that promise to enhance performance either contain a prohibited substance or are an example of false advertising. The reality is that a significant percentage (5-20 %) of supplements contain prohibited substances, either by inadvertent contamination or deliberate adulteration, during the production process. This phenomenon has been demonstrated repeatedly and sporting federations as well as anti-doping organisations continue to impress this warning upon athletes. For example, several athletes have been recently sanctioned over the stimulant methylhexaneamine (MHA), explicitly prohibited since 2009. This was considered to be a dietary supplement from geranium oil, despite the fact that several studies, including a very recent one demonstrated that its presence in supplements was not from geranium oil but due to the addition of
synthetic MHA. Whether natural or synthetic, athletes need to avoid these types of products. Many athletes continue to take supplements to try and improve recovery from training or to gain a performance edge in competition or are advised that supplements are necessary for health maintenance. Dietary supplement use by high-level athletes is estimated at 65-95 percent. Supplement commercialisation is a multibillion dollar industry where many claims are made with little scientific evidence; regulation for purity or side effects is still lacking in many countries. Members of the athletes’ entourage often push substances without sufficiently understanding physiology or nutrition. There are a very limited number of dietary supplements which are permitted and considered ergogenic. Athletes need to focus on proper training, optimal recovery practices and wholesome nutrition regimens before they even consider supplements. Some education programmes appear to be resulting in decreased supplement use among Olympic athletes [13015].

**Governance around sports supplementation**

Supplementation has become an integral part of most high-performance sporting programmes. This is true around the world. Any supplementation programme in high-performance sport should be based on three pillars:

- Athlete safety
- Evidence-based science
- Compliance with the World Anti-Doping Agency (WADA) Code.

If these three pillars underpin a sporting organisation’s supplementation policy, the sporting organisation will minimize the risk of being implicated in a doping scandal. High-performance sporting organisations, even relatively small organisations, should have a “supplementation panel” comprising at least three of a sports nutritionist, the head of strength and conditioning, the athletic performance manager and the team/organisation doctor. This panel needs to decide the range of supplements that are going to be used by the organisation/team, understanding that the above “three pillars” must be satisfied when including any particular supplement in the programme. Supplementation protocol should be such that there can be no alteration to the supplements used without unanimous agreement of the panel. That is, no single member of the panel should be able to introduce a new supplement or strategy without the agreement of their peers [13027].

If an athlete truly believes he or she should take a dietary supplement, according to a WADA statement everything should be done to minimise the risk [13015]:

- Do not rely on advice from friends, fellow athletes or coaches but undergo a proper evaluation by a qualified physician and/or sports nutrition professional familiar with sport and anti-doping rules. It is quite likely that dietary supplements are not necessary and nutrient deficiencies may be corrected from food sources
- Avoid any product making claims of performance enhancement or any exaggerated claims or uses the words: “stimulant, energy or muscle booster, enhancer, legal or alternate steroid, extreme, blast, weight loss”. Even if no prohibited substance is listed on the label, the product may be spiked with one
- Herbal stimulants and prohormones are especially high risk. Use of the terms herbal or natural does not in any way mean that the product does not contain a prohibited substance
- Some companies offer guarantees of purity or are certified by other companies that do quality control. Verify the third party testing system reputation and remember there are no absolute guarantees
- Avoid any company that states their products are WADA approved. WADA or its accredited laboratories never test supplements or any products when not part of a doping control process. WADA cannot recommend any company or quality control system. In order to guarantee purity, each product batch would have to be tested for all prohibited substances
- Avoid products containing multiple ingredients as there is a higher risk of contamination. Vitamins and minerals (often classified as supplements) should be from reputable pharmaceutical companies and should not be mixed with other products
- Seek guidance from your anti-doping organisation about recent information on contaminated or dangerous products in your part of the world

Although athletes must exhibit utmost caution when using supplements due to risk of contamination, governmental authorities also have a duty to endeavour to ensure proper regulation and quality control within the supplement industry. Some initiatives are trying to improve this situation. According to Article 10, UNESCO International Convention against Doping in Sport, governments must encourage producers and distributors of dietary or nutritional supplements to establish marketing best practices, including accurate labelling, quality assurance and avoidance of false marketing. In a survey (UNESCO Conference of Parties 2011), only 43 percent of governments responded that they implemented extensive or substantial measures to address these issues. Furthermore, a more systematic approach is needed for analysing risks and benefits of dietary supplements. The real risks to health of ingesting potentially dangerous substances contained in poorly regulated supplements are occasionally lost in the discussion of inadvertent doping. Anti-doping regulations were developed over many years to promote fairness in sport and to protect the health of the athlete. Athletes are keen to improve their performance and nutrition may play an integral part in their overall plan. However, when athletes embark upon using performance-enhancing supplements, the risks often outweigh the benefits. Improved regulation of the dietary supplement industry would go a long way towards reducing the risks, but the onus remains on the athlete to make the right choices [13015].

**Role of sports medicine specialists**

The involvement of the sports medicine specialist doctor in the supplement panel is critical. The organisations that are under most scrutiny in Australia appear to have allowed supplementation to take place without the input or oversight of the team doctor. This highlights what was believed to be a widespread weakness in high-performance sport. Team doctors providing sports medicine services to high-performance teams often limit their involvement to matters of illness and injury, allowing supplementation policies and protocols to be controlled by others in the organisation. Such flawed systems must be eliminated from high-performance sport. Medical practitioners who are not prepared to maintain the currency of their own knowledge around supplementation and doping and further contribute to ethical supplementation practices should not be involved with high-performance sporting teams [13027].

**Legislation**

There is no clear distinction between the regulation of food, supplements and medicines in
South Africa. Consequently, grey areas exist in implementing the legislation, particularly in the supplement industry. The increase in supplement sales in South Africa can be attributed to aggressive marketing by manufacturers whose claims are not always supported by published peer-reviewed evidence. Such claims often go unchecked, resulting in consumers being mislead about the role of supplements. As a result of poor regulation, contaminants or adulterants in supplements may also cause insidious effects unrelated to the listed ingredients. To assess the regulations, legislation, and claims associated with nutritional supplement products in South Africa peer-reviewed literature and the relevant South African statutes were consulted. The National Health Act incorporates the Medicine Control Council, which is charged with ensuring the safety, quality and effectiveness of medicines, and related matters, including complementary/alternative medicines. The South African Institute for Drug-Free Sport and Amendment Act provides for testing athletes for using banned substances, but currently does not concern itself with monitoring nutritional supplements for contaminants or adulterants that may cause a positive drug test, which has implications for sports participants and also the health of the general population. The implementation of the Consumer Protection Act 68 of 2008 (CPA) could protect consumer rights if it is administered and resourced appropriately [11370].

Theoretical aspects

Diet can significantly influence athletic performance, but recent research developments have substantially changed our understanding of sport and exercise nutrition. Athletes adopt various nutritional strategies in training and competition in the pursuit of success. The aim of training is to promote changes in the structure and function of muscle and other tissues by selective modulation of protein synthesis and breakdown in response to the training stimulus. This process is affected by the availability of essential amino acids in the post-exercise period. Athletes have been encouraged to eat diets high in carbohydrate, but low-carbohydrate diets up-regulate the capacity of muscle for fat oxidation, potentially sparing the limited carbohydrate stores. Such diets, however, do not enhance endurance performance. It is not yet known whether the increased capacity for fat oxidation that results from training in a carbohydrate-deficient state can promote loss of body fat. Preventing excessive fluid deficits will maintain exercise capacity, and ensuring adequate hydration status can also reduce subjective perception of effort. This latter effect may be important in encouraging exercise participation and promoting adherence to exercise programmes. Dietary supplement use is popular in sport, and a few supplements may improve performance in specific exercise tasks. Athletes must be cautious, however, not to contravene the doping regulations. There is an increasing recognition of the role of the brain in determining exercise performance: various nutritional strategies have been proposed, but with limited success. Nutrition strategies developed for use by athletes can also be used to achieve functional benefits in other populations [12364].

Scientific nutrition strategy

It was investigated whether an athlete’s self-chosen nutrition strategy (A), compared with a scientifically determined one (S), led to an improved endurance performance in a laboratory time trial after an endurance exercise. S consisted of about 1000 mL/h fluid, in portions of 250 mL every 15 min, 0.5 g sodium/L, 60 g glucose/h, 30 g fructose/h, and 5 mg caffeine/kg body mass. Eighteen endurance-trained cyclists (16 male; 2 female) were tested using a randomized crossover-design at intervals of 2 weeks, following either A or S. After a warm-up, a maximal oxygen uptake test was performed. Following a 30-min break, a 2.5-h
endurance exercise on a bicycle ergometer was carried out at 70% maximal oxygen uptake. After 5 min of rest, a time trial of 64.37 km (40 miles) was completed. The ingested nutrition was recorded every 15 min. In S, the athletes completed the time trial faster (128 vs 136 min) and with a significantly higher power output (212 vs 184 W). The intake of fluid, energy (carbohydrate-, mono-, and disaccharide), and sodium was significantly higher in S compared with A during the endurance exercise. In the time trial, only sodium intake was significantly higher in S. It was concluded that a time trial performance after a 2.5-h endurance exercise in a laboratory setting was significantly improved following a scientific nutrition strategy [12365].

**Attempts to measure effects of supplements**

The Danish Fitness and Nutrition Council has examined the scientific literature to evaluate the performance and health-related aspects of consuming dietary supplements in the context of physical activity. Certain nutritional supplements such as creatine and caffeine have documented ergogenic effects in specific situations. However, for the moderately physically active adult and healthy individual, who already consumes an energy- and nutrient balanced diet, consuming any currently legal dietary supplement does not seem to confer additional benefits on performance or health [09309].

Several nutritional strategies have been used in cycling to improve performance. Carbohydrate feeding during exercise has been shown to be effective, but recent studies have suggested that recommendations may have to be adjusted to take into account recent findings. Protein co-ingested with carbohydrate during exercise has received a lot of recent interest, but the evidence is equivocal, at best. Thus, in the absence of a plausible mechanism, it is difficult to see how protein would increase endurance performance. There also has been a lot of interest in training with low glycogen to maximize training adaptations, but the longer-term effects upon performance are still unclear. Various supplements have been suggested to improve endurance performance, but most of these nutrition supplements lack the scientific support that would warrant the recommendation [09310].

The regular performance of resistance exercises and the habitual ingestion of adequate amounts of dietary protein from high-quality sources are two important ways for older persons to slow the progression of and treat sarcopenia, the age-related loss of skeletal muscle mass and function. Resistance training can help older people gain muscle strength, hypertrophy muscle, and increase whole body fat-free mass. It can also help frail elderly people improve balance and physical functioning capabilities. Inadequate protein intake will cause adverse metabolic and physiological accommodation responses that include the loss of fat-free mass and muscle strength and size. Findings from controlled feeding studies show that older persons retain the capacity to metabolically adjust to lower protein intakes by increasing the efficiency of nitrogen retention and amino acid utilization. However, they also suggest that the recommended dietary allowance of 0.8 g protein per kg and day might not be sufficient to prevent subtle accommodations and blunt desired changes in body composition and muscle size with resistance training. Most of the limited research suggests that resistance training-induced improvements in body composition, muscle strength and size, and physical functioning are not enhanced when older people who habitually consume adequate protein (modestly above the recommended daily intake) increase their protein intake by either increasing the ingestion of higher-protein foods or consuming protein-enriched nutritional supplements [08373].

*Measurements of enzyme levels*
Total creatin kinase (CK) and lactate dehydrogenase (LDH) serum levels depend on age, gender, race, muscle mass, physical activity, and climatic conditions. High creatine kinase serum levels in athletes following rest and without any further predisposing factors should prompt a full diagnostic workup, with special regards to signs of muscle weakness or other signs not always evident. In subjects who have silent myopathy, repeated intense prolonged exercise may produce negative effects, because given the continuous loss of muscle proteins, it does not induce the physiological muscle adaptations to physical training. Serum total LDH and specific isozyme activities change with the training status of the athlete. Variation in LDH isozymes profile might have a role in studying muscle response to training [08376].

**Molecular markers in dietary supplement research**

In laboratory and clinical studies of diet and dietary supplement interventions more overt clinical markers include imaging tests, biopsy samples, prostate-specific antigen kinetics, and urinary testing. Many molecular markers are currently available, including antiapoptotic and apoptotic proteins, cell adhesion molecules, cell cycle compounds, growth factors, angiogenic markers, and proliferative and inflammatory signals. Protein kinases and transcription factors should also be considered for diversity. Testing of numerous molecular markers has become critical in gaining preliminary insight into the potential impact of a novel diet and supplemental agents [11373].

**Analysis of actual content in supplements**

In recent years the availability of so-called legal highs over the Internet has hugely increased. There has been a recent explosion in the number of substances that can be purchased from the Internet marketed as legal highs. A survey of Internet availability published in April 2009 found 39 individual UK online legal-high retailers selling a total of 1308 products. These substances are sold as “not for human consumption” and for a variety of uses, such as research chemicals, plant food, and bath salts, but it is clear that they are intended for human consumption and that the intended market is as a replacement for either 3,4-methylenedioxymethamphetamine (MDMA, ecstasy) or cannabis on the recreational drugs scene. In fact, recent figures suggest that there has been a decrease in the use of MDMA with the suggestion that this is not due to a decrease in recreational drug use but simply a switch to more readily available legal highs. The term “legal high” carries with it a perception of safety and acceptability and although many of the compounds advertised as being the active ingredient in the currently marketed products are not controlled, many of these have as yet not been tested on humans and the purity of the products is unknown. This is an unregulated area and is simply being driven by the market. 2009 and 2010 saw a significant increase in legislation in the UK to try and curb the availability and use of legal highs with a number of modification orders to the Misuse of Drugs Act. Analysis of 24 products claiming to be legally purchased from 18 UK-based websites obtained in a six-week period following the April 2010 ban of cathinones revealed that 63 percent of the products contained these controlled substances. Clearly this is unknown to the user and may well be unknown to the online retailer. As substances are controlled, new substances quickly appear and are marketed as being better than previous products. The synthesis of many of the active ingredients of these second-generation legal highs such as 5,6-methylenedioxy-2-aminoindane (MDAI), 5-iodo-2-aminoindane (5-IAI), and 6-(2-aminopropyl)benzofuran (6-APB) have been previously published; however, little is known about their effects on humans. Another problem highlighted is that substances labeled as the same product may in fact be structural isomers of the expected active ingredient which are unknown within the literature.
Numerous online legal-high retailers market a broad variety of products which are advertised as research chemicals, bath salts, or plant food although clearly intended for human consumption as recreational drug replacements. No guidelines exist as to what is sold and in what purity. Consumers are led to believe that purchased goods are entirely legal. In one study, several legal-high products were purchased and analyzed for their content. The powdered products were screened with attenuated total reflectance – Fourier Transform Infrared (ATR-FTIR) followed by gas chromatography-mass spectrometry (GC-MS) analysis of methanol extracts. Spectra were compared to reference standards and the NIST library. Results showed that 6 out of 7 products did not contain the advertised active ingredient. Moreover, five samples contained the controlled substances benzylpiperazine and 1-[3-(trifluoromethyl)phenyl]piperazine combined with caffeine. Seven samples were purchased online as legal highs and characterized by FTIR and GC-MS. The FTIR study revealed that 6 out of 7 samples did not contain the claimed drug but large quantities of caffeine. The presence of large amounts of caffeine was confirmed by GC-MS. Moreover, it was found that only one of the purchased samples contained MDAI as claimed. Five samples were a mixture of the controlled substances BZP and 3-TFMPP combined with caffeine. As BZP and 3-TFMPP are both controlled substances, users of these Internet products are in possession of illegal substances having purchased them assuming them to be legal. Another issue of concern, previously highlighted by others, is the lack of consistency between products of the same name. If purchasers use different suppliers for the same-named product, it is also highly likely that they could be using products with different active ingredients.

**Quality assurance of dietary supplements**

The use of dietary supplements is widespread in the general population, in athletes and recreational exercisers, and in military personnel. A wide array of supplements is available, but protein-containing products are consistently among the most popular, especially among those who engage in resistance training. There are significant risks associated with the use of unregulated dietary supplements. Risks include the absence of active ingredients, the presence of harmful substances (including microbiological agents and foreign objects), the presence of toxic agents, and the presence of potentially dangerous prescription-only pharmaceuticals. There is ample evidence of athletes who have failed doping tests because of the use of dietary supplements. There is also growing evidence of risks to health and of serious adverse events, including a small number of fatalities, as a result of supplement use. The risk associated with the use of protein powders produced by major manufacturers is probably low, and the risk can be further reduced by using only products that have been tested under one of the recognized supplement quality assurance programs that operate in various countries. Nevertheless, a small risk remains, and athletes, soldiers, and other consumers should conduct a cost-benefit analysis before using any dietary supplements.

**Perceptions of nutritional supplementation**

The purpose of one investigation was to examine the nutritional supplement intake of athletes from a state-based sports institute. Athletes (n=72) from seven sports (kayaking, field hockey, rowing, waterpolo, swimming, athletics and netball) completed a questionnaire detailing their daily usage and rationale therefore. The large majority (63/72) of surveyed athletes reported using nutritional supplements, with no difference between female and male athletes. Kayakers (6.0) consumed a higher number of nutritional supplements than swimmers (4.0), field hockey (1.5), rowing (2.4), waterpolo (2.3), athletics (2.5) and netball (1.7) athletes. The athletes believed that nutritional supplements are related to performance.
enhancements (65 %), positive doping results (63 %), and that heavy training increases supplement requirements (65 %). The cohort was equivocal as to their health risks (56 %) or their need with a balanced diet (53 %). The most popular supplements were minerals (46 %), vitamins (43 %), other (32 %), iron (31 %), caffeine (22 %), protein (17 %), protein-carbohydrate mix (14 %), creatine (13 %) and glucosamine (4 %). The majority of supplementing athletes (n=63) did not know their supplements active ingredient (62 %), side effects (57 %) or mechanism of action (54 %) and admitted to wanting additional information (57 %). Only half of the athletes knew the recommended supplement dosages (53 %). The performance enhancing perception may explain the large proportion of athletes that reported using nutritional supplements, despite over half of the athletes believing that supplements are not required with a balanced diet and can cause positive doping violations [10216].

Motives for use of supplements

One study examined incidence of sport-related injury, interest in supplements to treat injury, and sources of supplement information among 145 college athletes (89 males, 56 females). A survey was used to assess sport-related injuries, interest in three categories of supplements to treat injury, and sources of supplement information among college athletes who used athletic training room and weight training facilities. Sport-related injuries were experienced by 91 percent of athletes (93 % males, 88 % females). Overall, 17 percent of participants were interested in supplements to improve circulation, 34 percent for joint and soft tissue repair, and 22 percent to reduce inflammation. Significant sex differences were not found for any supplements in any categories evaluated. Males were more likely than females to rely on strength coaches (37 %, 20 %) for supplement information. Athletic trainers (71 % of athletes), coaches (60 %), and physicians (41 %) were the primary professionals, and the internet (79 %), magazines (68 %), and television (52 %) the most popular sources of media for supplement information. The majority of athletes experience injury during their college athletic career and 17 to 34 percent express an interest in supplements for injury treatment. Athletes would benefit from scientifically sound guidance to identify appropriate supplements for injury treatment and internet sites for supplement information. Future research should identify if athletes are more likely to increase supplement use when they are injured or if supplement use is more prevalent among athletes who are prone to injury [07228].

The widespread use of nutritional supplements among athletes is poorly understood. The prevalence of supplement intake and users' knowledge have been researched independently leading to useful, but disconnected, information on supplement use. The "UK Sport 2005 Drug Free Survey" data (n=874) were re-analysed. The use of selected supplements varied widely as follows: multivitamin (73 %), vitamin C (70 %), echinacea (31 %), iron (30 %), magnesium (11.0%) and ginseng (8.3%). Associations with motive were found in 8 of the 10 test pairs which were expected from literature precedents, however only weak associations exist. Of these, four were associated with avoidance of sickness, multivitamin, vitamin C, and Echinacea. The remaining 4 associations were: no time to prepare meals with ginseng and multivitamin, overcoming injuries with magnesium. These results suggest a lack of understanding regarding supplements and health maintenance, except for vitamin C and echinacea. Furthermore, supplement use is apparently independent of physicians/dieticians' advice, except for iron. This may suggest a widespread circumvention of expert advice in the growing area of supplement use and therefore should be addressed to underscore potential health risks [07229].

Use of supplements administered by a doctor to the Canadian Olympic athletes was measured by a questionnaire. The percentage of current users was 69 percent in the Atlanta
Games and 74 percent in the Sydney Games. Use of supplements was also measured by a self administered questionnaire distributed to the World Master Athletes in Germany. A total of 69 percent of the men used nutritional supplements. The use of supplements in the general US population of men was lower, around 47 percent in the National Health and Nutrition Examination Survey. This survey suggests that subjects reporting strenuous physical activity are more likely to be supplement consumers. The high use of supplements in professional athletes is not surprising, especially because they are recommended in order to reduce physical exercise-induced oxidative stress and tissue damage. Growing evidence indicates that reactive oxygen species are responsible for exercise-induced protein oxidation and contribute to muscle fatigue. In addition, high-level physical activity may lead to suppression of the immune system, which could be compensated for by supplementation with dietary micronutrients [07230].

Attitudes towards dietary supplements

The aim of one study was to examine the prevalence of (daily) dietary-supplement (DS) use among elite adolescent athletes and to differentiate use by different types of DS according to their function. Data were analyzed for associations between users of these DS types, sociodemographic, sport-specific characteristics, and opinion on the need for DS. In addition, sources of supply and information were examined. In the framework of the GOAL Study, 1,138 German elite adolescent athletes (14-18 years) answered questions about DS. The data were analyzed to identify groups at risk for using DS after a classification by supplemental function. Of the young athletes, 91.1% reported DS use during the previous month. (Daily) DS use was significantly associated with gender, kind of sport, and the weekly duration of sporting activity. Furthermore, some athletes were required to use DS by their sporting organization. DS use was more likely in these athletes than in those whose sporting organizations had no such requirement. Overall, DS with short- and long-term supplemental function were mostly associated with the use of magnesium. However, DS with medium-term muscle-building function played an important role among daily users. The main source of information about DS was coaches; main source of supply was parents. Professional education is urgently needed, as 9 out of 10 athletes used DS, and strong positive opinions toward the use of DS were present, particularly in the DS users [12374].

Stacking

In one summary, stacking was defined as the consumption of two or more supplements at the same time in an attempt to maximise results. This practice originated from anabolic steroid regimes of body builders and other resistance training athletes where products were combined, often to address the side effects or potentiate the actions of individual products. A more global view of supplement stacking in sports nutrition finds that supplement combinations can be deliberate or unintentional. Deliberate stacking aims to take advantage of positive physiological responses that arise from combining nutrients, foods or compounds (e.g. vitamin C enhancing iron absorption). Few studies have examined the possible benefits to stacking and have produced equivocal results despite theoretical support. Combining creatine with beta-alanine had a unique effect on delaying fatigue while stacking creatine with hydroxy-B-methylbutyrate produced additive effects on lean body mass. The combination of beta-alanine (intracellular) and bicarbonate (extracellular) buffers for events involving sustained high-intensity exercise that produces significant acidosis warrants comprehensive study. While stacking some supplements may provide additional benefits, some athletes may not be aware that taking multiple supplement products creates the potential for doubling up on some ingredients or co-ingesting ingredients that are best not combined. Inadvertent or unintentional stacking increases the risk of unintended negative
consequences or adverse reactions such as interference with nutrient absorption (e.g., combining caffeine and iron supplements). Overdosing on single ingredients from multiple sources can also occur. For example, toxic levels of zinc may be consumed from the combination of daily dietary intake (15+mg), one or more multivitamin mineral supplements (15+mg), protein shake (10 mg), recovery shake (10 mg), sports bar (15 mg) and immunity supplement (5+mg); this total of over 70 mg/day exceeds the upper safe limit of 45 mg. High zinc levels are assessed and monitored with a blood test, with high levels increasingly being reported in regular and frequent sports supplement use. Athletes should be aware of combining supplements and possible adverse reactions and have supplement use reviewed regularly by a registered sport nutritionist or sports dietitian [12300].

For injury prevention

The topic of exercise-induced skeletal muscle injury has received considerable attention in recent years. Likewise, strategies to minimise the injury resulting from heavy resistance exercise have been studied. Over the past 15 years, several investigations have been performed focused on the role of nutritional supplements to attenuate signs and symptoms of muscle injury. Of these, some have reported favourable results, while many others have reported no benefit of the selected nutrient. Despite these mixed findings, recommendations for the use of nutritional supplements for the purposes of attenuating muscle injury are rampant within the popular fitness media and athletic world, largely without scientific support. Those nutrients include the antioxidant vitamin C (ascorbic acid) and vitamin E (tocopherol), N-acetyl-cysteine, flavonoids, L-carnitine, astaxanthin, beta-hydroxy-beta-methylbutyrate, creatine monohydrate, essential fatty acids, branched-chain amino acids, bromelain, proteins and carbohydrates. A discussion of all published peer-reviewed articles in reference to these nutrients and their impact on resistance exercise-induced skeletal muscle injury is presented, in addition to a brief view into the potential mechanism of action for each nutrient. Based on the current state of knowledge, the following conclusions can be made with regard to nutritional supplements and their role in attenuating signs and symptoms of skeletal muscle injury occurring as a consequence of heavy resistance exercise: there appears to be a potential role for certain supplements (vitamin C, vitamin E, flavonoids, and L-carnitine); these supplements cannot effectively eliminate muscle injury, only attenuate certain signs and symptoms; it is presently unclear what the optimal dosage of these nutrients is (whether used alone or in combination); it is unclear what the optimal pretreatment period is; and the effectiveness is largely specific to non-resistance trained individuals. Ultimately, because so few studies have been conducted in this area, it is difficult to recommend with confidence the use of selected nutrients for the sole purpose of minimising signs and symptoms of resistance exercise-induced muscle injury, in particular with regard to resistance-trained individuals [07219].

Effects of energy conditioning on food preferences and choice

One study investigated the development of conditioned preferences for foods varying in energy content in human adults in a laboratory setting. In a within-subjects design, 44 participants consumed high and low energy yoghurt drinks (255 kcal and 57 kcal per 200 ml serving, respectively) first thing in the morning following 8 h of fasting, every day for two weeks, with 5 exposures to each yoghurt drink on alternate days. The high and low energy yoghurt drinks were paired with two coloured labels (blue or pink), with the pairings fully counter-balanced. Every day of the third (test) week, participants were given a free choice of either consuming the pink or the blue labelled yoghurt drink. Participants chose the high energy drink significantly more often over the low energy drink, suggesting a conditioned preference for a delayed (energy) reward. These findings provide further evidence for energy
based learning in human adults. This study also provides a new approach to the conditioning paradigm (cueing energy via a coloured label instead of flavour) and includes a new and important measure in this research area (preference instead of liking) [11372].

**Side effects of dietary supplements**

In recent years there has been a significant increase in the consumption of dietary energy supplements (DES) associated with the parallel advertising against obesity and favoring high physical performance. It was presented a case and outcome of a young patient who developed acute mixed liver injury (hepatocellular and cholestatic) after ingestion of various "over the counter" products to increase muscle mass and physical performance (NO Xplode®, creatine, L-carnitine, and Growth Factor ATN®). The diagnosis was based on the exclusion of other diseases and liver biopsy findings. The dietary supplement and herbal multivitamins industry is one with the highest growth rates in the market, with annual revenues amounting to billions and constantly lacking scientific or reproducible evidence about the efficacy and/or safety of the offered products. Furthermore, and contrary to popular belief, different forms of injury associated with these natural substances have been documented particularly in the liver, supporting the need of a more strict regulation [12375].

**Nutritional supplement screening**

Sweetened beverage and fast-food intake have been identified as important targets for obesity prevention. However, there are few brief dietary assessment tools available to evaluate these behaviors among adolescents. The objective of one research was to examine reliability and validity of a 22-item dietary screener assessing adolescent consumption of specific energy-containing and non-energy-containing beverages (nine items) and fast food (13 items). The screener was administered to adolescents (ages 11 to 18 years) recruited from the Minneapolis/St Paul, MN, metro region. One sample of adolescents completed test-retest reliability of the screener (n=33, primarily white adolescents). Another adolescent sample completed the screener along with three 24-hour dietary recalls to assess criterion validity (n=59 white adolescents). Test-retest assessments were completed approximately 7 to 14 days apart, and agreement between the two administrations of the screener was substantial, with most items yielding Spearman correlations and kappa statistics that were >0.60. When compared to the gold standard dietary recall data, findings indicate that the validity of the screener items assessing adolescents' intake of regular soda, sports drinks, milk, and water was fair. However, the differential assessment periods captured by the two methods (i.e. 1 month for the screener vs 3 days for the recalls) posed challenges in analysis and made it impossible to assess the validity of some screener items. Overall while these screener items largely represent reliable measures with fair validity, the findings highlight the challenges inherent in the validation of brief dietary assessment tools [09320].

**Appropriate regulations**

A large number of recreational and elite athletes use nutritional supplements in hopes of improving performance. These aids can be costly and potentially harmful, and the advertised ergogenic gains are often based on little or no scientific evidence. Due to the lack of regulation of the dietary supplement industry, an abundance of supplement products of dubious value, content, and quality are now available around the world. Many supplement products contain substances that are prohibited in sport or that have been associated with significant morbidity and mortality. For athletes, lack of knowledge or misinformation has
been established despite numerous sources of information being available, and the reasons for, and implications of, unsupervised and unrestricted supplement use require further attention. In addition to the necessity of an appropriate regulation of dietary supplements, nutritional education and scientifically sound guidance for athletes is required. Intervention and prevention efforts should be particularly targeted to adolescents [09321].

Quantitation of use of supplements in sports

To determine dietary supplementation practices and opinions, preferred means for dietary supplement (DS) education, and antidoping opinions among elite Canadian athletes varying in age and gender. A total of 582 high-performance athletes (314 male, 268 female) representing 27 sports with a mean age of 20 years completed a validated questionnaire assessing dietary supplement practices and opinions by recall. Sport categories included varsity, Canadian Sport Centre Calgary, and National Sport School. There was extensive DS use, with 88 percent of participants taking one or more dietary supplement (mean of 3 DS per user) during the previous 6 months. Overall, sport drinks (22 %), sport bars (14 %), multivitamins and minerals (14 %), protein supplements (9 %), and vitamin C (6 %) were most frequently reported. Older athletes were significantly more likely to report greater DS usage; to be advised by teammates, health food store retailers, and magazines; to prefer supplementation education via individual interviews; to claim awareness of anti-doping rules; and to perceive anti-doping compliance. Relative to gender, significant differences were observed for the types of dietary supplement reported; supplementation advisors; justifications for dietary supplement use; and awareness of anti-doping regulations. It was concluded that utilization of this validated and reliable questionnaire has the potential for broad use and provides insight into the factors that influence dietary supplement use in elite athletes [07227].

Athletes use dietary supplements in order to increase energy, maintain strength, enhance performance, maintain health and immune system and prevent nutritional deficiencies. A recent increase in DS use has been observed in various sports and especially among elite athletes. There are several studies estimating that supplement use among athletes is common and varies between 59 to 88 percent multivitamins, minerals, proteins and energy drinks being most common products being consumed. Most supplement users consume more than one product and the amount of supplements used varies between age groups, gender and different sports. A Norwegian study reported a great difference of supplement use between different sport groups: power sport athletes had the most frequent use of supplemental creatine, proteins/amino acids, vitamins and minerals while cross-country skiers had the most frequent intake of iron, vitamin C and fish oils. Athletes are willing to use many kinds of dietary supplements, although researches have not been able to prove that most supplements perform as claimed. In their recent statement, American Dietetic Association (ADA) lists ergogenic aids into four groups according to their safety and efficiency:

- those that perform as claimed
- those that may perform as claimed but for which there is insufficient evidence of efficacy at this time
- those that do not perform as claimed
- those that are dangerous, banned, or illegal and, therefore, should not be used.

Group one contains creatine, caffeine, sport drinks, gels and bars, sodium bicarbonate and proteins and amino acids. On the contrary, group three includes majority of the ergogenic
aids currently on the market including widely used ginseng and branched chain amino acids. When it comes to vitamin and mineral supplementation, according to ADA using them does not improve performance among individuals who consume nutritionally adequate diets. The aim of yet another study was to assess the frequency of use of dietary supplements (DS) among large sample of elite Finnish athletes and to describe possible changes in dietary supplement use between the years 2002 and 2009 in a prospective follow-up study conducted on Olympic athletes. The first survey was conducted on Olympic athletes in 2002 (n=446) and the follow-up study was conducted between 2008 and 2009 (n=372). In 2002, a total of 81 percent of the athletes used dietary supplements (a mean of 3 ± 3 DS per user) and in 2009, a total of 73 percent of the athletes (a mean of 3 ± 3 per DS user) used them. After adjusting for age-, gender- and sport type, the odds ratio for use of any dietary supplement was significantly less in 2009 as compared with 2002 results. Decrease in DS use was observed in all supplement subgroups (vitamins, minerals, nutritional supplements). Athletes in speed and power events and endurance events reported use of any dietary supplement significantly more often than team sport athletes both in 2002 and 2009. In year 2009, the frequency of all dietary supplement use increased when athlete's age increased and the increase was significant in older age groups: of the athletes under 21 years 63 percent, 21-24 years 83 percent and over 24 years 90 percent consumed nutritional supplements. Based in our study, there seems to be a lowering trend of dietary supplement use among elite Finnish athletes although differences between sport subgroups and age groups are considerable [11244].

Although dietary nutrient intake is often adequate, nutritional supplement use is common among elite athletes. However, high-dose supplements or the use of multiple supplements may exceed the recommended daily allowance (RDA) of particular nutrients or even result in a daily intake above tolerable upper limits (UL). One case report presented nutritional intake data and supplement use of a highly trained male swimmer competing at international level. Habitual energy and micronutrient intake were analysed by 3 daily dietary reports. Supplement use and dosage were assessed, and total amount of nutrient supply was calculated. Micronutrient intake was evaluated based on RDA and UL as presented by the European Scientific Committee on Food, and maximum permitted levels in supplements (MPL) are given. The athlete's diet provided adequate micronutrient content well above RDA except for vitamin D. Simultaneous use of ten different supplements was reported, resulting in excess intake above tolerable UL for folate, vitamin E and Zn. Additionally, daily supplement dosage was considerably above MPL for nine micronutrients consumed as artificial products. Risks and possible side effects of exceeding UL by the athlete are discussed. Athletes with high energy intake may be at risk of exceeding UL of particular nutrients if multiple supplements are added. Therefore, dietary counselling of athletes should include assessment of habitual diet and nutritional supplement intake. Educating athletes to balance their diets instead of taking supplements might be prudent to prevent health risks that may occur with long-term excess nutrient intake [11245].

Intake of dietary supplements is widespread among athletes in developed countries. This study evaluated the use of dietary supplements in athletes from a developing country. Dietary supplementation practices of 113 national-level athletes age 15-35 years in Sri Lanka were assessed. All athletes from track-and-field, badminton, football, swimming, cycling, and karate squads who consented to participate in the study were administered an anonymous questionnaire by an interviewer. Information on number of supplements taken, frequency of use, nature of product, rationale, sources of advice, and reasons for taking supplements was obtained. Most athletes (94 %) consumed dietary supplements. On average, 3.7 products/day were consumed. Footballers had significantly lower intake of supplements than other athletes (footballers 71 %, others 98 %). They also consumed fewer products per day (footballers 0.7, others 3.5). Popular supplements included multivitamins, vitamin E, calcium,
energy foods and drinks, and creatine. Multiple supplement use was common, with 29 percent athletes taking 4 products/day. The athletes sought advice on supplement use from sports doctors (45 %), team coaches (40 %), or friends (15 %). Most took supplements to improve performance (79 %), and 19 % claimed to take supplements to improve their overall health status [10217].

Survey data from 847 high-performing athletes in the UK were analysed using descriptive statistics. The survey, conducted by UK Sport, consisted of questions regarding knowledge of the prohibited substances, testing procedure, nutritional supplement use and perceptions of the doping problem. The proportion of supplement users and the relative use of each supplement were compared by age, gender and professional status. Among the 874 high-performing athletes in the UK sample, 59 percent reported the use of at least one nutritional supplement. Among supplement users, 83 percent used more than one and 12 percent reported use of more than five nutritional supplements. The average number of supplements used by athletes in the users’ sample was 3 (1674 instances with 520 athletes), indicating that supplements are used in combinations. Of the 9 supplements listed, multivitamins (73 %) and vitamin C (71 %) were used most, followed by creatine (36 %), whey protein (32 %), echinacea (31 %), iron (30 %) and caffeine (24 %). Less than 11 percent reported the use of magnesium or ginseng. Creatine use was typically associated with males regardless of status and across all ages, whereas iron was characteristically used by females. A “typical” supplement user is male, between 24 and 29 years of age, involved in professional sport and using a combination of supplements. Male professional players between age 30 and 34 years, and female non-professional athletes between 24 and 29 years of age also represented a considerable proportion of supplement users. Athletes older than 40 years of age were practically non-users. Concomitant use of supplements is characteristic of male users more than females [08377].

One study examined incidence of sport-related injury, interest in supplements to treat injury, and sources of supplement information among 145 college athletes (89 males, 56 females). A survey was used to assess sport-related injuries, interest in three categories of supplements to treat injury, and sources of supplement information among college athletes who used athletic training room and weight training facilities. Sport-related injuries were experienced by 91 percent of athletes (93 % males, 88 % females). Overall, 17 percent of participants were interested in supplements to improve circulation, 34 percent for joint and soft tissue repair, and 22 percent to reduce inflammation. Significant sex differences were not found for any supplements in any categories evaluated. Males were more likely than females to rely on strength coaches (37 %, vs 20 %) for supplement information. Athletic trainers (71 % of athletes), coaches (60 %), and physicians (41 %) were the primary professionals, and the internet (79 %), magazines (68 %), and television (52 %) the most popular sources of media for supplement information [08380].

A recent study estimates that 15.2 percent of American adults use nonprescription dietary supplements for weight loss. Sale of ephedrine- and ephedrine-alkaloid-containing products was prohibited by the Food and Drug Administration in February 2004 after research demonstrated an increased risk of arrhythmia, mortality and hypertension following use of products containing these sympathomimetics. Subsequently, nutritional supplement manufacturers have turned to other products to promote weight loss. In a case report a 28-year-old woman with no prior psychiatric history who was hospitalized secondary to an acute psychotic episode. The patient reported starting several weight-loss and nutritional sports supplements approximately one week prior to admission. The relationship between the onset of psychosis and the initiation of the dietary supplements strongly suggests a correlation exists [08381].
The purpose of one investigation was to examine the nutritional supplement intake of athletes from a state-based sports institute. Athletes (n=72) from seven sports (kayaking, field hockey, rowing, waterpolo, swimming, athletics and netball) completed a questionnaire detailing their daily usage and rationale therefore. The large majority (63/72) of surveyed athletes reported using nutritional supplements, with no difference between female and male athletes. Kayakers (6.0 ± 2.9) consumed a higher number of nutritional supplements than swimmers (4.0 ± 2.2), field hockey (1.5 ± 1.0), rowing (2.4 ± 1.4), waterpolo (2.3 ± 2.4), athletics (2.5 ± 1.9) and netball (1.7 ± 1.0) athletes. The athletes believed that nutritional supplements are related to performance enhancements (47/72), positive doping results (45/72), and that heavy training increases supplement requirements (47/72). The cohort was equivocal as to their health risks (40/72) or their need with a balanced diet (38/72). The most popular supplements were minerals (46 %), vitamins (43 %), other (32 %), iron (31 %), caffeine (22 %), protein (17 %), protein-carbohydrate mix (14 %), creatine (13 %) and glucosamine (4 %). The majority of supplementing athletes (n=63) did not know their supplements active ingredient (62 %), side effects (57 %) or mechanism of action (54 %) and admitted to wanting additional information (57 %). The performance enhancing perception may explain the large proportion of athletes that reported using nutritional supplements, despite over half of the athletes believing that supplements are not required with a balanced diet and can cause positive doping violations [09313].

Combination with anabolic steroids
